Bessemer and Heywood's patent also mentions another machine for the expression of oils from the seeds, &c. by pressure in connection with water, or water rendered slightly alkaline. A sectional drawing of it is represented in *fig.* 1581. A is a cast-iron cistern, having semicircular ends, and open on the upper side. At one end of it is fixed a cylindrical vessel, B, with hemispherical ends. The vessel is of considerable strength, and should be capable of withstanding a pressure of 5,000 lbs. to the square inch. It is held in an upright position by a flange, C, formed upon it, and extending around one-half of its circumference. This flange rests upon a similar one formed around the upper side of the cistern, A, and is bolted thereto. At the upper part of the vessel B is formed a sort of basin, B^1, the edge of which supports an arch-shaped piece of iron, D. At the centre of the basin there is an opening into the vessel, and an hydraulic cup-leather, E, is secured within the opening by means of the collar, G. In the bottom of the vessel B there is also an opening, into which is fitted a cup-leather, H, secured in its place by the ring *j*, which is firmly bolted to the vessel B. A strong wrought-iron rod, K, extends from the top of the arch D, down through the vessel B, having two enlargements or bosses, K^1, K^2, formed upon it, which are fitted to the cup-leathers. The upper part of rod K has a screw formed upon it at K³, which passes through the boss D¹ and enters the boss N, in which a screw-thread is formed. The boss, N, is provided with handles, P, by turning which the rod K may be raised or lowered when required. R is a pipe, through which water may be injected into the vessel A, by a force-pump, such as is generally employed to work hydraulic presses. S is a cock, whereby a portion of the contents of the vessel B may be run off, and the pressure relieved when necessary. The two bosses, K¹ and K², being of equal area, whatever pressure may be exerted within the vessel B, it does not tend to raise or lower the rod K; but such pressure, acting on the cup-leathers, will keep the joint tight, and prevent the matters under pressure from leaking out. After a certain quantity of oil or oleaginous matters have been expressed from vegetable or animal substances, the remaining portions which they contain are more difficult to obtain, and we therefore treat the oil, in combination with the substances in which it is contained, in the following manner:—

The aforesaid substances, after coming from the oil-press or mill, are mixed with as much warm water, or water slightly impregnated with alkaline matter, as will reduce them to a semi-fluid state. They are then to be operated on in the apparatus last described. For this purpose the handles P P are turned round, and the boss K² withdrawn from its opening, while the boss K², which is much longer, will still close the lower aperture. The semi-fluid materials are then put into the basin B¹, and fall from thence into the vessel B; when it is fully charged, the rod K is again lowered into the position shown in the figure. The communication with the hydraulic press-pump is then made by means of a cock attached to the pump, from which the water flows, through the pipe R, into the vessel B, and thus with a few strokes of the pump the whole of the contents of the vessel B will be subjected to the requisite pressure. An interval of a few minutes is then allowed for the combination of the oil and water, and the cock S is then opened, and a small portion of the fluid contents of the vessel allowed to escape into the cistern. The pressure being thus relieved, the handles P P are to be again turned so as to lift the rod K sufficiently high to withdraw the boss K² from the lower opening; the contents of the vessel B will then flow out into the cistern A, and the boss K², being again lowered so as to close the lower aperture, the refilling of the vessel may take place for another operation. The pressure thus brought upon the mixture of oleaginous matters and water will cause the oil therein contained to mix with the water, and form a milky-looking fluid, from which the oil may be afterwards separated from the water, either by repose in large vessels, or by evaporating the water therefrom by heat. When the oil is to be used for soap-making, and some other purposes, this combination of oil and water may be used without such separation. When seed-oil is thus obtained, the mucilaginous matters assist in combining these fluids. After the materials have been drawn off from the cistern A, and passed through a strainer, the solid portions are to undergo another pressing, in order to displace the remaining portion of their fluid contents. In some cases it will be found advantageous to boil up the milky-looking fluid resulting from the operation last described, in order to coagulate the albuminous portions, and otherwise assist in the purification of the oil.

The quantities of oil produced by the various seeds vary greatly, and also different samples of the same kind of seed.

The following notes of Mr. E. Woolsey, and his remarks upon the subject of seed-crushing, will be valuable:—

'The chief point of difference depends upon the quality of seed employed. Heavy seed will yield most oil; and seed ripened under a hot sun, and where the flax is not gathered too green, is the best. The weight of linseed varies from 48 lbs. to 52 lbs. per imperial bushel; probably a very fair average is 49 lbs., or 392 lbs. per imperial quarter. I inspected one of the seed-crusher's books, and the average of 15 trials of a quarter each of different seeds in the season averaged $14\frac{1}{2}$ gallons of $7\frac{1}{2}$ lbs. each; say, 109 lbs. of oil per quarter. The crusher, who uses only the hydraulic press, and one pressing, informed me that

Archangel seed will yield from . . .	15 to 16 gals.	(of $7\frac{1}{8}$ lbs. each).	
Best Odessa	18 and even 19	,,	,,
Good crushing seed	$15\frac{1}{2}$	,,	,,
Low seed, such as weighs 48 lbs. per bushel .	$13\frac{1}{2}$	,,	,,

'The average of the seed he has worked, which he represents to be of an inferior quality, for the sake of its cheapness, yields $14\frac{1}{2}$ gallons per quarter. I had some American seed which weighed $52\frac{1}{4}$ lbs. per imperial bushel, ground and pressed under my own observation, and it gave me 111 lbs. of oil; that is to say, 418 lbs. of seed gave 111 lbs. of oil $= 26\frac{56}{100}$ per cent. A friend of mine, who is a London crusher, told me the oil varied according to the seed from 14 to 17 gallons; and when you consider the relative value of seeds, and remember that *oil* and *cake* from any kind of seed is of the *same value*, it will be apparent that the yield is very different; for example,

July 25, 1836, prices of seed,	East India linseed worth . .	52*s*. per quarter.
	Petersburg linseed . . .	48*s*. to 52*s*. ,,
	Odessa	52*s*. ,,

The difference of 4*s*. must be paid for in the quantity of oil which at 38*s*. 6*d*. per cwt. (the then price) requires about 11½ lbs. more oil expressed to pay for the difference in the market value of the linseed. Another London crusher informed me that East India linseed will produce 17 gallons, and he seemed to think that that was the extreme quantity that could be expressed from *any seed*. The average of last year's Russian seed should be about 14 gallons; Sicilian seed, 16 gallons.

Place	Engine-power	Hydraulic presses	Stampers	Rollers	Edge-stones	Kettles	Work done,—reduced to an hour	Number of pressings
France	10 horse-ower	1 hydraulic, 200 tons	5 light stampers	1 pair rolls	1 pr. edge-stones	5 table kettles small size heated by steam	1 English quarter per working hour	2 pressings.
London	20 horse-power	1 hydraulic, 800 tons	13 light stampers	1 pair rolls	2 pr. edge-stones	8 table kettles small size heated by fire	2 English quarters per working hour	2 ditto.
London	12 horse-power, but the engine is used also for other work	none	9 light stampers	2 pair rolls, used also for other purposes	2 pr. edge-stones, used also for other purposes	4 table kettles small size heated by fire	⅞ English quarter per working hour	2 ditto.
Hull .	18 horse-engine, old construction	none	3 very heavy stampers	1 pair rolls	1 pr. edge-stones	3 double case large size steam kettles	1¼ English quarter per working hour	1 ditto.
Ditto .	22 horse-engine	none	6 very heavy stampers	2 pair rolls	2 pr. edge-stones	6 double case large size steam kettles	Not known	1 ditto.

'*Rape-seed*—I have not turned my attention to the quantity of oil extracted from this seed; but a French crusher (M. Geremboret), on whom, I think, one may place considerable dependence, told me, that

3½ lbs. of best Cambray rape-seed yielded . .	1 lb. of oil.	
3¾ ,, common rape-seed	1	,,
4¼ ,, ,, poppy-seed	1	,,

'Rape-seed yields from 52 lbs. to 56 lbs. per imperial bushel.'

The following Table shows the quantity of oils obtained from some seeds, fruits, &c.:—

100 parts of each	Oil per cent.	100 parts of each	Oil per cent.
Walnuts	40 to 70	Wild mustard seed . .	30
Castor-oil seeds . . .	62	Camelina seed . . .	28
Hazel nuts	60	Weld seed	29 to 36
Garden cress seed . .	56 to 58	Gourd seed . . .	25
Sweet almonds . . .	40 to 54	Lemon seed . . .	25
Bitter almonds . . .	28 to 46	Onocardium acanthe, or bear's foot . . .	25
Poppy seeds	56 to 63	Hemp seed . . .	14 to 25
Oily radish seed . .	50	Linseed	11 to 22
Sesamum (jugoline) . .	50	Black mustard seed . .	15
Lime-tree seeds . . .	48	Beech mast . . .	15 to 17
Cabbage seed . . .	30 to 39	Sunflower seeds . . .	15
White mustard . . .	36 to 38	Stramonium, or thornapple, seeds	15
Rape, colewort, and Swedish turnip seeds . . .	33·5	Grape-stones . . .	14 to 22
Plum kernels . . .	33·3	Horse-chestnuts . .	1·2 to 8
Colza seed	36 to 40	St. Julian plum . . .	18
Rape seed	30 to 36		
Euphorbium (spurge seed)	30		

To obtain the above proportions of oil, the fruits must be all of good quality, deprived of their pods, coats, or *involucra*, and of all the parts destitute of oil.

Purification of Oils.—As the oils are obtained from the mills they generally contain some albuminous and mucilaginous matter, and some other impurities which require to be removed in order to render the oil perfectly clear and fit for burning, &c. Several processes have been proposed for this purpose, but the one most generally used is that known as Thénard's process.

Although concentrated sulphuric acid acts so strongly on the oils, it is found that, when added only in small quantities, it attacks principally the impurities first. Thénard's process consists in adding gradually 1 or 2 per cent. of sulphuric acid to the oil, previously heated to 100°, and well mixing them by constant agitation. To effect this the process may be carried on in a barrel fixed on an axis and kept revolving, or in a barrel which is itself immoveable, but having fixed on its axis a moveable fan. After the action of the acid is complete, which is known by the oil, after 24 hours' rest, appearing as a clear liquid, holding flocculent matter in suspension, there is added to it a quantity of water, heated to 140°, equal to about two-thirds of the oil; this mixture is well agitated until it acquires a milky appearance. It is then allowed to settle, when, after a few days, the clarified oil will rise to the surface, while the flocculent matter will have fallen to the bottom of the acid liquid. The oil may then be drawn off, but requires to be filtered to make it perfectly clear. The filtration is always a difficult matter, and is conducted in various ways. It is sometimes placed in tubs, in the bottom of which there are conical holes filled with cotton, but the holes become speedily choked with solid matters. Another and more speedy process is by the means of a displacing-funnel, the apertures in the diaphragm being stopped with cotton.

Several patents have been taken out for the purification of oils; some passing hot air through the oil while at the same time exposed to the action of light; others, passing steam through the oil.

Cogan's process is a combination of the latter with Thénard's. He operates upon about 100 gallons of oil, and for this quantity he uses about 10 lbs. of sulphuric acid, which he dilutes previously with an equal bulk of water. This acid mixture is added to the oil, placed in a suitable vessel, in three parts, the oil being well stirred for about an hour between each addition. It is then stirred for 2 or 3 hours, in order to ensure a perfect mixture, and thus let every particle of the oil be acted on by the acid. It then has assumed a very dark colour. After being allowed to stand for 12 hours, it is transferred to a copper boiler, in the bottom of which are holes, through which steam is admitted, and, passing in a finely-divided state through the oil, raises it to the temperature of 212°. This steam process is carried on for 6 or 7 hours; the oil is then transferred to a cooler, having the shape of an inverted cone, terminating in a short pipe, provided with a stop-cock, inserted in its side a little distance from the bottom. After being allowed to stand till the liquids are separated, which generally takes about 12 hours, the acid liquor is drawn off through the pipe at the bottom, and the clear oil by the stop-cock in the side of the cooler; all below this tap is generally turbid, and is clarified by subsidence, or mixed with the next portion of oil.

Sometimes an infusion of nut-galls is used to separate the impurities, the tannic acid contained in which renders the impurities less soluble; the infusion is well mixed with the oil by agitation, and, after separating the two liquids, the oil is deprived of any tannic acid it may have retained, by treating it with acetate of lead, or sulphate of zinc. When the oil is to be used for machinery it must be dried by treatment with freshly-calcined sulphate of lime, or carbonate of soda.

General Remarks on the Non-drying Oils.

Olive Oil.—Few vegetables have been so repeatedly noticed and so enthusiastically described by the ancient writers as the olive tree. The *preserved* or *pickled olives* are the green, unripe fruit deprived of part of their bitterness by soaking them in water, and then preserved in an aromatised solution of salt. There are several varieties met with in commerce, but the most common are the *small French* or *Provence olive* and the *large Spanish olive.* When ripe the fruit abounds in a bland fixed oil, which is an unctuous fluid, of a pale yellow or greenish yellow colour, with scarcely any smell and a bland and mild taste. In cold weather it deposits white fatty globules (a combination of oleine and margarine). Pure olive oil has less tendency to become rancid than most other fixed oils, but the second qualities rapidly become rancid, owing probably to some foreign matters. It is not a drying oil, and is less apt to thicken by exposure to the air, and for this reason is preferred for greasing delicate machinery and clock-work. Brande described a process for preparing it for these latter purposes. The oil is subjected to cold, when it principally solidifies; the portion, however, which still remains liquid is poured off from the solid portion. A piece of sheet-lead, or some shot, are then placed in it, and it is exposed in a corked phial to the action of sunshine. A white matter gradually separates, after which the oil becomes clear and colourless, and is fit for use. Some oil prepared by this process kept its consistence very well for four or five years while in a stoppered bottle, but when exposed to the atmosphere it began to thicken, and did not answer so well as was expected by the watchmaker who tried it, from its appearance before exposure to the air.

The principal object in the process appears to be to get as pure oleine as possible, but the purer the oleine the more likely is it to become thick. According to Kerwych, oleine of singular beauty may be obtained by mixing two parts of olive oil with one part of caustic soda-lye, and macerating the mixture for twenty-four hours with frequent agitation. Weak alcohol must then be poured into it, to dissolve the margarine soap, whereby the oleine, which remains unsaponified, is separated, and floats on the surface of the liquid. This being drawn off, a fresh quantity of spirit is added, till the separation of the oleine be complete.

It has a slightly yellowish tint, which may be removed by digesting with a little animal charcoal in a warm place for twenty-four hours. By subsequent filtration, the oleine is obtained limpid and colourless, and of such quality that it does not thicken with the greatest cold, nor does it affect either iron or copper instruments immersed in it. There are four different kinds of olive oil known in the districts where it is prepared:—1. *Virgin* oil; 2. *Ordinary* oil (*huile ordinaire*); 3, Oil of the *infernal regions* (*huile d'enfer*); 4. Oil prepared by *fermentation*.

1. *Virgin oil.*—In the district Montpellier they apply the term *virgin oil* to that which spontaneously separates from the paste of crushed olives. This oil is not met with in commerce, being all used by the inhabitants of the district, either as an emollient remedy, or for oiling the works of watches. In the district of Aix they give the name *virgin oil* to that which is first obtained from the olives ground to a paste in a mill, and submitted to a slight pressure two or three days after collecting the fruit. Thus, there is no virgin oil brought from Montpellier, but a good deal of it is brought from Aix.

2. *Ordinary oil.*—In the district of Montpellier, this oil is prepared by pressing the olives, previously crushed and mixed with boiling water. At Aix, the *ordinary oil* is made from the olives which have been used for obtaining the *virgin oil*. The paste, which has been previously pressed, is broken up, a certain quantity of boiling water is poured over it, and it is then again submitted to the press. By this second expression, in which more pressure is applied than in the previous one, an oil is obtained somewhat inferior in quality to the *virgin oil*. The oil is separated from the water in a few hours after the operation.

3. *Oil of the infernal regions* (*huile d'enfer*).—The water which has been employed in the preceding operation is, in some districts, conducted into large reservoirs, called the *infernal regions*, where it is left for many days. During this period, any oil that might have remained mixed with the water separates, and collects on the surface. This oil being very inferior in quality, is only fit for burning in lamps, for which it answers very well. It is sometimes called *lamp oil*.

4. *Fermented oil* (*huile fermentée*).—This is obtained in the two above-named districts, by leaving the fresh olives in heaps for some time, and pouring boiling water over them before pressing the oil. But this method is very seldom put in practice, for the olives during the fermentation lose their peculiar flavour, become much heated, and acquire a musty taste, which is communicated to the oil.

The fruity flavour of the oil depends upon the quality of the olives from which it has been pressed, and not upon the method adopted in its preparation.

When olive oil is mixed with *nitrous acid* or *nitrate of mercury*, it solidifies after some time, and forms a solid fat, of a light yellow colour, which is called *elaidine*. It is the oleine of the oil that is affected, and appears to undergo a molecular change, for the *elaidine* is said to have the same ultimate composition as oleine itself.

Olive oil is used as food and in salads, hence it is often called *salad oil*.

Oil of Almonds.—The tree (*Amygdalus communis*) which yields the almond is a native of Syria and Barbary, but is now abundant throughout the south of Europe, and grows even in England, though here the fruit seldom ripens. The oil is obtained by expression from the bitter or sweet almonds, but most generally from the former, from the fact of their being cheaper, and the residual cake being more valuable, yielding by distillation with water the *essential oil of almonds*; when the presence of water is carefully avoided, the oil obtained from them is quite as good as that obtained from the sweet almonds; but when water is present with the almonds, as would be the case if they were deprived of their skins by maceration in water, the oil would possess a more or less acrid taste. The average produce is from 48 to 52 lbs. from 1 cwt. of almonds (*Pereira*). When recently expressed it is turbid, but by rest and filtration becomes perfectly transparent. It possesses generally a slight yellow colour, which becomes considerably paler by exposure to sunshine. It has a mild bland taste, and little or no odour. It is less easily congealed by cold than olive oil. It speedily becomes rancid, and should be kept in well-stoppered bottles. It is soluble in 25 parts of cold alcohol, and in 6 parts of boiling alcohol, and mixes in all proportions with ether. It is used for the same purposes as olive oil, in medicine, &c.; it is nutritious, but difficult of digestion; it is often used mixed with gum or yolk-of-egg as an emulsion.

Almond oil is sometimes adulterated with olive oil, poppy, and teel oil; and some commercial samples of oil seem to be only olive, mixed with a little almond oil.

Teel Oil, or *Oil of Sesamum.*—The seeds which yield this oil are obtained from the *Sesamum orientale*, and are much esteemed in South Carolina, where they are called *oily grain*, and are made into soups and puddings, like rice. The fresh seeds yield a warm pungent oil, which loses its pungency after a year or two, and is then used for salad: it is often mixed with olive oil for soaps, &c.

Oil of Behen or Ben.—This oil is obtained by expression from the seeds of a plant (*Moringa aptera*) indigenous to Arabia and Syria, and cultivated in the West Indies.

Beech Oil.—The nut of the *Fagus sylvatica* yields two kinds of oil, one a turbid oil, and the other a clear oil, slightly yellow, and very thick; it is used in France in cooking, also for illuminating purposes; and the poor of Silesia use it instead of butter.

Oil of Mustard.—The seeds of the white mustard (*Sinapis alba*) yield about 36 per cent. of a yellow fatty oil, that does not solidify by cold. The seeds of the *Sinapis nigra* yield about 18 per cent. of a similar oil.

Rape-seed Oil is expressed from the seeds of various kinds of *Brassica*; the seeds are used when quite dry, being often submitted to heat to coagulate the albumen. The oil requires considerable purification before it is fit for use. There are various methods of purifying the oil. Thénard's process, before mentioned, serves well; Dr. Rudolph Wagner found a solution of chloride of zinc an advantageous substitute for sulphuric acid in the clarification of the oil; Deutsch recommends subjecting the oil to heat until it begins to decompose, and then keeping it in a gentle state of ebullition for a few hours; a scum forms and separates, and, after a few days' rest, the oil is fit for use. Warburton agitates the oil with a certain quantity of a solution of caustic soda, which dissolves the impurities; these separating with the small quantity of soap formed, the oil is afterwards washed with water. English rape-seed yields the best oil; it is used for illuminating, for the manufacture of soap, for oiling woollen stuffs in the process of manufacture, in the preparation of leather, and for lubricating machinery.

Butter of Cacao is prepared from the cacao-nut, the seed of the *Theobroma cacao.*

Plum-kernel Oil.—An oil expressed from the kernel of the *Prunus domestica*, resembling the oil of sweet almonds.

The *Cocoa-nut oil* of commerce is obtained from the kernel of the nut of the *Cocos nucifera*, &c. It is a white solid, possessing a peculiar odour and a mild taste. It is composed principally of a peculiar fat, *cocinine*, and a small quantity of oleine; it speedily becomes rancid. It is employed in the manufacture of candles and soap; it makes a good marine soap that will lather with sea-water; in Ceylon it is used as a pomatum. There is another oil expressed from the bark of the same trees, and used by the Cingalese as an ointment in cutaneous diseases.

Laurel Oil, known also as oil of Bag, is obtained from the berries of the *Laurus nobilis*. See Laurel Oil.

Ground-Nut Oil.—This is obtained from the fruit of the *ground-nut* plant (*Arachis hypogæa*). According to Dr. Buchner this plant belongs to the *Leguminosæ*, and the fruit is a netted yellowish-grey pod, of from 1 to 3 inches long, and 4 to 9 lines thick, in which are contained two or three brownish-red ovate seeds, of the size of a small hazel-nut. Their parenchyma is white, very nutritious and oily; on which account the *Arachis*, which is indigenous to the tropical parts of America, has been transplanted to Asia and Africa, and even to the south of Europe, and is in that climate frequently cultivated and employed for the manufacture of the oil. The oily seeds possess a sweet taste, somewhat like that of haricot beans, and are used in tropical climates partly raw, and partly prepared into a sort of chocolate, which, however, is not equal to that prepared from cacao. The oil is employed for the same purposes as olive oil. It is of a somewhat greenish colour; and has a specific gravity of 0·9163 at 60° Fahr.

Colza Oil. See Colza.

Piney Tallow.—This is prepared from the fruit of the *Vateria Indica*, a tree which grows in Malabar. It is obtained by boiling the fruit with water, and collecting the fat which rises to the surface. It is white, greasy to the touch, and of an agreeable odour. Its fusing-point is at about 95°; its specific gravity at 59° is 0·926, and at 95°, 0·8965. It answers well for the manufacture of soap and candles; but is little known in this country.

Spindle-tree Oil.—The oil of the spindle-tree (*Euonymus Europæus*), is yellowish, rather thick, with the odour of colza oil, of a bitter and acrid taste. It is solid at 5° Fahr.

Butter of Nutmegs.—This is commonly known in the shops as *expressed oil of mace*, and is prepared by beating the nutmegs to a paste, placing them in a bag and exposing them to steam, and afterwards pressing between heated plates. It is imported in oblong cakes (covered by some leaves), which have the shape of common bricks, only smaller. It is of an orange colour, firm consistence, fragrant odour, like that of nutmegs. The genuine article may be known by being soluble in four times its weight of boiling alcohol, or half that quantity of boiling ether. Its principal use is in medicine. It must not be confounded with *essential oil of mace.*

The Drying Oils.

Linseed Oil.—The oil is obtained by expression from the seeds of the common flax (*Linum usitatissimum*), either with or without the aid of heat; the latter, being known as cold-drawn linseed oil, is better than that expressed by heat.

Linseed oil is easily saponified, yielding a mixture of oleate and margarate of the alkali, and a large quantity of glycerine.

It is acted on rapidly by nitric acid, producing margaric acid, pimelic acid, and some oxalic acid.

Chlorine and bromine act on it, yielding thick, coloured products: when linseed oil is heated in a retort it gives off, before entering into ebullition, large quantities of white vapours, which condense to a limpid, colourless oil, possessing the odour of new bread. As soon as the ebullition commences these vapours cease; the oil froths up, and at length there is left a thick gelatinous residue, very much resembling caoutchouc.

The principal use of linseed oil is in making paints and varnishes. It attracts oxygen rapidly from the air and solidifies, and this property is what renders it so valuable for these purposes: it is the most useful of all the drying oils. The small quantities of vegetable-albumen and mucilage which the oil naturally contains appear, according to Liebig, to impair to a certain extent its drying qualities, and the real object which is obtained by boiling these oils with litharge, or acetate of lead and litharge, is the removal of these substances; the oil then being brought more directly in contact with the oxygen of the atmosphere, dries up more rapidly. It was previously thought that some of the litharge was reduced to metallic lead, oxidising at the same time some of the linoleine; but Liebig's opinion seems to be more likely to be correct. The boiling of the oil requires some little care. A few hundredths of litharge is added to the oil, or some use acetate of lead and litharge, and, as before stated, about an eighth part of resin; this is boiled with the oil, the scum removed as it forms, and, when the oil has acquired a reddish colour, the source of heat is removed, and the oil allowed to clarify by repose. Liebig thinks heat is not necessary, and his process for treating the drying oils, in order to increase their siccative properties, has already been mentioned. According to MM. E. Barruel and Jean, the resinification of the drying oils may be effected by the smallest quantities of certain substances, which would act in the manner of ferments. The borate of manganese acts in this way; a thousandth part of this salt being sufficient to determine the rapid desiccation of these oils.

Linseed oil is used in the manufacture of printer's ink. Being heated in a vessel until it takes fire, it is allowed to burn some time, then it is tightly covered; and subsequently mixed with about one-sixth of its weight of lamp-black.

The thin, gummed silks receive the last of their many layers with boiled linseed-oil; it is also used for leather-varnishes and for oil-cloths.

The residue, after the expression of the oil from the seeds, is called oil-cake, and is sold for feeding cattle; that obtained from the English linseed is the best.

Walnut Oil.—This is obtained by expression from the ordinary walnuts deprived previously of their skin, which are the produce of a tree (*Juglans regia*) which is a native of Persia, but cultivated in this country for the sake of the nuts.

When recently prepared it is of a greenish colour, but by age becomes a pale yellow. According to M. Saussure its specific gravity at 53·6° Fahr. is 0·9283, and at 201° Fahr., 0·871. It has no odour, but an agreeable taste. At 5° Fahr. it thickens, and at 17·5° Fahr. it forms a whitish mass. The nuts yield about 50 per cent. of oil. It dries still more rapidly even than the linseed oil. It is principally used for paints and varnishes, and from its lighter colour, it is often used for white paints.

Oil of the Hazel-nut.—This is extracted from the seeds of the *Corylus avellana*, which yield about 60 per cent. of the oil. It is liquid, has only a slight colour, no odour, and a mild taste. Its specific gravity at 59° Fahr. is 0·9242; at 14° Fahr. it solidifies.

Poppy Oil.—This is expressed from the seeds of the common poppy (*Papaver somniferum*), which grows wild in some parts of England. It is cultivated in very large quantities in Hindostan, Persia, Asia Minor, and Egypt, for the sake of the opium which is obtained from the capsules. It is cultivated in Europe for the capsules, which are used in medicine, and for the oil extracted from the seeds. The oil is obtained by expression from the seeds, which do not possess any of the narcotic properties of the capsules. These seeds are sold for birds, under the name of *maw-seed*.

It is used sometimes for burning; and, after treatment with litharge or subacetate of lead, is used for paints.

Hemp-seed Oil.—The seed of the common hemp (*Cannabis sativa*) yield, by expression, from 14 to 15 per cent. of their weight of a fixed oil. It is obtained principally from Russia, but the native places of the plant are Persia, Caucasus, and hills in the north of India. The seeds are small, ash-coloured, shining bodies. They are demulcent and oleaginous, but possessing none of the narcotic properties of the plant. They are employed for feeding cage-birds, and it has been stated that the plumage of certain birds, as the bullfinch and goldfinch, becomes changed to black by the prolonged use of this seed. When fresh this oil is greenish, but becomes yellow by age; it has a disagreeable odour, and insipid taste. It is sometimes used for illuminating-purposes, but, being a drying oil, it forms a thick varnish, and thus clogs the wick; it is used also in making soft soap, and in paints. When boiled with litharge or subacetate of lead it forms a good varnish.

Sunflower Oil.—The seeds of the sunflower (*Helianthus annuus*) yield about 15 per cent. of a limpid oil, having a clear yellow colour. It has an agreeable odour, and mawkish taste. Its specific gravity at 60° is 0·9263; at 9° Fahr. it becomes solid. It is sometimes employed as food, as well as for illuminating-purposes, and for making soap.

Castor Oil.—The castor-oil plant has been known from the remotest ages. Caillaud found the seeds of it in some Egyptian sarcophagi, supposed to have been at least 4,000 years old. Some people imagine it is the same plant that is called the *gourd* in Scripture. It was called *κρότων* by the Greeks, and *ricinus* by the Romans. It is a native of India, where it sometimes grows to a considerable size, and lives several years. There appear to be several species of the *Ricinus*; the officinal is the *Ricinus communis*, or *Palma Christi*.

The seeds are oval, somewhat compressed, about 4 lines long, 3 lines broad, and 1½ line thick; externally they are pale grey, but marbled with yellowish-brown spots and stripes.

The oil may be obtained from the seeds by expression, by boiling with water, or by the agency of alcohol. Nearly all that is consumed in England is obtained by expression. See Castor Oil.

Castor oil is said to be adulterated sometimes with croton oil, to increase its activity, this is a dangerous sophistication; it is also mixed with some cheap fixed oils. The latter adulteration has been said to be detected by the solubility of castor oil in alcohol; but, unfortunately, castor oil may contain as much as 33 per cent. of another fixed oil, and yet be soluble in its own volume of alcohol (*Pereira*), this oil possessing the property of rendering other oils soluble in spirit.

Grape-seed Oil.—The grape-stones (*Vitis vinifera*) yield about 11 per cent. of their weight of a fixed oil, which is, when fresh, of a clear yellow colour, but becomes brown by age. It has an insipid taste, and little or no odour. Its specific gravity at 60° Fahr. is 0·9202; at 3° Fahr. it becomes solid. It is not of much value for illuminating purposes; but in some southern localities it is used for food.

Oil of the Pine and Fir trees.—In the Black Forest, in Germany, an oil is extracted from the cleaned seeds of the *Pinus picea* and *P. abies*. It is limpid, of a golden-yellow colour, and resembles in smell and taste the oil of turpentine. Its specific gravity at 60° Fahr. is 0·93; it only congeals at −22° Fahr. It is very fluid, and dries rapidly.

Oil of Camelina.—This is extracted from the seeds of the *Myagrum sativum*. It is of a clear yellow colour, with but little smell or taste, and dries rapidly by exposure to the air.

The Oil of Belladonna-seeds.—This oil is extracted in Wurtemberg from the seeds of the *Atropa belladonna*, and is there used for lighting and cooking. It is limpid, of a golden-yellow colour, insipid taste, and no odour.

Oil of Tobacco-seeds.—The seeds of the *Nicotiana tabacum* yield about 31 per cent. of their weight of a drying oil, which is limpid, of a greenish-yellow colour, and no odour. It does not possess any of the narcotic principles of the plant.

Cotton-seed Oil.—Many attempts have been made to render fit for use the oil obtained from the seeds of the cotton-plant (*Gossypium Barbadense*, &c.), as immense quantities of these seeds are allowed to rot, or used only as manure upon the cotton-lands of the south of the United States of America. When obtained by expression, the oil which runs from the press is of a very dark red colour. It, however, deposits some of the colouring-matter by standing, as well as a portion of semi-fluid fat; and in cold weather this is precipitated in large quantities; and only partially redissolves again by increase of temperature. The great obstacle to the use of the oil thus obtained is its colour, which appears to be derived from a dark, resinous substance, presenting itself in small dots throughout the seed. These may readily be seen by examining a section of the seeds with a lens, or even with the naked eye (*Mr. Wayne, Pharmaceutical Journal*, xvi. 335). In bleaching the oil loses from 10 to 15 per cent., a portion of which may be again recovered and used for making soap, for which purpose cotton-seed oil seems best fitted. It is a drying oil, and consequently not well fitted for machinery; and, when burnt, rapidly clogs the wick. A very good soap for common purposes is made from it in New Orleans.

Mr. Wayne also states, 'that the oil, to be made profitably, should either be manufactured in the vicinity of the cotton-plantation, as the seeds, from the attached fibre, are bulky, and the cost of transportation great; or the seed should be hulled at the spot, and shipped to the place where it is to be pressed in that condition, as it requires three or four bushels of seed in the wool to produce one bushel of hulled seed ready for the mill. The hull and attached fibre are useful for paper stock; and the cake, left after the extraction of the oil, is nearly as valuable a food for cattle as that of linseed.

'It appears that boiling the crushed seeds with water yields a very bland, light coloured oil.

'The desire to bring this oil into use still exists, for a sample of it was sent a few months since from a merchant in America to a friend of mine to see if he could succeed in purifying it, which no doubt will ultimately be effected by some one.'

Croton Oil.—This oil is obtained from the seeds of the *Croton Tiglium* by expression, or by the use of alcohol. It is a most violent purgative, and its only use is in medicine. See Pereira's *Materia Medica.*

Animal Oils.

The only oils which will be mentioned here are lard oil, tallow oil, and neat's-foot oil. The solid fats will be described under their different heads. See Stearine.

Lard Oil.—This oil is now imported largely from America; and is obtained by subjecting ordinary hog's-lard to pressure, when the liquid part separates, while the lard itself becomes much harder. It is employed for greasing wool, for which purpose it answers very well, and may be obtained at a low price. According to Braconnet, lard yields 0·62 of its weight of this oil, which is nearly colourless. Specific gravity 0·915 (*Chevreul*). 100 parts of boiling alcohol dissolve 123 parts of it.

Tallow Oil.—This oil is obtained from tallow by pressure. The tallow is melted, and, when separated from the ordinary impurities by subsidence, is poured into vessels, and allowed to cool slowly to about 80°, when the stearine separates in granules, which may be separated from the liquid part by straining through flannel, and is then pressed, when it yields a fresh portion of liquid oil. It is employed in the manufacture of some of the best soaps.

Neat's-foot Oil.—After the hair and hoofs have been removed from the feet of oxen, they yield, when boiled with water, a peculiar fatty matter, which is known under the name of *neat's-foot oil*; after standing, it deposits some solid fat, which is separated by filtration: the oil then does not congeal at 32°, and is not liable to become rancid. It is often mixed with other oils. This oil is used for various purposes, especially, owing to its remaining liquid at so low a temperature, for oiling church clocks, which require, in consequence of the cold they are exposed to, an oil which is not liable to solidify.

Fish Oils.

Although the whale is not, truly speaking, a fish, the oil obtained from it is classed among the fish oils; and those which will be described here are, whale oil, porpoise oil, seal oil, and cod-liver oil. The three former are all known under the name *train oil.*

Whale Oil.—The capture of the whales is a large commercial undertaking; many well-manned ships, and fitted out at a great expense, proceed every year from England, Holland, France, and other nations, into the Arctic zone in search of these animals, and especially the Greenland species (*Balæna mysticetus*). This valuable animal has produced to Britain 700,000*l.* in one year, and one cargo has been known to be worth 11,000*l.* The Greenland whale inhabits the polar seas; its length is from 60 to 70 feet when full-grown. When the whales are captured they are secured alongside the ship, and the process of *flensing* commences. The men, having shoes armed with long iron spikes to maintain their footing, get down on the huge and slippery carcass, and, with very long knives and sharp spades, make parallel cuts through the blubber, from the head to the tail. A band of fat, however, is left around the neck, called the *kent,* to which hooks and ropes are attached for the purpose of shifting round the carcass. The long parallel strips are divided across into portions, weighing about half a ton each; and, being separated from the flesh beneath, are hoisted on board, chopped into pieces, and put into casks. During the homeward voyage the animal matters, &c. attached to the blubber, undergo decomposition to a certain extent, while there is at the same time a peculiar fat formed, which is a compound of glycerine and *phocenic acid,* and which imparts the disagreeable odour peculiar to train oil. Dumas has shown that this acid is identical with valerianic acid. After the decomposition of the blubber, the oil runs from it easily, and the whole is put into casks with perforated bottoms, placed over tanks for receiving the oil. The oil is heated to about 212°, to facilitate the separation of the impurities; and, in order to further purify it, some use a solution of tannin, to precipitate the gelatine present; others use different metallic salts, as acetate of lead. On the western coast of Ireland the whale is sometimes captured, and yields a large quantity of very good oil, superior to sperm oil for illuminating purposes. The sperm whale (*Physeta macrocephalus*) does not yield so much oil as the Greenland whale, but yields considerably more of the valuable substance *spermaceti.*

Train oil is of a brownish colour, with a disagreeable odour. It is used for lighting, in the manufacture of soaps, and in the preparation of leather.

Seal Oil.—The seal-fishery of Newfoundland has now become the most important part of the trade of that colony. Although, perhaps, not so extensive a staple as the cod-fishery, yet, when capital and time employed, &c., are taken into consideration, it is the most profitable business of that colony.

A quarter of a century ago, there were only about 50 vessels, varying from 30 to 60 tons burthen, engaged in this branch of trade; but it has since been gradually increasing, until upwards of 400 vessels are engaged in the trade.

The vessels engaged in this business are from 75 to 200 tons burthen. Those lately added to the sailing fleet, and which are now considered of the most suitable sizes, range from 130 to 160 tons. Vessels of this size carry from 40 to 50 men. The season of embarking for this voyage is from the 1st to the 15th of March. The voyage seldom exceeds two months, and is often performed in two or three weeks. Several vessels make two voyages in the season, and some perform the third voyage within the space of two months and a half.

The seals frequenting the coast of Newfoundland are supposed to whelp their young in the months of January and February; this they do upon pans and fields of ice, on the coast, and to the northward of Labrador. This ice—or the 'whelping ice,' as it is termed—from the currents and prevailing northerly and north-east winds, trends towards the east and north-east coast of Newfoundland, and is always to be found on some part of the coast after the middle of March, before which time the seals are too young to be profitable.

The young seal does not take to the water until it is three months old. They are often discovered in such numbers within a day's sail of the port, that three or four days will suffice to load a vessel with the *pelts,* which consist of the skin and fat attached, this being taken off while the animal is warm; the carcass, being of no value, is left on the ice. The young seals are accompanied by the old ones, who take to the water on the approach of danger. When the ice is jammed, and there is no open water, large numbers of the old seals are shot. The young seals are easily captured; they offer no resistance, and a slight stroke of a bat on the head readily despatches them. When the pelts are taken on board, sufficient time is allowed for them to cool on deck. They are then stowed away in bulk in the hold, and in this stage they reach the market of St. John's and other ports in the island. Five-sevenths of the whole catch reach the St. John's market. A thousand seals are considered as a remunerating number: but the majority of the vessels return with upwards of 3,000, many with

5,000 and 6,000, and some with as many as 7,000, 8,000, and 9,000. Seals were formerly sold by tale; they are now all sold by weight—that is, so much per cwt. for fat and skin.

The principal species captured are the hood and harp seal. The bulk of the catch consists of the young hood and harp in nearly equal proportions. The best and most productive seal taken is the young harp. There are generally four different qualities in a cargo of seals, namely—the young harp, young hood, old harp and bedlamer (the latter is the year-old hood), and the old hood. There is a difference of 2*s.* per cwt. in the value of each denomination.

The first operation after landing and weighing is the skinning, or separating the fat from the skin; this is speedily done, for an expert skinner will skin from 300 to 400 young pelts in a day. After being dry-salted in bulk for about a month, the skins are sufficiently cured for shipment, the chief market for them being Great Britain. The fat is then cut up, and put into the seal-vats.

The seal-vat consists of what are termed the crib and pan. The crib is a strong wooden erection, from 20 to 30 feet square, and 20 to 25 feet in height. It is firmly secured with iron clamps, and the interstices between the upright posts are filled in with small round poles. It has a strong timber floor, capable of sustaining 300 or 400 tons. The crib stands in a strong wooden pan, 3 or 4 feet larger than the square of the crib, so as to catch all the drippings. The pan is about 3 feet deep, and tightly caulked. A small quantity of water is kept on the bottom of the pan, for the double purpose of saving the oil in case of a leak, and for purifying it from the blood and any other animal matter of superior gravity. The oil made by this process is all cold-drawn: no artificial heat is applied in any way, which accounts for the unpleasant smell of seal oil. When the vats begin to run, the oil drops from the crib upon the water in the pan; and as it accumulates it is casked off, and ready for shipment. The first running, which is caused by compression from its own weight, begins about the 10th of May, and will continue to yield what is termed *pale seal oil*, from two to three months, until from 50 to 70 per cent. of the quantity is drawn off, according to the season, or in proportion to the quantity of old seal fat being put into the vats. From being tougher, this is not acted upon by compression, nor does it yield its oil until decomposition takes place; and hence it does not, by this process, produce pale seal oil. The first drawings from the vats are much freer from smell than the latter. As decomposition takes place, the colour changes to straw, becoming every day, as the season advances, darker and darker, and stinking worse and worse, until it finally runs brown oil. As this running slackens, it then becomes necessary to turn over what remains in the vats. The crib being generally divided into nine apartments or pounds, this operation is performed by first emptying one of the pounds, and dispersing the contents over the others, and then filling and emptying them alternately, until the entire residue, by this time a complete mass of putrefaction, is turned over. By this process a further running of brown oil is obtained. The remains are then finally boiled out in large iron pots, which, during the whole season, are kept in pretty constant requisition for boiling out the cuttings and clippings of the skinning and other parts of the pelts, which it is not found advisable to put into the vats. The produce of this, and the remains of the vats, are what is termed the 'boiled seal oil.' These operations occupy about six months, and terminate towards the end of September.

During the months of July, August, and September, the smell and effluvia from the vats and boiling operation are almost insufferable. The healthy situation of St. John's, from its proximity to the sea and the high and frequent local winds, is doubtless the cause of preventing much sickness at this season of the year. The men more immediately employed about the seal-vats have a healthy and vigorous appearance.

Some improvement has taken place since the great fire of 1846, when all the seal-vats in the town were destroyed. Many of the manufacturers have erected their new vats on the south or opposite side of the harbour; but there still remain sufficient vestiges of the seal trade to cause a summer residence in the town of St. John's anything but desirable. Even the country for several miles around St. John's affords no protection from these horrible stenches. The animal remains from the vats, and the offal from the cod-fish are found to be such a valuable manure, that they are readily purchased by the farmers in the neighbourhood; and from whatever quarter the wind blows, the pedestrian in his rural walk has little chance of breathing a genial atmosphere.

Mr. S. G. Archibald directed his attention to some mode of improving the manufacture of the seal oil. The result of several experiments upon the different qualities of seal's fat satisfied him that the whole produce of the fishery, if taken while the material is fresh, as it generally arrives in the market, and subjected to a process of artificial heat, was capable of yielding, not only a uniform quality of oil, but the oil so produced was much better in quality than the best prepared by the old process, and free from the unpleasant smell common to all seal oil. His subsequent experiments resulted in the invention of a steam apparatus for rendering seal and other oils, which has been found to answer an admirable purpose, and for which he received letters-patent under the Great Seal of the Island of Newfoundland.

The advantage of this process must be manifest, when it is understood that twelve hours suffice to *render* the oil, which by the old process requires about six months; that a uniform quality of oil is produced superior to the best *pale* by the old process, and free from smell; that a considerable percentage is saved in the yield, and what is termed *pale seal*, produced from the old as well as from the young seal. Besides, if this process were universally adopted, the manufacturing season would cease by the 31st of May, and the community would be saved from the annoyance attending the old process.

Porpoise Oil.—This oil very much resembles whale oil.

Cod-liver Oil.—This oil is obtained principally from the livers of the common cod (*Callarias; Gadus Morrhua*), previously called *Asellus major*, and also from some allied species, as the Dorse (*Gadus callarias*), the Coal Fish (*Merlangus carbonarius*), the Burbot (*Lota vulgaris*), the Ling (*Lota molva*), and the Torsk (*Brosimus vulgaris*). The mode of preparing this oil varies in different countries; that found in the London market is the produce of Newfoundland, where, according to Pennant, it is thus procured:—Some spruce boughs are pressed hard down into a half tub, having a hole through the bottom; upon these the livers are placed, and the whole exposed to the sun. As the livers become decomposed the oil runs from them, and is caught in a vessel placed under the tub.

De Jongh describes three kinds of cod-liver oil: the *pale*, *pale brown*, and *brown*.

Pale cod-liver Oil.—This is golden-yellow; without disagreeable odour; not bitter, but leaves a peculiar acrid, fishy taste in the mouth; has a slight acid reaction; sp. gr. 0·923 at 63·5° Fahr. Cold alcohol dissolves from 2·5 to 2·7 per cent. of the oil; hot alcohol from 3·5 to 4·5 per cent. It is soluble in ether in all proportions.

Pale brown cod-liver Oil.—Colour of Malaga wine; odour not disagreeable; bitterish, leaving an acrid, fishy taste in the throat; reacts feebly as an acid; sp. gr. 0·924 at 63·5° Fahr. A little more soluble in alcohol than the *pale oil*.

Dark brown cod-liver Oil.—This is dark brown, and by transmitted light is greenish; it possesses a disagreeable odour, and a bitter and empyreumatic taste, which remains some time in the fauces; it is slightly acid; sp. gr. 0·929 at 63·5° Fahr. Still more soluble in alcohol than the *pale brown oil*.

Cod-liver oil is principally used in medicine; for a fuller description of it, see Pereira's *Materia Medica*.

Dugong Oil.—This oil has been used instead of cod-liver oil, principally in Australia; but as very little, *if any*, real Dugong oil has reached England, it will merely require a short notice here. The Dugong is an herbivorous animal, belonging to the order of *Sirenia*, and is found on the northern coast of Australia, in the Red Sea, the Persian Gulf, and also in the Indian seas. It has received different names by different nations. In the Indian seas it is sometimes found of a large size, from 18 to 20 feet long; but in Australia it is seldom caught of more than 12 or 14 feet. In its general form it resembles the common whale. Its favourite haunts are the mouths of rivers and straits between proximate islands, where the depth of water is but trifling (3 or 4 fathoms), and where, at the bottom, grows a luxuriant pasturage of submarine algæ and fuci, on which it feeds. The oil is obtained by skinning the animal and then boiling down the 'speck.' It was used by the natives of Australia originally for burning.

Adulteration of the Oils.—Owing to the large quantities of oil of various kinds which are now used, and their difference in price, many are the adulterations which take place. Thus the best olive oil for the table is mixed with oils of less value, as poppy oil, sesame oil, or ground-nut oil; and the second olive oil, for the manufactures, with colza oil; and again colza oil itself mixed with poppy, camelina, and linseed oils, but more frequently with whale oil, &c. Various means have been proposed to discover these admixtures. M. Lefebvre proposed to take advantage of the difference of density of the several oils, but this is a very insufficient test, as many of the oils have nearly the same density.

M. Poutet treats the oil to be tested with one-twelfth of its weight of a solution of nitrate of mercury, containing hyponitric acid; this latter substance converts the oleine of most of the non-drying oils into a solid substance, *elaidine*. By this means pure olive oil will become perfectly solid after an hour or two, whereas poppy oil and the drying oils in general remain perfectly liquid; it would therefore result that olive oil adulterated with these latter oils would be prevented from solidifying more or less, according to the quantity of these oils present. An improvement in this process

General Table of Reactions.

is to substitute nitric acid, saturated with hyponitric acid, for the nitrate-of-mercury solution. The sample to be tested is shaken with two or three per cent. of this acid, and then placed in a cool place, and the moment of solidification noticed. It is always better also to treat a sample of oil of known purity to the same test at the same time, and compare the results. If the sample tested be pure, it will solidify quite as quickly as the sample which serves for comparison. One hundredth of poppy oil present will delay the solidification 40 minutes (*Gerhardt*), and of course the greater the quantity of admixture, the more will it be delayed.

M. Maumène takes advantage of the greater amount of heat given out by the admixture of concentrated sulphuric acid with the drying oils than takes place with olive oil under the same circumstances. MM. Heydenreich and Penot employ sulphuric acid also to detect the different oils, but they notice the peculiar colorations which take place on contact of the concentrated acid with the different kinds of oils. Their test is thus performed:—one drop of concentrated sulphuric acid is added to 8 or 10 drops of the oil, placed on a piece of white glass, resting on a sheet of white paper; different colorations appear, which they state are characteristic of the different oils; thus olive oil gives a deep yellow tint, becoming greenish by degrees; colza oil, a greenish blue; poppy oil, a pale yellow tint, with a dirty grey outline; hempseed oil, a very deep emerald tint; and linseed oil becomes brownish red, passing directly into blackish brown, &c. These reactions are, however, uncertain; the age of the oil, mode of extraction, &c., altering them greatly.

Marchand states that a mixture of poppy oil and olive oil, when thus treated, developes, after a certain time, on their outline, a series of colours, rose, lilac, then blue, and more or less violet-coloured, according to the proportion of poppy oil, while pure olive oil becomes of a dirty grey, then yellow and brown.

As the means of detecting the various fraudulent admixtures is of great commercial value, the late F. C. Calvert's valuable paper on the adulteration of oils is referred to. —*Pharmaceutical Journal*, xiii. 356.

The accompanying table of reactions (see opposite page) will be found very useful.

Of the more important oils we imported in the years from 1868 to 1873 inclusive, as follows:—

		1868	1869	1870	1871	1872	1873

Turpentine oil	. cwts.	108,897	119,893	89,178	178,615	220,292	234,177

OILS, VOLATILE, ETHEREOUS, OR ESSENTIAL. The volatile oils occur in every part of odoriferous plants, whose aroma they diffuse by their exhalation; but in different organs of different species. Certain plants, such as thyme and the scented *Labiatæ* in general, contain volatile oil in all their parts; but others contain it only in the blossoms, the seeds, the leaves, the root, or the bark. It sometimes happens that different parts of the same plant contain different oils; the orange, for example, furnishes three different oils, one of which resides in the flowers, another in the leaves, and a third in the skin or epidermis of the fruit. The quantity of oil varies not only with the species, but also in the same plant with the soil, and especially with the climate; thus, in hot countries it is generated most profusely. In several plants the volatile oil is contained in peculiar orders of vessels, which confine it so closely that it does not escape in the drying, nor is dissipated by keeping the plants for many years. In other species, and particularly in flowers, it is formed continually upon their surface, and flies off at the moment of its formation.

Volatile oils are usually obtained by distillation. For this purpose the plant is introduced into a still, water is poured upon it, and, heat being applied, the oil is volatilised by the aid of the watery vapour at the temperature of 212°, though when alone it would probably not distil over unless the heat were 100° more.

There are a few essential oils which may be obtained by expression from the substances which contain them; such as the oils of lemons and bergamot, found in the pellicle of the ripe fruits of the *Citrus limonum* and *C. bergamia*, or the lemon and the bergamot. The oil comes out in this case, with the juice of the peel, and collects upon its surface.

For collecting the oils of odoriferous flowers which have no peculiar organs for imprisoning them, and therefore speedily let them exhale, such as violets, jasmine, tuberose, and hyacinth, another process must be resorted to. See PERFUMERY.

Essential oils differ much from each other in their physical properties. Most of them are yellow, others are colourless, red or brown; some again are green, and a few are blue. They have a powerful smell, more or less agreeable, which immediately after their distillation is occasionally a little rank, but becomes less so by keeping. The odour is seldom as pleasant as that of the recent plant. Their taste is acrid, irritating, and heating, or merely aromatic when they are largely diluted with water or other substances. They are not greasy to the touch, like the fat oils, but, on the contrary, make the skin feel rough. They are almost all lighter than water, only a very few falling to the bottom of this liquid; their specific gravity lies between 0·847 and 1·096; the first number denoting the density of oil of citron, and the second that of oil of sassafras. Although styled volatile oils, the tension of their vapour, as well as its specific heat, is much less than that of water. The boiling-point differs in different kinds, but it is usually about 316° or 320° Fahr. Their vapours sometimes render reddened litmus-paper blue, although they contain no ammonia. When distilled by themselves, the volatile oils are partially decomposed; and the gaseous product of the portion decomposed always carry off a little of the oil. When they are mixed with clay or sand, and exposed to a distilling heat, they are in a great measure decomposed; or when they are passed in vapour through a red-hot tube, combustible gases are obtained, and a brilliant porous charcoal is deposited in the tube. On the other hand, they distil readily with water, because the aqueous vapour formed at the surface of the boiling fluid carries along with it the vapour of the oil produced in virtue of the tension which it possesses at the 212th degree Fahr. In the open air the volatile oils burn with a shining flame, which deposits a great deal of soot. The congealing-point of the essential oils varies greatly; some do not solidify till cooled below 32°, others at this point, and some are concrete at the ordinary temperature of the atmosphere.

When exposed to the air the volatile oils change their colour, become darker, and gradually absorb oxygen. This absorption commences whenever they are extracted from the plant containing them; it is at first considerable, and diminishes in rapidity as it goes on. Light contributes powerfully to this action, during which the oil disengages a little carbonic acid, but much less than the oxygen absorbed; no water is formed. The oil turns gradually thicker, loses its smell, and is transformed into a resin, which becomes eventually hard. De Saussure found that oil of lavender, recently distilled, had absorbed, in four winter months, and at a temperature below 54° Fahr., 52 times its volume of oxygen, and had disengaged twice its volume of carbonic acid gas; nor was it yet completely saturated with oxygen. The stearescence of anise-seed oil absorbed at its liquefying temperature, in the space of 2 years, 156 times its volume of oxygen gas, and disengaged 26 times its volume of carbonic acid gas. An oil which has begun to experience such an oxidisement is composed of a resin dissolved in the unaltered oil; and the oil may be separated by distilling the solution along with water. To preserve oils in an unchanged state, they must be put in phials, filled to the top, closed with ground-glass stopples, and placed in the dark.

Volatile oils are little soluble in water, yet enough so as to impart to it by agitation their characteristic smell and taste.

They are soluble in alcohol, and the more so the stronger the spirit is. Some volatile oils, devoid of oxygen, such as the oils of turpentine and citron, are very sparingly soluble in dilute alcohol; while the oils of lavender, pepper, &c. are considerably so. Such combinations form the odoriferous spirits which the perfumers incorrectly call waters, as *lavender water, eau de Cologne, eau de jasmin*, &c. They become turbid by admixture of water, which seizes the alcohol, and separates the volatile oils. Ether also dissolves all the essential oils.

These oils combine with several vegetable acids, such as the acetic, the oxalic, the succinic, the fat acids (stearic, margaric, oleic), the camphoric, and suberic.

With the exception of the oil of cloves, the volatile oils do not combine with the salifiable bases. They have been partially combined with caustic alkali, as in the case of Starkey's soap. This is prepared by triturating recently-fused caustic soda in a mortar, with a little oil of turpentine, added drop by drop, till the mixture has acquired the consistence of soap. The compound is to be dissolved in spirits of wine, filtered and distilled. What remains after the spirit is drawn off, consists of soda combined with a resin formed in the oil during the act of trituration.

The essential oils dissolve all the fat oils, the resins, and the animal fats.

In commerce, these oils are often adulterated with fat oils, resins, or balsam of capivi dissolved in volatile oil. This fraud may be detected by putting a drop of the oil on paper and exposing it to heat. A pure essential oil evaporates without leaving any residuum, whilst an oil mixed with any of the above substances leaves a translucent stain upon the paper. If fat oil be present, it will remain undissolved, on mixing the adulterated essential oil with thrice its volume of spirit of wine of specific gravity 0·840. Resinous matter mixed with volatile oil is easily detected, being left in the alembic after distillation. Oil diluted with spirit of wine forms a milky emulsion on the addition of water; the alcohol is absorbed by the water, and the oil afterwards found on the surface, in a graduated glass tube, will show by its quantity the amount of the adulteration.

Oil of bitter almonds is prepared by exposing the bitter-almond cake, from which he bland oil has been expressed, in a sieve to the vapour of water rising within the still. The steam, as it passes up through the bruised almond *parenchyma*, carries off its volatile oil, and condenses along with it in the worm. The oil which first comes over, and which falls to the bottom of the water, has so pungent and penetrating a smell, that it is more like cyanogen gas than hydrocyanic or prussic acid. This oil has a golden yellow colour; it is heavier than water; when much diluted, it has an agreeable smell, and a bitter burning taste. When exposed to the air, it absorbs oxygen, and lets fall a heap of crystals of benzoic acid. Perfumers formerly employed a great quantity of this oil in scenting their soaps. But nitro-benzole is now used, instead of the essential oil of bitter almonds, in flavouring. See BENZOLE; NITRO-BENZOLE. A similar oil is obtained by distilling the following substances with water:—the leaves of the peach (*Amygdalus Persica*), the leaves of the bay-laurel (*Prunus lauro-cerasus*), and the bruised kernels of cherry- and plum-stones. All these oils contain hydrocyanic acid, which renders them poisonous, and they also generate benzoic acid, by absorbing oxygen on exposure to air.

Oil of anise-seed is extracted by distillation from the 'seeds' of the *Pimpinella anisum*.

Oil of bergamot is extracted by pressure from the rind of the ripe fruit of the *Citrus bergamia*.

Oil of cajeput is prepared in the Moluccas, by distilling the dry leaves of the *Melaleuca cajeputi*. Cajeput is a native word, signifying merely a white tree. This oil is green; it has a burning taste, a strong smell of camphor, turpentine, and savine.

The oil of caraway is extracted from the seeds (cremocarps) of the *Carum carui*.

The oil of cassia, from the *Cinnamomum cassia*, is yellow passing into brown.

The oil of chamomile is extracted by distillation from the flowers of the *Anthemis nobilis*. It has a blue colour when quite fresh, but becomes yellow by exposure; it possesses the peculiar smell of the plant.

Oil of cinnamon is extracted by distillation from the bark of the *Laurus cinnamomum*. It is produced chiefly in Ceylon from the pieces of bark unfit for exportation. It is distilled over with difficulty, and the process is promoted by the addition of salt water, and the use of a low still.

The oil of cloves is extracted from the dried flower-buds of the *Caryophyllus aromaticus*. It is colourless, or yellowish, has a strong smell of the cloves, and a burning taste. It is one of the least volatile oils.

The oil of elder is extracted by distillation from the flowers of the *Sambucus nigra*.

Oil of fennel is extracted by distillation from the seeds of the *Anethum Fœniculum*.

Oil of juniper is obtained by distilling juniper berries along with water. These should be bruised, because their oil is contained in small sacs or reservoirs, which must be laid open before the oil can escape. It is limpid and colourless, or sometimes of a faint greenish yellow colour.

The oil of lavender is extracted from the flowering spike of the *Lavandula vera*.

Oil of lemons is extracted by pressure from the yellow peel of the fruit of the lemon or *Citrus limonum*.

The oil of mace lets fall, after a certain time, a concrete oil under the form of a crystalline crust, called by John *myristicine*.

The oil of nutmegs is extracted chiefly from mace, which is the inner epidermis of these nuts.

The oil of orange-flowers, called *neroli*, is extracted from the fresh flowers of the *Citrus aurantium*. When recently prepared it is yellow; but when exposed for two hours to the rays of the sun, or for a longer time to diffuse daylight, it becomes of a yellowish-red. It is very fluid, lighter than water, and has a most agreeable smell. The aqueous solution, known under the name of orange-flower water, is used as a perfume.

The oil of parsley is extracted from the *Apium Petroselinum*.

The oil of pepper is extracted from the *Piper nigrum*.

The oil of peppermint is extracted from the *Mentha piperita*.

The oil of pimento is extracted from the envelopes of the fruit of the *Eugenia pimenta*, which afford 8 per cent. of it.

The oil of rhodium is extracted from the wood of the *Convolvulus scoparius*.

The oil of roses, called the *attar* or *otto*, is extracted from the petals of the *Rosa centifolia* and *R. sempervirens*.

The oil of rosemary is extracted from the *Rosmarinus officinalis*.

The oil of saffron is extracted from the *stigmata* of the *Crocus sativus*. It is narcotic.

The oil of sassafras is extracted from the woody root of the *Laurus sassafras*.

Oil of savine is extracted from the leaves of the *Juniperus sabina*.

Oil of thyme is obtained from the *Thymus vulgaris*.

Oil of wormwood is distilled from the *Artemisia absinthium*.

Oil of turpentine. See TURPENTINE.

OIL-STONE. A peculiar slate-stone found in Turkey and elsewhere, which forms a better whetstone than any other substance. The finest are found in the interior of Asia Minor, and being imported, are known as Turkey hones or oil-stones.

OLD RED SANDSTONE. A geological formation so called; named by Sedgwick and Murchison, *Devonian*, as portions of the system are peculiarly developed in Devonshire. See SANDSTONE.

OLEATES are saline compounds of oleic acid with the bases.

OLEFIANT GAS is the name originally given to bi-carburetted hydrogen. See CARBURETTED HYDROGEN.

OLEIC ACID. A neutral oil, obtained by saponifying mutton-fat with potash, and decomposing the soap with sulphuric acid. The fat acids are dissolved in hot alcohol; the solution on cooling is expressed, and the operation frequently repeated. Oleic acid is insoluble in water, but soluble in alcohol and ether. Its formula appears to be $C^{36}H^{33}O^3,HO$ ($\mathbf{C^{18}H^{34}O^2}$).

OLEINE, or *Lipyle*. Obtained by boiling tallow in alcohol. It is regarded as an *oleate of oxide of glyceryle*. It constitutes the more fluid portion of oils.

OLEOGRAPH. The name given to a picture printed in oils. It is prepared by a process of block-printing.

OLIBANUM is a gum-resin, used only as incense in Roman Catholic churches.

OLIVE OIL. See OILS.

ONICOLO, or **NICOLO**. A variety of onyx having a ground of deep brown, in which is a band of bluish-white. It is used for cameos, and differs from the ordinary onyx in a certain blending of the two colours.—H. W. B.

ONYX. A mineral belonging to the chalcedonic variety of quartz. It resembles agate, excepting that the colours are arranged in flat horizontal planes. When the layers consist of *sard* and white *chalcedony*, the stone is called *sardonyx*.

These stones were formerly more prized than they are at present, and were frequently cut in cameo and intaglio.

OOLITE. (*Oolith*, Ger. From *ὠόν*, an egg, and *λίθος*, *a stone*.) A geological term. Those varieties of limestone which are composed of an aggregation of small spherical concretions resembling in appearance the roe of a fish, and bound together by a calcareous cement. When first quarried they are generally soft, but harden by exposure to the air and the evaporation of the water.

The particles are generally formed of concentric layers of carbonate of lime arranged round a grain of sand, a fragment of shell, or some organic substance, forming the nucleus around which the calcareous matter has been deposited.

The name Roestone, from the fanciful resemblance of these oolitic concretions to the roe of a fish, has likewise been given to this kind of limestone when the grains are of small sizes; when of comparatively large dimensions, as in some beds of Inferior Oolite in the neighbourhood of Cheltenham, they are distinguished by the name of Peastone or Pisolite (from *πίσον*, *a pea*, and *λίθος*, *stone*).

In geological nomenclature, the term Oolite has a more extended signification, and is applied indiscriminately to the entire accumulation of strata consisting of limestones, marls, clays, and sands, intervening between the Trias or New Red and the Wealden formations, in consequence of the limestones of those deposits frequently possessing an oolitic structure. Of these, Portland stone, Coral Rag, Bath or Great Oolite, and Inferior Oolite are the most important in an economical point of view, owing to their furnishing fine descriptions of freestone, suitable for building and ornamental purposes, both from their tints, which are either white or cream coloured, and the large blocks in which they can be obtained.

The well-known white freestone obtained from Caen in Normandy is an Oolitic limestone belonging to the Bath or Great Oolite formation.

Although the oolite formations constitute the chief repositories of limestones possessing an oolitic structure, they are not confined to those groups of strata, but are met with in other formations, as for instance in some beds of carboniferous or mountain limestone in the neighbourhood of Bristol, as well as very largely in that of Ireland.—H. W. B.

OOLITIC LIMESTONE. Limestones of the Oolitic series of rocks, such as Bath stone, Portland stone, and Caen stone. See LIMESTONE.

OOST, or **OAST.** The provincial name of the stove in which picked hops are dried.

OPAL. An ornamental stone. The following are the more important varieties of the opal:—*The precious opal*, exhibiting a play of rich colours. *Fire opal* or *girasol*, with hyacinth-red and yellow reflections. *Common opal, semi-opal*; non-opalescent varieties. *Hydrophane*; non-transparent, but becoming so by immersion in water. *Cacholong*; nearly opaque, of a bluish-white colour. *Hyalite*; colourless, pellucid, or white. *Opal jasper, wood opal*; and several others. All these are composed of silica in the gelatinising or colloidal state, with more or less water, and occasionally, as accidental admixtures, other bodies in small proportions. By analyses the following results have been obtained as regards the silica:—The precious opal of Hungary contains 92 per cent. of silica; the fire opal of Mexico, 92; the fire opal of Faroe, 88·73; semi-opal of Hanau, 82·75; semi-opal of Kaschau, 92·16; and the cacholong of Faroe, 95·82.

Opal may be regarded as an uncleavable quartz. Its fracture, conchoidal; lustre, vitreous or resinous; colours, white, yellow, red, brown, green, grey; lively play of light. Hardness, 5·5 to 6·5; specific gravity, 2·091. It occurs in small kidney-shaped and stalactitic shapes, and large tuberose concretions. The phenomena of the play of colours in precious opal have not been satisfactorily explained. Haüy attributes the play of colours to the fissures of the interior being filled with films of air, agreeably with the law of Newton's coloured rings. Mohs, however, thinks this would produce iridescence merely. Brewster concludes that it is owing to fissures and cracks in the interior of the mass of a uniform shape.

The precious opal stands high in estimation, and is considered one of the most valuable gems, the size and beauty of the stone and the variety of the colours determining its value. The so-called 'mountain of light,' an Hungarian opal in the Great Exhibition of 1851, weighed 526½ carats, and was estimated at 4,000*l.* sterling.

In Vienna is a precious opal weighing 17 oz.; and it is said a jeweller of Amsterdam offered half a million of florins for it, which was refused.

Hydrophane, or *Oculis mundi*, is a variety of opal without transparency, but acquiring it when immersed in water, or in any transparent fluid.

Hungary has long been the chief locality of precious opal, where it occurs near Kaschau, along with common and semi-opal, in a kind of porphyry. Fine varieties have, however, been discovered in the Faroe Islands; and most beautiful ones, sometimes quite transparent, near Gracios-a-Dios, in the province of Honduras, America. Precious opal has also been recently found in Queensland, and to a less extent in New South Wales. The red and yellow bright coloured varieties of fire opal are found near Zimapan, in Mexico. In modern times, fine opals of moderate bulk have been frequently sold at the price of diamonds of equal size; the Turks being particularly fond of them. The estimation in which opal was held by the ancients is hardly credible. Nonius, the Roman senator, preferred banishment to parting with his favourite opal, which was coveted by Mark Antony. Opal which appears quite red when held against the light, is called *girasol* by the French; a name also given to the sapphire, or corundum asteria, or star-stone.

OPEN-CAST. *A miner's term*, signifying that the mineral is obtained by open workings, and not by mining.

OPERAMETER is the name given to an apparatus invented by Samuel Walker, of Leeds. It consists of a train of toothed wheels and pinions enclosed in a box, having indexes attached to the central arbor, like the hands of a clock, and a dial-plate; whereby the number of rotations of a shaft projecting from the posterior part of the box is shown. If this shaft be connected by any convenient means to the working parts of a gig-mill, shearing-frame, or any other machinery of that kind for dressing cloths, the number of rotations made by the operating-machine will be exhibited by the indexes upon the dial-plate of this apparatus.

A similar clock-work mechanism, called a *counter*, has been for a great many years employed in the cotton-factories, and in the pumping-engines of the Cornish and other mines, to indicate the number of revolutions of the main-shaft of the mill, or of the strokes of the piston. A common pendulum, or spring-clock, is commonly set up alongside of the counter; and sometimes the indexes of both are regulated to go together.

OPIUM is the juice which exudes from incisions made in the heads of ripe poppies (*Papaver somniferum*). rendered concrete by exposure to the air. The best opium which is found in the European markets comes from Asia Minor and Egypt; what is imported from India is reckoned inferior in quality. This is the most valuable of all the vegetable products of the gum-resin family, and very remarkable for the complexity of its chemical composition.

The following list contains most of the varieties of opium known in commerce:—

- Smyrna opium, from *Turkey* or the *Levant*.
- Constantinople opium.
- Egyptian opium.
- Trebizond opium, *Persian opium*.
- Indian opium. *Benares, Malwa,* and *Patna*.
- English opium.
- French and German opium.

See Watts's 'Dictionary of Chemistry.'

Our Consul in China, reporting on the opium trade, says that the use and abuse of opium are much exaggerated. Taking the total import into China at 12,800,000 lbs. in the year, what is that for a population numbering about 400,000,000? He states that the use of opium is confined to narrower limits than is generally supposed; and excess in its consumption is the exception, not the rule. To confirmed smokers it becomes a necessity of existence; by others it is regarded as a luxury. Mr. Hughes, British Consul at Hankow, gives the Chinese credit for a growing preference of the native opium on account of its mildness, which makes it easier to give up its use temporarily, or abandon it altogether, without serious effect upon the health. He says the production of native opium is very considerable; and his colleague, M. Blancheton, after a visit to Szechuen, estimates the nett value of all the opium grown in that province at about 35,000,000 taels sycee (the Hankow tael averages a fraction over 6*s.*); but the figures are given as 'anything but certain.' Mr. Morgan, Consul at Tient-sin, thinks there are some grounds for anticipating that the prohibitory edict will be executed more efficiently than others which have preceded it; and Acting-Consul Harvey, at Newchwang, reports that in that province the action of the authorities in enforcing the prohibition of the growth of opium has lessened the production, and raised the price nearly to that of foreign opium.

OPOBALSAM is the balsam of Peru in a dry state. See BALSAM OF PERU.

OPOPONAX. This is a gum-resin; the dried milky juice which exudes by incision from the root of the parsnip-like plant *Opoponax Chironium*; this plant is found abundantly growing wild in Macedonia and Sicily.

The gum was formerly used in medicine. Referring to the plant, Dioscorides names it *Panax Herculeum*, from Hercules, who was supposed to have discovered it. In his time it was one of the three celebrated panacea or universal medicines; at a later period it was not administered internally, but was in general use in the form of an ointment for the cure of wounds. So recently as fifty years ago it was one of the standard drugs of the apothecary, but then chiefly employed in the form of a plaster.

OPUS ALEXANDRIUM. A mosaic pavement, consisting of geometric figures in black and red tesseræ on a white ground.

ORANGE. A well-known fruit. See CITRUS.

ORANGE-CHROME. A subchromate of lead; a fine orange-coloured pigment, which is very durable. See CHROMATES OF LEAD.

ORANGE-DYE is given by a mixture of red or yellow dyes in various proportions. Arnotto alone dyes orange; but it is a fugitive colour.

ORCHELLA WEEDS. The cylindrical and flat species of *Roccella* used in the manufacture of *Orchil* or *Archil*, and *Cudbear*, are so called by the makers.

The following list of orchella weeds is given by Pereira:—

- Angola orchella, *Roccella fuciformis*.
- Madagascar orchella, *R. fuciformis*.
- Mauritius orchella.
- Canary orchella, *R. tinctoria*.
- Cape de Verd orchella, *R. tinctoria*.
- Azore orchella, *R. tinctoria*.
- Madeira orchella, *R. tinctoria* and *R. fuciformis*.
- Lima orchella, large and round, *R. tinctoria*.
- Lima orchella, small and flat, *R. fuciformis*.
- Cape of Good Hope orchella, *R. hypomecha*.
- Barbary orchella, *R. tinctoria*.
- Corsican and Sardinian orchella, *R. tinctoria*.

Dr. Pereira says:—'Mr. Harman Visger, of Bristol, informs me that every lichen but the best orchella weed is gone, or rapidly going, out of use; not from deterioration of their quality, for, being allowed to grow, they are finer than ever, but because the Angola weed is so superior in quality, and so low priced and abundant, that the product of a very few other lichens would pay the expense of manufacture.'

In the 'Philosophical Transactions' for 1848, Dr. Stenhouse has a valuable paper on the colouring-matters of the lichens. From it we extract his directions for estimating the colouring-matter in lichens by means of a solution of hypochlorite of lime:—

Any convenient quantity of the orchella weed may be cut into very small pieces, and then macerated with milk of lime, till the colouring-matter is extracted. Three or four macerations are quite sufficient for this purpose, if the lichen has been sufficiently comminuted. The clear liquors should be filtered and mixed together. A solution of bleaching-powder of known strength should then be poured into the lime solution from a graduated alkalimeter. The moment the bleaching-liquor comes in contact with the lime solution of the lichen, a blood-red colour is produced, which disappears in a minute or two, and the liquid has only a deep yellow colour. A new quantity of the bleaching-liquid should then be poured into the lime solution, and the mixture carefully stirred. This operation should be repeated so long as the addition of the hypochlorite of lime causes the production of the red colour, for this shows that the lime solution still contains unoxidised colorific principle. Towards the end of the process, the bleaching-solution should be added by only a few drops at a time, the mixture being carefully stirred between each addition. We have only to note how many measures of the bleaching-liquid have been required to destroy the colouring-matter in the solution, to determine the amount of the colorific principle it contained. Dr. Stenhouse suggests the following method for extracting the colorific principle for transport:—Cut the lichens into small pieces, macerate them in wooden vats with milk of lime, and saturate the solution with either muriatic or acetic acid. The gelatinous principle is then to be collected on cloths and dried by a gentle heat. In this way the whole of the heat can be easily extracted, and the dried extract transported from the most distant localities. See ARCHIL; LICHENS.

ORCHIL. See ARCHIL.

ORCIN is the name of the colouring-principle of several of the lichens. The lichen dried and pulverised is to be exhausted by boiling alcohol. The solution filtered hot lets fall, in the cooling, crystalline flocks, which do not belong to the colouring-matter. The supernatant alcohol is to be distilled off, the residuum is to be evaporated to the consistence of an extract, and triturated with water till this liquid will dissolve no more. The aqueous solution, reduced to the consistence of syrup, and left to itself in a cool place, lets fall, at the end of a few days, long brown brittle needles, which are to be freed by pressure from the mother-water, and dried. That water being treated with animal charcoal, filtered and evaporated, will yield a second crop of crystals. These are orcin. See LICHEN; LITMUS. See also Watts's 'Dictionary of Chemistry.'

ORDEAL BEAN. The Calabar bean; the seeds of *Physostigma venatum*, Balf.

ORE. The natural chemical compound of a metal with some other element, such as oxygen, sulphur, arsenic, &c. These elements have been sometimes termed *mineralisers*; and when metals are found free from them they are called *native* metals, and not *ores*.

OREIDE is the name given by MM. Meurier and Valient, of Paris, to an alloy which has a golden brilliancy. It is composed of copper 100, zinc 17, magnesia 6, sal-ammoniac 3·6, quicklime 1·80, and tartar of commerce 9.

The copper is first melted, and then the other things are added by small portions at a time, skimming, and keeping in fusion for about half an hour.

The oreide, which is a brass, has a fine grain, is malleable, takes a most brilliant polish, and, if it tarnishes, its lustre is restored by acidulated water.

ORELLIN. A yellow colouring-matter contained in arnatto. It is soluble in water, in alcohol, and ether. It dyes alumed goods yellow.

ORES, DRESSING OF. See DRESSING OF ORES.

ORICHALCUM. An old alloy, called also *false silver*.

ORIENTAL EMERALD. The name given to green sapphire.

ORIENTAL TOPAZ. The name given to yellow sapphire.

OR-MOLU. A brass, in which there is less zinc and more copper than in the ordinary brass; the object being to obtain a nearer imitation of gold than ordinary brass affords. In many of its applications the colour is heightened by means of a gold lacquer, but in some cases, and, as we think, with very great advantage, the true colour of the alloy is preserved after it has been properly developed by means of dilute sulphuric acid.

ORPIMENT (Eng. and Fr.; *Operment*, *Rauschgelb*, Ger.; *Yellow sulphide of arsenic*) is found native in many parts of the world, as in Hungary, Turkey, China, &c.; the finest specimens being brought from Persia, in brilliant yellow masses, of a lamellar texture, called 'golden orpiment.'

Native orpiment is the *auripigmentum*, or *paint of gold*, of the ancients. It was so called in allusion to its use and its colour, and also because it was supposed to contain gold. From this term the common name of '*orpiment*,' or '*gold paint*,' has been derived.

In nature it is found most generally in amorphous masses of a bright yellow colour, but sometimes in crystals, which are oblique rhombic prisms; these crystals are flexible, of a yellow colour, and possess a brilliant lustre. See ARSENIC.

Native orpiment has a specific gravity of about 3·48. Orpiment is also prepared artificially, chiefly in Saxony, by subliming in cast-iron cucurbits, surmounted by conical cast-iron capitals, a mixture in due proportions of sulphur and arsenious acid. As thus obtained, it is in yellow compact opaque masses, of a glassy aspect; yielding a powder of a pale yellow colour.

Artificial orpiment seems to be a substance of uncertain composition, it containing sometimes, according to Guibourt, 94 per cent. of arsenious acid, and only 6 per cent. of the tersulphide of arsenic. On this account it is much more soluble in water than the native orpiment, and consequently a much more powerful poison. It has been administered several times with criminal intentions, and in many of the cases proved fatal. Orpiment is the colouring-matter of the pigment called king's yellow, which is a mixture of arsenious acid with a little tersulphide of arsenic, just as the sample analysed by Guibourt. See KING'S YELLOW.

A proper tersulphide of arsenic may be obtained by passing a stream of sulphuretted hydrogen gas through a solution of arsenious acid in hydrochloric acid. It falls as a brilliant yellow amorphous powder.

Tersulphide of arsenic is insoluble in water and dilute acids, but is decomposed by nitric acid and *aqua regia*. It fuses easily, and when heated in air burns with a pale blue flame, generating arsenious and sulphurous acids. In close vessels it sublimes unchanged. It is dissolved by ammonia, and the caustic fixed alkalis forming colourless solutions, from which it is again precipitated by the addition of an acid. The alkaline sulphides also dissolve it, forming double salts, from which solutions it is precipitated even more completely than from the former, by the addition of an acid.

According to Dr. Paris, Delcroix's depilatory, called *poudre subtile*, consists of quicklime, orpiment, and some vegetable powder.

Orpiment is used by pyrotechnists, and as a pigment: the best kinds of native orpiment being reserved for artists.

ORRIS-ROOT. The dried rhizomes of several species of *Iris*.

ORTHOCLASE. See FELSPAR.

OSIER. *Salix.* The Willow-Tree. About 300 species of these plants have been described. The common white willow is a native of Great Britain and many parts of Europe, and is extensively cultivated. The wood is soft, and is employed in making various small articles. The charcoal prepared from it is considered superior to any other for the manufacture of gunpowder. The bark is very bitter, and from it a bitter principle, *salicine*, is obtained, which has been used with some advantage as a substitute for quinine, and it is sometimes used for adulterating that drug. See SALICINE.

OSMIUM is one of the rare metals, most generally found in the ores of platinum, in which it was discovered by Mr. Tennant in 1803. These ores generally contain the metals palladium, rhodium, osmium, ruthenium, and iridium, mixed with the platinum.

The process for obtaining osmium from these ores has been much simplified by M. Frémy. After the exhaustion of the ores by *aqua regia* there remains a residue, which often contains titaniferous iron and chrome iron; but the most important constituent is an alloy existing in flat plates or scales, of a white colour and metallic lustre, and which was formerly thought to contain only osmium and iridium, but later experiments have proved the presence of ruthenium, and a little rhodium. Frémy takes advantage of the oxidability of osmium and of the volatility of its peroxide. His process consists in roasting the alloy in a current of dry air; for this purpose the residue above mentioned is placed in a porcelain or platinum tube, and heated to redness.

The equivalent of osmium is 99·6; and its symbol, Os.

Five compounds of osmium and oxygen exist, viz.:—*Protoxide*, OsO; it is a dark green powder, slowly soluble in acids. *Sesquioxide*, Os^2O^3, has never been obtained pure; it is formed by heating a solution of osmate of ammonia, when a brown powder falls, which is this compound mixed with some ammonia, which explodes feebly when heated. *Binoxide*, OsO^2, is a black powder, insoluble in acids, and burning to osmic acid when heated in the air. *Osmious acid*, OsO^3; this only exists in combination; it forms a rose-red crystalline powder with potassa ($KO,OsO^3,2HO$); this salt is obtained by adding alcohol to a solution of osmate of potassa; the osmic acid is reduced by the alcohol, and this salt is precipitated; on attempting to separate this acid, it is decomposed into binoxide and osmic acid. *Osmic acid*, OsO^4; the preparation of this compound has already been described; it melts, and even boils, below

212°: its vapour is irritating and deleterious, and has a peculiarly offensive odour, hence the name of the metal from *ὀσμή, an odour.* Three combinations of osmium and chlorine are known: *protochloride*, OsCl; *sesquichloride*, Os^2Cl^3 (this only exists in solution); and *bichloride*, $OsCl^2$ (this exists only in a double salt, with chloride of potassium, $OsCl^2 + KCl$). Osmium combines also with phosphorus and sulphur.

OSMIUM-IRIDIUM, or *Iridosmine.* This alloy is found with platinum in the province of Choco, in South America, and in the Ural Mountains. It was first discovered by Mr. Smithson Tennant in the black scales which remain when native platinum is dissolved in *aqua regia.* It is rather abundant with the alluvial gold of California, occurring in small bright lead-coloured scales, sometimes six-sided (*Dana*). It has been recently found in Gippsland, Victoria.

The following analysis of this alloy is by Berzelius:—Iridium 46·77, osmium 49·35, iron 0·74, rhodium 3·15. See Iridium.

OSMOSE FORCE. See Exosmose and Endosmose.

OSTEOCOLLA. The glue obtained from bones, by removing the earthy phosphates with muriatic acid, and dissolving the cartilaginous residuum in water, at a temperature considerably above the boiling-point.

OTTO, OTTAR, or **ATTAR OF ROSES** (from an Arabic word signifying *aroma*), is a volatile oil, too well-known to require description as to its odour and uses. It is obtained by distilling roses with water. It is manufactured extensively at Ghazipoor in Hindostan, as well as at Shiraz in Persia. Polier says that, to obtain a little less than 3 drachms of otto from 100 lbs. of rose-petals in India, it requires a most favourable season, and the operation to be carefully performed. According to Donald Munro, the otto is procured without distillation, merely by macerating the petals in water; and in India it is sometimes thus prepared: the roses macerating in water are exposed to the sun, when the oil separates and floats on the water. It has also been said to be obtained at Damascus, and other parts of Asia Minor, by the dry distillation of the rose at the temperature of a salt-water bath.

It has little colour. It is combustible; and its vapour forms with oxygen an explosive mixture. Its specific gravity at 90° Fahr. is 0·832. At 57° Fahr., 1,000 parts of alcohol (specific gravity 0·806) dissolve 7 parts; and at 72° Fahr., 33 parts of otto.

Otto of roses consists of two volatile oils: one solid and the other liquid at ordinary temperatures, in the proportion of about one of the former to two of the latter. To separate them, the otto must be frozen, and compressed between folds of blotting-paper, which absorb the liquid, and leave the solid oil. They may also be separated by alcohol (of specific gravity 0·8), which dissolves the liquid and scarcely any of the solid oil. The solid oil, according to Saussure, contains only carbon and hydrogen, and these in equal number of atoms, and is therefore isomeric with oil of turpentine; it occurs in crystalline plates, fusible at 95° Fahr. The liquid oil has not been carefully examined; it is uncertain whether it contains nitrogen, or only carbon, hydrogen, and oxygen.

Turkey supplies the commercial world with otto of roses. The rose-farms are principally situated in the low countries of the Balkan between Selimno and Carloya as far as Philippolis in Bulgaria. It is the Christian inhabitants of this district that are chiefly engaged in the business.

Kizaulik in Roumelia is the head-quarters of the trade. Turkey yields from 50,000 to 75,000 ounces per annum. The average importation of otto of roses into Britain is 12,000 ounces, very nearly the whole of which is from Turkey.

A small quantity of otto of roses is produced in the south of France and in Savoy and the Italian borders.

Pure Turkish otto of roses congeals at + 58° Fahr., and boils at 432° Fahr. Italian otto of roses congeals at + 62° Fahr. A sample otto of roses produced from English-grown roses at Mitcham, remained solid at + 70° Fahr., but above that temperature at once became liquid.

Otto of roses, like other articles that are of value, is systematically adulterated, principally with essence of geranium; when this is the case, the boiling-point is lowered, and the congealing-point raised. The insertion of a sample of otto in a bottle into water cooled with ice is a very good physical test of purity. Spermaceti was at one time used to sophisticate otto, but its insolubility in alcohol rendered it too easily detected.

OUT-CROP. A geological and mining term, to signify that the edge of any inclined stratum, bed of coal, or mineral vein, comes to the surface.

OXALATES are saline compounds of the bases with oxalic acid.

OXALIC ACID (*Acide oxalique*, Fr.; *Sauerkleesäure*, Ger.) is now the object of a considerable chemical manufacture. It is usually prepared, upon the small scale, by the following process:—

One part of sugar is gently heated in a retort with five parts of nitric acid, of specific gravity 1·42, diluted with twice its weight of water; copious red fumes are disengaged, and the oxidation of the sugar proceeds rapidly. When the action slackens, heat may be again applied to the vessel, and the liquid concentrated, by distilling off the excess of nitric acid until it deposits crystals on cooling. These crystals are purified by redissolving in a small quantity of water, and re-crystallisation.

Oxalic acid occurs in aggregated prisms when it crystallises rapidly, but in tables of greater or less thickness when slowly formed. They lose their water by crystallisation in the open air, fall into powder, and weigh 0·28 less than before; but still retain 0·14 parts of water, which the acid does not part with, except in favour of another oxide, as when it is combined with oxide of lead. The effloresced acid contains 20 per cent. of water, according to Berzelius.

The effloresced acid may be sublimed in a great measure without decomposition; whereas the ordinary crystallised acid, containing the three equivalents of water, is decomposed by a high temperature into carbonic and formic acids, and carbonic oxide. The crystals of oxalic acid dissolve in eight parts of water at 60° Fahr., and in their own weight, or less, of boiling water; they are also soluble in spirit. The aqueous solution has an intensely sour taste and most powerful acid reaction, and is highly poisonous. In cases of poisoning with this acid the proper antidote is chalk or magnesia, as these substances form with oxalic acid compounds almost insoluble in water, the lime compound being much less soluble than the magnesian. The formula of the crystallised acid is $C^2O^3,HO + 2HO$ (**$C^2H^2O^4 + 2H^2O$**); the effloresced acid, C^2O^3,HO (**$C^2H^2O^4$**). Oxalic acid is decomposed by hot sulphuric acid into a mixture of carbonic oxide and carbonic acid. The binoxides of lead and manganese effect the same change, becoming reduced to protoxides, which combine with the unaltered acid.

By exposing 100 parts by weight of dry sugar to the action of 825 parts of hot nitric acid of 1·38 specific gravity, evaporating the solution down to one-sixth of its bulk, and setting it aside to crystallise, from 58 to 60 parts of beautiful crystals of oxalic acid may be obtained, according to Schlesinger.

Oxalic acid may be produced by the action of nitric acid upon most vegetable substances, and especially from those which contain no nitrogen, such as well-washed sawdust, starch, gum, and sugar. The latter is the article generally employed, and possesses many advantages over every other material. Treacle, which is a modification of sugar, also comes within the same ranges. A spirit of exaggeration prevails in respect to the amount of produce attainable by oxalic-acid makers from a given weight of sugar. The generality of the statements is absurdly false. One cwt. of good treacle will yield about 116 lbs. of marketable oxalic acid; and the same weight of good brown sugar may be calculated to produce about 140 lbs. of acid. As a general rule, 5 cwts. of saltpetre, or an equivalent of nitrate of soda, with 2½ cwts. of sulphuric acid, will generate sufficient nitric acid to decompose 1 cwt. of good sugar, and yield, as above, 140 lbs. of fair marketable oxalic acid, free from superfluous moisture.

On the large scale leaden vessels, or wood vessels lined with lead, are employed in the manufacture of oxalic acid. For this purpose square open vessels, 8 feet square and 3 feet deep, are a convenient size, the liquor being heated by means of steam passed through a coil of lead pipe. A coil of about 48 feet of one-inch pipe in a vessel of the size above mentioned is sufficient to keep the liquor at the required temperature. In using these vessels, the liquor (whatever it may be) to be converted into oxalic acid is put into them together with the acid employed, and heated until the required decomposition is effected. The liquor is then drawn off by a syphon, or by a cock placed at the bottom of the vessel, into shallow leaden vessels, or wooden vessels lined with lead, to cool and crystallise, and the mother-waters are drawn off from the crystals, and used in the next operation.

A process for the conversion of formic acid into oxalic acid has been patented by Mr. Jullion; and also a process for obtaining oxalic acid from uric acid, this latter being produced from guano, patented by Dr. Wilson Turner. But owing to the cheapness of sugar, these processes are of no commercial value. The patents taken out of late years for the manufacture of oxalic acid have been chiefly confined to the saving of nitric acid, by reconverting the red fumes of nitrous and hyponitric acids into nitric acid.

Instead of cane-sugar or treacle, the saccharine substance obtained by the action of an acid on potato starch is sometimes employed. For this purpose the potatoes are well washed, and then reduced into a fine pulp by rasping, grinding, or other suitable means; such pulp is then washed two or three times, by placing it in water, and well stirring it therein, then permitting the pulp to subside, and running off the water. The pulp thus obtained is next placed in an open vessel of lead, or wood lined with lead, with as much water as will allow of the mixture being boiled freely, by means of steam passed through leaden pipes placed therein. Into the mixture of pulp and water, about 2 per cent. by weight (of the potatoes employed) of sulphuric acid (oxalic acid acts more rapidly) is to be stirred in, which will be at the rate of from 8 to 10 per cent. of acid on the quantity of farina contained in the potatoes; the whole is now to be boiled for some hours, until the pulp of the potatoes is converted into saccharine matter, the completion of this process being readily ascertained by applying a drop of tincture of iodine to a small quantity of boiling liquor placed on the surface of a piece of glass, when, if there be any farina remaining unconverted, a purple colour will be produced. The saccharine product thus obtained is then filtered through a horse-hair cloth, after which it is carefully evaporated in any convenient vessel, until a gallon of it weighs about 14 or 14½ lbs.; it is now in a proper condition to be employed in the manufacture of oxalic acid, by the application of nitric acid, as in the case of operating from sugar or treacle. Horse-chestnuts, deprived of their outer shells, are also applicable to the manufacture of oxalic acid when treated in the way above described for potatoes.

Instead of operating with sulphuric acid, the farina of potatoes and of chestnuts may be treated with diastase, and converted into a liquor similar to that obtained after evaporation from the farina and sulphuric acid before mentioned, using about the same proportion of diastase as before directed for sulphuric acid. In this case the liquor is made of the required strength at once, and the processes of filtration and evaporation are rendered unnecessary.

A new method of preparing oxalic acid, said to be cheaper than any other process, has been introduced by Messrs. Roberts, Dale, and Co. A mixed solution of caustic soda and potash, in the proportion of two equivalents of the former to one of the latter, is evaporated to a sp. gr. of about 1·35. It is then made into a thick paste with sawdust, and heated, with constant stirring, on an iron plate, when the mass intumesces and disengages much inflammable gas. The mixture is then exposed for some hours to a temperature of 400° F., and the grey powder thus obtained is treated with water at about 60° F. The oxalate of soda which remains undissolved is then washed, and decomposed with slaked lime; the oxalate of lime being decomposed in turn by sulphuric acid, and the oxalic acid thus obtained in a free state.

Almost the only commercial article made from oxalic acid is the binoxalate of potash or salt of sorrel. This substance results from the decomposition of carbonate of potash by an excess of oxalic acid. The carbonate of potash is first dissolved in hot water, and the oxalic acid added until the effervescence ceases; after which a similar quantity of oxalic acid to that previously employed is thrown in, and the solution is boiled for a few minutes; and then it is set aside to crystallise. The crystals, after being drained and dried, are fit for the market.

Oxalic acid is employed chiefly for certain styles of discharge in calico-printing (which see), and for whitening the leather of boot-tops. Oxalate of ammonia is an excellent reagent for detecting lime and its salts in any solution. The acid itself, or the binoxalate of potash, is often used for removing ink or iron-mould stains from linen.

OX; OXEN. A sub-tribe of animals belonging to the class *Mammalia*, order *Ruminantia*, family *Bovidæ*, or hollow-horned ruminants. The ox appears from the earliest periods to have been a domesticated animal. Its importance to man is great; not only does its flesh form an article of food, but its skin, its horns, and its hoofs are employed in the arts and manufactures.

OXFORD CHROME. An oxide of iron used in oil and water-colour painting.

OXFORD CLAY. An argillaceous or clayey deposit which is well developed in the neighbourhood of Oxford. It forms the base of the Coral Rag or Coralline Oolite, and extends across England in a north-easterly direction from Weymouth, in Dorsetshire, to the river Humber. Its general character is that of a tough brown or bluish-black clay, sometimes attaining a thickness of five or six hundred feet. It furnishes admirable pasture; a favourable example of which is afforded by the vale of Blackmoor, in Dorsetshire, so famous for its dairy produce.—H. W. B.

OX GALL. A mucous, transparent, ropy liquid, of a greenish brown colour, with a bitter taste, obtained from the gall bladder of the ox. It has many uses in the arts. See Watts's 'Dictionary of Chemistry' (article BILE).

OXIDE OF TIN. See TIN and PUTTY POWDER.

OXIDES are compounds containing oxygen in definite proportions.

They are usually divided into *basic oxides*, which unite with acids; *acid oxides*, which neutralise basic oxides, combining with them; and *neutral oxides*, which do not unite with either bases or acids. In addition to these, are *saline oxides*, or compounds which are produced by the union of two oxides of the same metal.

OXIDES, *for polishing*. The finest *crocus* and jeweller's *rouge* are thus prepared:—Crystals of sulphate of iron are taken from the pans in which they have crystallised, and are put at once into crucibles, or cast-iron pots, and exposed to a high temperature; the greatest care being taken to avoid the presence of dust.

The least-calcined portions are of a scarlet colour, and form the jewellers' rouge for polishing gold or silver articles. The more calcined portions are of a purple or bluish-purple colour, and these form crocus for polishing brass or steel. It is found that the blue particles, which are those which have been exposed to the greatest heat, are the hardest. It will, of course, be understood that the result of the action of heat is to drive off the sulphuric acid from the protoxide of iron, which becomes peroxidised in the process.

Lord Rosse, in the 'Philosophical Transactions,' thus describes his process of preparing his polishing powder:—

'I prepare the peroxide of iron by precipitation with water of ammonia, from a pure dilute solution of sulphate of iron. The precipitate is washed, pressed in a screw-press till nearly dry, and exposed to a heat, which in the dark appears a dull low red. The only points of importance are, that the sulphate of iron should be pure, and the water of ammonia should be decidedly in excess, and that the heat should not exceed that I have described. The colour will be a bright crimson, inclining to yellow. I have tried both potash and soda pure, instead of water of ammonia, but after washing with some degree of care, a trace of the alkali still remained, and the peroxide was of an ochrey colour, and did not polish properly.'

Jewellers' rouge is, however, frequently prepared in London by precipitating sulphate of iron with potash, well working the yellow oxide, and calcining it until it acquires a scarlet colour.

Crocus is sometimes prepared after the manner recommended by Mr. Heath. Chloride of sodium and sulphate of iron are well mixed in a mortar; the mixture is then put into a shallow crucible, and exposed to a red heat. Vapour escapes and the mass fuses. When no more vapour escapes, remove the crucible, and let it cool. The colour of the oxide of iron produced, if the fire has been properly regulated, is a fine violet—if the heat has been too high it becomes black. The mass when cold is to be powdered and washed, to separate the sulphate of soda. The powder of crocus is then to be submitted to a process of careful elutriation, and the finer particles reserved for the more delicate work.

OXIDES OF IRON. Four definite combinations of iron and oxygen are known, namely:—*Protoxide*, FeO; *sesquioxide*, Fe^2O^3; *black or magnetic oxide*, $Fe^3O^4 = FeO, Fe^2O^3$; *Ferric acid*, FeO^3. See IRON.

OXIDES OF LEAD and **TIN.** These are both used for polishing. For oxide of tin, see PUTTY POWDER.

OXIDISED OIL. At a meeting of the Society of Arts, on April 4, 1862, Mr. Frederick Walton read a paper 'On the introduction and use of elastic gums and analogous substances,' which described a new preparation bearing the above name. The following is Mr. Walton's description of the manufacture:—

'Whilst engaged, about two years ago, in a series of experiments on the manufacture of artificial leather, it was of the greatest importance to the success of the material that it should have a coat of fine varnish, which, whilst drying quickly, possessed the flexibility of india-rubber. Copal varnish has always been accounted the best varnish, but made with drying oil combined with gum opal at a high temperature, it will not, of course, be dry, until the action of oxidation has reduced the oil contained therein into a solid film. Whilst revolving in my mind this knotty difficulty, and presenting every phase of it to careful thought, it suddenly occurred to me that if the oil was first dried into a skin, like those I had often seen on paint-cans, but, like other people, had before considered as waste, was dissolved in a volatile solvent, like india-rubber sheet, that the semi-resinous material would immediately, on the evaporation of the solvent, resume, like india-rubber, the form it was in prior to solution. By dipping panes of glass into linseed oil, and allowing the films or layers to dry, then repeating the process, I imitated the manufacture of india-rubber from the milk, and thereby produced a solid elastic substance, composed of many layers of perfectly oxidised oil. Up to this stage I had done nothing new or original, for the oil-sheet manufacturers have for more than a century waterproofed linen by layers of oil. But to treat this semi-resinous matter and render it available to purposes of manufacture, will be admitted to be perfectly new, and I now proceed to describe the invention. Having accumulated a quantity of solid oxidised oil by drying it upon extensive surfaces of any kind, such as prepared cloth, stretched in frames, as described in my patent of January 27, 1860, I then scraped or peeled it off by suitable means.

'At first, as before stated, my attention was solely directed to the attainment of a speedily-drying, flexible varnish at a moderate temperature, but very few experiments with this oxidised oil led me to notice its rubber-like qualities, which I at once conceived might, with further manipulation, and with some combinations, be developed more fully, and become a very valuable substitute for that article.

'Encouraged by success at every step, I proceeded, and soon found that by crushing the solid oxidised oil obtained in sheets as described in my patent, and working it thoroughly in hot mixing rolls, I produced a substance which required only the cohesive nature, which in the early part of this paper we noticed as existing so strongly in india-rubber. The addition of a small proportion of shellac soon gave that which was wanting, and I found in my power a material singularly like caoutchouc when worked into dough, and which could be rolled on to fabrics in the same manner and with the same facility—giving a perfect waterproof cloth, unlike oil-cloth, but having the rubber finish and flexibility. Pigments could easily be added to give colour; the addition of resins gave other, or rather varied proportions of adhesion, useful as affording the means of uniting fabrics as by rubber. Fibre, whether flock or cork, mixed in and rolled into sheets, gave me samples of kamptulicon and other floor-cloths.

'Not only has this singular product been thus assimilated to rubber for uses on fabrics, or combined with fibre for floor-cloths, but it is capable of being worked with pigment and vulcanised exactly as india-rubber has been, and forms a hard compound, like vulcanite and ebonite, excepting that the sulphur is not necessary.'

This preparation has not yet found a place amongst manufactures, and the list of applications given in the last Edition is no longer useful.

OXYGEN (*Oxygène*, Fr.; *Sauerstoff*, Ger.) is a permanent gas, and is best obtained by heating a mixture of chlorate of potash and binoxide of manganese, when the chlorate is decomposed into oxygen and chloride of potassium, $KClO^6 = KCl + O^6$. Oxygen may be obtained from binoxide of manganese alone by the action of heat; but in this case, when used with chlorate of potash, the binoxide seems only to act in moderating the evolution of oxygen from the chlorate. When chlorate of potash alone is used, the evolution of gas does not commence so soon, and often is given off rather suddenly at first, and may cause the fracture of the glass vessel.

Oxygen was first discovered by Dr. Priestley in England, and Scheele in Sweden, in 1774, about the same time, but independently of each other. Dr. Priestley called it *dephlogisticated air*, and Scheele *empyreal air*. It was Lavoisier who gave it the name of *oxygen*, from the idea that it was the acidifying principle in all acids (from *ὀξύς*, acid, and *γεννάω*, I beget, or give rise to); but this name has of late years been shown to be a false one. Oxygen may be obtained from several substances, viz. by heating red oxide of mercury, $HgO = Hg + O$; or by heating three parts of bichromate of potash with four parts of oil of vitriol in a glass retort. The products in the latter case are sulphate of potash, sulphate of chromium, water, and oxygen.

Oxygen is colourless, odourless, tasteless, incombustible, but the most powerful agent in maintaining combustion. According to Regnault, 100 cubic inches of this gas weigh, at 60° Fahr. and barometer at 30 inches, 34·19 grains, and its specific gravity is 1·1056. According to Berzelius and Dulong, its sp. gr. is 1·1026.

Of all known substances oxygen is the most abundant in nature, for it constitutes at least three-fourths of the known terraqueous globe. Water contains eight-ninths of its weight of oxygen; and the solid crust of our globe probably consists of at least one-third part by weight of this principle; for silica, carbonate of lime, and alumina, —the three most abundant constituents of the earth's strata—contain each about one-half their weight of oxygen. Oxygen also constitutes about twenty per cent. by volume, or about twenty-three per cent. by weight, of the atmosphere; and it is an essential constituent of all living beings. Plants, in the sunlight, absorb carbonic acid, decompose it—keeping the carbon and liberating the oxygen; while animals, on the other hand, absorb oxygen and give off carbonic acid. Oxygen is *the* great supporter of combustion; substances which burn in air burn with greatly-increased brilliancy in pure oxygen. Several propositions have been made to produce intense light by the use of pure oxygen gas, in the place of atmospheric air. The Drummond Light, the Bude Light, Fitzmaurice's Light, and others, employ oxygen in combination with hydrogen or carburetted hydrogen at the moment of entering into combustion; and some of these bring in the additional aid of a solid incandescent body, as lime, to increase the intensity of the illuminating power. The useful employment of any of these plans appears to depend upon the production of oxygen by some cheaper process than any at present employed.

Maréchal and Tessié du Mothay prepare oxygen by heating the manganates, permanganates, chromates, and ferrates of the alkalis, in a current of steam. The manganate of soda is used for this purpose in America.

The manganate is crushed to a coarse powder, and is then placed in elliptical retorts, 7 feet long, 1 foot wide, and 2 feet deep. These are placed horizontally, the ellipse being vertical. A current of super-heated steam is then passed through the mass, at first slowly, afterwards more rapidly; when the heat has become sufficiently high, part of the oxygen is eliminated, and passes off with the steam, which latter, being condensed, oxygen remains in a state of tolerable purity. The condensers used are similar to those employed in gas-works to separate the less volatile constituents from the coal-gas. They are simply a system of upright cast-iron U-pipes inverted. The water thus formed is sufficient in quantity to wash all soluble impurities from the gas. Farther impurities are removed in a scrubber, whence the oxygen passes, fit for use, into the gas-holder.

After the manganate of soda has been subject to the action of the steam for about ten minutes, the current is shut off, and atmospheric air blown in its place, the effect of which is to re-oxidise so much of the soda-salt as has parted with its oxygen. The nitrogen of the air escapes. After ten minutes the air is cut off and steam reintroduced, which, as before, carries with it oxygen into the condensers.

Some difficulties have been found in working this process. Theoretically, the manganate should continue to yield oxygen *ad infinitum*; but, in practice, it is found that after being some time in use it loses its porosity, and consequently does not permit the steam to act through its whole mass. It becomes, therefore, necessary to recharge the retorts after not very long intervals. It is believed that, if the steam could be kept perfectly dry throughout the process, a result much more nearly approaching that predicted by theory, would be attained to.

OZOKERITE or **OZOCERITE.** A mineral wax found in the Urpeth Colliery, Newcastle-on-Tyne, at Uphall in Linlithgowshire, and in one or two of the collieries, in South Wales. Its composition is, usually, hydrogen 13·79, carbon 86·20. Ozokerite is found in considerable quantity in Moldavia and in Galicia, and has been used for the distillation of paraffin and the manufacture of candles. See CANDLES; PARAFFIN.

OZONE and **ANTOZONE.** The most convenient method of procuring ozone, or rather an ozonised atmosphere, is to place in a large bottle of air, which can be completely closed, a stick of *phosphorus* freshly scraped. Sufficient distilled water should be poured into the bottle to partially cover the phosphorus; the vessel should then be closed with the stopper, and kept in a room at a temperature between 60° and 70°. The phosphorus is oxidised in the bottle in the usual way; and, during this process of oxidation, a portion of the oxygen passes to the state of ozone, and is diffused through the air in the bottle. The test for its presence is a slip of paper moistened with a solution of starch and iodide of potassium. When ozone is produced, this paper on immersion acquires a blue colour, owing to the oxidation of the potassium, and the production of iodide of starch. If a similar slip of paper is put into a similar bottle of air containing distilled water without phosphorus, no change is produced. In a warm room, the evidence of the presence of ozone in a bottle is usually procured in about ten or twelve minutes; but the maximum quantity of ozone is found in it from two to ten hours. Only a small part of the oxygen (from 1-50th to 1-200th) appears to undergo this change; and if kept long, the ozone may be lost by combining with the oxidising phosphorus. So if the iodide paper be left in the bottle, the blue colour will after a time disappear by the ozone combining with the iodine to form iodic acid. It is not produced in dry oxygen, nor in humid air, or in oxygen mixed with certain gases or vapours which prevent the oxidation of the phosphorus; but it appears to be more readily produced, *cæteris paribus*, when oxygen is mixed with nitrogen, hydrogen, or carbonic acid. By washing and decantation, the ozonised air, which is quite insoluble in water, may be deprived of the phosphorus-vapour associated with it, and kept in well-closed bottles. It is speedily lost by diffusion. Graham found that ozone traversed dry and porous stoneware. Ozone may be produced on a small scale by placing a piece of phosphorus with water in a watch-glass, and inverting over this another glass containing the test-paper or liquid.

Ozone is produced by passing the electric spark silently into pure and *dry* oxygen. Frémy and Becquerel found that pure oxygen contained in a sealed tube, when treated for a sufficient time with a series of electric sparks, underwent a complete conversion into ozone, as the whole contents of the tube, when broken, were absorbed by a solution of alkaline iodide, in which it was immersed. In the electrolytic decomposition of water, the oxygen at the positive pole has ozonic properties, provided the poles employed are of gold or platinum. The hydrogen evolved gave no indication of ozone. Faraday found that a mixture of iodide of potassium and starch was decomposed at the positive pole, even after the gaseous oxygen had been made to pass through a tube containing a layer of cotton soaked in a solution of potash. The object of this arrangement was to arrest any acid which might be simultaneously produced, and thus lead to the decomposition of the iodide. Dr. Letheby found that the ozone thus evolved at the positive pole possessed the same power of colouring strychnia as the oxygen (ozone) liberated by sulphuric acid from the peroxides of manganese and lead, and from chromic acid.

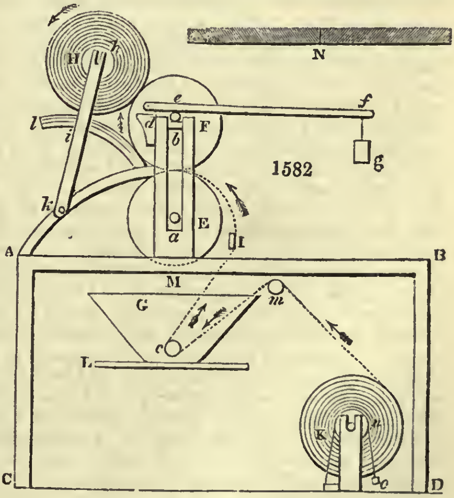
In 1850, Schönbein found that ozone was a product of the slow combustion of *ether*. If a small quantity of ether be poured into a jar or bottle, and a clean glass rod, heated to about 500°, is introduced, acid vapours are given off which redden wetted litmus at the mouth of the jar, and which set free iodine from iodide of potassium, causing the blueing of starch-paper impregnated with this salt. Clean platinum, and even copper or iron, will produce similar effects. The residuary ether in the jar at the same time acquires new properties—those of *antozone*. It bleaches sulphate of indigo, and converts chromic into perchromic acid. *Antozone* is usually produced during this slow combustion of ether, but its existence as a separate principle is exceedingly hypothetical—it is probably a peroxide of hydrogen. See 'Ozone and Antozone,' by Cornelius B. Fox, M.D.; and Watts's 'Dictionary of Chemistry.'

P

PACKFONG. An East Indian alloy, forming a white metal like German silver. It is the Chinese nickel-silver. It appears to contain copper, zinc, and nickel.

PACO, or **PACOS,** is the Peruvian name of an earthy-looking ore, which consists of brown oxide of iron, with almost imperceptible particles of native silver disseminated through it.

PADDING MACHINE (*Machine à plaquer*, Fr.; *Klatsch*, or *Grundermaschine*, Ger.), in calico-printing, is the apparatus for imbuing a piece of cotton cloth uniformly with any mordant. In *fig.* 1582, A B C D represents in section a cast-iron frame, supporting two opposite standards above M, in whose vertical slot the gudgeons *a b* of two copper or bronze cylinders, E F, run; the gudgeons of E turn upon fixed brasses or plummer blocks; but the superior cylinder F rests upon the surface of the under one, and may it with greater or less force by means of the weighted lever *d e f g*, whose centre of motion is at *d*, and which bears down upon the axle of F. K is the roller upon which the pieces of cotton cloth intended to be padded are wound, several of them being stitched endwise together. They receive tension from the action of a weighted belt, *o n*, which passes round a pulley, *n*, upon the end of the roller K. The trough G, which contains the colouring-matter or mordant, rests beneath the cylinder upon the table L, or other convenient support. About two inches above the bottom of the trough there is a copper dip roller, C, under which the cloth passes, after going round the guide roller *m*. Upon escaping from the trough, it is drawn over the half-round stretcher-bar at I, grooved obliquely right and left, as shown at N, whereby it acquires a diverging extension from the middle, and enters with a smooth surface between the two cylinders E F. These are lapped round 6 or 7 times with cotton cloth, to soften and equalise their pressure. The piece of goods glides obliquely upwards, in contact with one-third of the cylinder F, and is finally wound about the uppermost roller H. The gudgeon



of H revolves in the end of the radius *h k*, which is jointed at *k*, and moveable by a mortise at *i* along the quadrantal arc towards *l*, as the roller K becomes enlarged by the convolutions of the web. The under cylinder E receives motion by a pulley or rigger upon its opposite end, from a band connected with the driving-shaft of the printshop. To ensure perfect equability in the application of the mordant, the goods are in some works passed twice through the trough; the pressure being increased the second time by sliding the weight *g* to the end of the lever *d f*. See Calico-Printing.

PADDLE. *A metallurgical term.* The name of a tool used by the iron-puddler.

PADDY. The Indian name for rice in the unhusked condition.

PÆONIN, or *Coralline.* See Carbolic Acid.

PAGING MACHINE. A self-acting machine for paging books and numbering documents, by Messrs. Waterlow and Sons, is of a very ingenious character. The numbering apparatus consists of five discs, which are provided with raised figures on their periphery, running from 1, 2, 3, &c., to 0; and these figures serve (like letter-press type) to print the numbers required. The discs are mounted at the outer end of a vibrating frame or arm on a common shaft, to which the first or units disc is permanently fixed; and the other four discs (viz. those for marking tens, hundreds, thousands, and tens of thousands) are mounted loosely thereon, so that they need not, of necessity, move when the shaft is rotating: but they are severally caused to move in the following order:—the tens disc performs one-tenth of a revolution for every revolution of the units disc; the hundreds disc makes one-tenth of a revolution for every revolution of the tens disc, and so on. As the discs rise from the paper after every impression, the units disc is caused to perform one-tenth of a revolution (in order that the next number printed may be a unit greater than the preceding one) by a driving click taking into the teeth of a ratchet-wheel, fixed on the left-hand end of the shaft. The movement of the other discs is effected, at intervals, by means of a spring catch, affixed to the side of the units disc, and rotating therewith; which catch, each time that the units disc completes a revolution, is caused by a projection on the inner surface of the vibrating frame to project behind one of the raised figures on the tens disc, and carry it round one-tenth of a revolution on the next movement of the units disc taking place; and then, the catch having passed away from the projection, no further increase in the number imprinted by the tens disc will be effected until the units disc has performed another revolution. Every time that the tens disc completes a revolution, the spring catch causes the hundreds disc to move forward one-tenth of a revolution, and similar movements are imparted to the remaining discs at suitable times. The shaft is prevented from moving, except when it is acted on by the driving click, by a spring detent or pull entering the notches in the periphery of a wheel fixed on the right-hand end of the shaft; and thus the discs are held steady while numbering, and a clear and even impression of the figure is ensured. The leaves of the book to be paged or numbered are laid on the raised part of the table of the machine, covered with vulcanised india-rubber, and as each page is numbered it is turned over by the attendant, so as to present a fresh page on their next descent. As the discs ascend after numbering each page, an inking apparatus (consisting of three rollers mounted in a swing frame, and revolving in contact with each other, so as to distribute the ink which is fed to the first roller evenly on to the third or inking roller) descends and inks the figures which are to be brought into action, when the numbering apparatus next descends. By this means books or documents may be paged or marked with consecutive numbers. For printing duplicate sets of numbers, as for bankers' books, a simple and ingenious contrivance is adopted. This consists in the employment of an additional ratchet-wheel, which is acted on by the driving click that moves the ratchet-wheel above mentioned, and is provided with a like number of teeth to that wheel. But the diameter of the additional ratchet-wheel is increased to admit of the teeth being so formed that the driving click will be thereby held back from contact with every alternate tooth of the first-mentioned ratchet-wheel; and thus the arrangement of the numbering discs will remain unchanged, to give, on their next descent, a duplicate impression of the number previously printed; but, on the re-ascending of the numbering apparatus, the click will act on a tooth of both ratchet-wheels, and move both forward one-tenth of a revolution; and, as the shaft accompanies the first ratchet-wheel in its movements, the number will consequently be changed.

Messrs. Schlesinger and Co. have introduced a paging machine, the capabilities of which are similar to the above, but somewhat differently obtained. The numbering discs in this instance are provided with ten teeth, with a raised figure on the end of each tooth; and they receive the change motion from cog-wheels mounted below them on the same frame. At each descent of the frame a stationary spring catch or hook piece drives round the wheel one tooth, that gears into the teeth of the units disc, and thereby causes the units disc to bring forward a fresh figure. The toothed wheels are somewhat narrower than the numbering discs, but one tooth of each wheel is enlarged laterally to about double the size of the other teeth; so that at the completion of every revolution of the wheel the projecting tooth shall act upon a tooth of the next disc, and carry that disc forward one-tenth of a revolution. By this means the requisite movements of the discs for effecting the regular progression of the numbers are produced; the first wheel driving its own disc, and communicating motion at intervals to the next disc, and the other wheels each receiving motion at intervals from the disc with which it is connected, and transmitting motion, at still greater intervals of time, to the next disc.

The machine is caused to print the figures in duplicate by drawing the spring catch out of action at every alternate descent of the frame, and thereby preventing any change of the figures taking place until after the next impression.

The numbers may be increased two units at each impression, so as to print all even or all odd numbers, by bringing a second catch into action, which causes the unit disc to advance one step during the ascending movement of the frame, in addition to the advance during the descent of the same.

PAINTS are colouring-matters in combination with oil. In most cases for the ordinary paints the basis is white lead, with the colouring agents derived from the mineral or vegetable kingdom mixed with it. This does not apply to artists' colours (see COLOURS). The advantages of lead are, that its carbonate (or white lead) actually combines with the oil, whereas white zinc is merely mechanically suspended in it. In the one case we have a plaster spread over the wood or canvas to which the paint is applied, in the other we have only a fine powder held by the oil so long as it continues permanent, but which washes out when the oily coating begins to give way.

Oxide of zinc, or white zinc, is, however, much used as a paint. Ground with oil, it does not cover the surface of wood so well as a lead paint does, owing to the condition in which it exists, as already explained. It has, however, one advantage over white lead, as it is not liable to tarnish or blacken when exposed to the action of sulphide of hydrogen. It has been stated that white zinc is not injurious, as white lead is, to the health of the painter. This is very questionable. It has been found that the long-continued use of white zinc paint produces a distressing nausea.

A white paint has been made from the oxide of *bismuth*; but the metal is too scarce to make it an article of commercial value. A *tungsten* white was made in tolerably large quantities a few years since, and it was advertised as possessing many advantages; as it has not maintained its ground, we may therefore suppose that the promises were not fulfilled.

Copper is largely used as a paint. The most brilliant greens are compounds of the oxide of this metal with arsenic and other bodies. There are also several blues of great value produced from copper.

Iron.—The oxides of iron, in various forms, are employed in the production of yellow, brown, and black paints. A very beautiful black is produced by calcining with care spathic iron ore, the white carbonate of iron; the result is a black magnetic oxide, which mixes well with oil, and forms a most permanent covering for out-of-door work. Calcined hæmatitic iron ores are also found to produce most permanent colours, which resist the action of the weather in a remarkable manner.

Anthracite, ground to an impalpable powder, has been extensively used, when mixed with a drying oil as a black paint. A considerable quantity of this paint was manufactured at Bideford, in North Devon, where the anthracite is obtained from the well-known culm measures of that district. Nearly all paints employed by the ordinary house-painter should be, however, lead paints to which colour has been imparted by the use of some of the metallic oxides. For artists' paints, see COLOURS; LEAD, OXICHLORIDE; and WHITE LEAD.

PAINTS, GRINDING OF. There are many pigments, such as common orpiment, or king's yellow, and verdigris, which are strong poisons; others which are very deleterious, and occasion dreadful maladies, such as white lead, red lead, chrome yellow, and vermilion; none of which can be safely ground by hand with the slab and muller, but should always be triturated in a mill. The emanations of white lead cause, first, that dangerous disease the *colica pictonum*, afterwards paralysis, or premature decrepitude and lingering death.

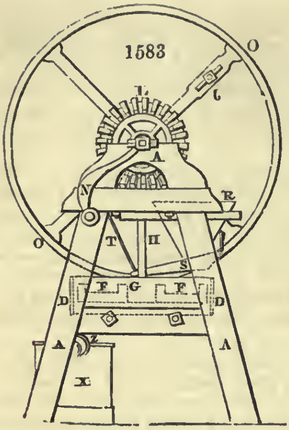
Figs. 1583, 1584, and 1585 exhibit the construction of a good colour-mill in three views: *fig.* 1583 being an elevation shown upon the side of the handle, or where the power is applied to the shaft; *fig.* 1584 a second elevation, taken upon the side of the line *c d* of the plan or bird's-eye view, *fig.* 1585.

The frame-work A A of the mill is made of wood or cast-iron, strongly mortised or bolted together, and strengthened by the two cross iron bars B B. *Fig.* 1586 is a plan of the millstones. The lying or nether millstone C, *fig.* 1584, is of cast iron, and is channelled on its upper face by corn millstones. It is fixed upon the two iron bars

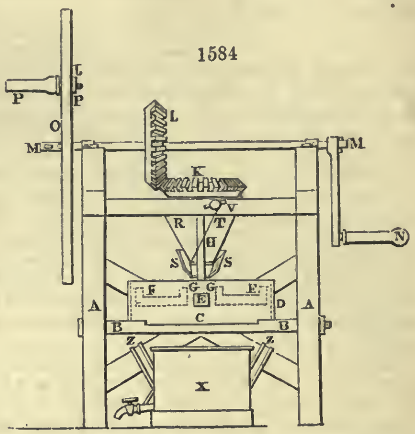
B B, but may be preferably supported upon the three points of adjustable screws, passing up through bearing-bars. The millstone, C, is surrounded by a large iron hoop, D, for preventing the pasty-consistenced colour from running over the edge. It can escape only by the sluice-hole E, *fig.* 1584, formed in the hoop, and is then received in the tub X, placed beneath.

The upper or moving millstone, F, is also made of cast iron. The dotted lines indi-

1583

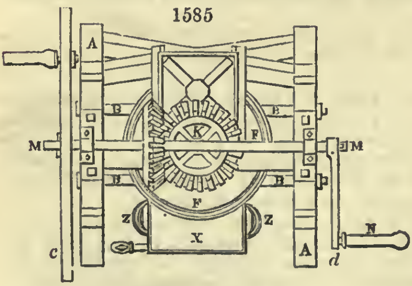


1584

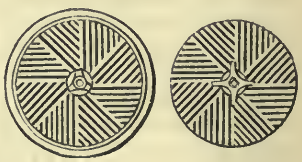


cate its shape. In the centre it has an aperture with ledges, G, G; there is also a ledge upon its outer circumference, sufficiently high to confine the colour which may occasionally accumulate upon its surface. An upright iron shaft, H, passes into the turning-stone, and gives motion to it. A horizontal iron bevel-wheel, K, *figs.* 1584, 1585, furnished with 27 wooden teeth, is fixed upon the upper end of the upright

1585



1586



shaft H. A similar bevel-wheel, L, having the same number of teeth, is placed vertically upon the horizontal iron axis M M, and works into the wheel K. This horizontal axis, M M, bears at one of its ends a handle or winch, N, by which the workman may turn the millstone F; and on the other end of the same axis the fly-wheel, Q, is made fast, which serves to regulate the movements of the machine. Upon one of the spokes of the fly-wheel there is fixed in like manner a handle, P, which may serve upon occasion for turning the mill. This handle may be attached at any convenient distance from the centre by means of the slot and screw-nut J. The colour to be ground is put into the hopper R, below which the bucket, S, is suspended for supplying the colour uniformly through the orifice in the millstone G. A cord or chain, T, by means of which the bucket, S, is suspended at a proper height for pouring out the requisite quantity of colour between the stones, pulls the bucket obliquely, and makes its beak rest against the square upright-shaft H. By this means the bucket is continually agitated in such a way as to discharge more or less colour, according to its degree of inclination. The copper cistern, X, receives the colour successively as it is ground; and when full it may be carried away by the two handles Z Z; or it may be emptied by the stopcock Y, without removing the tub. For many purposes, as for colour-printing, it is highly important that the paint used should be in the finest possible state. To effect this, at Messrs. De La Rue's and some other large establishments, the colours are passed between finely-polished steel rollers which are, by screws, brought very close together.

PAINTS, VITRIFIABLE. See Porcelain; Pottery; and Stained Glass.

PALISANDER WOOD. A name employed on the Continent for rosewood. Holtzapffel has the following remarks on this wood:—

'There is considerable irregularity in the employment of this name; in the work of Bergeron a kind of striped ebony is figured as *bois de Palixandre*; in other French works this name is considered a synonym of *bois violet*, and stated as a wood brought by the Dutch from their South American colonies, and much esteemed.'

PALLADIUM, a metal possessed of valuable properties, was discovered in 1803, by Dr. Wollaston, in native platinum. It constitutes about 1 per cent of the Columbian ore, and from ¼ to 1 per cent. of the Uralian ore of this metal; occurring nearly pure in loose grains of a steel-grey colour, passing into silver-white, and of a specific gravity of from 11·8 to 12·14; also as an alloy with gold in Brazil; and it is also found in many varieties of native gold. In the nitro-muriatic solution of native platinum, if a solution of cyanide of mercury be poured, the pale yellow cyanide of palladium will be thrown down, which, being ignited, affords the metal. This is the ingenious process of Dr. Wollaston. The palladium present in the Brazilian gold ore may be readily separated as follows:—

Melt the ore along with 2 or 3 parts of silver, granulate the alloy, and digest it with heat in nitric acid of specific gravity 1·3. The solution containing the silver-palladium, for the gold does not dissolve, being treated with chloride of sodium or with hydrochloric acid, will part with all its silver in the shape of a chloride. The supernatant liquor being concentrated and neutralised with ammonia will yield a rose-coloured salt in long silky crystals, the ammonio-chloride of palladium, which, being washed in ice-cold water, and then ignited, will yield 40 per cent. of metal.

Palladium is one of the hardest of the metals; its colour is not so bright as that of silver; it is malleable, ductile, and capable of being welded. This metal is more oxidisable than silver, for it tarnishes in air at the ordinary temperature; when heated in air it becomes blue at first from partial oxidation; but if the temperature be increased, this colour disappears and its brightness returns.

Palladium is sometimes substituted for silver in the manufacture of mathematical instruments. The commoner metals may be plated with palladium by the electrotype process. Palladium is sometimes used in the construction of accurate balances, and for some of the works of chronometers. An alloy of palladium and silver is employed by the dentists from the circumstance that it does not tarnish. The influence of palladium in protecting silver from tarnishing is a remarkable and valuable property. The Wollaston medal, given by the Geological Society in honour of its discoverer, was formerly made of palladium.

PALMITIC ACID. $C^{32}H^{32}O^4$ ($\mathbf{C^{16}H^{32}O^2}$). This acid was first discovered in palm-oil, from which it derived its name; it has since been found in many other natural productions, and may also be manufactured artificially from many other substances. It is contained, for instance, in bees'-wax, and that in considerable quantities; the portion of the wax insoluble in boiling alcohol is called *myricine*, and is a palmitate of *myricyle*. This *myricine* requires a *strong* solution of potash to saponify it, and then the palmitic acid is obtained as a palmitate of potash, from which it may be separated by adding an acid.

Several chemical processes have been introduced for obtaining palmitic acid, but none of them have been used commercially for obtaining it, which is largely used in making candles. When thus required, it is obtained in the same manner as stearic acid, by distilling with high-pressure steam. See Candles.

When pure, palmitic acid is a colourless solid substance, without smell, lighter than water. It is quite insoluble in water, but freely soluble in boiling alcohol or ether. These solutions have an acid reaction, and when concentrated become almost solid on cooling; but if more dilute, the palmitic acid separates in groups of fine needles. It fuses at 143·6° Fahr.; and becomes, on cooling, a mass of brilliant pearly scales. It unites with bases to form salts, most of which are insoluble in water. It may also be made to unite with glycerine to form *palmitin*, in which state it previously existed in palm-oil.

PALMITIN. This is the principal constituent of fresh palm-oil. It may be obtained from it by the following process:—

The palm-oil is subjected to pressure to remove the liquid portions; the solid portion is then boiled with alcohol, which dissolves the free fatty acids which may be present. The residue is then crude palmitin; and it is purified by repeated crystallisations with ether. When thus obtained it is in small crystals; these fuse, and become, on cooling, a semi-transparent mass, which may be easily reduced to powder. It is almost entirely insoluble in cold alcohol, and only slightly soluble in boiling alcohol, from which it again separates, on cooling, in flakes. It is soluble in all proportions in boiling ether.

M. Duffy states that there are three modifications of palmitin, differing in their melting-point: the first melting at 115° Fahr., the second melting at 142° Fahr., and the third at 145·2° Fahr.

PALM-OIL. See OILS.

PALM-SUGAR. The juices of many of the palms yield a saccharine matter, from which cane-sugar can be extracted.

PALM-TREE. The woods obtained from the various palms of the tropics pass under different names in commerce, according to the patterns they present. The only two varieties much used are: the Betel-nut palm, or *Areca catechu*, which yields a wood of a light yellow-brown colour; and the Cocoa-nut palm, *Cocos nucifera*. This wood is of a chestnut-brown colour. It is much employed for joists, water-troughs, &c., in small quantities for marquetry, and other ornamental works. We receive this wood under the various names of palm, palmetto, palmyra, nutmeg, leopard, and porcupine woods. The last two receive their names accordingly as the section is made in one direction or another.

If the wood is cut horizontally it exhibits dots, like spice; when cut obliquely, the markings are something like the quills of the porcupine.

PALM-WAX, the produce of the *Ceroxylon Andicola*, a palm growing in tropical America. The stem of the tree is thickly covered with wax, which is scraped off and softened and purified in hot water. It is mixed with tallow to render it less brittle; and in this state it is used in South America for candles. The leaves of the *Carnauba palm* are coated with a layer of wax, which peels off, and is collected when the leaves are dried. Teschemaker informs us that the leaves of the dwarf-palm are imported into the United States from the West Indian Islands for the use of the hatters; they are thickly covered with wax. See CARNAUBA.

PANIFICATION. The making of bread. See BREAD.

PANTILE. A curvilinear tile, so formed to facilitate the flow of water. *Plain tiles* are flat tiles.

PAPAVERINE. $C^{40}H^{21}NO^{8}$ ($\mathbf{C^{20}H^{21}NO^{4}}$). One of the many alkaloïds contained in opium. It was discovered by Merck in 1850, but has been chiefly examined by Dr. Anderson.

PAPER-COAL. (*Papierkohle*, Ger.) A name given to certain layers of lignite, from their leaf-like character; this mineral is known also as *Dysodile*.

PAPER-CUTTING. Some machines have been patented for this purpose; one by Mr. Crompton of Farnworth, and another by Enoch Miller. Mr. Edward Cowper patented a machine which has been extensively employed, and which, therefore, we must describe. It consists of a machine, with a reel on which the web of paper of very considerable length has been previously wound; this web of paper being of sufficient width to produce two, three, or more sheets when cut.

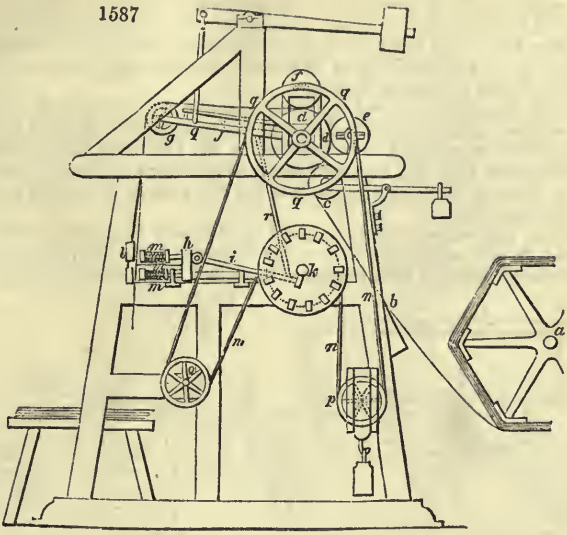
The several operative parts of the machine are mounted upon standards, or framework, of any convenient form or dimensions, and consist of travelling endless tapes to conduct the paper over and under a series of guide-rollers; of circular rotatory cutters for the purpose of separating the web of paper into strips equal to the widths of the intended sheets; and of a saw-edged knife, which is made to slide horizontally, for the purpose of separating the slips into such portions or lengths as shall bring them to the dimensions of a sheet of paper.

The end of the web of paper from the reel *a*, *fig.* 1587, is first conducted up an inclined plane, *b*, by hand; it is then taken hold of by endless tapes extended upon rollers, as in Mr. Cowper's Printing-Machine. These endless tapes carry the web of paper to the roller *c*, which is pressed against the roller *d* by weighted levers, acting upon the plummer-blocks that its axle is mounted in. The second roller, *d*, may be either of wood or metal, having several grooves formed round its periphery for the purpose of receiving the edges of the circular cutters, *c*, mounted upon an axle turning upon bearings in the standards or frame.

In order to allow the web of paper to proceed smoothly between the two rollers, *c*, *d*, a narrow rib of leather is placed round the edges of one or both of these rollers, for the purpose of leaving a free space between them, through which the paper may pass without wrinkling.

From the first roller, *c*, the endless tapes conduct the paper over the second, *d*, and then under a pressing-roller, *f*, in which progress the edges of the circular knives, *c*, revolving in the grooves of the second roller, *d*, cut the web of paper longitudinally into strips of such width as may be required, according to the number of the circular cutters and distances between them.

1587



The strips of paper proceeding onward from between the knife-roller, *d*, and pressing-roller, *f*, conducted by tapes, until they reach a fourth roller, *g*, when they are allowed to descend, and to pass through the apparatus designed to cut them transversely; that is, into sheet-lengths.

The apparatus for cutting the strips into sheets is a sliding knife, placed horizontally upon a frame at *h*, which frame, with the knife *e*, is moved to and fro by a jointed rod, *i*, connected to a crank on the axle of the pulley *k*. A flat board or plate, *l*, is fixed to the standard frame in an upright position, across the entire width of the machine, and this board or plate has a groove or opening cut along it opposite to the edge of the knife. The paper descending from the fourth roller, *g*, passes against the face of this board, and as the carriage with the knife advances, two small blocks, mounted upon rods with springs, *m m*, come against the paper, and hold it tight to the board or plate *l*, while the edge of the knife is protruded forward into the groove of that board or plate, and its sharp saw-shaped teeth passing through the paper, cut one row of sheets from the descending strips; which, on the withdrawing of the blocks, fall down, and are collected on the heap below.

The power for actuating this machine is applied to the reverse end of the axle on which the pulley *k* is fixed, and a band, *n n n n*, passing from this pulley over tension-wheels, *o*, drives the wheel, *q*, fixed to the axle of the knife-roller, *d*; hence this roller receives the rotatory motion, which causes it to conduct forward the web of paper; but the other rollers, *c* and *f*, are impelled slowly by the friction of contact.

The rotation of the crank on the axle of *k*, through the intervention of the crank-rod *i*, moves the carriage *h*, with the knife, to and fro at certain periods, and when the spring blocks *m* come against the grooved plate *l*, they slide their guide rods into them, while the knife advances to sever the sheets of paper. But as sheets of different dimensions are occasionally required, the lengths of the slips delivered between each return of the knife are to be regulated by enlarging or diminishing the diameter of the pulley *k*, which will of course retard or facilitate the rotation of the three conducting rollers, *c*, *d*, *f*, and cause a greater or less length of the paper to descend between each movement of the knife carriage.

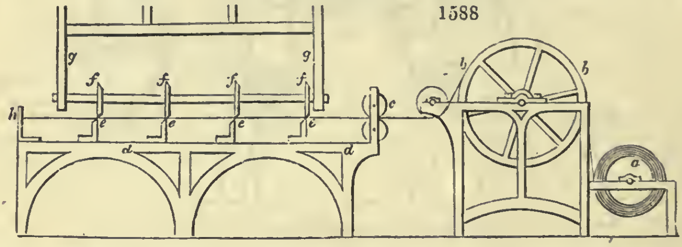
The groove of this pulley *k*, which is susceptible of enlargement, is constructed of wedge-formed blocks, passed through its sides, and meeting each other in opposite directions, so that on drawing out the wedges a short distance, the diameter of the pulley becomes diminished; or by pushing the wedges further in, the diameter is increased; and a tension wheel, *p*, being suspended in a weighted frame, keeps the band always tight.

As it is necessary that the paper should not continue descending while it is held by the blocks, *m m*, to be cut, and yet that it should be led on progressively over the knife roller, *d*, the fourth roller, *g*, which hangs in a lever, *j*, is made to rise at that time, so as to take up the length of paper delivered, and to descend again when the paper is withdrawn. This is effected by a rod, *r*, connected to the crank on the shaft of the aforesaid roller *k*, and also to the under part of the lever, *j*, which lever hanging loosely upon the axle of the knife-roller *d*, as its fulcrum, vibrates with the under-roller, *g*, so as to effect the object in the way described.

The patentee states that several individual parts of this machine are not new, and that some of them are to be found included in the Specifications of other persons, such as the circular cutters *c*, which are employed by Mr. Dickinson (CARD-CUTTING), and the horizontal cutter *h*, by Mr. Hansard; he therefore claims only the general arrangement of the parts in the form of a machine for the purpose of cutting paper, as the subject of his invention.

The machine for cutting paper contrived by Mr. John Dickinson, of Nash Mills, was patented in January 1829. The paper is wound upon a cylindrical roller, *a*, *fig.* 1588, mounted upon an axle, supported in an iron frame or standard. From this

1588



roller the paper in its breadth is extended over a conducting drum *b*, also mounted upon an axle turning in the frame or standard, and after passing under a small guide roller, it proceeds through a pair of drawing or feeding rollers, *c*, which carry it into the cutting machine.

Upon a table *d*, *d*, firmly fixed to the floor of the building, there is a series of chisel-edged knives, *e*, *e*, *e*, *e*, placed at such distances apart as the dimensions of the cut sheets of paper are intended to be. These knives are made fast to the table, and against them a series of circular cutters *f*, *f*, *f*, *f*, mounted in a swinging frame *g*, *g*, are intended to act. The length of paper being brought along the table over the edges of the knives up to a stop, *h*, the cutters are then swung forwards, and by passing over the paper against the stationary knives, the length of paper becomes cut into three separate sheets.

The frame *g*, *g*, which carries the circular cutters *f*, *f*, *f*, *f*, hangs upon a very elevated axle, in order that its pendulous swing may move the cutters as nearly in a horizontal line as possible; and it is made to vibrate to and fro by an excentric, or crank, fixed upon a horizontal rotatory shaft extending over the drum *b*, considerably above it, which may be driven by any convenient machinery.

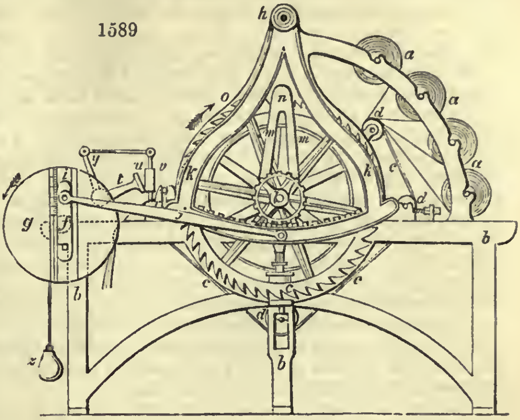
The workmen draw the paper from between the rollers, *c*, and bring it up to the stop *h*, in the intervals between the passing to and fro of the swing-cutters.

The following very ingenious apparatus for cutting the paper web transversely into any desired lengths, was made the subject of a patent by Mr. E. N. Fourdrinier, in June 1831, and has since been performing its duty well in many establishments.

Fig. 1589 is an elevation, taken upon one side of the machine; and *fig.* 1590 is a longitudinal section. *a*, *a*, *a*, *a*, are four reels, each covered with one continuous sheet of paper; which reels are supported upon bearings in the framework *b*, *b*, *b*. *c*, *c*, *c*, is an endless web of felt-cloth passed over the rollers *d*, *d*, *d*, *d*, which is kept in close contact with the under side of the drum *e*, *e*, seen best in *fig.* 1590.

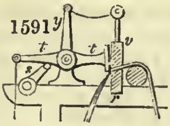
The several parallel layers of paper to be cut, being passed between the drum, *e*, and the endless felt *c*, will be drawn off their respective reels, and fed into the machine, whenever the driving-band is slid from the loose to the fast pulley upon the end of the main shaft *f*. But since the progressive advance of the paper-webs must be arrested during the time of making the cross cut through it, the following apparatus becomes necessary:—A disc, *g*, which carries the pin or stud of a crank, *i*, is made fast to the end of the driving shaft *f*. This pin is set in an adjustable sliding piece, which may be confined by a screw within the bevelled graduated groove, upon the face of the disc *g*, at variable distances from the axis, whereby the excentricity of the stud *i*, and of course the throw of the crank, may be considerably varied. The crank stud, *i*, is connected by its rod *j*, to the swinging curvilinear rack *k*, which takes into the toothed wheel *l*, that turns freely upon the axle of the feed-drum *e*, *e*. From that wheel the arms, *m m*, rise, and bear one or more palls, *n*, which work in the teeth of the great ratchet-wheel *o o*, mounted upon the shaft of the drum *e*.

1589

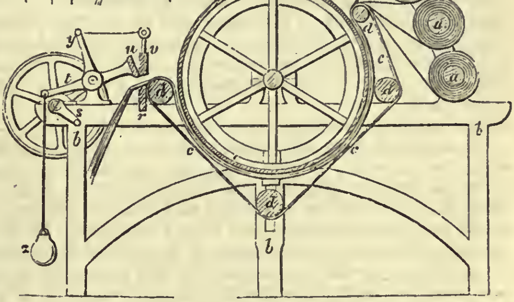


The crank-plate *g* being driven round in the direction of its arrow, will communicate a see-saw movement to the toothed arc *k*, next to the toothed wheel *l*, in gearing with it, and an oscillatory motion to the arms *m m*, as also to their surmounting pall *n*. In its swing to the left hand, the catch of the pall will slide over the slope of the teeth of the ratchet-wheel *o*; but in its return to the right hand, it will lay hold of these teeth, and pull them, with their attached drum, round a part of a revolution. The layers of paper in close contact with the under half of the drum will be thus drawn forward at intervals, from the reels, by the friction between its surface and the endless felt, and in lengths corresponding to the arc of vibration of the pall. The knife for cutting these lengths transversely is brought into action at the time when the swing arc is making its inactive stroke, viz. when it is sliding to the left over the slopes of the ratchet-teeth *o*. The extent of this vibration varies according to the distance of the crank stud *i*, from the centre, *f*, of the plate *g*, because that distance regulates the extent of the oscillations of the curvilinear rack, and that of the rotation of the drum *e*, by which the paper is fed forwards to the knife apparatus. The proper length of its several layers being by the above-described mechanism carried forward over the bed, *r*, of the cutting knife or shears *r*, *v*, whose under blade, *r*, is fixed, the wiper *s*, in its revolution with the shaft *f*, lifts the tail of the lever *t*, consequently depresses the transverse moveable blade *v* (as shown in *fig.* 1591), and slides the slanting blades across each other obliquely, like a pair of scissors, so as to cause a clean cut across the plies of paper. But just before the shears begin to operate, the transverse board, *u*, descends to press the paper with its edge, and hold it fast upon the bed *r*. During the action of the upper blade *v*, against the under *r*, the fall board *u* is suspended by a cord passing across pulleys from the arm *y* of the bell-crank lever *t*, *t*. Whenever the lifter cam, *s*, has passed away from the tail of the bell-crank *t*, the weight *z*, hung upon it, will cause the blade *v* and the pinching board *u*, to be moved up out of the way of the next length of paper, which is regularly brought forward by the rotation of the drum *e*, as above described. The upper blade of the shears is not set parallel to the shaft of the drum, but obliquely to it, and is, moreover, somewhat curved, so as to close its edge progressively upon that of the fixed blade. The blade *v* may also be set between two guide pieces, and have the necessary motion given to it by levers.

1591



1590



PAPER-HANGINGS, called more properly by the French, *papiers peints*. The art of making paper-hangings has been copied from the Chinese, among whom it has been practised from time immemorial. The English first imported and began to imitate the Chinese paper-hangings; but being long exposed to a high Excise duty upon the manufacture, they have only recently carried it to that extent and degree of refinement which the French have been enabled to do, unchecked by taxation. The first method of making this paper was stencilling; by laying upon it, in an extended state, a piece of pasteboard having spaces cut out of various figured devices, and applying different water-colours with the brush. Another piece of pasteboard, with other patterns cut out, was next applied, when the former figures were dry, and new designs were thus imparted. By a series of such operations, a tolerable pattern was executed, but with no little labour and expense. The processes of the calico-printer were next resorted to, in which engraved blocks, of the pear or sycamore, were employed to impress the coloured designs.

Paper-hangings may be distinguished into two classes: 1, those which are really painted, and which are designed in France under the title of *papiers peints*, with brilliant flowers and figures; and 2, those in which the designs are formed by foreign matters applied to the paper, under the name of *papier tontisse*, or flock paper.

The operations common to paper-hangings of both kinds may be stated as follow:—

1. The paper should be well sized.
2. The edges should be evenly cut by an apparatus like the bookbinder's press.
3. The ends of each of the 24 sheets which form a piece should be nicely pasted together; or a web of paper should be taken.
4. Laying the grounds is done with earthy colours of coloured lakes thickened with size, and applied with brushes.

An expert workman, with one or two children, can lay the grounds of 300 pieces in a day. The pieces are now suspended upon poles near the ceiling, in order to be dried. They were then rolled up and carried to the apartment where they are polished, by being laid upon a smooth table, with the painted side undermost, and rubbed with the polisher. Pieces intended to be satined are grounded with fine Paris plaster, instead of Spanish white; and are not smoothed with a brass polisher, but with a hard brush attached to the lower end of a swing polishing rod. After spreading the piece upon the table with the grounded side undermost, the paper-stainer dusts the upper surface with finely-powdered chalk of Briançon, commonly called talc, or with China clay, and rubs it strongly with the brush. In this way the satiny lustre is produced.

The printing operations are as follow:—

Blocks about two inches thick, formed of three separate boards glued together, of which two are made of poplar, and one (that which is engraved) of pear-tree or sycamore, are used for printing paper-hangings, as for calicoes. The grain of the upper layer of wood should be laid across that of the layer below. As many blocks are required as there are colours and shades of colour. To make the figure of a rose, for example, three several reds must be applied in succession, the one deeper than the other, a white for the clear spaces, two and sometimes three greens for the leaves, and two wood colours for the stems; altogether from 9 to 12 for a rose. Each block carries small pin-points fixed at its corners to guide the workman in the insertion of the figure exactly in its place. An expert hand places these guide pins so that their marks are covered and concealed by the impression of the next block; and the finished piece shows merely those belonging to the first and last blocks.

In printing, the workman employs the same *swimming-tub* apparatus which has been described under block-printing (see Calico-Printing), takes off the colour upon his blocks, and impresses them on the paper extended upon a table in the very same way. The tub in which the drum or frame covered with calf-skin is inverted contains simply water thickened with parings of paper from the bookbinder, instead of the pasty mixture employed by the calico-printers. In impressing the colour by the block upon the paper, he employs a lever of the second kind, to increase the power of his arm, making it act upon the block through the intervention of a piece of wood, shaped like the bridge of a violin. The tool is called *tasseau* by the French. A child is constantly occupied in spreading colour with a brush upon the calf-skin head of the drum or sieve, and in sliding off the paper upon a wooden trestle or horse, in proportion as it is finished. When the piece has received one set of coloured impressions, the workman, assisted by his little aid, called a drawer, hooks it upon the drying poles under the ceiling. A sufficient number of pieces should be provided to keep the printer occupied during the whole at least of one day, so that they will be dried and ready to receive another set of coloured impressions by the following morning.

All the colours are applied in the same manner, every shade being formed by means of the blocks, which determine all the beauty and regularity of the design. A pattern drawer of taste may produce a very beautiful effect.

When the piece is completely printed, the workman looks it all over, and if there be any defects, he corrects them by the brush or pencil, applying first the correction of one colour, and afterwards of the rest.

A final satining, after the colours are dried, is communicated by the friction of a finely-polished brass roller, attached by its end gudgeons to the lower extremity of a long swing frame; and acting along the cylindrical surface of a smooth table, upon which the paper is spread.

The *fondu* or rainbow style of paper-hangings is produced by means of an assortment of oblong narrow tin pans, fixed in a frame, close side to side, each being about 1 inch wide, 2 inches deep, and 8 inches long; the colours of the prismatic spectrum, red, orange, yellow, green, &c., are put in a liquid state, successively in these pans; so that when the oblong brush A, B (*fig.* 1592), with guide ledges, *a*, *c*, *b*, is dipped into them across the whole of the parallel row at once, it comes out impressed with the different colours at successive points, *e*, *e*, *e*, *e*, of its length, and is then drawn by the paper-stainer over the face of the woollen drum-head, or sieve of the swimming tub, upon which it leaves a corresponding series of stripes in colours, graduating into one another like those of the prismatic spectrum. By applying his block to the *tear*, the workman takes up the colour in rainbow hues, and transfers these to the paper. *f*, *f*, *f*, *f*, show the separate brushes in tin sheaths, set in one frame.

1592

The operations employed for common paper-hangings are also used for making flock paper, only a stronger size is necessary for the ground. The flocks are obtained from the woollen-cloth manufacturers, being cut off by their shearing machines, called *lewises* by the English workmen, and are preferred in a white state by the French paper-hanging makers, who scour them well, and dye them of the proper colours themselves. When they are thoroughly stove-dried, they are put into a conical fluted mill, like that for making snuff, and are properly ground. The powder thus obtained is afterwards sifted by a bolting machine, like that of a flour-mill, whereby flocks of different degrees of fineness are produced. These are applied to the paper after it has undergone all the usual printing operations. Upon the workman's left hand, and in a line with his printing table, a large chest is placed for receiving the flock powders: it is 7 or 8 feet long, 2 feet wide at the bottom, 3½ feet at top, and from 15 to 18 inches deep. It has a hinged lid. Its bottom is made of tense calf-skin. This chest is called the *drum*; it rests upon four strong feet, so as to stand from 24 to 28 inches above the floor.

The block which serves to apply the adhesive basis of the velvet powders, bears in relief only the pattern corresponding to that basis, which is formed with linseed oil, rendered drying by being boiled with litharge, and afterwards ground up with white lead. The workmen call this the *encaustic*. It is put upon the cloth which covers the inverted swimming tub, in the same way as the common colours are, and is spread with a brush. The workman daubs the blocks upon the *encaustic*, spreads the pigment even with a kind of brush, and then applies it by impression to the paper. Whenever a sufficient surface of the paper has been thus covered, the child draws it along into the great chest, sprinkling the flock powder over it with his hands; and when a length of 7 feet is printed, he covers it up within the drum, and beats upon the calf-skin bottom with a couple of rods to raise a cloud of flock inside, and to make it cover the prepared portion of the paper uniformly. He now lifts the lid of the chest, inverts the paper, and beats it back lightly, in order to detach all the loose particles of the woolly powder.

By the operation just described, the velvet down being applied everywhere of the same colour, would not be agreeable to the eye, if shades could not be introduced to relieve the pattern. For this purpose, when the piece is perfectly dry, the workman stretches it upon his table, and by the guidance of the pins in his blocks, he applies to the flock surface a colour in distemper, of a deep tint, suited to the intended shades, so that he dyes the wool in its place. Light shades are produced by applying some of his lighter water-colours.

Gold-leaf is applied upon the above mordant, when nearly dry; which then forms a proper gold size; and the same method of application is resorted to as for the ordinary gilding of wood. When the size has become perfectly hard, the superfluous gold-leaf is brushed off with a dossil of cotton-wool or fine linen.

The colours used by the paper-hangers are the following:—

1. *Whites.*—These are either white lead, good whitening, or a mixture of he two.

2. *Yellows.*—These are frequently vegetable extracts; as those of weld, or of Avignon or Persian berries, and are made by boiling the substances with water.

Chromo yellow is also frequently used, as well as the *terra di Sienna* and yellow ochre.

3. *Reds* are almost exclusively decoctions of Brazil-wood.

4. *Blues* are either Prussian blue or blue verditer.

5. *Greens* are: Scheele's green, a combination of arsenious acid and oxide of copper; the green of Schweinfurth, or green verditer; as also a mixture of blues and yellows. The use of arsenic in paper-hangings has of late (1859) been the subject of much discussion, and many absurd statements have been made respecting its injurious effects. See ARSENIC.

It has been suggested by Piesse that paper variously coloured in the pulp may have designs printed upon them after the same manner as calicos are printed, sometimes by a discharge-mordant, or by chemical reagents applied by an engraved roller, so as to modify the colour of the pulp.

6. *Violets* are produced by a mixture of a blue and red in various proportions, or they may be obtained directly by mixing a decoction of logwood with alum.

7. *Browns, Blacks,* and *Greys.*—Umber furnishes the brown tints. Blacks are either common ivory- or Frankfort black; and greys are formed by mixture of Prussian blue and Spanish white.

All the colours are rendered adhesive and consistent by being worked up with gelatinous size or a weak solution of glue, liquefied in a kettle. Many of the colours are previously thickened, however with starch. Sometimes coloured lakes are employed.

PAPER, INDELIBLE CHEQUE. The facility with which ordinary-written characters can be expunged from paper by chemical bleaching-liquids, acids, and alkalis, has led to the adoption by bankers, for their cheques and drafts, of papers which present obstacles to the fraudulent alteration of the amount and intent of these documents.

Instances of this description of forgery have occasionally occurred. In the spring of 1859 a cheque was paid at a branch of the Bank of England in which both the amount had been altered and the crossing extracted by chemical means.

In 1822 William Robson patented a method of securing bankers' cheques by printing upon their surface vegetable colours equally fugitive with common writing-ink.

This method, and its extension to the tinting of writing-papers in the pulp, has been generally adopted by bankers. Those papers which exhibit the perfection of Robson's principle are limited in practice almost exclusively to certain tints obtained from logwood.

Mr. Baildon's paper is a tinted one, from which the colour is removed. The patentee states that he offers *absolute integrity and security* from alteration for any document once issued; and this is obtained by a fluid or ink, which, when used, becomes, in fact, a *permanent dye,* different from any inks yet introduced for this purpose, which are *pigments.* The least attempt to tamper with the ink or paper is instantly detected by a *dark stain* in the paper, which can *never be removed.*

As early as 1817 Gabriel Tigere patented a method of manufacturing 'writing-paper from which it would be extremely difficult, if not impossible, afterwards to extract or discharge any writing from such paper.' This paper was impregnated during the sizing process with the ferrocyanide of potassium.

Mr. William Stone's patent, 1851, was an effort to supply the deficiencies of this method. He added a solution of cyanide of potassium and starch to the ferro- or ferridcyanide of potassium. This method has been fully carried out into practice, but it failed to give the complete security desired. The chemical defects of Tigere's method may be stated thus:—Although admirable in the protection it affords against the application of acids, it is powerless to resist the bleaching-powers of such substances as common chloride of lime (bleaching-powder) in solution; and the ink may also be removed by the application of either of the caustic alkalis. In Stone's method, although by the application of bleaching agents containing chlorine the paper is stained by the blue compound termed the iodide of starch, this is removed again by the application of an alkali.

The Linen Company Bank of Scotland employ green-coloured cheque-paper, on which the sum drawn is written for with a discharge-ink.

In 1837 David Stevenson patented the manufacture of a paper which he specified as containing 'a solution of manganese, mixed with a solution of prussiate of potassa in a liquid form, and mixed with the pulp whereof the writing-paper is to be made.'

In June 1859, Mr. Robert Barclay patented a process of manufacturing a white writing-paper, on which writing-ink is stated to be unalterable for fraudulent purposes by any existing chemical process. He incorporates in the paper an insoluble ferrocyanide and an insoluble salt of manganese, and provides against the discoloration of the paper in the sizing process (which has been a serious objection in practice to the use of the ferrocyanide of potassium) by discarding the use of alum, and sizing the paper by the acetate of alumina in lieu of it. This paper was examined by Professor Brande of the Mint, Professor Miller of King's College, and Mr. R. Warrington of Apothecaries' Hall, who reported favourably on the invention. Writing placed upon this paper strengthens in intensity when exposed to damp, sea, air, or water: influences which ordinarily cause common writing-ink to fade and become illegible.

Dr. Hodges of Belfast, and some others have patented chemically-prepared papers for the use of bankers; but, as far as our enquiries have gone, most bankers appear to think they are already sufficiently secured by the known methods of engraving and printing.

PAPER, MANUFACTURE OF. It is much to be regretted that in tracing the origin of so curious an art as that of the manufacture of modern paper, any definite conclusion as to the precise time or period of its adoption should hitherto have proved altogether unattainable. The Royal Society of Sciences at Göttingen, in 1755 and 1763, offered considerable premiums for that especial object, but unfortunately all researches, however directed, were utterly fruitless. The most ancient manuscript on *cotton paper* appears to have been written in 1050, while Eustathius, who wrote towards the end of the 12th century, states that the Egyptian papyrus had gone into disuse but a little before his time. To reconcile, however, in some measure, contradictory accounts, it may be observed that, on some particular occasions, and by some particular persons, the Egyptian paper might have been employed for several hundred years after it ceased to be in general use; and it is quite certain, that although the new invention must have proved of great advantage to mankind, it could only have been introduced by degrees. Amongst the records which are now preserved in the Record Office, will be found a letter addressed to Henry III., and written previously to 1222, which appears to be upon strong paper, of mixed materials. Several letters of the following reign, which are there preserved, are evidently written on *cotton* paper. Were we able to determine the precise time when paper was first made from cotton, we should also be enabled to fix the invention of the art of paper-making as it is now practised; for the application of cotton to the purposes of paper-making requires almost as much labour and ingenuity as the use of linen rags. Some have conceived, and probably with sufficient reason, that China originally gave birth to the invention. Certain it is, that the art of making paper from vegetable matter reduced to pulp was known and understood there long before it was practised in Europe, and the Chinese have carried it to a high degree of perfection. Several kinds of their paper evince the greatest art and ingenuity, and are applied with much advantage to many purposes. One especially, manufactured from the inner bark of the bamboo, is particularly celebrated for affording the clearest and most delicate impressions from copper-plates, which are ordinarily termed *India proofs*. The Chinese, however, make paper of various kinds, some of the bark of trees, especially the mulberry-tree and the elm, but chiefly of the bamboo and cotton-tree; and occasionally from other substances, such as hemp, wheat-, or rice-straw. To give an idea of the manner of fabricating paper from these different substances, it will suffice (the process being nearly the same in each) to confine our observations to the method adopted in the manufacture of paper from the bamboo—a kind of cane or hollow reed, divided by knots, but larger, more elastic, and more durable than any other reed. The whole substance of the bamboo is at times employed by the Chinese in this operation, but the younger stalks are preferred. The canes, being first cut into pieces of four or five feet in length, are made into parcels, and thrown into a reservoir of mud and water for about a fortnight, to soften them; they are then taken out, and carefully washed, every one of the pieces being again cut into filaments, which are exposed to the rays of the sun to dry, and to bleach. After this they are boiled in large kettles, and then reduced to pulp in mortars, by means of a hammer with a long handle; or as is more commonly the case, by submitting the mass to the action of stampers, raised in the usual way by cogs on a revolving axis. The pulp being thus far prepared, a glutinous substance extracted from the shoots of a certain plant is next mixed with it in stated quantities, and upon this mixture chiefly depends the quality of the paper.

As soon as this has taken place the whole is again beaten together until it becomes a thick viscous liquor, which, after being reduced to an essential state of consistency, by a further admixture of water, is then transferred to a large reservoir or vat, having on each side of it a drying stove, in the form of a ridge of a house, that is, consisting of two sloping sides touching at top. These sides are covered externally with an exceedingly smooth coating of stucco, and a flue passes through the brickwork, so as to keep the whole of each side equally and moderately warm. A vat and a stove are placed alternately in the manufactory, so that there are two sides of two different stoves adjacent to each vat. The workman dips his mould, which is sometimes formed merely of bulrushes, cut in narrow strips, and mounted in a frame, into the vat, and then raises it out again, the water passing off through the perforations in the bottom, and the pulpy paper-stuff remaining on its surface. The frame of the mould is then removed, and the bottom is pressed against the sides of one of the stoves, so as to make the sheet of paper adhere to its surface, and allow the sieve (as it were) to be withdrawn. The moisture, of course, speedily evaporates by the warmth of the stove, but before the paper is quite dry, it is brushed over on its outer surface with a size made of rice, which also soon dries, and the paper is then stripped off in a finished state, having one surface exquisitely smooth, it being seldom the practice of the Chinese to write or print on both sides of the paper. While all this is taking place, the moulder has made a second sheet, and pressed it against the side of the other stove, where it undergoes the operation of sizing and drying, precisely as in the former case.

That very delicate material, which is brought from China in pieces only a few inches square, and commonly, but erroneously, termed *rice paper*, is in reality but the pith of the *Aralia papyrifera*, obtained by cutting the stem spirally round the axis, and afterwards flattening it by pressure. That it is not an artificial production may very readily be perceived by contrasting one of the more translucent specimens with a piece of the finest manufactured paper, by the aid of the microscope.

The precise period at which the manufacture of paper was first introduced into Europe appears to be rather a matter of uncertainty. Paper-mills, moved by water-power, were in operation in Tuscany at the commencement of the fourteenth century; and at Nuremberg, in Germany, one was established in 1390, by Ulman Stromer, who wrote the first work ever published on the art of paper-making. He seems to have employed a great number of persons, all of whom were obliged to take an oath that they would not teach any one the art of paper-making, or make it on their own account. In the following year, when anxious to increase the means of its production, he met with such strong opposition from those he employed, who would not consent to any enlargement of the mill, that it became at length requisite to bring them before the magistrates, by whom they were imprisoned, after which they submitted by renewing their oaths. Two or three centuries later, we find the Dutch, in like manner, so extremely jealous with respect to the manufacture, as to prohibit the exportation of moulds, under no less severe a penalty than that of death.

With reference to any particular *time* or *place* at which this inestimable invention was first adopted in England, all researches into existing records contribute little to our assistance. The first paper-mill erected here is commonly attributed to Sir John Spielman, a German, who established one in 1588, at Dartford, for which the honour of knighthood was afterwards conferred upon him by Queen Elizabeth, who was also pleased to grant him a licence 'for the sole gathering for ten years of all rags, &c., necessary for the making of such paper.' It is, however, quite certain that paper-mills were in existence here long before Spielman's time. Shakspeare, in the Second Part of Henry the Sixth, the plot of which appears laid at least a century previously, refers to a paper-mill. In fact, he introduces it as an additional weight to the charge which Jack Cade is made to bring against Lord Say: 'Thou hast most traitorously corrupted,' says he, 'the youth of the realm in erecting a grammar school: and whereas, before, our forefathers had no other books but the score and the tally, thou hast caused printing to be used, and, contrary to the king, his crown and dignity, thou hast built a paper-mill.'

The earliest trace of the manufacture in this country occurs in a book printed by Caxton, about the year 1490, in which it is said of John Tate—

> Which late hathe in England doo make thys paper thynne,
> That now in our Englyssh thys booke is printed inne.'

His mill was situate at or near Stevenage, in Hertfordshire, and that it was considered worthy of especial notice is evident from an entry made in Henry the Seventh's Household Book, on May 25, 1498—'For a rewarde geven at the paper-mylne, 16*s.* 8*d.*' And again in 1499—'Geven in rewarde to Tate of the mylne, 6*s.* 8*d.*'

Still, it appears far less probable that Shakspeare alluded to this mill, although established at a period corresponding in many respects with that of occurrences referred to in connection, than to that of Sir John Spielman's, which, standing as it did in the immediate neighbourhood of Jack Cade's rebellion, and being esteemed so important at the time as to call forth the marked patronage of Queen Elizabeth; while the extent of the operations carried on there, if we may judge from the remarks of a poet of the time, were equally calculated to arouse undivided national interest; one can hardly help thinking, that the prominence to which Shakspeare assigns the existence of a paper-mill, coupled, as such allusion is, with an acknowledged liberty, inherent in him, of transposing events, to add force to his style, as also with very considerable doubt as to the exact year in which he wrote the play, that the reference made was to none other than that of Sir John Spielman's establishment of 1588, concerning which we find it said—

'Six hundred men are set to work by him,
That else might starve or seek abroad their bread,
Who now live well, and go full brave and trim,
And who may boast they are with paper fed.'

Be the introduction or establishment of the invention, so far as this country is concerned, when it may, little progress appears to have resulted therefrom, even so late as the middle of the seventeenth century. In 1695, a company was formed in Scotland 'for manufacturing white writing and printing paper,' relating to which, 'Articles concluded and agreed upon at a general meeting at Edinburgh, the 19th day of August,' in the same year, may still be seen by those who are sufficiently curious in the library of the British Museum. It is also recorded in the 'Craftsman' (910), that William the Third granted the Huguenots refuged in England a patent for establishing paper-manufactories, and that Parliament likewise granted to them other privileges, amongst which, in all probability, that very unsatisfactory practice of putting up each ream with two quires composed entirely of sheets spoiled in course of production. Their undertaking, however, like that of many others, appears to have met with very little success.

In fact, the making of paper here scarcely reached any high degree of perfection until about 1760–5, at which period the celebrated James Whatman established his reputation at Maidstone.

The Report of the Juries of the Great Exhibition of 1851 contains an unfortunate error with reference to the position of Mr. Whatman at that time. It is there stated that he gained his knowledge of the manufacture prior to establishing these well-known mills, 'by working as a journeyman in most of the principal paper manufactories of the Continent,' which is altogether an erroneous assertion; for Mr. Whatman, previously to his being engaged as a manufacturer, was an officer in the Kent Militia, and acquired the information, which eventually rendered him so successful, by travelling in the suite of the British Ambassador to Holland, where the best papers were then made, and the insight thus obtained enabled his genius to effect the great improvements afterwards so universally admitted.

At the present time, Whatman's papers are manufactured at two mills, totally distinct, both of which are still worked by the descendants of Mr. Whatman's successors; the paper in the one case being readily distinguished by the water-mark, 'J. Whatman, Turkey Mill,' and in the other, by the water-mark simply 'J. Whatman,' but bearing upon the upper wrapper of each ream the original and well-known stamp, containing the initials L. V. G., which are those of L. V. Gerrevink, as celebrated a Dutch manufacturer prior to Mr. Whatman's improvements as Mr. Whatman's name has since become in all parts of the world.

The comparatively recent application of continuous or rotatory motion has effected wonderful results in the singular conversion of pulp into paper.

The largest paper now made by hand, which is termed Antiquarian, measures 53 inches by 31, and so great is the weight of liquid pulp employed in the formation of a single sheet, that no fewer than nine men are required, besides additional assistance, in raising the mould out of the vat by means of pulleys; while by the aid of the *paper machine*, the most perfect production may be ensured, of a continuous length, and eight feet wide, without any positive necessity for personal superintendence. As an evidence of the enormous length of paper sometimes produced, two rolls were exhibited in 1851, one of which measured 750 yards, and the other 2,400 yards in length.

The principle of paper-making by machinery is simply this: instead of employing moulds and felts of limited dimensions, as was originally the practice, the peculiar merit of the invention consists in the adaptation of an endless wire-gauze to receive the paper-pulp, and again an endless felt, to which in progress the paper is transferred; and thus by a marvellously delicate adjustment, while the wire at one end receives but a constant flow of liquid pulp, in the course of two or three minutes the finished fabric is carefully wound on a roller at the other extremity.

It is a fact, which certainly deserves to be noticed for its singularity as well as for the strong point of view in which it places the merits of this invention, that an art of such great importance to society as that of the manufacture of paper, should have remained for at least eight centuries since paper is first believed to have been in use, and that upwards of 200 of those years should have elapsed since its first introduction into England, without any mechanical improvement whatever as regards the processes which were then employed. It is true, that various attempts from time to time were made, but in every instance they appear to have met with very little success. In France, an ingenious artist (Monsieur Montgolfier) contrived three figures in wood to do the work of the vatman, the coucher, and the layer; but, after persevering for six months, and incurring considerable expense, he was at length compelled to abandon his scheme. And although paper was previously manufactured in China, in Persia, and indeed throughout all Asia, sometimes of considerable length, it was so, not by machinery, but by means of a mould of the size of the paper intended to be made, suspended like a swing, and having men placed at the distance of about every four feet, for the purpose of producing an uniform shaking motion, after the mould had been immersed in the vat, in order to compact the pulp.

Such, then, was the rude state of this important manufacture, even up to the commencement of the present century, when a small working model of a continuous machine was introduced into this country from France by Mr. John Gamble, a brother-in-law to Monsieur Leger Didot, the proprietor at that time of the paper manufactory at Essonne.

The individual to whose genius we owe that beautiful contrivance, which has since been adopted wherever the want which it was designed to remedy has been truly felt, and which has contributed in an eminent degree to the advancement of civilisation, was an unassuming clerk in the establishment of Monsieur Didot, named Louis Robert, who following his favourite pursuit of inventing and improving, not unfrequently had to bear the reproach of wasting time on an invention that could never be brought to perfection. Fortunately, however, the patience and attention of this persevering man were at length sufficiently rewarded by the completion of a small model not larger than a bird organ, which enabled him to produce paper of a continuous length although but the width of a piece of tape. So successful was this performance that his employer, instead of continuing to thwart his progress, was now induced to afford him the means of making a model upon a larger scale, and in a few months a machine was completed capable of making paper the width of Colombier (24 inches), for which the consumption in France was very great. After a series of experiments and improvements, Louis Robert applied to the French Government for a patent or *brevet d'invention*, which he obtained in 1799 for a term of fifteen years, and was awarded the sum of 8,000 francs as a reward for his ingenuity. The Specification of this patent is published in the second volume of the 'Brevets d'Inventions Expirés.' Shortly afterwards, M. Didot purchased Louis Robert's patent and paper-machine for 25,000 francs, to be paid by instalments; but not fulfilling his engagements, the latter commenced legal proceedings, and recovered possession of his patent, by a decision dated June 23rd, 1801. Towards the close of the year 1800 M. Didot proposed to his brother-in-law, Mr. Gamble, that patents should be taken out in England, and suggested that he being an Englishman, and holding a situation under the British Government, would in all probability accomplish it without much difficulty. To this proposition Mr. Gamble assented, and in the month of March 1801, he left Paris for London, where, happily for the vigorous development of this project, he obtained an introduction immediately upon his arrival to one of the principal wholesale stationery houses in Great Britain—a firm of considerable opulence—and to those gentlemen he mentioned the nature and circumstances of his visit, at the same time showing them several rolls of the paper of great length, which had been made at Essonne by Louis Robert's machine, and which induced them to take a share in the patent.

The firm alluded to was that of the Messrs. Fourdrinier—a name which has indeed become alike famous and unfortunate—and this transaction it was which first connected them with the paper-machine. In the year 1801, Mr. Gamble returned to Paris, and concerted measures with Monsieur Leger Didot and Louis Robert, to have the working model, which was then at Essonne, sent over to England to assist in the construction of other machines; and the following year M. Didot arriving in London, was introduced by Mr. Gamble to the Messrs. Fourdrinier, when a series of experiments for improving the machine was considered desirable and at once commenced. But in order to accomplish the arduous object which those gentlemen then had in view, they laboured without intermission for nearly six years, when, after incurring an expense of 60,000*l*., which was borne exclusively by the Messrs. Fourdrinier, they at length succeeded in giving some further organisation and connection to the mechanical parts, for which they likewise obtained a patent, and finding eventually that there was little prospect of being recompensed for labour and risk, or even reimbursed their expenses, unless Parliament should think proper to grant an extension of the patent, they determined upon making a fresh application to the Legislature for that purpose. But, it would appear that although in the Bill as it passed the House of Commons, such prolonged period extended to fourteen years, in the Lords it was limited to seven, with an understanding that such term should be extended to seven years more in the event of the patentees proving, upon a future application, that they had not been sufficiently remunerated. No such application, however, was made, in consequence of a Standing Order of the House of Lords, placed on their Journals subsequently to the passing of the said act; which regulation had the effect of depriving the Messrs. Fourdrinier of any benefit whatever from the invention; and ultimately, so great were the difficulties they had to encounter, and so little encouragement or support did they receive, that the time and attention required to mature this valuable invention, and the large capital which it absorbed, were the means of reducing those wealthy and liberal men to the humiliating condition of bankruptcy.

In reverting strictly to the manufacture of paper, the nature of some of the materials employed first claim attention. Silks, woollens, flax, hemp, and cotton, in all their varied forms, whether as cambric, lace, linen, holland, fustian, corduroy, bagging, canvas, or even as cables, are or can be used in the manufacture of paper of one kind or another. Still, rags, as of necessity they accumulate and are gathered up by those who make it their business to collect them, are very far from answering the purposes of paper-making. Rags, to the paper-maker are almost as various in point of quality or distinction, as the materials which are sought after through the influence of fashion. Thus the paper-maker, in buying rags, requires to know exactly of what the bulk is composed. If he is a manufacturer of white papers, no matter whether intended for writing or printing, silk or woollen rags would be found altogether useless, inasmuch as it is well known, the bleach will fail to act upon any animal substance whatever. And although he may purchase even a mixture in proper proportions adapted for the quality he is in the habit of supplying, it is as essential in the processes of preparation that they shall previously be separated. Cotton in its raw state, as may be readily conceived, requires far less preparation than a strong hempen fabric, and thus, to meet the requirements of the paper-maker, rags are classed under different denominations, as for instance, besides *fines* and *seconds*, there are *thirds*, which are composed of fustians, corduroy, and similar fabrics; *stamps* or *prints* (as they are termed by the paper-maker), which are coloured rags, and also innumerable foreign rags, distinguished by certain well-known marks, indicating their various peculiarities. It might be mentioned, however, that although by far the greater portion of the materials employed are such as have already been alluded to, it is not from their possessing any exclusive suitableness—since various fibrous vegetable substances have frequently been used, and are indeed still successfully employed—but rather on account of their comparatively trifling value, arising from the limited use to which they are otherwise applicable.

To convey some idea of the number of substances which have been really tried; in the library of the British Museum may be seen a book printed in Low Dutch, containing upwards of sixty specimens of paper, made of different materials, the result of one man's experiments *alone*, so far back as the year 1772. In fact, almost every species of tough fibrous vegetable, and even animal substance, has at one time or another been employed: even the roots of trees, their bark, the bine of hops, the tendrils of the vine, the stalks of the nettle, the common thistle, the stem of the hollyhock, the sugar-cane, cabbage-stalks, beet-root, wood-shavings, sawdust, hay, straw, willow, and the like. Straw is frequently used in connection with other materials, such as linen or cotton rags, and even with considerable advantage, providing the processes of preparation are thoroughly understood. Where such is not the case, and the silica contained in the straw has not been destroyed (by means of a strong alkali), the paper will invariably be found more or less brittle; in some cases so much so as to be hardly applicable to any purpose whatever of practical utility. The waste, however, which the straw undergoes, in addition to a most expensive process of preparation, necessarily precludes its adoption to any great extent. Two inventions have been patented for manufacturing paper entirely from wood. One process consists in first boiling the wood in caustic soda-lye in order to remove the resinous matter, and then washing to remove the alkali; the wood is next treated with chlorine gas or an oxygenous compound of chlorine in a suitable apparatus, and washed to free it from the hydrochloric acid formed: it is now treated with a small quantity of caustic soda, which converts it instantly into pulp, which has only to be washed and bleached, when it will merely require to be beaten for an hour or an hour and a half in the ordinary beating-engine, and made into paper. The other invention is very simple, consisting merely of a wooden box enclosing a grindstone, which has a roughened surface, and against which the blocks of wood are kept in close contact by a lever, a small stream of water being allowed to flow upon the stone as it turns, in order to free it of the pulp, and to assist in carrying it off through an outlet at the bottom. Of course the pulp thus produced cannot be employed for any but the coarser kinds of paper. For all writing and printing purposes, which manifestly are the most important, nothing has been discovered to greatly lessen the value of rags, neither is it at all probable that there will, inasmuch as rags, of necessity, must continue accumulating; and before it will answer the purpose of the paper-maker to employ new material, which is not so well adapted for his purpose as the old, he must be enabled to purchase it for considerably less than it would be worth in the manufacture of textile fabrics; and, besides all this, rags possess in themselves the very great advantage of having been repeatedly prepared for paper-making by the numerous alkaline washings which they necessarily receive during their period of use.

With all the drawbacks attending the preparation of straw, it is an exceedingly useful material for the manufacture of certain kinds of paper. A thick brown paper, of tolerable strength, may be made from it cheaply; but for printing or writing purposes only an inferior description can be produced, and of little comparative strength to that of rag-paper. Its chief and best use is that of imparting stiffness to common newspaper. Some manufacturers prefer for this purpose an intermixture of straw with paper shavings, and others, in place of the paper shavings, give the preference to rags. The proportion of straw used in connection with rags or paper-shavings varies from 50 to 80 per cent.

The cost of producing two papers of equal quality, one entirely from straw and the other entirely from rags, would be very nearly equal; the preparation, which includes power, labour, and chemicals, being very much greater in the case of the straw; indeed from two to three times as much as that of rags.

In order to reduce the straw to a suitable consistency for paper-making, it is placed in a boiler with a large quantity of strong alkali, and with a pressure of steam equal to 120 lbs., and sometimes to 150 lbs., per square inch; the extreme heat being attained in super-heating the steam after it leaves the boiler, by passing it through a coiled pipe over a fire, and thus the silica becomes destroyed, and the straw softened to pulp, which, after being freed from the alkali by washing it in cold water, is subsequently bleached and beaten in the ordinary rag-engine, to which we shall presently refer.

The annual consumption of rags in this country alone far exceeds 120,000 tons, three-fourths of which are imported, Italy and Germany furnishing the principal supplies.

All that can be said as to the suitableness of fibre in general may be summed up in very few words: any vegetable fibre having a corrugated edge, which will enable it to cohere in the mass, is fit for the purpose of paper-making. Among the many fibres that have been introduced for use in this manufacture, the most important undoubtedly is the coarse grass known as *Esparto* in Spain, and as *Alfa* in Northern Africa. It was first imported by Mr. Noble in 1851, but it was not until the scarcity of cotton was felt during the American War that paper-makers fully realised the value of esparto fibre; in 1868 as much as 96,000 tons were imported. Other fibres have recently been used, such as those of the diss-grass, the dwarf-palm, the baobab-tree, and the New Zealand flax; but it is said that none of these can successfully compete with esparto. Canada rice has recently been recommended as an excellent paper-making material.

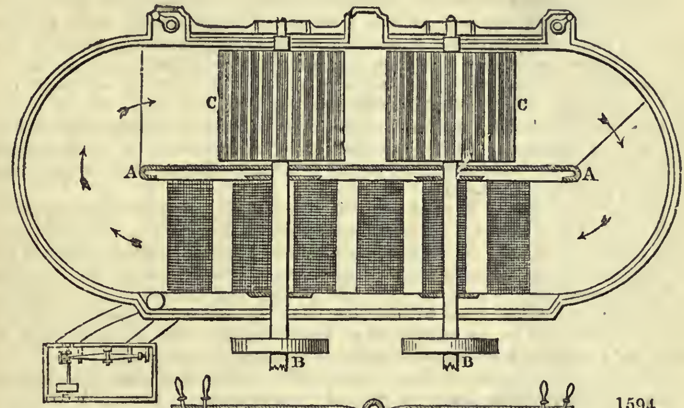
In considering the various processes or stages of the manufacture of paper, we have first to notice that of carefully sorting and cutting the rags into small pieces, which is done by women; each woman standing at a table-frame, the upper surface of which consists of very coarse wire-cloth; a large knife being fixed in the centre of the table, nearly in a vertical position. The woman stands so as to have the back of the blade opposite to her, while at her right hand, on the floor, is a large wooden box, with several divisions. Her business consists in examining the rags, opening the seams, removing dirt, pins, needles, and buttons of endless variety, which would be liable to injure the machinery, or damage the quality of the paper. She then cuts the rags into small pieces, not exceeding 4 inches square, by drawing them sharply across the edge of the knife; at the same time keeping each quality distinct in the several divisions of the box placed on her right hand. During this process, much of the dirt, sand, and so forth, passes through the wire-cloth into a drawer underneath, which is occasionally cleaned out. After this, the rags are removed to what is called the *dusting-machine*, which is a large cylindrical frame covered with similar coarse iron wire-cloth, and having a powerful revolving shaft extending through the interior, with a number of spokes fixed transversely, nearly long enough to touch the cage. By means of this contrivance, the machine being fixed upon an incline of some inches to the foot, the rags, which are put in at the top, have any remaining particles of dust that may still adhere to them effectually beaten out by the time they reach the bottom.

The rags being thus far cleansed, have next to be boiled in an alkaline lye or solution, made more or less strong as the rags are more or less coloured, the object being to get rid of the remaining dirt and some of the colouring-matter. The proportion is from 4 to 10 lbs. of carbonate of soda with one-third of quicklime to the cwt. of material. In this the rags are boiled for several hours, according to their quality.

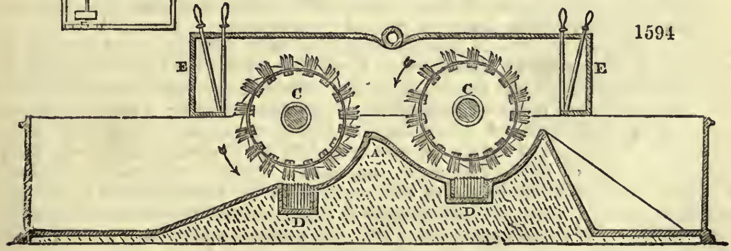
The method generally adopted is that of placing the rags in large cylinders, which are constantly, though slowly, revolving, thus causing the rags to be as frequently turned over, and into which a jet of steam is cast with a pressure of something near 30 lbs. to the square inch.

After this process of cleansing, the rags are considered in a fit state to be torn or macerated until they become reduced to a pulp, which was accomplished, some fifty years since, by setting them to heat and ferment for many days in close vessels, whereby in reality they underwent a species of putrefaction. Another method subsequently employed was that of beating them by means of stamping-rods, shod with iron, working in strong oak or stone mortars, and moved by water-wheel machinery. So rude and ineffective, however, was this apparatus, that no fewer than

1593



1594



40 pairs of stamps were required to operate a night and a day in preparing 1 cwt. of material. At the present time the average weekly consumption of rags, at many paper-mills, exceeds even 30 tons. The cylinder- or engine-mode of comminuting rags into paper-pulp appears to have been invented in Holland, about the middle of the last century, but received very little attention here for some years afterwards. The accompanying figures (*figs.* 1593 and 1594) will serve to convey some idea of the wonderful rapidity with which the work is at present accomplished. No less than *twelve tons* per week can now be prepared by means of this simple contrivance. The horizontal section (*fig.* 1594) represents an oblong cistern, of cast iron, or wood lined with lead, into which the rags, with a sufficient quantity of water, are received. It is divided by a partition, as shown (A), to regulate the

course of the stuff; the spindle upon which each cylinder, C, moves, extending across the engine, and being put in motion by a band-wheel or pinion at the point, B. One cylinder is made to traverse at a much swifter rate than the other, in order that the rags may be the more effectually triturated. The cylinders, C, as shown in the vertical section, are furnished with numerous cutters, running parallel to the axis, and again beneath them similar cutters are mounted (D) somewhat obliquely, against which, when in motion, the rags are drawn by the rapid rotation of the cylinders, and thus reduced to the smallest filaments requisite, sometimes not exceeding the sixteenth of an inch in length; the distance between the fixed and moveable blades being capable of any adjustment, simply by elevating or depressing the bearings upon which the necks of the shaft are supported. When in operation, it is of course necessary to enclose the cylinders in a case, as shown, E E, otherwise a large proportion of the rags would, inevitably, be thrown out of the engine. The rags are first worked coarsely, with a stream of water running through the engine, which tends effectually to wash them, as also to open their fibres; and in order to carry off the dirty water, what is termed a *washing drum* is frequently employed, consisting simply of a framework covered with very fine wire-gauze, in the interior of which, connected with the shaft or spindle, which is hollow, are two suction tubes, and by this means, on the principle of a syphon, the dirty water constantly flows away through a larger tube running down outside, which is connected with that in the centre, without carrying away any of the fibre.

After this, the mass is placed in another engine, where, if necessary, it is bleached by an admixture of chloride of lime, which is retained in the engine until its action becomes apparent. The pulp is then let down into large slate cisterns to steep, prior to being reduced to a suitable consistency by the beating-engine, as already described. The rolls or cylinders, however, of the beating-engine are always made to rotate much faster than when employed in washing or bleaching, revolving probably from 120 to 150 times per minute, and thus, supposing the cylinders to contain 48 teeth each, passing over eight others, as shown in the figures, effecting no fewer than 103,680 cuts in that short period. From this the great advantage of the modern engine over the old-fashioned mortar machine, in turning out a quantity of paper-pulp, will be at once apparent. The introduction of colouring-matter in connection with the paper-manufacture is accomplished simply by its intermixture with the pulp while in process of beating in the engine.

Although the practice of blueing paper is not, perhaps, so customary now as was the case a few years back, the extent to which it is still carried may be a matter of considerable astonishment. On its first introduction, when, as regards colour, the best paper was anything but pleasing, so striking a novelty would no doubt be hailed as a great improvement, and as such received into general use, but the superior delicacy of a *first-class* paper now made without any colouring-matter whatever, and without any superfluous marks on its surface, is so truly beautiful, both in texture and appearance, as to occasion some surprise that it is not more generally used.[1]

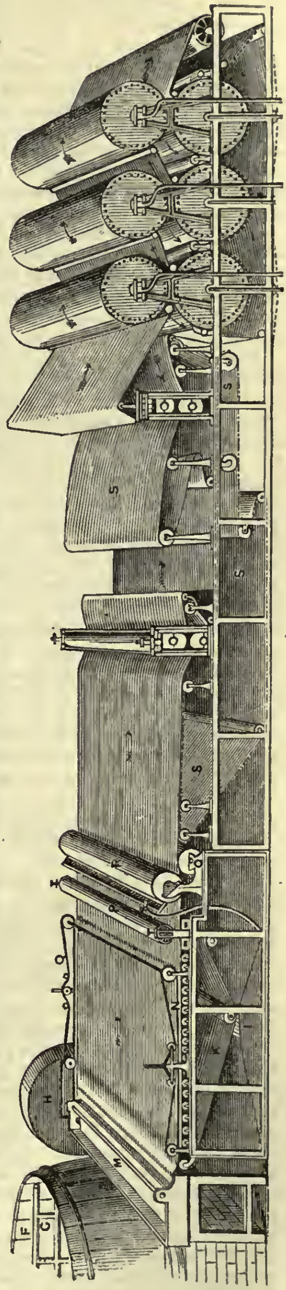
Common materials are frequently and very readily employed, through the assistance of colouring-matter, which tends to conceal imperfections. Indeed, it would e difficult to name an instance of apparent deception more forcible than that which is accomplished by the use of ultramarine. Until recently the fine blueish tinge given to many writing-papers was derived from the admixture of that formerly expensive, but now, being prepared artificially, cheap, mineral blue; 1 pound of ultramarine going farther than 4 of smalts, the former necessarily meets with more extended application, and where its use is rightly understood, and the materials employed instead of being fine rags, comparative rubbish, excessively bleached, its application proves profitable to the paper-maker in concealing for a time all irregularities, and making the paper surpass in appearance the best kinds. The oxide of cobalt, generally termed *smalts*, has still the advantage over the ultramarine of imparting a colour which will endure for a much longer period.

At first the introduction of ultramarine led to some difficulty in sizing the paper, for so long as smalts continued to be used, any amount of alum might be employed, and it was actually added to the size to preserve it from putrefaction. But since artificial ultramarine is bleached by alum, it became of course necessary to add this salt to the size in very small proportions, and, as a natural consequence, the gelatine was no longer protected from the action of the air, which led to incipient decomposition, and in such cases the putrefaction once commenced, proceeded even after the size was dried on the paper, and gave to it a most offensive smell, which rendered the paper unsaleable. This difficulty, however, has now been overcome, and providing the size be quite free from taint when applied to the paper, and quickly dried, putre-

[1] See Richard Herring's 'Pure Wove Writing Paper.'

faction will not subsequently occur; but if decay has once commenced, it cannot be arrested by drying only.

1594



The operation of paper-making, after the rags or materials to be used have been thus reduced and prepared, may be divided into two kinds: that which is carried on in hand-mills, where the formation of the sheet is performed by manual labour; and that which is carried on in machine-mills, where the paper is produced upon the machine wire-cloth in one continuous web.

With respect to hand-made papers, the sheet is formed by the vatman's dipping a mould of fine wire-cloth fixed upon a wooden frame, and having what is termed a deckle, to determine the size of the sheet, into a quantity of pulp which has been previously mixed with water to a requisite consistency; when, after gently shaking it to and fro in a horizontal position, the fibres become so connected as to form one uniform fabric, while the water drains away. The deckle is then removed from the mould, and the sheet of paper turned off upon a felt, in a pile with many others, a felt intervening between each sheet, and the whole subjected to great pressure, in order to displace the superfluous water; when, after being dried and pressed without the felts, the sheets are dipped into a tub of fine animal size, the superfluity of which is again forced out by another pressing; each sheet after being finally dried, undergoing careful examination before it is finished.

Thus we have, first, what is termed the *water-leaf*, the condition in which the paper appears after being pressed between the felts—this is the first stage. Next, a sheet from the bulk, as pressed without the felts, which still remains in a state unfit for writing on, not having been sized. Then a sheet after sizing, which completely changes its character; and lastly, one with the finished surface. This is produced by placing the sheets separately between very smooth copper-plates, and then passing them through rollers, which impart a pressure of from 20 to 30 tons. After only three or four such pressures, it is simply called 'rolled,' but if passed through more frequently, the paper acquires a higher surface, and is then called 'glazed.'

The paper-making machine is constructed to imitate in a great measure, and in some respects to improve, the processes used in making paper by hand; but its chief advantages are the increased rapidity with which it accomplishes the manufacture, and the means of producing paper of any size which can practically be required.

By the agency of this admirable contrivance, which is so adjusted as to produce the intended effect with unerring precision, a process which, in the old system of paper-making, occupied about three *weeks* is now performed in as many *minutes*.

The paper-making machine (*fig.* 1594) is supplied from the 'chests' or reservoir, F, into which the pulp descends from the beating-engine, when sufficiently ground; being kept in constant motion, as it descends, by means of the agitator, G, in order that it shall not settle. From this reservoir the pulp is again conveyed by a pipe into what is technically termed the 'lifter,' H, which consists of a cast-iron wheel, enclosed in a wooden case, and having a number of buckets affixed to its circumference. The trough, I, placed immediately beneath the endless wire, K, is for the purpose of receiving the water which drains away from the pulp during the process of manufacture, and as this water is frequently impregnated with certain chemicals used in connection with paper-making, it is returned again by a conducting spout, into the 'lifter,' where, by the rotation of the buckets, both the pulp and back-water become again thoroughly mixed, and are together raised by the lifter through the spout, L, into the trough, M, where the pulp is strained by means of a sieve or 'knotter,' as it is called, which is usually formed of brass, having fine slits cut in it to allow the comminuted pulp to pass through, while it retains all lumps and knots; and so fine are these openings, in order to free the pulp entirely from anything which would be liable to damage the quality of the paper, that it becomes necessary to apply a means of exhaustion underneath, in order to facilitate the passage of the pulp through the strainer.

The lumps collected upon the top of this knotter, more particularly when printing-papers are being manufactured, are composed to a considerable extent of india-rubber, which is a source of much greater annoyance to the paper-maker than is readily conceived. For, in the first place, it is next to impossible in sorting and cutting the rags to free them entirely from the braiding, and so forth, with which ladies adorn their dresses; and, in the next, the bleach failing to act upon a substance of that character, the quality of the paper becomes greatly deteriorated by the large black specks which it occasions, and which, by the combined heat and pressure of the rolls and cylinders, enlarge considerably as it proceeds.

Passing from the strainer, the pulp is next made to distribute itself equally throughout the entire width of the machine, and is afterwards allowed to flow over a small lip or ledge, in a regular and even stream, whence it is received by the upper surface of the endless wire, K, upon which the first process of manufacture takes place. Of course the thickness of the paper depends in some measure upon the speed at which the machine is made to travel, but it is mainly determined by the quantity of pulp allowed to flow upon the wire, which, by various contrivances, can be regulated to great nicety. Paper may be made by this machine considerably less than the thousandth of an inch in thickness, and, although so thin, it is capable of being coloured, it is capable of being glazed, it is capable of receiving a water-mark; and, what is perhaps still more astonishing, a strip not exceeding 4 inches in width is sometimes capable of sustaining a weight of 20 lbs., so great is its tenacity.

But to return to the machine itself. The quantity of pulp required to flow from the vat, M, being determined, it is first received by the continuous woven wire, K, upon which it forms itself into paper; this wire-gauze, which resembles a jack-towel, passing over the small copper rollers, N, round the larger one, marked O, and being kept in proper tension by two others placed underneath. A gentle vibratory motion from side to side is given to the wire, which assists to spread the pulp evenly, and also to facilitate the separation of the water; and by this means, aided by a suction-pump, the pulp solidifies as it advances. The two black squares on either side of the 'dandy' roller, P, indicate the position of two wooden boxes, from which the air is partially exhausted, thus causing the atmospheric pressure to operate in compacting the pulp into paper, the water and moisture being drawn through the wire and the pulp retained on the surface.

Next, we have to notice the deckle or boundary straps, Q, which regulate the width of the paper, travelling at the same rate as the wire, and thus limiting the spread of pulp. The 'dandy' roller, P, is employed to give any impression to the paper that may be required. We may suppose, for instance, that the circumference of that roller answers exactly to the length or breadth of the wire forming a hand-mould, which, supposing such wire to be fixed or curved in that form, would necessarily leave the same impression as when employed in the ordinary way. Being placed between the air-boxes, the paper becomes impressed by it when in a half-formed state, and whatever marks are thus made the paper will effectually retain. The two rollers following the dandy, marked R and O, are termed couching-rollers, from their performing a similar operation in the manufacture of machine-made papers to the business of the coucher in conducting the process by hand. They are simply wooden rollers covered with felt. In some instances, however, the upper couch-roll, R, is made to answer a double purpose. In making writing- or other papers where smalts, ultramarine, and various colours are used, considerable difference will frequently be found in the tint of the paper when the two sides are compared, in consequence of the colouring-matter sinking to the lower side by the natural subsidence of the water, or from the action of the suction-boxes; and, to obviate this, instead of employing the ordinary couch-roll, which acts upon the *upper* surface of the paper, a hollow one is substituted, having a suction-box within it, acted upon by an air-pump, which tends in some measure to counteract the effect justly considered as objectionable. Merging from these rollers, the paper is received from the wire-gauze by a coutinuous felt, s, which conducts it through two pairs of pressing-rollers, and afterwards to the drying-cylinders. After passing through the first pair of rollers, the paper is carried along the felt for some distance and then turned over, in order to receive a corresponding pressure on the other side, thus obviating the inequality of surface which would otherwise be apparent, especially if the paper were to be employed for books.

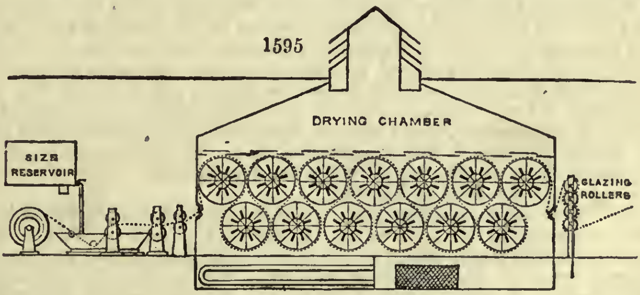
The advantage gained by the use of so great a length of felt is simply that it becomes less necessary to stop the machine for the purpose of washing it, than would be the case if the felt were limited in length to its absolute necessity.

In some instances, when the paper being made is sized in the pulp with such an ingredient as *resin*, the felt becomes so completely clogged in the space of a few hours, that unless a very great and apparently unnecessary length of felt be employed, a considerable waste of time is constantly incurred in washing or changing the felt.

The operation of the manufacture will now be apparent. The pulp flowing from the reservoir into the lifter, and thence through the strainer, passes over a small lip to the continuous wire, being there partially compacted by the shaking motion, more thoroughly so on its passage over the air-boxes, receiving any desired marks by means of the dandy-roller passing over the continuous felt between the first pressing-rollers, then turned over to receive a corresponding pressure on the other side, and from thence off to the drying-cylinders, which are heated more or less by injected steam; the cylinder which receives the paper first being heated less than the second, the second than the third, and so on; the paper, after passing over those cylinders, being finally wound upon a reel, as shown, unless it be printing-paper, which can be sized sufficiently in the pulp by an admixture of alum, soda, and resin, or the like; in which case it may be at once conducted to the cutting-machine, to be divided into any length and width required. But, supposing it to be intended for writing purposes, it has first to undergo a more effectual method of sizing, as shown in the accompanying drawing; the size, in this instance, being made from parings obtained from tanners, curriers, and parchment-makers, as employed in the case of hand-made papers. Of course, sizing in the pulp or in the engine offers many advantages; but as gelatine, or animal size, which is really essential for all good writing qualities, cannot at present be employed during the process of manufacturing by the machine without injury to the felts, it becomes necessary to pass the web of paper, after it has been dried by the cylinders, through this apparatus.

In most cases, however, the paper is at once guided as it issues from the machine, through the tub of size, and is thence carried over the skeleton drums shown, inside each of which are a number of fans rapidly revolving; sometimes there are forty or fifty of these drums in succession, the whole confined in a chamber heated by steam.

1595



A paper-machine, with the sizing-apparatus attached, sometimes measures, from the wire-cloth, where the pulp first flows on, to the cutting-machine at the extremity, no less than 1,000 feet. The advantage of drying the paper in this manner over so many of these drums is, that it turns out much harder and stronger than if dried more rapidly over heated cylinders. Some manufacturers adopt a peculiar process of sizing, which, in fact, answers very much better, and is alike applicable to papers made by hand or by machine, provided the latter description be first cut into pieces or sheets of the required dimensions. The contrivance consists of two revolving felts, between which the sheets are carried under several rollers through a long trough of size; being afterwards hung up to dry upon lines previously to rolling or glazing. The paper thus sized becomes much harder and stronger, by reason of the freedom with which the sheets can contract in drying; and this is mainly the reason why paper made by hand continues to be so much tougher than that made by the machine.

in consequence of the natural tendency of the pulp to contract in drying, and consequently becoming, where no resistance is offered, more entwined and entangled, which of course adds very considerably to the strength and durability of the paper. In making by the machine, this tendency is completely checked.

The following note from a correspondent is well worthy the attention of paper-manufacturers:—

'You are most probably aware that, in the paper-machine, the pulp or half-stuff, after leaving the plane of wire, is pressed between rollers and becomes paper, and then only requires to be made dry and smooth. These objects are effected by the machine conducting the paper over the polished surfaces of large cylinders heated by steam, and afterwards through a series of heavy and highly-polished metal rollers, which are in some cases also heated by steam to increase the effect. Now, a great advantage would be gained by electro-plating those cylinders and rollers with nickel.' (See NICKEL; ELECTRO-METALLURGY.) 'A surface far superior to that of burnished steel would be obtained; being harder than steel, it would not become scratched, and, no rust being formed, it would be always clean and bright. The paper would be found to possess a surface like ivory, the pores being entirely filled up. The only cleaning required, and that at long intervals, would be washing with soap and water, and rubbing with a dry leather. The expense (about ½*d.* per square inch) would be very trifling as compared with that of grinding and re-burnishing; and, if all the bright parts of the machine were electro-plated with nickel, a vast saving of expense in labour would be effected. I am strengthened in these conclusions by the fact, that photographers find that, after passing prints when damp through ordinary steel rollers, an impression is left on them, which, if not cleaned off immediately, causes the steel to rust, and which rust cannot be got rid of without grinding and re-burnishing.'

It may be interesting to mention, that the first experiment for drying paper by means of heated cylinders was made at Gellibrand's calico-printing factory, near Stepney; a reel of paper, in a moist state, having been conveyed there from Dartford in a post-chaise. The experiment was tried in the presence of the patentees of the paper-machine and Mr. Donkin, the engineer, and proved highly satisfactory; and the adoption of copper cylinders, heated by steam, was thenceforward considered indispensable.

The next operation to be noticed, now that the paper is finished, is that of cutting it into standard sizes. Originally, the wheel upon which it was finally wound was formed so that its diameter might be lessened or increased at pleasure, according to the sizes which were required. Thus, for instance, supposing the web of paper was required to be cut into sheets of 18 inches in length, the diameter of the reel would be lessened to 6 inches, and thus the circumference to 18 inches, or, if convenient, it would be increased to 36 inches, the paper being afterwards cut in two by hand with a large knife; the width of the web being regulated by the deckle-straps, Q, to either twice or three times the width of the sheet, as the case might be. However, in regard to the length, considerable waste, of necessity, arose from the great increase in the circumference of the reel as the paper was wound upon it, and to remedy this, several contrivances have been invented. To dwell upon their various peculiarities, or separate stages of improvement, would prove of little comparative interest to the general reader; it will, therefore, be well to limit attention to the cutting-machine, of which an illustration is given (*fig.* 1596), which is unquestionably the best, as well as the most ingenious, invention of the kind.

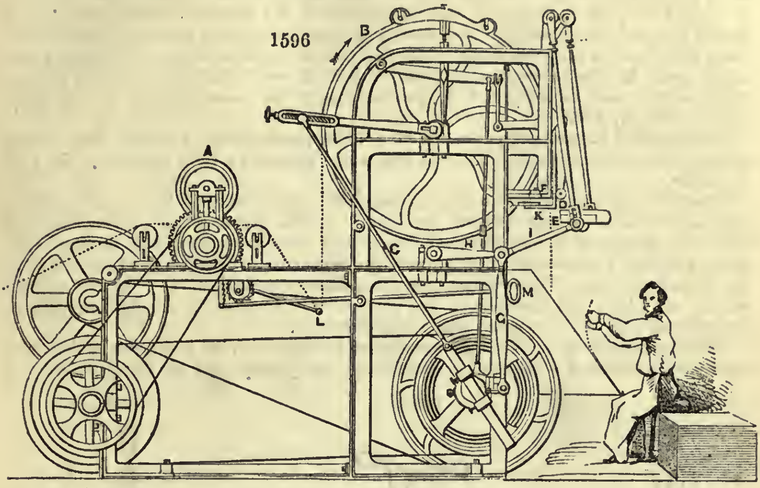
The first movement or operation peculiar to this machine is that of cutting the web of paper longitudinally into such widths as may be required; and this is effected by means of circular blades, placed at stated distances, which receive the paper as it issues direct from the other machinery, and, by a very swift motion, much greater than that at which the paper travels, slit it up with unerring precision wherever they may be fixed.

A pair of those circular blades is shown in the drawing, A (*fig.* 1596), the upper one being much larger than the lower, which is essential to the smoothness of the cut. And not only is the upper blade larger in circumference, but it is also made to revolve with much greater rapidity by means of employing a small pinion, worked by one at least twice its diameter, which is fixed upon the same shaft as the lower blade, to which the motive-power is applied. The action aimed at is precisely such as we obtain from a pair of scissors.

The web, as it is termed by the paper-maker, being thus severed longitudinally, the next operation is that of cutting it off into sheets of some particular length horizontally; and to do this requires a most ingenious movement. To give a very general idea of the contrivance, the dotted line represents the paper travelling on with a rapidity in some cases of 80 feet per minute, and yet its course has to be temporarily arrested while the required separation is effected, and that, too, without the paper accumulating in any mass, or getting creased in the slightest degree.

The large drum, B, over which the paper passes in the direction indicated by the arrows, has simply an alternating motion, which serves to gather the paper in such

1596



lengths as may be required; the crank arm, C, which is capable of any adjustment either at top or bottom, regulating the extent of the movement backwards and forwards, and thus the length of the sheet. As soon as the paper to be cut off has passed below the point D, at which a *presser* is suspended, having an alternating motion given to it in order to make it approach to, and recede from, a stationary presser-board, it is taken hold of as it descends from the drum, and the length pendant from the presser is instantly cut off by the moveable knife, E, to which motion is given by the crank F, the connecting-rod G, the lever H, and the connecting-rod I. The combined motion of these rods and levers admits of the moveable knife, E, remaining nearly quiescent for a given time, and then speedily closing upon the fixed knife, K, cutting off the paper in a similar manner to a pair of shears, when it immediately slides down a board, or, in some instances, is carried along a revolving felt, at the extremity of which several men or boys are placed to receive the sheets, according to the number into which the width of the web is divided.

As soon as the pressers are closed for a length of paper to be cut off, the motion of the gathering-drum is reversed, smoothing out the paper upon its surface, which is now held between the pressers; the tension-roll, L, taking up the slack in the paper as it accumulates, or rather gently bearing it down, until the movement of the drum is again reversed to furnish another length. The handle, M, is employed merely to stop a portion of the machinery, should the water-mark not fall exactly in the centre of the sheet, when by this means it can be momentarily adjusted.

The paper being thus made, and cut up into sheets of stated dimensions, is next looked over, and counted out into quires of 24 sheets, and afterwards into reams of 20 quires, which subsequently are carefully weighed, previously to their being sent into the market.

Connected with the manufacture of paper, there is one point of considerable interest and importance, and that is, what is commonly, but erroneously, termed the *water-mark*, which may be noticed in the 'Times' newspaper, in the Bank of England notes, cheques, and bills, as also in every postage- and receipt-stamp of the present day.

The curious, and in some instances absurd terms, which now puzzle us so much in describing the different sorts and sizes of paper, may frequently be explained by reference to the various paper-marks which have been adopted at different periods. In ancient times, when comparatively few people could read, pictures of every kind were much in use where writing would now be employed. Every shop, for instance, had its sign, as well as every public-house, and those signs were not then, as they often are now, only painted upon a board, but were invariably actual models of the thing which the sign expressed—as we still occasionally see some such sign as a beehive, a tea-canister, or a doll, and the like. For the same reason, printers employed some device, which they put upon the title-pages and at the end of their books; and paper-makers also introduced marks, by way of distinguishing the paper of their manufacture from that of others; which marks, becoming common, naturally gave their names to different sorts of paper. And, since names often remain long after the origin of them is forgotten and circumstances are changed, it is not surprising to find the old names still in use, though in some cases they are not applied to the same things which they originally denoted. One of the illustrations of ancient water-marks given in the accompanying plate, that of an open hand with a star at the top, which was in use as early as 1530, probably gave the name to what is still called *hand* paper, *fig.* 1597.

Another very favourite paper-mark, at a subsequent period, 1540–60, was the jug or pot, which is also shown, *fig.* 1598, and would appear to have originated the term *pot* paper.

The fool's-cap was a later device, and does not appear to have been nearly of such long continuance as the former, *fig.* 1599. It has given place to the figure of Britannia, or that of a lion rampant supporting the cap of liberty on a pole. The name, however, has continued, and we still denominate paper of a particular size by the title of *foolscap*. The original figure has the cap and bells, of which we so often read in old plays and histories as the particular head-dress of the fool, who at one time formed part of every great man's establishment.

The water-mark of a *cap* may sometimes be met with of a much simpler form than just mentioned—frequently resembling the jockey-caps of the present day,

with a trifling ornamentation or addition to the upper part. The first edition of 'Shakespeare,' printed by *Isaac Jaggard and Ed. Blount*, 1623, will be found to contain this mark, interspersed with several others of a different character. No doubt the general use of the term *cap* to various papers of the present day owes its origin to marks of this description.

The term *imperial* was in all probability derived from the finest specimens of papyri, which were so called by the ancients.

Post paper seems to have derived its name from the post-horn, which at one time was its distinguishing mark, *fig.* 1600. It does not appear to have been used prior to the establishment of the General Post-office (1670), when it became the custom to blow a horn, to which circumstance no doubt we may attribute its introduction. The mark is still frequently used, but the same change which has so much diminished the number of painted signs in the streets of our towns and cities, has nearly made paper-marks a matter of antiquarian curiosity; the maker's name being now generally used, and the mark, in the few instances where it still remains, serving the purpose of mere ornament, rather than that of distinction.

Water-marks, however, have at various periods been the means of detecting frauds, forgeries and impositions, in our courts of law and elsewhere, to say nothing of the protection they afford in the instances already referred to, such as bank notes, cheques, receipt, bill, and postage-stamps. The celebrated Curran once distinguished himself in a case which he had undertaken by shrewdly referring to the water-mark, which effectually determined the verdict. And another instance, which may be introduced in the form of an amusing anecdote, occurred once at Messina, where the monks of a certain monastery exhibited, with great triumph, a letter as being written by the Virgin Mary with her own hand. Unluckily for them, however, this was not, as it easily might have been, written upon the ancient papyrus, but on paper made of rags. On one occasion a visitor, to whom this was shown, observed, with affected solemnity, that the letter involved also a *miracle*, for the paper on which it was written was not in existence until several centuries after the mother of our Lord had died.

A further illustration of the kind occurs in a work entitled 'Ireland's Confessions,' which was published respecting his fabrication of the Shakspeare manuscripts,—a literary forgery even still more remarkable than that which is said to have been perpetrated by Chatterton, as Rowley's Poems.

The interest which at the time was universally felt in this production of Ireland's may be partially gathered from the fact, that the whole of the original edition, which appeared in the form of a shilling pamphlet, was disposed of in a few hours; while so great was the eagerness to obtain copies afterwards, that single impressions were sold in an auction-room at the extravagant price of a guinea.

This gentleman tells us, at one part of his explanation, that the sheet of paper which he used was the outside of several others, on some of which accounts had been kept in the reign of Charles the First; and being at that time wholly unacquainted with the water-marks used in the reign of Queen Elizabeth, 'I carefully selected (says he) two half-sheets, not having any mark whatever, on which I penned my first effusion.' A few pages further on, he writes—'Being thus urged forward to the production of more manuscripts, it became necessary that I should possess a sufficient quantity of old paper to enable me to proceed; in consequence of which I applied to a bookseller, named Verey, in Great May's Buildings, St. Martin's Lane, who, for the sum of five shillings, suffered me to take from all the folio and quarto volumes in his shop the fly-leaves which they contained. By this means I was amply stored with that commodity; nor did I fear any mention of the circumstance by Mr. Verey, whose quiet unsuspecting disposition, I was well convinced, would never lead him to make the transaction public, in addition to which he was not likely even to know anything concerning the supposed Shakspearian discovery by myself, and even if he had, I do not imagine that my purchase of the old paper in question would have excited in him the smallest degree of suspicion. As I was fully aware, from the variety of water-marks which are in existence at the present day, that they must have constantly been altered since the period of Elizabeth, and being for some time wholly unacquainted with the water-marks of that age, I very carefully produced my first specimens of the writing on such sheets of old paper as had no mark whatever. Having heard it frequently stated that the appearances of such marks on the papers would have greatly tended to establish their validity, I listened attentively to every remark which was made upon the subject, and from thence I at length gleaned the intelligence that a jug was the prevalent water-mark of the reign of Elizabeth, in consequence of which I inspected all the sheets of old paper then in my possession, and having selected such as had the jug upon them, I produced the succeeding manuscripts upon these, being careful, however, to mingle with them a certain number of blank leaves, that the production on a sudden of so many water-marks might not excite suspicion in the breasts of those persons who were most conversant with the manuscripts.'

Thus, this notorious literary forgery, through the cunning ingenuity of the perpetrator, ultimately proved so successful as to deceive many learned and able critics of the age. Indeed, on one occasion a kind of certificate was drawn up, stating that the undersigned names were affixed by gentlemen who entertained no doubt whatever as to the validity of the Shakspearian production, and that they voluntarily gave such public testimony of their convictions upon the subject. To this document several names were appended by persons as conspicuous for their erudition as they were pertinacious in their opinions.

The water-mark in the form of a letter *p*, of which an illustration is given, *fig.* 1601, was taken from Caxton's well-known work, 'The Game of the Chesse,' a *fac-simile* of which has been published as a tribute to his memory. Paper was made expressly for the purpose, in exact representation of the original, and containing this water-mark, which will be found common in works printed by him.

The ordinary mode of effecting such paper-marks as we have been describing is that of affixing a stout wire in the form of any object to be represented to the surface of the fine wire-gauze, of which the hand-mould, or machine dandy roller is constructed.

The perfection, however, to which water-marks have now attained, which in many instances is really very beautiful, is owing to a more ingenious method which has been patented, and is adopted by the Bank of England, as affording considerable protection to the public in determining the genuineness of a bank-note.

To produce a line water-mark of any autograph or crest, we might either engrave the pattern or device first in some yielding surface, precisely as we should engrave a copper-plate for printing, and afterwards, by immersing the plate in a solution of sulphate of copper, and electrotyping it in the usual way, allow the interstices of the engraving to give as it were a casting of pure copper, and thus an exact representation of the original device, which, upon being removed from the plate, and affixed to the surface of the wire-gauze forming the mould, would produce a corresponding impression in the paper; or, supposing perfect identity to be essential, as in the case of a bank-note, we might engrave the design upon the surface of a steel die, taking care to cut those parts in the die deepest which are intended to give greater effect in the paper, and then, after having hardened, and otherwise properly prepared the die, it would be placed under a steam-hammer or other stamping apparatus, for the purpose of producing what is technically termed a 'force,' which is required to assist in transferring an impression from the die to a plate of sheet brass. This being done, the die with the mould-plate in it, would next be taken to a perforating or cutting machine, where the back of the mould-plate—that is, the portion which projects above the face of the die—would be removed, while that portion which was impressed into the design engraven would remain untouched, and this being subsequently taken from the interstices of the die and placed in a frame upon a backing of fine wire-cloth, becomes a mould for the manufacture of paper of the pattern which is desired, or for the production of any water-mark, autograph, crest, or device, however complicated.

Light and shade are occasioned by a very similar process, but one which perhaps requires a little more care, and necessarily becomes somewhat more tedious. For instance, in the former case the pulp is distributed equally throughout the entire surface of the wire forming the mould, whereas *now* we have to contrive the means of increasing to a very great nicety the thickness or distribution of the pulp, and at the same time to make provision for the water draining away. This has been accomplished by first taking the electrotype of the raised surface of any model or design, and again from that, forming in a similar manner a matrix or mould, both of which are subsequently mounted upon lead or gutta-percha, in order that they may withstand the pressure which is required to be put upon them in giving impression to a sheet of very fine copper wire-gauze, which, in the form of a mould, and in the hands of the vatman, suffices ultimately to produce those beautiful transparent effects in paper-pulp. The word 'Five' in the centre of the Bank of England note is produced in the same manner. The deepest shadows in the water-mark being occasioned by the deepest engraving upon the die, the lightest, by the shallowest, and so forth; the die being employed to give impression by means of the stamping press and 'force' to the fine wire-gauze itself, which by this means, providing the die be properly cut, is accomplished far more successfully than by any other process, and with the additional advantage of securing perfect identity.

It may be interesting to call attention to the contrast as regards the method of mould-making originally practised and that which has since been adopted by the Bank of England. In a pair of five-pound note moulds, prepared by the old process, there were 8 curved borders, 16 figures, 168 large waves, and 240 letters, which had all to be separately secured by the finest wire to the waved surface. There were 1,056 wires, 67,584 twists, and the same repetition where the stout wires were introduced to support the under surface. Therefore, with the backing, laying, large waves, figures, letters, and borders, before a pair of moulds was completed, there were some hundreds of thousands of stitches, most of which are now avoided by the new patent. But further, by this multitudinous stitching and sewing, the parts were never placed precisely in the same position, and the water-mark was consequently never identical. Now, the same die gives impression to the metal which transfers it to the water-mark, with a certainty of identity unattainable before, and one could almost say, never to be surpassed.

And may we not detect principles in this process which are not only valuable to the Bank, but to all public establishments having important documents on paper, for what can exceed the value of such a test for discovering the deceptions of dishonest men? One's signature, crest, or device of any kind, rendering the paper exclusively one's own, can now be secured in a pair of moulds, at the cost merely of a few guineas.

Manufactured paper, independently of the miscellaneous kinds, such as blotting, filtering, and the like, which are rendered absorbent by the free use of *woollen* rags, may be divided into three distinct classes, *viz.* writing, printing, and wrapping. The former again into *five*, cream-wove, yellow-wove, blue-wove, cream-laid, and blue-laid. The printing into *two*, laid and wove; and the latter into *four*, blue, purple, brown, and whited-brown, as it is commonly termed.

To obtain a simple definition of the mode adopted for distinguishing the various kinds, we must include, with the class denominated *writing* papers, those which are used for drawing, which being sized in like manner, and with the exception of one or two larger kinds, of precisely the same dimensions as those passing by the same name, which are used strictly for writing purposes (the only distinction, in fact, being, that the drawings are cream-wove, while the writings are laid), there would of course be no necessity for separating them. Indeed, since many of the sizes used for printing are exactly the same as those which would be named as writing papers, for the sake of abridgment we will reduce the distinctions of difference to but two heads, *fine* and *coarse*; under the latter, including the ordinary brown papers, the whited-brown, or small-hand quality, and the blues and purples used by grocers. The smallest size of the fine quality, as sent from the mill, measures 12½ by 15 inches, and is termed pot; next to that foolscap, 16½ by 13½; then post, 18¾ by 15¼; copy, 20 by 16½; large post, 20¾ by 16½; medium post, 18 by 22½; sheet-and-third foolscap, 22½ by 13¼; sheet-and-half foolscap, 24½ by 13¼; double foolscap, 27 by 17; double pot, 15 by 25; double post, 30½ by 19; double crown, 20 by 30; demy, 20 by 15½; ditto printing, 22½ by 17¾; medium, 22 by 17½; ditto printing, 23 by 18½; royal, 24 by 19; ditto printing, 25 by 20; super-royal, 27 by 19; ditto printing, 21 by 27; imperial, 30 by 22; elephant, 28 by 23; atlas, 34 by 26; columbia, 34½ by 23½; double elephant, 26¾ by 40; and antiquarian, 53 by 31. The different sizes of letter- and note-paper ordinarily used are prepared from those kinds by the stationer, whose business consists chiefly in smoothing the edges of the paper, and afterwards packing it up in some tasteful form, which serves to attract attention.

Under the characteristic names of coarse papers may be mentioned: Kent cap, 21 by 18; bag cap, 19½ by 24; Haven cap, 21 by 26; imperial cap, 22½ by 29; double 2-lb., 17 by 24; double 4-lb., 21 by 31; double 6-lb., 19 by 28; casing of various dimensions, also cartridges, with other descriptive names, besides middle hand, 21 by 16; lumber hand, 19½ by 22½; royal hand, 20 by 25; double small hand, 19 by 29; and of the purples, such significations as copy loaf, 16¾ by 21¾, 38-lb.; powder loaf, 18 by 26, 58-lb.; double loaf, 16½ by 23, 48-lb.; single loaf, 21½ by 27, 78-lb.; lump, 23 by 33, 100-lb.; Hambro', 16½ by 23, 48-lb.; titler, 29 by 35, 120-lb.; Prussian or double lump, 32 by 42, 200-lb.; and so forth, with glazed boards of various sizes, used chiefly by printers for pressing, which are manufactured in a peculiar manner by hand, the boards being severally composed of various sheets made in the ordinary way, but turned off the mould one sheet upon another, until the required substance be attained; a felt is then placed upon the mass and another board formed. By this means the sheets, when pressed, adhere more effectually to each other, and the boards consequently become much more durable than would be the case if they were produced by pasting. Indeed, if any great amount of heat be applied to pasteboards, they will split, and be rendered utterly useless. The glazing in this case is accomplished by friction.

To complete the category of coarse papers must be mentioned milled boards, employed in bookbinding, of not less than 150 descriptions, as regards sizes and substances. Still, however, an incomplete idea is conveyed of the extraordinary number of sizes and descriptions into which paper is at present divided. For instance, we have said with reference to writing qualities, that there are *five* kinds, cream-wove, yellow-wove, blue-wove, cream-laid, and blue-laid; and again, that of each of those kinds there are numerous sizes; but in addition there are, as a matter of course, various thicknesses and makes of each size and kind. In fact, no house in London, carrying on the wholesale stationery trade, is without a thousand different sorts; many keep stock of twice that number.[1]

[1] For further information upon this point, see the 'Practical Guide to the Varieties and Relative Values of Paper.' Longman & Co.

The quantity of paper manufactured in this country at the commencement of the eighteenth century appears to have been far from sufficient to meet the necessities of the time. Even in 1721 it is supposed that there were but about 300,000 reams of paper annually produced in Great Britain, which were equal merely to two-thirds of the consumption. But in 1784, the value of the paper manufactured in England alone is stated to have amounted to 800,000*l.*; and that, by reason of the increase in price, as also of its use, in less than twenty years it nearly doubled that amount.

It may be well to append some extracts from various Parliamentary returns relating to the Excise duties levied upon paper:—

In one return, specifying the rates of duty and amount of duty received upon each denomination of paper since 1770, it appears that the total amount of duty on paper manufactured in England for the year 1784 was 46,867*l.* 19*s.* 9¼*d.*, the duty at that time being divided into seven distinct classes or rates of collection; while twenty years after, when the mode of assessing the duty was reduced to but three classes, it had risen to 315,802*l.* 4*s.* 8*d.*; in 1830, fifteen years after, to 619,824*l.* 7*s.* 11*d.*; in 1835, for the United Kingdom, to 833,822*l.* 12*s.* 4*d.*, or, in weight, to 70,655,287 lbs., which was, again, within so short a period as fifteen years, very nearly doubled. Since 1859 it has not been possible to collect any exact information as to the quantity of paper made; with the cessation of the duty all means of obtaining returns ceased.

The latest returns of the paper-mills in working order in England give the number as 272; the mills in Scotland as 57; and those in Ireland as 21.

The character of the production in the English mills is given as follows:—

Making writing papers (hand-made)	21
„ „ „ (machine-made)	22
„ Printing News and Long Elephants	96
„ Cartridges	29
„ Grocery papers (white and coloured)	48
„ Small hands and caps	50
„ Browns	108

Considering the enormous extent of the paper-manufacture, and the vast improvements which have taken place in connection therewith, it is not a little remarkable that, with the exception of the unfortunate Fourdriniers, who sacrificed their all to present to mankind the bare principles of the art, as in the main they now exist, no other name should rest upon the page of history as being similarly associated with those many introductions and improvements which have successively raised the paper-manufacture to the apparently perfect standard which it has at length attained. It is true there would be no difficulty in recording the names of very many who, by the employment of the wealth which they have inherited, are now altogether unsurpassed as paper-manufacturers; and it is equally true that if we turn to the Reports of the Jurors of the Great Exhibition of 1851, we shall find many other names more or less distinguished by the greater or lesser importance of the materials or means for which they have themselves applied for and obtained the security of a patent. Still we search in vain for any name upon record as indicating the true genius to whom is chiefly owing the surpassing beauty of the finest specimens of the paper fabric.

Undoubtedly the most enterprising and successful paper-manufacturer of his day was Mr. William Joynson, of St. Mary Cray, Kent, who by individual effort succeeded in working his upward way from a poor and uneducated journeyman, in a humble paper-mill, to the level of the most respected, and probably the most wealthy of paper-manufacturers.

But Mr. Joynson, distinguished as he was for the superior finish of his writing papers, was not the originator of the process by which that finish was attained. At the cost of much time and some thousands of pounds, Mr. Joynson laboured to acquire a knowledge of the means by which that peculiar character and surface was so successfully accomplished, which, it is said, was first given to writing papers at the Hele paper-mills, near Collumpton, Devon, by the late Mr. John Dewdney. Not only in this respect, but in many others, Mr. Dewdney rendered very distinguished service to the art of paper-making; probably no man more so, and yet throughout his entire life as a paper-manufacturer he never once patented a single invention, or refused admitting to his mill any person who wished to go over it. Whether the same kind-hearted and generous spirit that appears uniformly to have prompted Mr. Dewdney in the conduct of his business would be consistent now-a-days, many may question, as indeed in practice most do; but with Mr. Dewdney it certainly answered no bad end, for after acquiring a competency for himself and each member of a large family, he quietly retired from the paper-manufacture; and in the early part of the year 1852, immediately after the Commissioners of the

Great Exhibition had awarded him a prize medal 'for the excellence of his writing papers, and also for the permanent dye of his blue papers for the use of starch manufacturers,' he disposed of his well-known mills and everything connected with them, to his old friend and competitor, Mr. Joynson, to whom to the last day of his life he continued warmly attached, and by whom he was ever consulted upon the various alterations and inventions which were adopted at St. Mary Cray.

The circumstances of Mr. Dewdney's decease formed a painful coincidence at the close of so remarkably energetic and useful a career. He it was who first introduced a steam-engine for paper-manufacture into the county of Devon; and at the Hele Station, adjoining the Hele mills, almost on the same spot where thirty years previously he reared his engine for manufacture, the engine of the express train from Bristol to Exeter struck him dead.

Another method of making paper, which was invented by Mr. Dickinson, consists in causing a polished hollow brass cylinder, perforated with holes or slits, and covered with wire-cloth, to revolve over and in contact with the prepared pulp. The cylinder being connected with a vessel from which the air has been exhausted, the film of pulp adheres to the hollow cylinder. It is then turned off continuously upon a solid one covered with felt, upon which it is condensed by the pressure of a third revolving cylinder, and is thence delivered to the drying rollers. This description of machine is not suitable for the manufacture of any paper requiring strength. Indeed, throughout the United Kingdom there are probably not more than a dozen in work, and those chiefly in the manufacture of thin tissue papers.

Since 1865 our *Imports* of papers and materials for paper, and our *Exports* of paper have been as follow:—

Importations of Paper for Printing or Writing:

1865	1866	1867	1868	1869	1870	1871	1872
cwts.	cwts.	cwts.	cwts.	cwts.	cwts.	cwts.	cwts.
143,524	159,008	174,429	177,220	169,274	173,616	158,885	205,510

Importation of Rags and Paper-making materials:

tons	tons	tons	tons	tons	tons	tons	tons
18,368	24,408	19,201	17,902	17,027	22,394	26,868	22,254

Importations of Esparto and other materials:

The *Imports* of paper for printing or writing made in 1873 were 195,336 cwts.; and in 1874, 192,200 cwts.

PAPER-BOX MAKING MACHINE. Among the most novel pieces of mechanical construction recently brought to public notice must be reckoned the machines invented by Mr. H. R. Heyl, Philadelphia, for making paper-boxes, and for the first time publicly exhibited at a recent monthly meeting of the Franklin Institute. The machines in question are the result of years of patient labour and perseverance, and the inventor is deserving of all praise for having so completely and efficiently triumphed over many difficulties. He has in the past seven years built three machines for making paper-boxes, the last and most perfect of which has just been completed, and is the one referred to as having been placed on exhibition. As to the usefulness of machinery to produce paper-boxes with greater rapidity and economy than by hand labour, little need be said, since a simple enumeration of the various branches of industry in which they are indispensable, affords superabundant evidence of their great utility—viz., perfumery, jewellery, hardware, trimmings, matches, and a host of other branches.

The first machine constructed by Mr. Heyl for this purpose was adapted to the automatic shaping, and fastening by paste, of the usual rectangular box, varying the style according to the materials used. The capacity of this machine is 2,000 boxes in ten hours—a capacity which is equivalent to the duty of ten of the most expert workmen employed during the same time.

The second machine has for its object the production of boxes for various purposes without the use of paste, the fastening of the edges of the paper being accomplished by delicate pieces of iron wire, measured and shaped by the machine into miniature staples, which are pressed through the material and clinched at the proper instant. The primary design of this second machine was the production, at rapid rate and cheaply, of match-boxes and other cheap receptacles for tacks, screws, and various small articles; and the substitution of wire-fastenings for the paste, besides greatly increasing the *duty* of the machine, is quite a desideratum on other accounts. It is said by those familiar with the details of such trades, that the delay in drying the boxes when pasted, which often occurs in damp weather, frequently interferes with the shipment of large invoices of goods; in some cases of protracted damp weather, the paper-boxes really mildew before they dry, and might ruin or seriously damage the goods packed in them. It was to obviate these obvious, but to others insuperable, difficulties, that the inventor has produced the wire-fastening machine we have alluded to. The work accomplished by it is not only neater and stronger than that done by hand, but the rate of production of one machine is that of seventy-five workmen. The method of fastening the edges of the paper with wire staples is as follows:—The wire is wound on a spool, from which the proper lengths are drawn by the machine for each box; the staples are formed and brought each to its place, at right angles with the box material, and are made at the proper moment to puncture it, upon which they are, an instant later, firmly clinched on the opposite surface, The power of impact exerted at right angles with an opposing surface is here beautifully illustrated; and be it remembered, that the entire production of the box is to be ascribed to the machine, every portion of the work being automatic. The machine sizes the slips of wrapper singly, and shapes them, and throws out a match-box complete—even to being touched with glue and sprinkled with sand—at the rate of 30,000 pieces per day of ten hours.

The third machine is simply a modified form of the one just described, in which its metallic fastenings and general movements are applied to the production of rectangular boxes of superior quality and of various sizes, applicable for safe packages and display of articles of luxury, &c. The completion of these machines is a realisation of the labour of seven years, and they are now busily plying their functions with perfect success.

The invention of the paper-box machine, by which the supply of articles indispensable to many of the small-ware producers is vastly increased and cheapened, cannot fail speedily to result in the complete substitution of machine-labour for the hand-labour formerly universally employed for the purpose; while, from its perfect adaptation to the uses for which it is designed, and the mechanical ingenuity displayed in its conception and design, it is worthy of all praise.

PAPIER-MÂCHÉ. The fine old philosopher Boyle says:—

'Though paper be one of the commonest bodies that we use, there are very few that imagine it is fit to be employed other ways, in writing and printing, or wrapping up of other things, or about some such obvious piece of service; without dreaming that frames of pictures, and divers fine pieces of embossed work, with other curious moveables, may, as trial has informed us, be made of it.'

The origin of the manufacture of articles for use or ornament from paper, is not very clearly made out; we are naturally led to believe, from the name, that the French must have introduced it. We find, however, a French writer ascribes the merit of producing paper ornaments, to the English. After describing some peculiar ornamental work, the writer proceeds:—

As this work had to be done on the spot, and with much rapidity of execution, in order to prevent the stucco from setting before it had acquired the intended form, the art was somewhat difficult; the workman had to design almost as he worked; therefore, to do it well, it was necessary that he should have some of the requirements and qualities of an artist. This circumstance, of course, tended very much to limit the number of workmen, and their pay became proportionally large. The artisans assumed more than belonged to their humble rank in life, and ultimately the workers in stucco combined together to extort from their employers a most inordinate rate of wages. It would be superfluous here to detail all that followed; it is sufficient to state that the total ruin of their art was the final result of these delusive efforts to promote their individual interests.

Contrivances were resorted to by the masters which soon supplanted the old mode of working in stucco. The art of moulding and casting in plaster, as previously practised in France, was generally introduced, and the art of preparing the *pulp of paper* became improved and extended, so as ultimately to render practicable the adoption of papier-mâché in the formation of architectural decorations. Thus, at last, was extinguished the original mode of producing stucco ornaments, and there probably has not been for many years a single individual in England accustomed to that business.

From the 'Gentleman's Magazine,' we learn that many of the fine old ceilings in deep relief of the Elizabethan era are of papier-mâché. The handsome ceilings in Chesterfield House are of this material.

A kind of papier-mâché has been introduced, called *fibrous slab*; for the preparation of this interesting material the coarse varieties of fibre only are required. These are heated and subjected to much agitation, to secure the reduction of the fibre to the proper size. This being effected, the pulp is removed and subjected to the action of the desiccating apparatus, or centrifugal drying machine. By the means of this apparatus the water is driven, by the action of the centrifrugal force, from the fibre, and the pulp can thus be obtained in a few minutes of an equal and proper degree of dryness, and this without the application of any heat. The mass thus obtained may be regarded as a very coarse mixture.

This fibrous pulp is next combined with some earthy matter to ensure its solidity, and certain chemical preparations are introduced, for the double purpose of preserving it from the attacks of insects and to ensure its incombustibility. The whole being mixed with a cementing size, is well kneaded together, steam being applied during the process. While the kneading process is going forward, an iron table running on wheels is properly adjusted and covered with a sail-cloth; this table being arranged so that it passes under an immense iron roller. The fibrous mixture is removed from the kneading troughs, and is laid in a tolerably uniform mass upon the sail-cloth, so as to cover about one-half of the table; over this again is placed a length of sail-cloth equal to that of the entire slab, as before. This being done, the table and roller are set in action, and the mass passes between them. It is thus squeezed out to a perfectly uniform thickness, and is spread over the whole table. The fibrous slab is passed through the rollers some three or four times, and it is then drawn off upon a frame fixed upon wheels prepared to receive it, by means of which it can be removed to the drying ground. The drying process of course varies much with the temperature and dryness of the air. It does not appear necessary that these slabs should dry too quickly, and there are many reasons why the process should not be prolonged.

We tried an experiment upon the non-inflammability of this material, by having a fire of wood made upon a slab and maintained there some time. When the ashes, still in a state of vivid combustion, were swept away, the slab was found to be merely charred by the intense heat. Beyond this, a piece of fibrous slab was thrown into the middle of the fire and the flames were urged upon it: under the influence of this intense action it did not appear possible to kindle it into a flame; it smouldered very slowly, the organic matter charring, but nothing more.

The Fibrous Slab Company produced a material which, in many of its applications, promised to prove of the greatest utility, while much additional value was given to it from the circumstance of its resisting the attacks of insects, and being non-inflammable. We believe, however, that this manufacture has been discontinued.

Papier-Mâché may be said, therefore, to consist of three varieties:—1. Sheets of paper pasted together, exposed to great pressure, and then polished; 2. Sheets of considerable thickness, made from ordinary paper-pulp; and 3. Such as we have described in the manufacture of the fibrous slab.—E. J. H.

A new composition was patented, in 1858, by Mr. John Cowdery Martin, which he designated a 'Plastic compound for the manufacture of articles in imitation of wood carvings, &c.' The patentee thus describes his process, and the resulting material:—

'The object I have had in view is the production of a plastic compound applicable to the manufacture of moulded articles, which, when hardened, resembles wood in the closeness of its texture and fibrous character throughout, and is particularly applicable to the manufacture of articles intended to imitate wood-carvings. The new manufacture may also be called *ceramic papier-mâché,* from the wax-like character of the compound when in a soft state, or before hardening. The compound consists of twenty-eight parts (dry) by weight of paper-pulp, or of any fibrous substances of which paper may be made, reduced to pulp by means of an ordinary beating engine, or other means used for the manufacture of pulp; twenty parts of resin, or rosin, or pitch, or other resinous substance. I prefer resin or rosin; ten parts of soda or potash to render the resin soluble; twenty-four parts of glue, twelve parts of drying oil, and one part of acetate or sugar of lead, or other substance capable of hardening or drying oil. The pulp after leaving the beating engine is to be drained and slightly pressed under a screw or other press, to free it partly from water. The resin and alkali are then to be boiled or heated together and well mixed. The glue is to be broken up in pieces and melted in a separate vessel with as much water as will cover it, and then to be added to the resin and alkali, which mixture is then to be added to the pulp and thoroughly incorporated with it. The acetate of lead well mixed in the oil is then to be added, and the whole mass or compound is then to be thoroughly mixed. The quantity of resin and alkali, in proportion to the glue used, might vary, or glue might even be dispensed with when the acetate of lead would be proportionally increased. After mixing the compound, it is to remain exposed to the air for three or four days before using, and to be continually turned to free it from some of its moisture, for the purpose of partially drying, when it is to be well kneaded, and again exposed to the air for a few hours; and this operation of kneading and partial drying may be repeated until the compound is considered to be sufficiently stiff and plastic, as, during the process of kneading or working together, it becomes extremely plastic, resembling from this quality, when sufficiently kneaded, wax or clay, and it may then be worked, pressed, or moulded into any required form. The compound may be kept in a plastic state for some weeks, or even months before using, if required, by keeping it from exposure to the air and occasionally kneading or working it together. The moulds should, previous to pressing therein the compound, be brushed with oil, or with oil in which is mixed a little acetate of lead. The article taken from the mould is to be thoroughly dried, and afterwards it may be baked in an oven at a moderate heat, the temperature to be low at first, and gradually increased, care being taken not to scorch or injure the fibres of the compound. The plastic compound so made and treated acquires many of the peculiarities of wood, as regards hardness and strength, and it may be cut, or carved and polished, if required. Any colour may be added to the compound when in a soft state, or two or more portions of the compound, stained with different colours, may be worked together to form a grain to more nearly imitate the appearance of wood. The use of the alkali being to render the resinous substance sufficiently soluble to combine with the wet pulp, a more or less quantity than that given in proportion to the resin may be used, according to the degree of solubility thought to be necessary. When potash is used, it may be dissolved in water before being heated with the resin. The quantity of glue may vary, and may be increased to twice the quantity of resin, or even more, or sufficiently so as to dispense with the acetate of lead, as it gives hardness, and with oil prevents the compound from sticking; but mixed in this manner it cannot be so well kneaded, and does not retain so fine an impression. I prefer using with the ingredients as above mentioned the acetate of lead; but half a part by weight of a solution of sulphuric or other acid, diluted with twenty times its volume of water, may be substituted for the one part of acetate of lead. The oil mixed with the other ingredients is used to prevent the compound from adhering to the surface of the moulds, but the less oil consistently with this object that is used, the better. Only half the proportion of oil stated to be used as above may be added at the time of mixing the ingredients of the compound, and the remainder may be added during the process of kneading or working up the mass. I wish it to be understood, although I prefer to use resin or rosin or pitch to form the compound, that other resinous bodies soluble with alkalis may be used, as the gums copal, mastic, elemi, lac, Canadian balsam, Venice turpentine, or other resinous bodies of a like kind, either separately, or mixed according to the facility with which they will combine with wet pulp, and the convenience with which the compound may be worked, as will be well understood by persons conversant with these substances.'

PAPIN'S DIGESTER. See DIGESTER.

PARAFFIN; from *parum affinis*, indicating the want of affinity which this substance exhibits to most other bodies.

Paraffin is a white substance, void of taste and smell; it has a specific gravity of 0·87; melts at 112° Fahr., and boils at a higher temperature, with the exhalation of white fumes; it is not decomposed by dry distillation; burns with a clear white flame, without smoke or residuum; and does not stain paper. It is decomposed neither by chlorine, strong acids, alkalis, nor potassium; and mixes by fusion with sulphur, phosphorus, wax, and resin. It dissolves readily in warm fat oils, in cold essential oils, and in ether, but sparingly in boiling absolute alcohol. It has been obtained by the destructive distillation of peat, wax, wood, bones, coal, and shale.

The solid obtained is manufactured into beautiful candles, more than 5,000 tons being employed annually in this manufacture. The lining of beer-barrels, the preserving of jams, fruits, and meats, and waterproofing and softening of fabrics, are some of its patented uses. It may also be used as an insulator. Soft paraffin is much employed in the lucifer-match manufacture. See NAPHTHA; MINERAL CANDLES; PEAT; DESTRUCTIVE DISTILLATION; PETROLEUM.

Paraffin is a generic term for a series of compounds of carbon and hydrogen, in which the hydrogen is in the highest proportion to the carbon in which these elements can unite. Marsh-gas, the lowest member of the series, contains 1 atom carbon to 4 of hydrogen; the other members thence ascend by an addition of CH^2 to very complicated molecules, thus:—

CH^4, marsh-gas or methane;
C^2H^6, ethane;
C^3H^8, propane; and so on.

Brodie obtained two paraffins from bees'-wax; one had C^{27}, and the other C^{30}; while paraffins still higher in the series are known to exist. By removal of two atoms of hydrogen, any member of the series may be removed into that of the olefines: thus, ethane −2H gives olefiant gas. Beginning with highly permanent gases, the paraffin series passes gradually into very volatile liquids, thence through those of less volatility into solids melting a little over ordinary temperature, and up by higher-melting solids to one fusing as high as 176° Fahr. The petroleum of commerce consists entirely of this series; whilst the so-called paraffin oils contain only ⅛th or ⅙th part of it, their other constituents being mainly olefines.

The softest of the solid paraffins boil over 600° F.; but those of the highest melting-point only decompose slightly by distillation. Chlorine passed through melted paraffin gradually converts it into a thick clear liquid like castor oil; but, by longer continued action, changes it to a brittle solid. Bromine acts on paraffin when both are heated together in sealed tubes. When equal quantities of sulphur and paraffin are heated together, a current of pure sulphuretted hydrogen is generated. Sulphuric acid, heated to a very high temperature, chars paraffin on contact, with evolution of sulphurous acid. Nitric acid reacts on it, producing an oily nitro-compound, and also acids of the succinic and butyric series.

The manufacture of paraffin and paraffin oils from cannel and shales has now become one of the important branches of national industry. The rapidity of its development is almost unexampled.

At the expiry, in 1861, of the patent of Messrs. Young & Co., a long list of wealthy and influential companies embarked in this new industry, principally in the Bathgate oil district, which has extended throughout nearly the whole of Linlithgow, and encroaches upon Edinburghshire; and the Leeswood oil district in Flintshire. But the great importation of American petroleum brought on a crisis in 1866; and ever since, through various causes, this new manufacture has been dwarfed from its first anticipated gigantic dimensions.

The Scotch oil works are almost exclusively supplied with shales, of which the most important is the Boghead or Torbane Hill mineral, the technical definition of which, whether coal or shale, was once the subject of so warm a controversy. It is found a little to the south of Bathgate. It takes precedence of all the raw materials for the distillation of paraffin and paraffin oils, both historically and in point of richness. It was the material originally worked by Mr. Young, as above described; but the limited basin containing it is now virtually worked out. The other shales of the district vary considerably in richness, both as regards the quantity and quality of the distilled products. See SHALES and MINERAL OILS.

In Flintshire three varieties of material were used: the *curly cannel*, the *smooth cannel*, and the *bottom shale* or 'bastard cannel.' But the high price now given for them by gas-makers has withdrawn the first two minerals from the raw material of the oil-manufacturer. The demonstration of their value as sources of paraffin, &c. is due entirely to the persevering efforts of Mr. W. C. Hussey Jones, during the years of 1861 and 1862, which finally resulted in the formation of the 'Leeswood-Green Cannel and Gas-Coal Company,' and the oil works of Messrs. Fernie & Co., at Leeswood in Flintshire, and at Saltney in Cheshire.

The Leeswood cannel-seam is from 5 to 6 feet thick in the best portions of the basin, which is but of a very limited area, and thins out at its boundaries. The upper portion of the seam consists of the smooth cannel, having a thickness of about 25 to 30 inches; next below is the curly cannel, about 18 inches in thickness; and below this the shale or bastard cannel, which varies considerably, both in thickness and richness. It ranges from about 14 inches to 2 feet in thickness. In some places, especially to the westward of Leeswood, this shale is replaced by a common bituminous coal, which, adhering firmly to the smooth cannels, seriously interferes with its value as a source of burning-oil; the distillate from this coal containing oils of the benzole and naphthaline series, giving red smoky flames. Northward, beyond the river Alyn, and towards Mold, the whole seam thins out to 18 or 24 inches, and contains only smooth cannel.

Besides these, there is a bituminous ironstone similar to the 'black-band ironstone' of Scotland, which comes in irregularly with the bottom shale; and a black shale forming the roof above the smooth. Both of these contain oil, but have not hitherto been regularly worked.

Curly cannel yields upon distillation about 30 per cent. of *crude* oil, of specific gravity varying from 875 to 890; smooth cannel, about 16 per cent. of *crude* oil, of specific gravity from 925 to 940; and the shale, which is very variable, yields from 12 to 15 per cent. of oil, specific gravity about 900.

As cannels yielding a coke are limited in area, and are valuable in gas-making, it is now found commercially unprofitable to use them in oil-making. All the Welsh seams above described, except the lowest one, are no longer put into the retorts;

consequently crude-oil making does not flourish in this, for three years, once busy centre. The Flintshire refiners now look to Scotland for the raw material of their manufacture. Many ingenious retorts designed specially to use cannel, some of which were fully described in a previous edition, are now abandoned.

In the extraction of crude oil, the cannel or shale has to be enclosed in a suitable vessel, subjected to the degree of heat necessary to drive off its condensible vapours, which vapours must pass through an outlet communicating with a suitable condensing apparatus.

This is simple enough; and, for the mere production of paraffin oils from cannel or shale, any kind of pot with an outlet-pipe, heated sufficiently by any kind of fire, will suffice; but to produce the maximum quantity of *condensible* vapours, and the *minimum* quantity of incondensible gas, with the greatest degree of rapidity, and with the smallest amount of outlay in plant, labour, and fuel, is a problem of some practical difficulty.

At first sight, the distillation of crude oil from cannels and shales appears almost identical with gas-making, and, accordingly, the early retorts were simply copies of those found by experience to be most suitable for gas-making.

It soon became understood, however, that some of the most important conditions to be observed are exactly the opposite of those upon which success in gas-making depends. In gas-making the desideratum is to obtain the maximum amount of permanently elastic gas, and the minimum of condensible vapours; in oil-making, we require to reduce the permanent gases to the minimum, or, if possible, to make none, and to obtain in their place the greatest possible quantity of condensible vapours. It is now well known that if these condensible vapours are exposed to a high temperature they are decomposed, and to a considerable extent converted into permanent gas, and that the proportion of permanent gas bears some relation to the excess of temperature; the greater the heat, the more incondensible gas and the less condensible vapours are formed. In gas-making, therefore, a very high temperature is desirable; in oil-making the great object is to subject the coal to no excess of temperature beyond that which is absolutely necessary for its distillation into condensible vapours.

Without dwelling further on obscure theoretical considerations, we may state generally that the practical result of excessive heat is, besides a wasteful production of permanent gas, the production of a crude oil of darker colour, higher specific gravity, and possessing a characteristic odour well known to practical oil-makers as that of 'burnt oil.' This burnt crude oil contains less solid paraffin, and is much more difficult to refine than crude oil made at a lower temperature from like material. It requires much more acid treatment, and even then produces burning-oil, which still retains the 'burnt' odour, and blackens the lamp-glasses.

The difficulties standing in the way of distillation at the proper temperature are: 1, the necessity of decomposing before distillation; 2, the varying boiling-points of the different products; 3, the law of radiation, which demands a higher temperature in the retort than that of coal; and 4, the commercial necessity of rapid working.

We will consider these *seriatim*; and, in describing the improvements and attempted improvements in retorts, refer each to the difficulty that it aims to overcome:—

1. Although these hydrocarbons known as paraffin oils and paraffin are obtained from the cannel by distillation, it is quite clear that they do not exist there as such. We may saturate a mass of the porous cannel coke with these hydrocarbons, or with crude solid paraffin, and produce a flaming coal thereby, which, upon careful distillation, will give back the volatile hydrocarbons; but this artificially-saturated coke is essentially different from the original cannel, as shown by the fact that we may remove the hydrocarbon from the saturated coke by pounding it and washing with a solvent of paraffin, &c., while the cannel itself resists the action of all such solvents. The same is the case with Boghead and paraffin shales generally, though they are not unfrequently described as porous minerals merely saturated with bituminous matter by infiltration. Mr. Gellatley of Bathgate proved this experimentally by converting paraffin into anthracene and naphthaline by passing its vapours through a red-hot tube.

The distillation of cannels and shales is thus a more complex process than the distillation of a volatile oil, a resin, or bitumen. In the latter case the substance is merely raised to its boiling-point, and this heat being maintained its vapour is driven off. In the distillation of coal, the first function of the heat is to overcome the chemical affinities which hold the hydrocarbon elements in the peculiar form in which they exist in the coal, and then after this separation to drive their vapours over. It is a compound process of decomposition and distillation, and the heat has to overcome the combined forces of chemical and cohesive attraction. Hence a considerably higher temperature than that of the mere boiling-point of the resultant hydrocarbons is necessary. Here, then, at the outset we encounter an insuperable necessity for heating the vapours considerably above their boiling-points—to a temperature, in fact, at which some degree of further decomposition must take place, and some amount of permanent gas must be formed.

2. The boiling-points of the different volatile hydrocarbons obtainable from the cannel or shale, range from about 200° to about 500° Fahr. In order to drive off the latter, we are compelled to raise the temperature to about 300° above the boiling-point of the former, exclusive of the excess of heat required for the primary decomposition described under No. 1.

3. When any kind of closed retort or oven is used which is charged internally, and the coal receives its heat from the outside, it is not merely necessary to raise the temperature of the sides of such retort to the decomposing and distillation-heat, but to something above this heat, as no body can give off any heat by radiation or convection to another body unless it be hotter than the body which is to receive the heat. As the quantity of heat communicated by radiation to a given surface varies inversely with the square of the distance from it, this difference of temperature requires to be increased very considerably, as we enlarge the retort in any manner that increases the distance of portions of the coal from its heated surface.

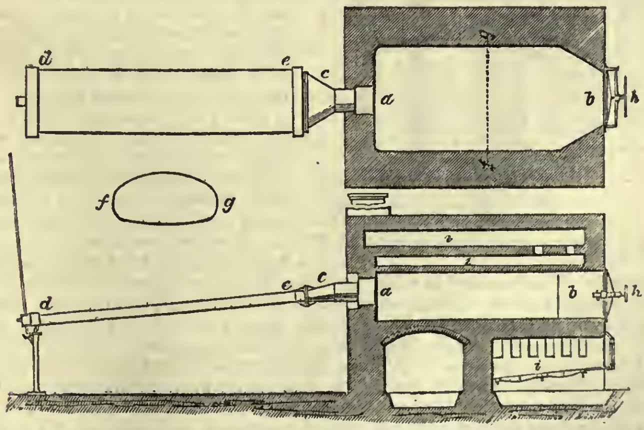
4. The commercial necessity of rapid working, in order to economise original outlay upon plant, drives us to enlarged retorts acting disadvantageously under No. 3, and to exaggerate the excess of temperature of the retort-surface, in order to effect rapid communication of heat.

It will be at once understood that the combined action of these four necessities is to expose the vapour that is formed to the action of the greatly-superheated retort-walls, and thereby decompose it. The primary object of all improvements, beyond those directed to economising labour and plant, is to overcome or diminish these sources of loss and deterioration; and, in describing the different forms of retort, we shall refer to their intent accordingly.

It will be readily seen that the first of these difficulties is insuperable, that the others for the most part can only be partially overcome, and thus that the process is necessarily wasteful to some extent. All crude-oil works until lately presented a painful manifestation of this in the flaring jets of gas that illuminated so vividly the surrounding country. But this waste gas is now utilised in supplying small towns, like Bathgate and West Calder in Scotland, with a cheap illuminant; or in generating heat for the boilers and retorts after the light condensible oil has been suitably removed from it. Young's Company recover in this way a gallon of mineral spirits in every thousand cubic feet of gas generated.

The first step made in Wales beyond using the common gas-retort was to increase greatly the width and diminish the height of the D-retort, and forming thereby the

1603



'flat D,' now very extensively used, and by most manufacturers still regarded as practically the most useful form of retort. As almost every firm has its particular pattern, we can only state dimensions generally: from 8 to 10 feet is the usual length; width, from 30 inches to 5 feet 6 inches, commonly 3 to 4 feet; and height, from 12 to 24 inches. The verdict of experience runs in favour of further flattening down to the 12 inches.

Fig. 1603 represents the general arrangement of Mr. Birkbeck's flat D's in plan and section, where *a b* is the body of the retort, *c* the outlet-pipe, *d e* the flat condenser, *f g*, transverse section of body of retort at *f' g'*, *h* the retort-door and screw-clamp, and *i i i* furnace and flue. These retorts are 5 feet 6 inches wide.

The advantage of such retorts over the D gas-retort is obvious upon consideration of difficulty No. 3. The coal is spread over a larger surface in a thinner layer, and yet a large quantity is included in one charge. All experience goes in favour of spreading out the coal in thin layers rather than packing it in a thick mass. The thinner the layer the smaller will be the difference of temperature between the retort itself and the least heated portion of its contents.

1604

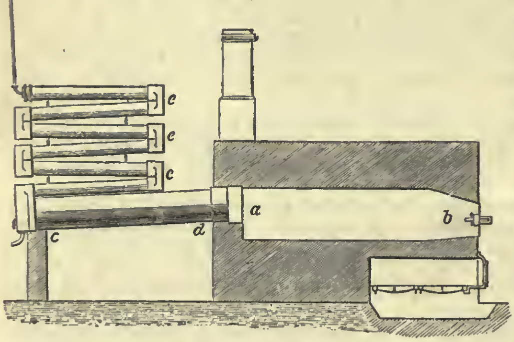


Fig. 1604 represents another form of flat D; *a b*, body of the retort; *c d*, main condenser and outlets; *e e e*, zigzag supplementary condenser made of cast spouting pipe. It is made by Bryan Johnson, of Chester.

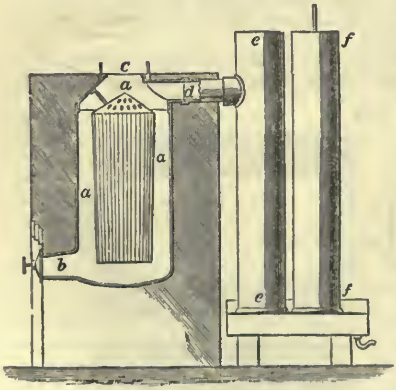
This retort differs but little from the previous one, excepting in having a large outlet with more direct communication with the condenser, and the modified form of the condenser itself. A large outlet is always advantageous, as by its means the vapours more readily escape from the decomposing action of the heated retort and its contents.

Fig. 1605 represents in section the upright retort of Mr. Holmes of Ruabon, where *a a a* is the body of the retort, *b* the discharging outlet for the coke, *c* the charging mouth, *d* the vapour-outlet, *e e* and *f f* the condensers.

1605

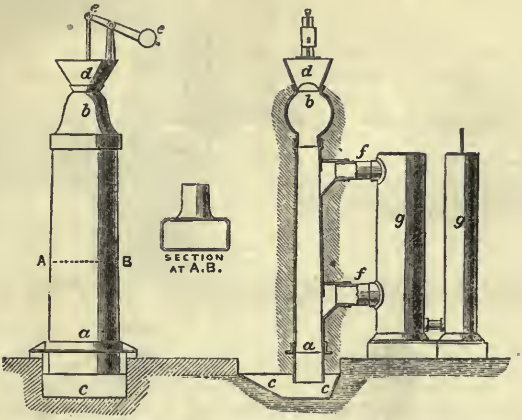


In this retort the internal cage shown in the figure serves the purpose of the shelves, &c. already described, as by its means the charge forms a layer occupying the space *a a a* in contact with the retort-walls, while the vapours pass into the cage and thence to the condenser. It is easily charged where the coal is brought from an upper level.

Fig. 1606 represents Bryan Johnson's modification of the Scotch upright retorts, which work a continuously-descending charge. Supposing the retort to be filled, the valve at *a* is opened, and a portion of the coke let down into the receiving water-tank, *c c*. The hopper, *d*, being filled with a corresponding quantity of fresh cannel or shale, the valve, *b*, is raised by means of the lever *e c*, and the retort is filled. This is repeated at short intervals, and thus the charge is gradually worked downwards. Theoretically, these retorts should be hottest at the bottom, and the heat gradually diminish upwards; but practically there is great difficulty in arranging the flues to obtain a regular gradation of heat on account of the rapidity with which the heated gases of the flues ascend when the draught is at all free.

In Scotland the common D-shaped gas-retort continues in a few crude works. The retorts in them are now set in benches naked to the fire, and the waste gas is also led below them; so that a saving of 4 cwts. of coal in each charge of shale is effected. But, after much controversy, a continuous vertical retort, similar to that in *fig.* 1606, but of a more oval shape is preferred. The merits of the case appear to be that parties desirous of making only crude oil should erect horizontal retorts, whilst refiners making their own *crude* should rely on verticals. The oil from vertical retorts has a

1606



specific gravity of 890°; that from horizontal retorts varies from 850° to 860°; but indeed has been as low as 840°. The latter commands the best price in the market; but the former is more cheaply made by the refiner; and it is more valuable, for though there is less burning-oil and naphtha, it contains 3 per cent. more paraffin. In the Scotch upright retort the distillation is *per ascensum*; and the condensers are simpler than those figured in the drawing; indeed, very complex forms of condensers were used in the first stages of coal-oil making; such as worm-tubes, with water-tanks and hydraulic mains of various patterns. It is now found that simple radiation is a sufficient cooling agent.

Mr. Young of Straiton, near Edinburgh, some years ago introduced a very effective retort resembling somewhat in section *fig.* 1605. But the cage is represented by a framework of impervious iron, round which the waste gases are first conducted away with the other products in this case by distillation *per descensum*, but afterwards reintroduced by a suitable opening play, assisting the small fire. Not only is coal saved, an item of importance even in days of cheap fuel, because such shale works are generally far from coal-pits, but more paraffin is obtained. The Oakbank Oil Company, Midcalder, have used these retorts with great satisfaction.

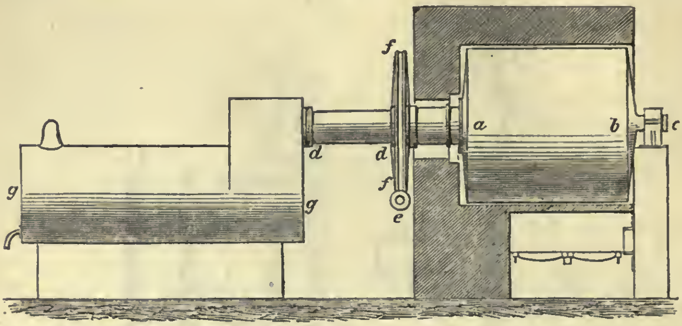
The revolving retort is an American invention. It is shown in elevation and section in *figs.* 1607, 1608, 1609, the lettering being the same in the sections and the elevation.

a a is the body of the retort, a cast-iron cylinder (wrought-iron has also been used) usually about 7 feet diameter and 7 feet long. The cylinder turns on the axles *c* and *d d*; the latter, *d d*, is hollow and serves also as the vapour-outlet to the condenser *g*, which has a second or supplementary condenser shown in section at *h*, connected with the first by the swan-neck *i i* (*fig.* 1608).

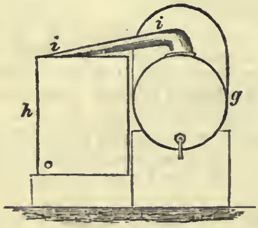
The cylinder or body of the retort is turned very slowly by means of an endless screw, *e*, working in a toothed-wheel, *f f*. The charging door, *k*, is on the opposite face of the cylinder. The heat is communicated from the furnace by means of an arched flue which embraces the whole of the cylinder. To charge the retort the door, *k*, is turned upwards, as shown in the figure; to discharge, it is by a half-revolution from this position brought to the lower side.

The action of these retorts will be easily understood. The charge is continually rolled over, and thus fresh portions are brought in direct contact with the heated surface. By this means a very rapid distillation is effected. In this respect they are most efficient. The objections to them are their costliness in the first place, and their liability to crack, from the unequal expansion of so large a surface of metal. They cannot be protected all round, as ordinary retorts are, by a casing of fire-bricks, and being thus exposed to the direct action of the fire are rapidly destroyed, especially if great care is not taken to remove the lining of carbon-deposit which forms on the inside. When ordinary cannel is used, they have to be cleaned out weekly, which involves a serious loss of time in cooling down and reheating all the surrounding brickwork. This difficulty is to a great extent overcome by working lumps of hard shale with the cannel, which is especially necessary when cannel slack, for which these retorts are best adapted, is used. Where the material to be used is liable to

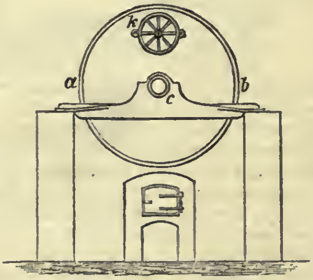
1607



1608



1609



soften and become at all adhesive when treated, these retorts are utterly useless. When it forms a hard clinker coke, they may with careful management be advantageously used, as the quantity of work done by them is very great.

Another difficulty is presented by a very friable material which readily crumbles into dust, as such dust flies over with the vapour and makes a very dirty oil.

Among the earlier efforts to improve the process of distillation of coal, &c., was the application of superheated steam. Several patents have been secured for this, the general object being to drive the heated vapour through a mass of coal broken into small pieces, and thereby apply the heat directly to each fragment, thus completely avoiding the third source of excessive temperature, besides affording an effectual means of regulating the temperature while diffusing it equally throughout the whole mass.

This method, though so admirable in theory, has failed in practice, after being well tried by Messrs. Young, by Messrs. Lavender and Co. at the Canneline Oil Works, Flintshire, and by others. It is now, as far as we are aware, altogether abandoned. The difficulties that have led to its abandonment were mainly the costliness of the superheating process, and the great amount of steam required to be formed in the first place, and then to be condensed. It must be remembered that while the latent heat of steam is equal to about 1000° Fahr., that of the hydrocarbons primarily to be distilled is not above one-tenth of this; thus every pound of steam requires for its condensation about ten times the amount of cooling surface which is necessary for the condensation of a pound of oil-vapour; and the complete condensation of the steam is necessary, as it obstinately retains an important quantity of oil-vapour diffused through it.

The use of heated gases, such as nitrogen, carbonic acid, &c., in the place of steam, overcomes this difficulty; but the cost of preparing the gases renders their application equally impracticable on the primary score of economy.

The 'meerschaum retort' is a modification of the principle of distilling the coal by *internal* application of heat. This is effected by means of a large chamber or kiln, rather than retort, constructed of fire-brick and shaped like a huge tobacco pipe-bowl, with which an exhaust-pipe like the stem of a tobacco-pipe communicates with the bottom. This exhaust-pipe communicates with suitable condensing chambers. The bowl or kiln is charged with the cannel or shale, on the top of which is laid a stratum of burning coke or a mixture of coke and slack. As soon as this upper stratum is in a state of full combustion, the exhaustion is commenced by means of a steam-jet, and the heated products of combustion are drawn down through the charge. That portion immediately below the fire is of course the first acted upon, the action commencing with a distillation of the most volatile products. As the heat increases, the more stubborn and denser vapours are driven downwards through the lower mass, and by their heat commence the distillation there. Subsequently, the upper layer of cannel having all its volatile constituents driven off, becomes a coke, and at this stage is so highly heated as to burn and give off combustion products, viz. carbonic oxide, &c., instead of distillation products, thus serving as fuel for the cannel below, and so on till the mass is coked to the bottom. When this is completed, the steam-jet is turned off, the exhaustion ceases, and the charge is drawn from below, a portion of it being used in its burning state for starting a neighbouring kiln, which should always be charged ready to commence working when its predecessor has reached this stage.

The size of Mr. Holmes' meerschaums is 12 feet high, and 8 feet diameter, internal measurement. They are to be charged to a depth of 10 feet, and to contain 12 tons of cannel.

Mr. Holmes' attempt to introduce this retort in Wales proved disastrous. In 1866, Mc Beth patented an adaptation of the principle to the ordinary Scotch retort [Spec. A.D. 1866, No. 2788]. Very poor shales were worked to profit; but the skill necessary to produce a good product in the daily working proved a serious drawback. Ordinary labour only is requisite for the common retorts. Messrs. Young and Stephens have patented a new retort similar to one already described, but doing without the aid of coal. Suppose four retorts, similar in section to *fig.* 1605, built in a bench, but the bottom of each open, and having attached to each a condensing apparatus, at the extremity of which is a steam-jet. Each cylinder receives a charge of shale which is renewed every 5 hours; a fire of coals is then lighted in the furnace, which begins distillation, at the same time igniting the lower layer of shale: a portion of this falls out into the space betwixt the furnace-wall and the retort and acts instead of coal. The condensers being now filled with vapours, the steam-jet is set in motion, and air is exhausted from the retort, the condensible vapours become crude-oil, and the incondensible gas is returned to play on the walls of the shale cylinders. The oil is of good specific gravity unburnt, very rich in paraffin, and equal in yield to the ordinary retorts. No coal is necessary, except when the distillation begins either at the commencement of the works or after a shut-down. Other inventors are busy on the problem, in making the material giving the valuable paraffin yield power for its extraction. On this solution mainly rests the possibility of our shale-oil manufacturers competing successfully with the petroleum from the American springs; and also of a more extended use of solid paraffin for many new processes in the arts. For the production of solid paraffin, a bye-product in mineral-oils when burning-oil brought 1*s.* 6*d.* to 3*s.* 6*d.* per gallon, is now a main source of income, when the former main product only brings 1*s.* per gallon or less nett at the works.

Boghead and the cannels usually yield from 1 to 1·4 per cent. of paraffin scales of raw materials used; Scotch shales, in ordinary manufacture, 3 to 4 per cent. But individual shales are known yielding a very large percentage of this substance, which, unlike the burning-oils, increases in commercial value. When bodies are worked for this alone, much of the expense of an oil-refinery will be saved; and the resulting oils in their manufacture may be sold almost at the price of waste substances.

Paraffin refiners receive supplies of their raw material from other natural sources. Peat-tar often contains a large percentage, but the resulting paraffin is very soft. Ozokerite and neft-oil, derived from the Caspian Sea and Hungary, now command high prices as sources of paraffin scales. Neft-oil is said to give 68 per cent. of distillate, consisting of 60 per cent. of crude paraffin and 8 per cent. of oil. The Galician ozokerite gives by distillation some 24 per cent. of paraffin, and 45 per cent. of oil.

The refining of the liquid portion of the crude oils is still conducted in the manner described. (See Shale and Mineral Oils.) A great many patents have been secured, a large proportion of them evidently based upon the theory that the refining of these oils is simply a process of oxidation analogous to that of the bleaching of vegetable colours. Some degree of oxidation undoubtedly does take place in the course of the refining process, but this is far from being the whole action. The sulphuric acid appears to act chiefly as a carbonising agent, and by heterogeneous adhesion to the carbonaceous or pitchy colouring-matters which it carries down with it in the form of 'acid-tar.' The theory of the action is, however, by no means fully understood. It still offers a most interesting field for a thorough investigation.

Among the many processes patented may be named the use of hypochlorite of lime, the application of chlorine gas to the vapours of the oils, of nascent chlorine to the liquid oil by the decomposition of hydrochloric acid or chloride of sodium with black oxide of manganese, the use of bichromate of potash and other chromates, and of free chromic acid, of the permanganates, and almost every known oxidising agent.

The sulphuric-acid treatment is the only method which has been found commercially successful. The proportion of acid required depends upon the oil, and must be determined by experiment. Generally speaking, the heavier oils require more acid than the lighter; but even this rule is subject to special exceptions.

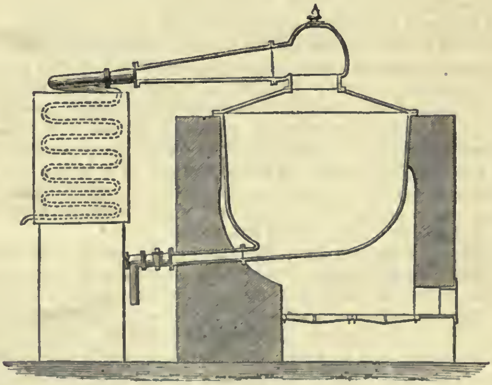
Many forms of agitators have been adopted, from simple tubs with a paddle to very complex devices worked by steam-power; the problem, however, is merely to keep a heavy liquid—sulphuric acid—stirred up amidst a lighter one—the crude, or 'once-run' oil. A *cast*-iron vessel, fitted with paddles working on an axle similar to a common churn, is the apparatus generally used. Upright cylindrical vessels, with an Archimedean screw working vertically to raise the acid from the bottom, have been used, but not extensively.

In some refineries the crude oil is treated with the acid and alkali, but more commonly it is 'once run,' as already described.

In all the stages of distillation for the refinery the use of superheated or dry steam is found very advantageous, not as the primary source of heat, but as an auxiliary. In accordance with the well-established law of diffusion of gases, the vapour from the boiling oil will diffuse much more readily into an atmosphere of steam than into one of its own vapour; and thus the superheated, or simply the dry steam, enables the distillation to be conducted at a lower temperature than would be necessary without it, which is a matter of considerable importance, not merely as regards the quantity of work done with given fuel, but also as affecting the quality of the oil produced.

The form of still most commonly used is shown in *fig.* 1610, usually of a capacity of 1,000 to 2,000 gallons. Much difference of opinion prevails among refiners as

1610



regards the merits of cast or wrought iron. Many serious conflagrations have lately occurred from the sudden cracking of cast-iron stills, which have led to a much more extensive use of wrought iron than formerly.

It is a common practice in the first running of crude oil to use a wrought-iron still, or still of cast iron with bottom outlet-pipe, like that in *fig.* 1610, for the first part of the process, until the heavier products begin to run over; then to run out the residue from this still into a small round bottom still, without bottom outlet, and then 'coke down,' that is, carry on the distillation to dryness. By this means the most dangerous stage is carried on in the smaller still, which is far less liable to rupture. Wrought-iron stills cannot well be used for coking down, the great heat required destroying the rivets.

In the refining of the solid paraffin considerable progress has been made.

In the first place, the crude oil is distilled over to dryness, 'coked down,' as already described. The heavy oil obtained from the latter stages of distillation is found to contain large quantities of bright crystalline scales of solid paraffin in suspension.

Paraffin is crystallised from the first distillation in several works; but it is usually 'bagged' from the second distillation. In the crude oil, the pitchy constituents seem to cling to the paraffin particles and hold them back from crystallisation, so that they form an amorphous greasy mass when the light oil only is distilled off from the crude. This grease, however, when distilled gives over a rich lubricating oil of pale brown colour, with the paraffin crystals in such a state of free suspension that they are readily separated at a low temperature. This separation of 'brown paraffin scale' is effected by 'bagging' and pressing. The bagging is simply a filtration in canvas bags, which are usually filled and tied up, then heaped together, or thrown into perforated boxes till the greater portion of the oil filters out. The contents of the bags are then submitted to a gradually-increasing hydraulic pressure till the utmost possible degree of dryness is obtained in the cake of crystalline scales.

The quantity of solid paraffin thus obtained depends in a great measure upon the temperature at which these operations are conducted, as the oil is a solvent to the paraffin, and the quantity it is capable of dissolving rapidly increases as the temperature rises. In small works this separation of paraffin is only conducted in cool weather; in larger works, refrigerating-machines are used.

The purification of the brown paraffin scale thus obtained is now effected by the simple process of dissolving it in a hot solution of the most volatile 'paraffin spirit.'

The scale having been dissolved in about an equal weight of spirit, the solution is set to cool in suitable vessels. As it cools, the solid paraffin recrystallises, in the course of which action it rejects the impurities associated with it, giving up its brown colour and the liquid solvent. The cooled mixture of crystal and spirit is again submitted to pressure, whereby the spirit is separated, and the crystals, now of a cream colour, are again dissolved in colourless spirit, and the same treatment repeated. A third treatment is usually necessary to obtain perfect purification, when beautiful crystals of exquisite snowy whiteness are obtained, presenting the most perfect contrast imaginable to the coal from which they are derived.

The chief drawback to this process is the waste of spirit by evaporation during the cooling and pressing processes. By careful and intelligent management this waste may be materially reduced. The refuse spirit, which has received the colouring-matter and other impurities from the brown scale, is easily refined by simple distillation, and may be used again and again. The brown refuse left in the still may be treated afresh as crude paraffin scale, as there always remains a portion of paraffin in it which continued in solution when the rest crystallised out. This, however, is of inferior quality, having a lower melting-point, and is usually sold in a semi-refined state for making common candles, burning in miners' lamps, &c.

In order to remove the last traces of the spirit, which if left behind, lowers the fusing-point, besides giving its odour to the paraffin, the scales are fused and heated to about 240° Fahr.; care being taken to go no higher than this, as at 260° the paraffin acquires a yellow colour similar to that of bees'-wax. It is therefore necessary that the spirit should be freely and fully volatile at or below 240°, and that all the heavy oil should be separated in the earlier stages of the process. This fused paraffin is run into moulds, and sold in cakes as 'paraffin wax,' which is now becoming the great staple material for the manufacture of the better class of candles. Every year the price of these candles has come down lower and lower, in consequence of the increased production by improved methods.

Paraffin as washed at these various stages is now used in candle-making according to the value of the manufactured material wanted.

Whiteness, freedom from smell, and a high melting-point, are the commercial tests upon which the value of paraffin depends.

The importance of the latter may easily be understood when we consider that the melting-point of the best paraffin is but 125° Fahr., while inferior qualities are much lower. Paraffin, like wax, resin, and such substances, softens at many degrees below its melting-point; hence candles made of an inferior paraffin are liable to bend over into strange shapes in a heated ball-room, or in a hot climate. This was very vexatiously and absurdly exemplified at the coronation of the Emperor Maximilian in Mexico, when at one of the festivals all the beautiful 'spermaceti' candles, ordered expressly from England, and numbering several thousands, though brilliantly successful at first, gradually softened as the throng increased, and finally bowed over altogether, flaring hideously, and guttering in streams upon the dresses of the visitors.

Price's Candle Company, Limited, have adopted a new patented method of paraffin refining with much advantage, the cost of working being very much less, and the yield of white paraffin notably larger than formerly. As no spirits are used, a loss of about 1 cwt. of them for every ton of finished paraffin is avoided. As redistillation of the expressed oils also ceases, no loss occurs in this way of solid paraffin in solution. Much more safety also accompanies the operations of the factory. The *rationale* of the process consists in subjecting the paraffin, after being previously washed with sulphuric acid and soda, to hot pressure and *filtration* at the same time. The following details of two experiments on the commercial scale show the working of the process:—

In the first experiment, good average scale was first boiled, and blocked into a cake, which, on being cold-pressed, yielded lubricating-oil and pressed cake; which, after being again boiled and blocked, was subjected to the new method, giving a hard paraffin, which, after treatment with acid, alkali, and ivory-black, yielded finished paraffin equal to that made with the ordinary process, and having a melting-point of 129°.

There was taken of the scale 200 cwts. 1 qr. 26 lbs., which gave:—

	cwts.	qrs.	lbs.	per cent.	
Finished paraffin	131	1	27	= 65·58	
Soft paraffin, &c., of the value of ⅘ths of original scale	35	0	12	17·51	
Dark rough oil	17	2	5	8·75	
				91·84	
Loss, including paraffin left in ivory-black	16	1	10	8·16	loss.
	200	1	26	100·00	

In the second experiment, scale of a low melting-point was treated as above; only submitted twice to the special process. A paraffin with a melting-point at 130° resulted:—

Of the scale taken—69 cwts. 26 lbs.—there remained—

	cwts.	qrs.	lbs.	per cent.	
White paraffin	39	3	27	= 57·83	
Soft paraffin, &c., valued at ⅘ths of original scale	18	1	27	26·74	
Rough dark oil	6	3	0	9·76	
				94·33	
	69	0	26	5·67	loss.
				100·000	

This process must be of immense service in extracting solid paraffin for its own sake from minerals in places where mineral spirits are not a drug, as in our own mineral-oil factories.

Paraffin is mixed with 5 to 15 per cent. of stearine when moulded into candles; and to do this thoroughly well the moulds must be kept for at least an hour in a bath of hot water, at a temperature of about 190° Fahr. The mixed stearic acid facilitates the colouring of paraffin candles.

The following particulars of the paraffin trade in Scotland, derived from an authentic source, cannot be without interest:—

It is difficult to obtain statistics of the yield of burning-oil, lubricating oil, and the other products derived from shale in the process of oil-making. Naturally enough, one manufacturer does not care to let another know the particulars of his production. Hence, at best, nothing more than an estimate can be arrived at; but this coming from a source which may be relied upon, will give a tolerably fair idea of the extent of this important trade. It is estimated that not less than 800,000 tons of shale are annually put into the retorts at the various Scotch oil works. The probable yield of crude oil from this source is reckoned at 25,000,000 gallons. To obtain this result, and also for the distillation of the crude, a great amount of fuel—say 500,000 tons—must be used. The principal product from the crude is, of course, burning-oil, of which from 300,000 to 350,000 barrels may be taken as the annual yield. Some of this is sent to the Continent, but the bulk is consumed in this country. Then we have of lubricating-oil, the demand for which appears to be increasing every day, say 9,800 tons. Also paraffin wax, of which the bulk is made into beautiful semi-transparent candles, and the commonest of it is used in the manufacture of lucifer-matches, say 5,800 tons. To these figures we may add some 2,300 tons of sulphate of ammonia, and several thousand barrels of coal-oil spirit. The probable commercial value of these products cannot fall far short of a million and a quarter sterling. This valuable industry has been developed in our midst in little more than 20 years, and has had to make headway against a variety of opposing elements to its present position. The deliveries during 1872 are somewhat short of 1871 and 1870; but this is accounted for by temporary causes, such as strikes among the workmen and miners, and the high prices of coal.

PARAGUAY TEA. The leaves of the *Ilex Paraguaiensis*, which are used as tea in Brazil. They appear, like tea, to contain some *theine*, with resin, tannic acid, oil, and albumen. Paraguay tea is known also as *Maté*.

PARA NUTS. The Brazil nut, which see.

PARCHMENT. (*Parchemin*, Fr.; *Pergament*, Ger.) This writing material has been known since the earliest times, but is now made in a very superior manner to what it was anciently, as we may judge by inspection of the old vellum and parchment manuscripts. The art of making parchment consists in certain manipulations necessary to prepare the skins of animals of such thinness, flexibility, and firmness, as may be required for the different uses to which this substance is applied. Though the skins of all animals might be converted into writing materials, only those of the sheep or the she-goat are used for parchment; those of calves, kids, and dead-born lambs for vellum; those of the he-goat, she-goat, and wolves for drum-heads; and those of the ass for battledores. All these skins are prepared in the same way, with slight variations, which need no particular detail.

They are first of all prepared by the leather-dresser. After they are taken out of the lime-pit, shaved, and well washed, they must be set to dry in such a way as to prevent their puckering, and to render them easily worked. The small manufacturers make use of hoops for this purpose, but the greater employ a *herse*, or stout wooden frame. This is formed of two uprights and two cross-bars solidly joined together by tenons and mortises, so as to form a strong piece of carpentry, which is to be fixed up against a wall. These four bars are perforated all over with a series of holes, of such dimensions as to receive slightly-tapered box-wood pins, truly turned, or even iron bolts. Each of these pins is transpierced with a hole like the pin of a violin, by means of which the strings employed in stretching the skin may be tightened. Above the *herse*, a shelf is placed, for receiving the tools which the workman needs to have always at hand. In order to stretch the skin upon the frame, larger or smaller skewers are employed, according as a greater or smaller piece of it is to be laid hold of. Six holes are made in a straight line to receive the larger, and four to receive the smaller skewers or pins. These small slits are made with a tool like a carpenter's chisel, and of the exact size to admit the skewer. The string round the skewer is affixed to one of the bolts in the frame, which are turned round by means of a key, like that by which pianos and harps are tuned. The skewer is threaded through the skin in a state of tension.

Everything being thus prepared, and the skin being well softened, the workman stretches it powerfully by means of the skewers; he attaches the cords to the skewers, and fixes their ends to the iron pegs or pins. He then stretches the skin, first with his hand applied to the pins, and afterwards with the key. Great care must be taken that no wrinkles are formed. The skin is usually stretched more in length than in breadth, from the custom of the trade; though extension in breadth would be preferable, in order to reduce the thickness of the part opposite the backbone.

The workman now takes the fleshing tool represented under CURRYING. It is a semi-circular double-edged knife, made fast in a double wooden handle. Other forms of the fleshing-knife edge are also used. They are sharpened by a steel. The workman seizes the tool in his two hands, so as to place the edge perpendicularly to the skin, and pressing it carefully from above downwards, removes the fleshy excrescences, and lays them aside for making glue. He now turns round the *herse* upon the wall, in order to get access to the outside of the skin, and to scrape it with the tool inverted, so as to run no risk of cutting the epidermis. He thus removes any adhering filth, and squeezes out some water. The skin must next be ground. For this purpose it is sprinkled upon the fleshy side with sifted chalk or slaked lime, and then rubbed in all directions with a piece of pumice-stone, 4 or 5 inches in area, previously flattened upon a sandstone. The lime soon gets moist from the water contained in the skin. The pumice-stone is then rubbed over the other side of the skin, but without chalk or lime. This operation is necessary only for the best parchment or vellum. The skin is now allowed to dry upon the frame; being carefully protected from sunshine, and from frost. In the arid weather of summer, a moist cloth needs to be applied to it from time to time, to prevent its drying too suddenly; immediately after which the skewers require to be tightened.

When it is perfectly dry, the white colour is to be removed by rubbing it with the woolly side of a lambskin. But great care must be taken not to fray the surface; a circumstance of which some manufacturers are so much afraid, as not to use either chalk or lime in the polishing. Should any grease be detected upon it, it must be removed by steeping it in a lime-pit for ten days, then stretching it anew upon the *herse*, after which it is transferred to the *scraper*.

This workman employs here an edge tool of the same shape as the fleshing-knife, but larger and sharper. He mounts the skin upon a frame like the *herse* above described; but he extends it merely with cords, without skewers or pins, and supports it generally upon a piece of raw calfskin, strongly stretched. The tail of the skin being placed towards the bottom of the frame, the workman first pares off, with a sharp knife, any considerable roughnesses, and then scrapes the outside surface obliquely downwards with the proper tools, till it becomes perfectly smooth: the fleshy side needs no such operation; and indeed, were both sides scraped, the skin would be apt to become too thin, the only object of the scraper being to equalise its thickness. Whatever irregularities remain, may be removed with a piece of the finest pumice-stone, well flattened beforehand upon a fine sandstone. This process is performed by laying the rough parchment upon an oblong plank of wood, in the form of a stool; the plank being covered with a piece of soft parchment stuffed with wool, to form an elastic cushion for the grinding operation. It is merely the outside surface that requires to be pumiced. The celebrated Strasburg vellum is prepared with remarkably fine pumice-stones.

If any small holes happen to be made in the parchment, they must be neatly patched, by cutting their edges thin, and pasting on small pieces with gum-water.

Parchment is coloured green only. The following is the process. In 500 parts of rain-water, boil 8 of cream of tartar and 30 of crystallised verdigris; when this solution is cold, pour into it 4 parts of nitric acid. Moisten the parchment with a brush, and then apply the above liquid evenly over its surface. Lastly, the necessary lustre may be given with white-of-eggs, or mucilage of gum arabic.

PARCHMENT, VEGETABLE, or **PARCHMENT PAPER.** Vegetable parchment is made from unsized paper, of which ordinary blotting-paper is an example, and is well adapted for the process. This is manufactured from rags of linen and cotton, thoroughly torn to pieces in the pulping machine, and it is found that long-fibred paper is not so good for the production of vegetable parchment as that which is more thoroughly pulped. The structure of the waterleaf may be regarded as an interlacement of vegetable fibres in every direction, simply held together by contact, and consequently offering a vast extension of surface and minute cavities to favour capillary action.

To make vegetable parchment, the waterleaf or blotting-paper is dipped in diluted sulphuric acid when the change takes place, and though nothing appears to be added or subtracted, the waterleaf loses all its previous properties and becomes vegetable parchment.

This very remarkable transformation is, however, a most delicate chemical process. The strength of the acid must be regulated to the greatest nicety, for if on the one hand it is too dilute, the fibre of the paper is converted into a soluble substance, probably dextrine, and its paper-like properties are destroyed. If, however, the acid be too strong, it also destroys the paper and renders it useless.

For the most perfect result, the sulphuric acid and water should be at ordinary temperatures in the proportion of about two volumes of oil of vitriol and one volume of water, and if the paper be simply damped before immersion, the strength of the acid is altered at these spots, and the part so acted upon is destroyed.

To make vegetable parchment, the waterleaf is dipped into the sulphuric acid exactly diluted to the desired strength, when in the course of a few seconds the paper will be observed to have undergone a manifest change, by which time the transformation is effected in all its essential points. The acid has then done its work, and is to be thoroughly removed from the paper, first, by repeated washings in water, and subsequently by the use of very dilute ammonia to neutralise any faint trace of acid which escapes the washing in water. All minute traces of sulphate of ammonia left by the former process are removed as far as possible by further washings, and in certain cases the infinitesimal trace of ammonia may be removed by lime or baryta.

The action and intent of these several processes are to render the vegetable parchment perfectly free from any acid or salt, and the object is thoroughly obtained in the large way.

When the paper has undergone its metamorphosis, it is simply dried, when it becomes vegetable parchment, differing from blotting-paper, and possessing peculiarities which separate it from every other known material. The surfaces of the paper appear to have undergone a complete change of structure and composition. All the cavities of the waterleaf are closed, and the surface is solidified to such an extent, that if a portion of vegetable parchment be heated over a flame, blisters will occur from pent-up steam, which are involved in the centre of the paper, and even in the aërial state the vapour cannot pass either surface. The material of the metamorphosed surfaces is certainly one of the most unalterable and unchangeable of all known organic substances, and requires a distinctive name to indicate its individuality.

From Dr. Hofmann's report on this remarkable substance we extract the following remarks:—

'In accordance with your request, I have carefully examined the new material called vegetable parchment, or parchment-paper, which you have submitted to me for experiment; and I now beg to communicate to you the results at which I have arrived.

'I may here state that the article in question is by no means new to me. I became acquainted with this remarkable production very soon after Mr. W. E. Gaine had made known his results; and I have now specimens before me which came into my possession as early as 1854.

'The substance submitted to me for examination exhibits in most of its properties so close an analogy with animal membrane, that the name adopted for the new material seems fully justified. In its appearance, vegetable parchment greatly resembles animal parchment: the same peculiar tint, the same degree of translucency, the same transition from the fibrous to the horn-like condition. Vegetable, like animal, parchment possesses a high degree of cohesion, bearing frequently-repeated bending and rebending, without showing any tendency to break in the folds; like the latter it is highly hygroscopic, acquiring by the absorption of moisture increased flexibility and toughness. Immersed in water, vegetable parchment exhibits all the characters of animal membrane, becoming soft and slippery by the action of water, without, however, losing in any way its strength. Water does not percolate through vegetable parchment, although it slowly traverses this substance like animal membrane by endosmotic action.

'In converting unsized paper into vegetable parchment, or parchment-paper, by the process recommended by Mr. Gaine—viz. by immersion for a few seconds in oil of vitriol diluted with half its volume of water—I was struck by the observation how narrow are the limits of dilution between which the experiment is attended with success. By using an acid containing a trifle more of water than the proportion indicated, the resulting parchment is exceedingly imperfect; whilst too concentrated an acid either dissolves or chars the paper. Time, also, and temperature are very important elements in the successful execution of the process. If the acid-bath be only slightly warmer than the common temperature, 60° Fahr. (15·5° Cent.)—such as may happen when the mixture of acid and water has not been allowed sufficiently to cool—the effect is very considerably modified. Nor do the relations usually observed between time, temperature, and concentration, appear to obtain with reference to this process; for an acid of inferior strength, when heated above the common temperature, or allowed to act for a longer time, entirely fails to produce the desired result. Altogether, the transformation of ordinary paper into vegetable parchment is an operation of considerable delicacy, requiring a great deal of practice; in fact, it was not until repeated failures had pointed out to me the several conditions involved in this reaction, that I succeeded in producing papers in any way similar to those which you have submitted to me for experiment.

'It is obvious that the transformation, under the influence of sulphuric acid, of paper into vegetable parchment, is altogether different from the changes which vegetable fibre suffers by the action of nitric acid; the cellulose receiving, during its transition into *pyroxylin* and *gun-cotton*, the elements of hyponitric acid in exchange for hydrogen, whereby its weight is raised, in some cases by 40, in others by as much as 60 per cent. As the nitro-compounds thus produced differ so essentially in composition from the original cellulose, we are not surprised to find them also endowed with properties altogether different; such as increased combustibility, change of electrical condition, altered deportment with solvents, &c., whilst vegetable parchment, being the result of a molecular transposition only, in which the paper has lost nothing and gained nothing, retains all the leading characters of vegetable fibre, exhibiting only certain modifications which confer additional value upon the original substance.

'The nature of the reaction which gives rise to the formation of vegetable parchment having been satisfactorily established, it became a matter of importance to ascertain whether the processes used for the mechanical removal of sulphuric acid from the paper had been sufficient to produce the desired effect. It is obvious that the valuable properties acquired by paper, by its conversion into vegetable parchment, can be permanently secured only by the entire absence or perfect neutralisation of the agent which produced them. The presence of even traces of *free* sulphuric acid in the paper would rapidly loosen its texture, the paper would gradually fall to pieces, and one of the most important applications which suggest themselves, viz. the use of vegetable parchment in the place of animal parchment for legal documents, would thus at once be lost. The paper was found to be entirely free from this acid.

'The absence of free sulphuric acid in the parchment-paper was, moreover, established by direct experiment. The most delicate test-papers, left for hours in contact with moistened vegetable parchment, did not exhibit the slightest change of colour.'

PARIAN. See Pottery.

PARIS BLUE. A bright blue obtained by heating aniline with chloride of tin. See Aniline.

PARIS RED. A fine iron rouge employed for polishing.

PARKSINE. A preparation so called from the inventor, Mr. Parks of Birmingham, was exhibited at the International Exhibition of 1862. It was made by incorporating castor oil, collodion (gun-cotton dissolved in ether), and wood-spirit. The mixture gradually solidifies, and eventually becomes a hard mass. While in the pasty condition it was moulded into a great variety of forms. It has not, however, taken its place as a manufacture. See Oxidised Oils.

PARQUETRY, *Parquetage.* Inlaid flooring. In most cases thin veneers are cut into geometric forms, and cemented to the planks which are to form the floors. Lately the Messrs. Arrowsmith have introduced their 'solid parquetry,' in which the wood is cut of the required thickness, and ingeniously joined together in geometric patterns. See Buhl; Marquetry; Reisner.

PARTING. See Gold and Silver, Refining of.

PARTRIDGE-WOOD. The wood of several trees appears to be imported under this name. It is principally used for walking-canes, and for umbrella- and parasol-sticks.

PARVOLINE. A volatile nitryle base found in the naphtha from the Dorset Shale. It is isomeric with cumidine. It is the highest known member of the pyridine series.

PASTEL is the French name of coloured crayons. Also a dye-stuff, allied to Indigo.

PASTES, or *Factitious Gems.* (*Pierres précieuses artificielles,* Fr.; *Glaspasten,* Ger.) See Gems, Artificial.

PASTILLE is the English name of small cones made of gum-benzoin, with powder of cinnamon and other aromatics, which are burned as incense, to diffuse a grateful odour, and conceal unpleasant smells in apartments. Pastille is the French name of certain aromatic sugared confections; called also *tablettes.* See Perfumery.

PATCHOULY. *Pachupat* or *Patscha-pat.* The herb, *Pogostemon Patchouli,* which is, on account of its pungent odour, used in perfumery. It is a herb-like plant, growing very much like sage, indigenous to Northern India; it is also found in China.

The plant grows readily in the hothouses in England; specimens are to be found at Kew and other gardens. The leaves have long been in use as a perfume, and preventive of moth. India-shawls used to be packed with patchouly, on account of its being inimical to vermin, and so efficacious in preserving them during a long voyage; it was thus patchouly was first introduced into Europe.

When the patchouly-plant is distilled it yields a dense essential oil, to which it owes its odour: this dissolved in alcohol, in the proportion of 2 ounces to 1 gallon of spirit, forms the 'essence of patchouly' of the shops. The essential oil of patchouly is one of the least volatile of any known; hence it is one of the most persistent of perfumes from plants. Under the ordinary conditions, the essential oil of patchouly is a fluid, and will not congeal, except by an excessively low temperature; but if the plant be distilled after it has been gathered several years, more than half the product will assume a crystallisable form, far less fragrant than the newer fluid essential oil, and would probably be quite odourless if repeatedly crystallised from alcohol.

The crystals of patchouly are rhombic-formed, with pyramidal summits; chemically they resemble camphor in composition. When the fluid essential oil of patchouly is submitted to fractional distillation, there comes at the highest temperature a peculiar blue body, termed by Piesse *azulene,* resembling the blue in the essential oil of wild camomile; it requires, however, further examination. See Perfumery.

PATENT YELLOW. An oxychloride of lead; called also Turner's Yellow and Montpelier Yellow. See Cassell Yellow.

PATINA. The green coating—carbonate of oxide of copper—which covers ancient bronzes and copper medals. True patina is an *ærugo,* or verdigris, produced by the long-continued action of carbonic acid on the metal buried in the soil. It is very commonly imitated by fraudulent dealers. *Patina*, or *Patella*, was also the name of a bowl made of either metal or earthenware.—*Fairholt.*

PAUL VERONESE GREEN. An artist's colour; a peculiarly-prepared carbonate of copper.

PEACH. A Cornish *miner's term*, given to chlorite and chloritic rocks. A *peachy lode* is a mineral vein containing this substance, generally of a bluish-green colour, and rather soft. See CHLORITE.

PEACH-WOOD, or *Nicaragua*, and sometimes termed *Saint Martha Wood*, is inferior to the other two named; but is much used in the dyehouse, and, for many shades of red, is preferred, although the colouring-matter is not so great. It gives a bright dye. The means of testing the quality of these woods by the dyer is similar to that described for logwood, with the same recommendations and precautions.—*Napier on Dyeing.*

PEACOCK-COPPER ORE. An iridescent copper pyrites, produced by a partial decomposition of the yellow ore. The boys and girls employed in the mines produce this condition artificially by putting the ordinary copper pyrites into warm water holding sulphate of copper in solution; and sell the beautifully-coloured specimens to strangers. A more effective way of producing this peacock copper is to take a lump of yellow copper-ore (*copper pyrites*), and, having bound a piece of copper wire around it, to connect the other end of the wire with a plate of copper. If this arrangement be made in a vessel divided by a porous partition, having a solution of sulphate of copper on the side in which the copper ore is placed, and salt and water on the other side, the change goes on rapidly, and the result is exceedingly permanent.

PEARLASH. Commercial carbonate of potash. See POTASH.

PEARL BARLEY. See BARLEY.

PEARLS (*Perles*, Fr.; *Perlen*, Ger.) are the productions of certain shellfish, such as the pearl-oyster. These mollusca are subject to a kind of disease caused by the introduction of foreign bodies within their shells. In this case their pearly secretion, instead of being spread in layers upon the inside of their habitation, is accumulated round these particles in concentric layers. Pearl consists of carbonate of lime, interstratified with animal membrane.

The oysters whose shells are richest in mother-of-pearl are most productive of these highly-prized spherical concretions. The most valuable pearl-fisheries are on the coast of Ceylon, and at Olmutz in the Persian Gulf; and their finest specimens are more highly prized in the East than diamonds, but in Europe they are liable to be rated very differently, according to the caprice of fashion. When the pearls are large, truly spherical, reflecting and decomposing the light with vivacity, they are much admired. But one of the causes which renders their value fluctuating, is the occasional loss of their peculiar lustre, without our being able to assign a satisfactory reason for it.

The following letter on the Ceylon pearl-fishery, recently written by E. W. H. Holdsworth, is of interest:—

'Skates are no new enemy to the pearl-oyster. It is an old idea among the divers that the several failures of the fishery have been due to the depredations of these fishes, and the subject was one of those to which my attention was specially directed when I was sent out by the Government in 1865 to enquire into the causes of the failure in the previous year. Skates naturally feed on shell-fish, and they are provided with teeth which enable them easily to crush the pearl-oyster, many of the broken pieces of shell being rejected, while other parts are swallowed with the oyster itself. But skates have no means of extracting the fish and leaving the shells uninjured. In 1864, when the Ceylon Government expected to obtain from the pearl-banks a revenue of 50,000*l.*, the principal bed was found covered with empty shells, a large portion of them with the valves united at the hinge, and otherwise uninjured. This was precisely the appearance which the oysters would have presented had they died a natural death, as I pointed out in my official reports. There were a few living oysters, and, in addition, a considerable number of broken shells. These last were doubtless the work of the skates.

Pearl-oysters attain their full superficial growth in about four years, but the shell thickens for two years more, and it is during this period the pearls rapidly increase in size. After about six years, the animal dies, the shell opens, and the contents disappear. It is, of course, desirable to leave the oysters on the banks as long as possible in order to obtain large pearls, but there is the danger of leaving them too long and losing them altogether. That is what occurred in 1864. I obtained ample evidence to satisfy me that the oysters should have been fished in 1863, for, according to official reports, they were beginning to die off in February of that year, and then there was no especial fear of skates. These fishes, however, were abundant in the following year; but, as I have said, there was the strongest evidence in the unbroken shells that most of the oysters had died a natural death.

'The banks, or beds, as they might more properly be called, are in from 7 to 9 fathoms water, and almost out of sight of land. They are exposed during great part of the year to strong and often irregular currents, which sweep the bottom, and from which no protection can be given; and the weather is generally so bad that a regular inspection of the banks of a fishery can only be carried on during the month of March. Skates are indigenous to the Ceylon seas, and they obviously cannot be kept away from the banks if they choose to go there; but I heard nothing after the inspection in March last of the army of monsters your correspondent speaks of: and I can only conclude that a short examination was made at the end of October, of which I have yet had no account. I hope, for the sake of the colony, that matters are not so bad as stated, for skates are undoubtedly capable of doing a vast deal of mischief, even if they do not devour all the oysters.'

Pearls of considerable beauty are found in Scotland. Mr. Alexander M. Cockburn thus describes them:—

'The beauty of lustre and form, and the fine opaque colour of the Scottish pearl, attract more attention now than formerly. The late Prince Consort ordered a necklace to be made of pearls of a certain size, which took more than twenty years to complete.

'The fishing for these pearls is now a regular trade. Fine and large specimens of pearls are found in the rivers Teith, Forth, Dee, Don, Earn, Tay, Tweed, and the rivers of Ross and Sutherlandshires. Country people often bring these treasures to town, and sell them for prices varying from a few shillings up to 25*l.* Scottish pearls are easily known from the fine Oriental pearls: they are of a different shade of colour. Pearls about the size of a pea bring as much as 15*l.* to 25*l.*; very large and fine ones from 30*l.* to 90*l.* The trade in these has increased very much within the last few years. A very fine specimen of Scottish pearl, mounted in gold, was sent from Edinburgh to the late Dublin Exhibition, the value of which was 500*l.*; it was set in enamel and gold as a tiara for a lady's head-dress.'

PEARLS, ARTIFICIAL. These are small globules, or pear-shaped spheroids of thin glass, perforated with two opposite holes, through which they are strung, and mounted into necklaces, &c., like real pearl ornaments. They must not only be white and brilliant, but exhibit the iridescent reflections of mother-of-pearl. The liquor employed to imitate the pearly lustre is called the *essence of the East* (*essence d'orient*), which is prepared by throwing into water of ammonia the brilliant scales, or rather the *lamellæ*, separated by washing and friction, of the scales of a small river-fish, the bleak, called in French *ablette*. These scales, digested in ammonia, having acquired a degree of softness and flexibility which allow of their application to the inner surface of the glass globules, they are introduced by suction of the liquor containing them in suspension. The ammonia is volatilised in the act of drying the globules. See Beckmann's 'History of Inventions' for an interesting account of this manufacture.

It is said that some manufacturers employ ammonia merely to prevent the alteration of the scales; that when they wish to make use of them, they suspend them in a well-clarified solution of isinglass, then pour a drop of the mixture into each bead, and spread it round the inner surface. It is doubtful whether by this method the same lustre and play of colours can be obtained as by the former. It seems, moreover, to be of importance for the success of the imitation that the globules be formed of a bluish, opalescent, very thin glass, containing but little potash and oxide of lead. In every manufactory of artificial pearls there must be some workmen possessed of great experience and dexterity. The French greatly excel in this ingenious branch of industry.

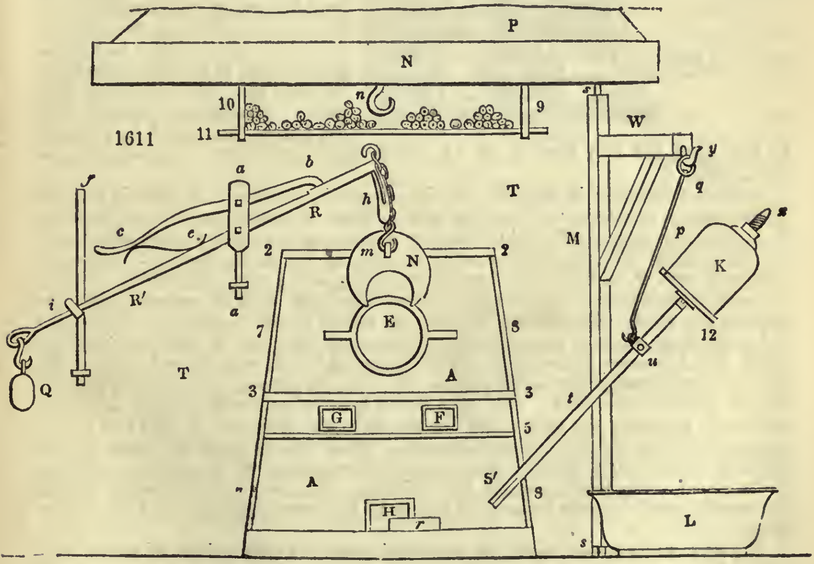
These false pearls were invented, in the time of Catherine de Medicis, by a person of the name of Jacquin. The manufacture of pearls is principally carried on in the department of the Seine in France. There are also manufactories in Germany and Italy, but to a small extent. In Germany, or rather Saxony, a cheap but inferior quality is manufactured. The globe of glass forming the pearl in inferior ones, being very thin, and coated with wax, they break on the slightest pressure. They are known by the name of German fish-pearls. Italy also manufactures pearls by a method borrowed from the Chinese: they are known under the name of Roman pearls, and are a very good imitation of natural ones; they have on their outside a coating of the nacreous liquid. The Chinese pearls are made of a kind of gum, and are covered likewise with the same liquid.

In the year 1834 a French artisan discovered an opaline glass of a nacreous or pearly colour, very heavy and fusible, which gave to the beads the different weights and varied forms found amongst real pearls. Gum, instead of wax, is now used to fill them, by which they attain a high degree of transparency, and the glassy appearance has been lately obviated by the use of the vapour of hydrofluoric acid. This acts in such a manner as to deaden the surface, and remove its otherwise glaring look.

The material out of which these beads are formed is small glass tubing, like that with which thermometers are made. The tubes for the bright-red pearls consist of two layers of glass, a white opaque one internally, and a red one externally; drawn from a ball of white enamel, coated in the Bohemian method with ruby-coloured glass, either by dipping the white ball into a pot of red glass, and thus coating it, or by introducing the ball of the former into a cylinder of the latter glass, and then cementing them so soundly together as to prevent their separation in the subsequent pearl processes. These tubes are drawn, in a gallery of the glasshouse, to 100 paces in length, and cut into pieces about a foot long. These are afterwards subdivided into cylindric portions, of equal length and diameter, preparatory to giving them the spheroidal form. From 60 to 80 together are laid horizontally in a row upon a sharp edge, and then cut quickly and dexterously at once by drawing a knife over them. The broken fragments are separated from the regular pieces by a sieve. These cylinder portions are rounded into the pearl shape by softening them by a suitable heat, and stirring them all the time. To prevent them from sticking together, a mixture of gypsum and plumbago, or of ground clay and charcoal, is thrown in among them.

Figs. 1611 and 1612 represent an apparatus for rounding the beads: *fig.* 1611 is a front view of the whole; *fig.* 1612 is a section through the middle of the former figure, in the course of its operation. The brick furnace, strengthened with iron bands, 2, 3, 5, 7, 8, has in its interior (see *fig.* 1612) a nearly egg-shaped space, B, provided with the following openings: beneath is the fire-hearth, C, with a round mouth, and

1611

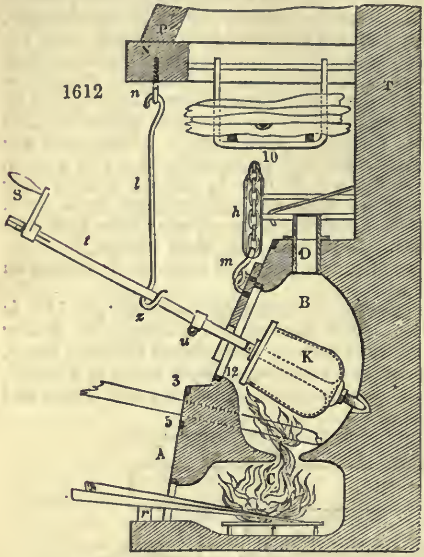


opposite are the smoke flue and chimney, D; in the slanting front of the furnace is a large opening, E, *fig.* 1611. Beneath are two smaller oblong rectangular orifices, F, G, which extend somewhat obliquely into the laboratory, B. H serves for introducing the wood into the fireplace. All these four openings are, as shown in *fig.* 1612, secured from injury by iron mouth-pieces. The wood is burned upon an iron or clay bottom piece, *r*. A semi-circular cover, N, closes during the operation, the large opening E, which at other times remains open. By means of a hook, *m*, and a chain, which rests upon a hollow arch, *h*, the cover N is connected with the front end of the long iron lever R, R'. A prop supports at once the turning axis of this lever and the catch *b*, *c*; the weight Q draws the arm R down, and thereby holds up N: E therefore remains open. By rods on the back wall, T T, the hook *i*, in which R′ rests, proceeds from *f*. When R′ is raised, R sinks. The catch, *c b*, enters with its front tooth into a slanting notch upon the upper edge of R, spontaneously by the action of the spring *c*, whereby the opening, E, is shut.

The small door, N, rises again with the front arm of the lever by the operation of the weight Q, of itself, as soon as the catch is released by pressure upon *c*.

The most important part of the whole apparatus is the drum, K, for the reception and rounding of the bits of glass. It may be made of strong copper, or of hammered or cast iron, quite open above, and pierced at the bottom with a square hole, into which the lower end of the long rod, *t*, is exactly fitted, and secured in its place by a screwed collector nut. The blunt point *x* (*fig.* 1611) rests during the working in a conical iron step of the laboratory, *fig.* 1612. On the mouth of the drum, K, a strong iron ring is fixed, having a bar across its diameter, with a square hole in its middle point, fitted and secured by a pin to the rod *t*, and turned by its rotation. The vessel K, and its axle *t*, are laid in a slanting direction; the axle rests in the upper ring *z*, at the lower end of the rod *l*, of which the other end is hung to the hook *n*, upon the mantel-beam, N. On the upper end of *t*, the handle, S, is fixed for turning round continuously the vessel K while the fire is burning in the furnace, the fuel being put not only in its bottom chamber, but also into the holes F, G (*fig.* 1611). The firewood is made very dry before being used, by piling it in logs upon the iron bars 9, 10, 11, under the mantel-piece, as shown in *figs.* 1611, 1612.

1612



After the operation is finished, and the cover N is removed, the drum is emptied of its contents, as follows:—Upon the axle *t*, there is, towards K, a projection at *u*. Alongside the furnace (*fig.* 1611) there is a crane, M, that turns upon the step, *s*, on the ground. The upper pivot turns in a hole of the mantel-beam, N. Upon the horizontal arm, W, of the crane there is a hook, *y*, and a ring, *q*, in which the iron rod *p* is moveable in all directions. When the drum is to be removed from the furnace, the crane, with its arm W, must be turned inwards; the under hook of the rod *p* is to be hung in the projecting piece *u*, and the rod *l* is lifted entirely out. After this, by means of the crane, the drum can be drawn, with its rod *t*, out of the furnace; and, through the mobility of the crane and its parts *p*, *q*, any desired position can be given to the drum. *Fig.* 1611 shows how the workman can with his hand applied to S′ depress the axle *t*, and thereby raise the drum, K, so high that it will empty itself into the pot L, placed beneath. When left to itself, the drum on the contrary hangs nearly upright upon the crane by means of the rod *p*, and may therefore be easily filled again in this position. The manner of bringing it into the proper position in the furnace, by means of the crane and the rod *l*, is obvious from *fig.* 1612.

The now well-rounded beads are separated from the pulverulent substance with which they were mixed by careful agitation in sieves; and they are polished and finally cleaned by agitation in canvas bags. See ABLETTE.

PEARL BUTTONS. Pearl-button making is thus practised: the blanks are cut out of the shell by means of a small revolving steel tube, the edge of which is toothed as a saw, after which they are flattened or reduced in thickness by splitting, which is aided by the laminar structure of the shell. At this stage, being held in a spring chuck, they are finished on both sides by means of a small tool: the drilling is effected by the revolution of a sharp steel instrument, which acts with great rapidity. Ornamental cuttings are produced by means of small revolving cutters, and the final brilliant polish is given by the friction of rotten-stone and soft soap upon a revolving bench.

PEARL SPAR. A name commonly applied to crystallised dolomite exhibiting curved faces.

PEARL WHITE or **PEARL POWDER** is a sub-nitrate of bismuth. See Bismuth.

PEAT AND TURF. Accumulations of vegetable matter may be chiefly composed either of succulent vegetation, grasses, or marsh plants, or of trees; and the structure and condition of woody fibre is well known to be very different from that of grasses and succulent plants. There are thus two very distinct kinds of material preserved, the one undergoing change much less rapidly than the other, and perhaps much less completely. It is easily proved that from the accumulation of forest trees has been obtained the imperfect coal called *lignite*, while from marsh plants and grasses, mixed occasionally with wood, we obtain *peat*, *turf*, and *bog*. All these substances consist to a great extent of carbon, the proportions amounting to from 50 to 60 per cent., and being generally greater in lignite than in turf. On the other hand, the proportion of oxygen gas is generally very much greater in turf than in lignite. The proportion of ash is too variable to be worth recording, but is generally sufficiently large to injure the quality of the fuel.

As a very large quantity of turf exists in Ireland, covering, indeed, as much as one seventh part of the island, the usual and important practical condition of this substance can be best illustrated by a reference to that country. This will be understood by the following account of its origin, abstracted from the 'Bog Report' of Mr. Nimmo. He says, referring to cases where clay spread over gravel has produced a kind of puddle preventing the escape of waters of floods or springs, and when muddy pools have thus been formed, that aquatic plants have gradually crept in from the borders of the pool towards their deep centre. Mud accumulated round their roots and stalks, and a spongy semi-fluid was thus formed, well fitted for the growth of moss, which now especially appeared; *Sphagnum* began to luxuriate; this absorbing a large quantity of water, and continuing to shoot out new plants above, while the old were decaying, rotting and compressing into a solid substance below, gradually replaced the water by a mass of vegetable matter. In this manner the marsh might be filled up while the central or moister portion, continuing to excite a more rapid growth of the moss, it would be gradually raised above the edges, until the whole surface had attained an elevation sufficient to discharge the surface-water by existing channels of drainage, and calculated by its slope to facilitate their passage, when a limit would be, in some degree, set to its further increase. Springs existing under the bog, or in its immediate vicinity, might indeed still favour its growth, though in a decreasing ratio: and here, if the water proceeding from them were so obstructed as to accumulate at its base, and to keep it in a rotten fluid state, the surface of the bog might be ultimately so raised, and its continuity below so totally destroyed, as to cause it to flow over the retaining obstacle and flood the adjacent country. In mountain districts the progress of the phenomenon is similar. Pools, indeed, cannot in so many instances be formed, the steep slopes facilitating drainage, but the clouds and mists resting on the summits and sides of mountains, amply supply their surface with moisture, which comes, too, in the most favourable form for vegetation, not in a sudden torrent, but unceasingly and gently, drop by drop. The extent of such bogs is also affected by the nature of the rocks below them. On quartz they are shallow and small; on any rock yielding by its decomposition a clayey coating they are considerable; the thickness of the bog, for example, in Knocklaid in the county of Antrim (which is 168 feet high), being nearly 12 feet. The summit-bogs of high mountains are distinguishable from those of lower levels by the total absence of large trees.

As turf includes a mass of plants in different stages of decomposition, its aspect and constitution vary very much. Near the surface it is light coloured, spongy, and contains the vegetable-matter but little altered; deeper, it is brown, denser, and more decomposed; and, finally, at the base of the greater bogs, some of which present a depth of 40 feet, the mass of turf assumes the black colour, and nearly the density, of coal, to which also it approximates very much in chemical composition. The amount of ash contained in turf is also variable, and appears to increase in proportion as we descend. Thus, in the section of a bog, 40 feet deep, at Tunahoe, those portions near the surface contained $1\frac{1}{2}$ per cent. of ashes, the centre portions $3\frac{1}{4}$ per cent., whilst the lowest four feet of turf contained 19 per cent. of ashes. In the superficial layers it may also be remarked, that the composition is nearly the same as that of wood, the succulent material being lost; and in the lower we find the change still more complete. Notwithstanding these extreme variations, we may yet establish the ordinary constitution of turf, and with certainty enough for practical use; and, on the average specimens of turf selected from various localities, the following results have been obtained:—

The calorific power of dry turf is about half that of coal; it yields, when ignited with oxide of lead, about 14 times its weight of lead. This power is, however, immensely diminished in ordinary use by the water which is allowed to remain in its texture, and which the spongy character of its mass renders it very difficult to get rid of. There is nothing which requires more attention than the collection and preparation of turf; indeed, for practical purposes, this valuable fuel is absolutely spoiled as it is now prepared in Ireland. It is cut in a wet season of the year; whilst drying, it is exposed to the weather: it hence in reality is not dried at all. It is very usual to find the turf of commerce containing one-fourth of its weight of water, although it then feels dry to the hand. But let us examine what affects the calorific power. 1 lb. of pure dry turf will evaporate 6 lbs. of water; now, in 1 lb. of turf as usually found there are $\frac{3}{4}$ lb. of dry turf, and $\frac{1}{4}$ lb. of water. The $\frac{3}{4}$ lb. can only evaporate $4\frac{1}{2}$ lbs. of water; but out of this it must first evaporate the $\frac{1}{4}$ lb. contained in its mass, and hence the water boiled away by such turf is reduced to $4\frac{1}{4}$ lbs. The loss is here 30 per cent., a proportion which makes all the difference between a good fuel and one almost unfit for use. When turf is dried in the air under cover it still retains one-tenth of its weight of water, which reduces its calorific power 12 per cent., 1 lb. of such turf evaporating $5\frac{1}{3}$ lbs. of water. This effect is sufficient, however, for the great majority of objects; the further desiccation is too expensive and too troublesome to be used, except in special cases.

The characteristic fault of turf as a fuel is its want of density, which renders it difficult to concentrate, within a limited space, the quantity of heat necessary for many operations. The manner of heating turf is, indeed, just the opposite to anthracite. The turf yields a vast body of volatile inflammable ingredients, which pass into the flues and chimney, and thus distribute the heat of combustion over a great space, whilst in no one point is the heat intense. Hence, for all flaming fires turf is applicable; there is, however, as some experiments made on Dartmoor show, some liability to that burning away of the metal which may arise from the local intensity of coke. If it be required, it is quite possible to obtain a very intense heat with turf.

The removal of the porosity and elasticity of turf, so that it may assume the solidity of coal, has been the object of many who have proposed mechanical and other processes for the purpose. It has been found that the elasticity of the turf-fibre presents great obstacles to compression, and the black turf, which is not fibrous, is of itself sufficiently dense.

Not merely may we utilise turf in its natural condition, or compressed or impregnated with pitchy matter, but we may carbonise it, as we do wood, and prepare turf-charcoal, the properties of which it is important to establish:—

By heating turf in closed vessels loss is avoided, but this process is expensive, and there is no compensation in the distilled liquors, which do not contain acetic acid in any quantity. The tar is often small in proportion; hence the charcoal is the only valuable product. Its quantity varies from 30 to 40 per cent. of dry turf. The products of the distillation of 1,157 lbs. of turf were found by Blavier to be charcoal, 474 lbs., or 41 per cent.; watery liquid, 226 lbs., or 19·3 per cent.; gaseous matter, 450 lbs., or 39 per cent.; and tar, 7 lbs., or 6 per cent.; but the proportion of tar is variable, sometimes reaching 24·5 per cent. when the turf is coked in close vessels.

The economical carbonisation of turf is best carried on in heaps, in the same manner as that of wood. The sods must be regularly arranged, and laid as close as possible; they are the better for being large, 15 inches long, by 6 broad, and 5 deep. The heaps, built hemispherically, should be smaller in size than the heaps of wood usually are. In general, 5,000 or 6,000 large sods may go to the heap, which will thus contain 1,500 cubic feet. The mass must be allowed to heap more than is necessary for wood; and the process requires to be very carefully attended to, from the extreme combustibility of the charcoal. The quantity of charcoal obtained in this mode of carbonisation is from 25 to 30 per cent. of the weight of dry turf.

For many industrial uses the charcoal so prepared is too light, as, generally speaking, it is only with fuel of considerable density that the most intense heat can be produced, but by coking compressed turf, it has already been shown that the resulting charcoal may attain a density of 1·040, which is far superior to wood-charcoal, and even equal to that of the best coke made from coal. As to calorific effects, turf-charcoal is about the same as coal-coke, and little inferior to wood-charcoal.

It is peculiarly important, in the preparation of the charcoal from the turf, that the material should be selected as free as possible from earthy impurities, for all such are concentrated in the coke, which may be thereby rendered of little comparative value. Hence, the coke from surface-turf contains less than 10 per cent. of ash, whilst that dense turf of lower strata contains from 20 to 30 per cent. This latter quantity might altogether unfit it for practical purposes.—*Ansted.*

Peat is cut and prepared in a very simple manner. The surface-matter being removed, a peculiar kind of spade, called a *slade*, is employed. This is a long spade, with a portion of the blade turned up at right angles on one side. With this the turf is cut out in the shape of thick bricks; these are piled loosely against each other to dry. The longer peat is kept, and allowed to dry, the more important it becomes as a heating agent.

On Dartmoor the peat is cut by the convicts, working in gangs; and, being dried, it is carefully stored in one of the old prisons. From this peat, by a most simple process, gas is made, with which the prisons at Prince Town are lighted. The illuminating power of this gas is very high. The charcoal left after the separation of the gas is used in the same establishment for fuel and for sanitary purposes, and the ashes eventually go to improve the cultivated lands of that bleak region. Attempts were made here many years since to distil the peat for naphtha, paraffin, &c., but the experiments not proving successful, the establishment was abandoned.

Experiments of a similar character have been made in Ireland, especially by a company working under the patents of Mr. Rees Reece. A Government Commission made their Report on these experiments. The whole matter was so ably examined by Sir Robert Kane (Director of the Museum of Irish Industry), and by his assistant, Dr. Sullivan, that we quote somewhat largely from their Report.

The object being to ascertain the necessary facts regarding the products of commercial value, the following was the course pursued:—

Specimens of turf representing the several ordinary varieties were separately experimented on, and the results examined.

The products of the distillation were collected as—1, charcoal; 2, tar; 3, watery liquids; 4, gases.

The relative quantities produced by 100 parts of peat were found to be—

	Average	Maximum	Minimum
Charcoal	29·222	39·132	18·973
Tarry products	2·787	4·417	1·462
Watery products	31·378	38·127	21·819
Gases	36·616	57·746	25·018

The peats yielding those proportions of products had been found to contain, previous to distillation, as dried in the air, a quantity of hygrometric moisture, and to yield a proportion of ashes in 100 parts, as follows:—

	Average	Maximum	Minimum
Moisture	19·71	29·56	16·39
Ashes	3·43	7·90	1·99

The several products of the distillation thus carried on were next specially examined for the several materials of which the quantities and commercial value had been the principal sources of the public interest of this inquiry.

The inquiry having reference, however, to the technical objects of the process, was carried on by examining the produce of

I. Tar, for—1, volatile oils; 2, fixed (less volatile) oils; 3, solid fats, or paraffin; 4, creosote.

II. Watery liquids, for—1, acetic acid; 2, ammonia; 3, pyroxylic spirit.

III. Gases for illuminating and heating power.

The following numbers will indicate the results obtained in average. All the details of the processes of separation, and the numbers of the individual experiments, were given in special reports.

In seven series of distillation in close vessels there was obtained from 100 parts of peat:—

	Average	Maximum	Minimum
Ammonia	0·268	0·404	0·181
or as			
Sulphate of ammonia	1·037	1·567	0·702
Acetic acid	0·191	0·286	0·076
or as			
Acetate of lime	0·280	0·419	0·111
Pyroxylic spirit	0·146	0·197	0·092
Volatile oils	0·790	1·262	0·571
Fixed oils	0·550	0·760	0·266
Paraffin	0·134	0·196	0·024

It is thus seen that the proportions of those products vary within wide limits, which are determined by differences of quality of the turf or temperature in the distillation.

Several trials were made to determine the amount of creosote present in the tar, but, although its presence could be recognised, its proportion was so minute as to render its quantitative estimation impossible. This circumstance constitutes an essential distinction between peat-tar and wood-tar, and indicates for the former an inferior commercial value, as the presence of creosote, now so extensively employed, is an element in the estimate of the price of tar obtained by distilling wood.

'It will be understood,' writes Sir Robert Kane, 'that the materials indicated in the foregoing Table by the names "fixed and volatile oils" are in reality mixtures of a variety of chemical substances of different volatilities and compositions—generally carbo-hydrogens—of which the further separation would be a labour of purely scientific curiosity, without having any bearing upon the objects of the present report. Although, therefore, those liquids were carefully examined, and observations made regarding their chemical history, I shall not embarrass the present report by reference to them in any other point of view than as products of destructive distillation, whose properties, analogous to the highly volatile and to the fixed oils repectively, may give them a commercial value such as has been represented. I may remark also, that, as a purely scientific question, the true nature of the solid fatty product is of much interest. The name paraffin has been given to this body, but in some of its characters it appears to deviate from those of the true paraffin, as described by Reichenbach to be obtained from wood-tar; those differences, however, should not contravene its commercial uses.' See PARAFFIN.

'The inquiry so far carried on sufficiently established that the peat, by destructive distillation in close vessels, yielded the several products that had been described, and were identical, or closely analogous, with those afforded in the distillation of wood or coal. The process in close retorts, however, being not at all that proposed or economically practicable for commercial purposes, it was necessary to proceed to determine whether the same varieties of peat, being distilled in a blast-furnace, with a current of air, so that the heat necessary for the distillation was produced by the combustion of the peat itself, would furnish the same products, and whether in greater or in less quantities than in the process in close vessels.

'For this purpose the cylinder, which in the former series of experiments had been set horizontally in the furnace, was placed surrounded by brickwork vertically, its mouth projecting a little at top, so that the tube for conveying away the products of the distillation passed horizontally from the top of the brickwork casing to the condensing-apparatus. Near the bottom of the cylinder the brickwork left a space where the cylinder was perforated by an aperture, 1¼ inch diameter, to which the tube of a large forge-bellows was adapted. The arrangement thus represented nearly the construction of an iron cupola. The cylinder being charged with peat, of which some fragments were first introduced lighted, and the blast being put on, the combustion spread, and the cover of the cylinder being screwed down, the distillation proceeded, the products passing with the current of air into the series of condensing-vessels, and the gases and air finally being conducted by a waste-pipe to the ash-pit of a furnace, where they were allowed to escape.

'By this means there was obtained, on a moderate scale, a satisfactory representation of the condition of air-blast distillation of peat which has been proposed as the commercial process. In so carrying it on, several interesting observations were made which will require to be noticed here in a general point of view.

'First, as to the nature and quantities of the products. The specimens of peat operated on were selected as similar to those employed in the former series of which the results have been quoted; and the products similarly treated were found to be, from 100 parts:—

	Average	Maximum	Minimum
Watery products	30·714	31·678	29·818
Tarry products	2·392	2·510	2·270
Gases	62·392	65·041	59·716
Ashes	4·197	7·226	2·493

'These several products having been further examined, as in the former case, gave from 100 parts of peat;—

	Average	Maximum	Minimum
Ammonia	0·287	0·344	0·194
or as			
Sulphate of ammonia	1·110	1·330	0·745
Acetic acid	0·207	0·268	0·174
or as			
Acetate of lime	0·305	0·393	0·256
Pyroxylic spirit	0·140	0·158	0·106
Volatile oils	1·059	1·220	0·946
Paraffin	0·125	0·169	0·086

'It is now important to compare these average results with those of the former series obtained by distillation in close vessels; we obtain—

	Average produce from close distillation	Average produce by air-blast distillation
Ammonia	0·268	0·287
or as		
Sulphate of ammonia	1·037	1·110
Acetic acid	0·191	0·207
or as		
Acetate of lime	0·280	0·305
Pyroxylic spirit	0·146	0·140
Oils	1·340	1·059
Paraffin	0·134	0·125

Experiments were made, at the request of Sir Robert Kane, by Dr. Hodges, Professor of Agriculture, to determine the commercial value of the peat products.

The quantities and nature of the products, as certified by Dr. Hodges, in the one trial which he superintended, compared with the Museum average results reduced to the same standard (Dr. Hodges' acetic acid having been 25 per cént. of real) are—

	Professor Hodges.		Museum.	
	From a ton.	From 100 parts.	From a ton.	From 100 parts.
Sulphate of ammonia	$22\frac{3}{4}$ lbs.	1·000	$24\frac{8}{10}$ lbs.	1·110
Acetic acid, real hydrated	$7\frac{1}{4}$ lbs.	0·328	$4\frac{2}{3}$ lbs.	0·207
Wood-naphtha	$83\frac{1}{4}$ oz.	0·232	$50\frac{1}{5}$ oz.	0·140
Tar	$99\frac{1}{2}$ lbs.	4·440	$53\frac{3}{4}$ lbs.	2·390

It hence is evident that the quantity of ammonia obtained at Newtown Crommelin is rather under that obtained at the Museum; but the produce of acetic acid, tar, and naphtha, has been found in average decidedly inferior to that stated, although the maximum results found in particular trials have approximated closely to Dr. Hodges' numerical results. There having been, however, apparently but a single trial so accurately followed up at Newtown Crommelin, it is necessary to contrast the results of the Museum experiments more specially with the quantitative produce expected by Mr. Reece.

Mr. Reece's statement of the produce from 100 tons of peat distilled is compared with the average results of the Museum trials in the following table:—

From 100 parts of peat.	Statement in Mr. Reece's prospectus.	Average results of Museum trials by blast-process.
Sulphate of ammonia	1·000	1·110
Acetate of lime	0·700	0·305
Wood-naphtha	0·185	0·140
Paraffin	0·104	0·125
Fixed oils	0·714	1·059
Volatile oils	0·357	

At the Sews the following manufacturing results were obtained in the year 1861 2, by Dr. B. Paul, at Sir James Matheson's works, from 100 tons of peat:—

749 gallons of oil with paraffin, @ 2*s.*		£74 18 0
From which is to be deducted—		
100 tons of peat @ 2*s.*	£10 0 0	
Cost of manufacture	28 14 6	
		38 14 6
Leaving a balance of		£36 3 6

On the contrary, the manufacturing experience of Mr. Sullivan, in Ireland, were—

150 gallons of oil @ 2*s.*		£15 0 0
300 lbs. of paraffin @ 1*s.*		15 0 0
52 gallons of wood-naphtha		2 10 0
3 cwts. of sulphate of ammonia		1 16 0
		£34 6 0
From this had to be deducted—		
100 tons of peat @ 4*s.*	£20 0 0	
Cost of manufacture	14 3 4	
		34 3 4
Leaving a balance of		0 2 8

In the present state of the oil-manufacture, 1*s.* per gallon would have to be deducted from the above-estimated results for burning oil.

Dr. Reynolds, as the Chairman of a Committee of the Royal Dublin Society on the use of peat by Siemens' regenerative furnace, reports very favourably of its use in manufactories requiring high heats. Ordinary air-dried peat, containing on an average 25 per cent. of water, when used in this furnace, compares more favourably with coal than in any other known way. The general heating power of 2½ tons of peat is about equivalent in practice to that of one ton of average coal; but in the Siemens' furnace its value appears equivalent to not less than 65 per cent. of that of Staffordshire coal. Mr. Siemens also states that peat mixed with 25 per cent. of coal-dust gives a richer gas than peat alone. At Carlstadt, Munkfors, Sweden, F. Lundin has employed peat in iron-smelting containing as much as 45 per cent. of water. The resulting gas, which contains about 33 lbs. of water to 100 lbs. dry gas, is deprived of its vapour in a condensing arrangement of iron tubes, weighing 3,500 lbs., laid crosswise, and on which a jet of water plays. The heat of the gas before condensation always melts lead easily, and sometimes zinc. The results have been so satisfactory that a national testimonial has been presented to the inventor. This peat-furnace is preferred to that fed by dry wood, which only produces in the generators gas of a temperature of 1394°; whereas the gas from the first furnace is 2666°; less water is lodged in the condensers and the repairs are less. It is said one Lundin furnace costs in Sweden about 900*l.*; and it utilises 1,700 tons of ore in a year [*vide Reports of the United States' Commissioners to the Paris Universal Exposition*, 1867].

There exists already above 100 patents for making and converting raw peat into fuel for steam and domestic purposes. The favourite methods with inventors of treating the crude peat have been compression by hydraulic power, separation of the vegetable fibre from the matrix, maceration, grinding, and rapid drying by heated air. These modes of dealing with peat are all liable to failure from various causes. Generally peat will yield an average of 70 per cent. of water, and any process that aims at getting rid of the water in a rapid manner has not been found to answer. The application of a high degree of heat seems to overbake the peat and rob it of a large amount of its calorific value. The attempt to abstract the ligneous fibre from the humus of the peat is a costly experiment, to deprive the peat of its most substantial and valuable material for the purposes of fuel.

The Clayton method is simply to cut the peat into fragments in its raw and moist state, drain off as much of the water as will freely run away; then masticate the fibres and whole mass of peat together in a machine until it becomes difficult to distinguish any ligneous fibre distinct from the humus in which it is so entirely mixed. The peat when first cut is put into what they call squeezing-trucks; these trucks are perforated in the bottom and sides, and in the journey to the works a large proportion of the free water is squeezed out by the action of a screw or lever. The mastication or trituration of the peat is effected by means of a vertical shaft carrying a series of cutting-blades set round like a screw, and by means of these the peat is forced down into a long horizontally-placed cylinder. A revolving shaft, on which are a forcing screw, and a set of discs forming a dissecting double screw, passes through the centre of this cylinder, and cutting-blades of hard steel are fitted on the end of the cylinder furthest from the hopper. The peat, being forced into the horizontal cylinder by the blades and screws, is driven by every revolution of the discs against the cutters, thus effectively reducing the whole to a pulpy mass.

The pulped peat is then forced out through orifices in the end of the cylinder on to rollers which carry it to trays, where it is cut into lengths, and then taken to drying sheds, where it remains about three days; it is then dry enough to be stacked in open racks, where the final drying is completed.

The most important feature in this system is the breaking up of the cellular tissues of the peat, and thus getting rid of the fixed moisture: and the remarkable reduction in the size of the blocks of peat during the process of drying shows that this is done in the most complete manner. The condensed peat becomes very firm and solid, and the whole process does not take more than seven or eight days. Messrs. Clayton, Son, and Howlett assert that this fuel can be produced at a cost of from five to six shillings a ton.

Danchelle's peat-fuel and peat-filters for sewage were exhibited at Manchester, in 1874. The samples of manufactured peat-fuel made from the light brown moss, of Red Moss, Horwick, Lancashire, differed from other specimens of peat-fuel, in that the humus and ligneous fibre of the peat were macerated and reduced to a state of a fine chocolate-paste. The machine used to effect this consists of a long cylinder, in which works a shaft armed with proper cutters and discs, by which the crude peat is soon reduced to the consistency of pasty pulp, and issues in a long roll of any shape or diameter; this is cut into briquettes by a wired frame, and the briquettes are dried in the usual way, under a covered shed; in drying, they lose in their bulk, but they are in a fortnight converted into a good hard fine-grained fuel, and when roasted with charcoal, are about one-third their original size. The producers of the Danchelle peat-fuel also convert the peat into *sewage filters* by incorporating the peat with a mixture of clay and charring them. Experiments have been made, and are continued with these filters, in Bradford, Yorkshire, and in Paris, and the results are stated to be very satisfactory. Peat-fuels are prepared in Sutherland by charring the peat, which has been broken up by a machine, so as to leave it in a rough granular state, and afterwards worked up with crude shale-tar, and pressed into bricks by a moulding machine. The quantity of shale-tar taken up by the vegetable peat is very considerable, and gives it a thoroughly carbonised appearance.

The Peat Fuel and Charcoal Company, by similar manipulation and drying, obtain a remarkable degree of density, and produce samples which are close-grained, hard, and look like mahogany.

Mr. Joshua Kidd has succeeded in obtaining an excellent charcoal from peat, which answers admirably as a fuel, and as a deodoriser. It is also used as a filtering medium for foul water and sewage.

In France, peat-charcoal under the name of *Charbon roux*, is much used for making gunpowder. The Duke of Sutherland has made extensive experiments on the production of peat-charcoal. Thirty tons of this charcoal are produced weekly on the Duke's estates, costing 11*l.* 10*s.* 9*d.*

Eichorne's process for condensing peat, produces balls of a hard, clean, and convenient size, burning with a bright flame, and gives an excellent heat. Their calorific value is said to be, when compared with coal, as coal, 1·00, ball-peat, 1·37.

Mr. Robert Kerretitchison breaks up his peat with a machine, by means of which it parts with a great deal of its water. It is then manufactured in a masticator, and finely-broken asphalt is mixed with the mass. It is then shaped into briquettes, and dried under sheds. Its specific weight is less than most other peats, the addition of asphalt adds to its cost, but gives it greater value for furnaces and for raising steam.

There are several other patentees of processes for preparing peat, which differ from those already named only in some minor details, the final result being in all of them nearly similar.

Dutch peat is simply cut from the fens into bricks and dried in the air. They sell, where cut, at 12*s.* 10*d.* a ton, and in the towns at 18*s.* or 19*s.*

Korte turf is obtained by dredging in low lying water-covered bogs. It is dredged, well-trodden, and then cut into short bricks and dried. It is sold largely to hotels and the better class houses in Holland; at the peat bogs it is 14*s.* 1*d.* per ton, in the towns, 18*s.* 11*d.* *Derril turf* is found under the sand driven on the coast of Holland; it is very compact, but not much used.

Many of the particulars above given are obtained from a Lecture on Peat given by Mr. J. Plant, on the samples of that fuel exhibited in the Peel Park Exhibition, Manchester 1874, before the Manchester Literary and Philosophical Society.

Mr. O'Hara, in the 'Dublin Quarterly Journal of Science,' estimates the peat bogs of Ireland at 1,576,000 acres, occupying the limestone plains, and 1,255,000 acres, on the hills and mountains, making a total of 2,831,000 acres. Mr. Plant estimates the extent of peat in Great Britain at 3,500,000 acres, therefore the total in the British Isles will be about 6,000,000 acres; consequently, if 12 feet is assumed as the average thickness, each acre will yield 12,000 tons of peat, on the whole at least 72,000,000,000 tons of valuable fuel.

The following account of the peat-industry in Germany is extracted from the 'Allgemeine Deutsche Polytechnische Zeitung,' which gives a good account of what is doing in the matter abroad:—

'Herr Busch, a landed proprietor in Gross-Massow, near Lauenburg, appears to be carrying on the peat-industry on his own estate, and communicates to our contemporary that he was delegated by the "Lauenburg Branch" of the "Pomeranian Agricultural Society" to examine and report upon a new peat-press constructed by Stuetzke Bros., jun., Lauenburg, which commanded at the time considerable attention. After having seen the machine in operation, he was so well satisfied with its capabilities that he recommended to his branch society the purchase of one. He reports the machine to be exceedingly simple in construction, capable of working up all manners of peat, requiring little power and almost juvenile attendance. The price of the same, although not definitely mentioned, seems to be somewhere between 20*l.* and 25*l.* The following description is given:—

'The peat-press consists of a wooden tub, about 6ft. high, and 2ft. wide, chained upon a kind of sledge. The wooden vessel contains an upright shaft which may be set in motion by means of a horse-gear. This shaft carries on the bottom an iron disc, above it two revolutions or turns of screw-blades, and above these four similar blades each forming a quadrant, and so arranged that they form a complete revolution. Knife-like projections in the wooden vessel prevent the peat revolving with the blades and shaft; the opening for the introduction of the raw peat is at the back on top; in front is the iron delivery, which may be opened by means of a lever, and contains a wooden conical mould, through which the peat issues in four endless strings or streams on an inclined table, on which it is cut in pieces or blocks of convenient length. The whole of the parts of the machine are so constructed that repairs are reduced to the very minimum. The machine requires one horse, three adults, and three or four boys or girls, according to the size and distance of the drying ground. If the peat to be worked lies entirely under water or has otherwise been rendered very soft or wet, it must be thrown up to dry a little; in the same way it has to be wetted if too dry. As a rule, it may be operated upon just as dug from the bog after removal of the top layer, but if the quality varies much at different depths it is desirable to mix the same in digging and throwing out. Two men dig the peat and cart it to the machine, which is placed as close as possible; a third feeds the machine, taking care to keep it constantly full, in order to facilitate the even discharge of the streams of moulded peat. If the latter cannot be moved forward on the wetted table without getting crushed and squeezed, then the pulp is too wet; if it crumbles, it is too dry; if the stream be uneven or incomplete, the mould is clogged, and may be opened at once and the obstruction removed. Very little practice overcomes and entirely avoids these difficulties. A girl or a boy stands on the left-hand side—from the machine—of the table, and cuts from the stream with a sort of wooden spade 4 inches square—while holding the former with the left hand—a length of 10 inches, and removes the same to the end of the table, from whence it is loaded on a cart by one of the remaining two or three children, and wheeled to the drying ground. If there is sufficient room, the pieces are simply laid side by side in a dry atmosphere. Three days suffice to air-dry the same, and in two or three weeks they can be stowed into large heaps. The writer here repeats that peat having gone through this machine dries much more quickly and burns with greater intensity of heat; also that the lightest and poorest stuff so worked is fitted for consumption under steam-boilers. One volume of this pressed peat is equal to about two of Hanover peat, or to three of ordinary cut peat, and the intensity of heat developed stands in the same proportion.

'One horse is sufficient for ten hours' work per day, the dynamometer only showing 80 lbs. to 95 lbs. on a beam 13 feet 6 inches long, according to the size of the mould and the condition of the raw material, making two rounds per minute at thirty-seven paces each, or a total of seventy-four paces per minute, the exertions of the animal not lying so much in the intensity of the pull, but in going round in a circle, and this one can do easier than another. Next to the regular speed of the horse, the production of the machine depends on the size of the moulds used. No. 1 is 3½ inches square, and produces, in 50 minutes—during which the horse makes 118 rounds by exerting a pull of 80 lbs. on the 13 feet 6 inches beam—1,000 pieces of peat 10 inches long, containing 122,500 cubic inches = 70⅞ cubic feet of wet peat. Absolutely dry, one of these pieces weighs 1 lb. loth. = 1 lb. ½ oz., or rather more, in English. No. 2 is 3¾ inches square, delivering in one hour and five minutes, and 150 rounds of the horse, 1,000 pieces of peat 10 inches long, the dynamometer showing 85 lbs. to 88 lbs. on the same length of beam. The bulk of wet peat thus delivered is 81⅜ cubic feet, one piece weighing 1 lb. 17 loth—say 1 lb. 8½ oz., English, rather more—when absolutely dry. Mould No. 3 is 4 inches square, and delivers in 1 hour 15 minutes, 144 rounds of the horse with a pull of 92 lbs. to 95 lbs., the same number of pieces, viz., 1,000 also 10 inches long, being 101¼ cubic feet of wet peat, which weigh when quite dry 2 lbs. ½ oz. each piece. Some cut the peat only 8 inches long, others 12 inches; 10 inches is the best result of a number of trials. He uses form No. 3. His hands have to produce 7,000 pieces per day, and he pays 6 sgr. (7·2*d.*) per 1,000; for turning over or re-stacking, 0·6*d.* per 1,000 each time. He turns his peat over three times, and pays 9*d.* per 1,000 in the stack, but this extra expenditure is more than covered by the greater value of the product and the saving of carriage by reason of the reduced bulk. Peat thus prepared from the 1st to the 20th May proved excellent fuel in the writer's steam distillery.'

PECTIC ACID (*Acid pectique*, Fr.; *Gallertsäure*, Ger.), so named on account of its gelatinizing property, (from *πητύα, coagulum*), exists in a vast number of vegetables. The easiest way of preparing it, is to grate the roots of carrots into a pulp, to express their juice, to wash the *marc* with rain or distilled water, and to squeeze it well; 50 parts of the marc are next to be diffused through 300 of rain-water, adding by slow degrees a solution of one part of pure potash, or two of bicarbonate. This mixture is to be heated, so as to be made to boil for about a quarter of an hour, and is then to be thrown boiling-hot upon a filter-cloth. It is known to have been well enough boiled when a sample of the filtered liquor becomes gelatinous by neutralising it with an acid. This liquor contains pectate of potash, in addition to other matters extracted from the root. The pectate may be decomposed by a stronger acid, but it is better tc decompose it by muriate of lime; whereby a pectate of lime, in a gelatinous form, quite insoluble in water, is obtained. This having been washed with cold water upon a cloth, is to be boiled in water containing as much muriatic acid as will saturate the lime. The pectic acid thus liberated, remains under the form of a colourless jelly, which reddens litmus-paper, and tastes sour, even after it is entirely deprived of the muriatic acid. Cold water dissolves very little of it; it is more soluble in boiling water. The solution is colourless, does not coagulate on cooling, and hardly reddens litmus-paper; but it gelatinises when alcohol, acids, alkalis, or salts are added to it. Even sugar transforms it, after some time, into a gelatinous state: a circumstance which serves to explain the preparation of apple, cherry, raspberry, gooseberry, and other jellies.

PECTIN, or vegetable jelly, is obtained by mixing alcohol with the juice of ripe currants, or any similar fruit, till a gelatinous precipitate takes place; which is to be gently squeezed in a cloth, washed with a little weak alcohol, and dried. Thus prepared, pectin is insipid, without action upon litmus; in small pieces, semi-transparent, and of a membranous aspect, like isinglass. Its mucilaginous solution in cold water is not tinged blue with iodine.

Frémy has published a very comprehensive investigation on the ripening of fruit, in which he shows that this peculiar body only exists in fruit arrived at maturity. Not a trace of pectin can be detected in the juice expressed from an unripe apple; but on boiling the juice for some seconds with the pulp, pectin immediately appears, and is indicated by the liquid becoming viscid. Frémy considers the following as the only way to procure pure pectin:—

From the juice of ripe pears, expressed in the cold, and filtered, the lime is to be separated by means of oxalic acid, and the albuminous substance by the aid of tannic acid. From this liquid pectin is now precipitated by means of alcohol; it separates in long threads, which after being washed with alcohol are to be dissolved in water, and again precipitated with alcohol. This is to be repeated three or four times, until the liquid is free from sugar and oxalic acid; hot water must be avoided in these operations.

PELLITORY OF SPAIN. *Pyrethrum officinale.* A native of the East. The root when chewed produces a hot sensation. It is used for toothache.

PELTRY. (*Pelleterie*, Fr.; *Pelzwerk*, Ger.) This term comprehends all the skins of the wild animals found in high northern latitudes, especially on the American continent. Under FUR these are described. It should be understood that when the skins are received in their unprepared state they are properly called *peltry* or *pelts*; when tawed or tanned they become *furs*. See FUR DRESSING.

PELT WOOL. Wool plucked from the pelts or skins of sheep after they are dead.

PEMMICAN. The North American Indians cut the muscular portions of meat into thin slices, having separated the fat, and dry it in the sun. This tough dry meat cannot undergo putrefaction; it is stamped closely together with a portion of fat, and preserved in buffalo- and deer-skins. This pemmican affords the largest amount of nutritive food in the least quantity of solid matter.

PENANG CANES are small palms which are brought from the island of Penang.

PENCIL BLUE. See CALICO-PRINTING.

PENCIL MANUFACTURE. (*Crayons, fabrique de*, Fr.; *Bleistifte Verfertigung*, Ger.) The word 'pencil' is used in two senses. It signifies either a small hair-brush employed by painters in oil and water-colours, or a slender cylinder of black-lead or plumbago, either naked or enclosed in a wooden case, for drawing black lines upon paper. The last sort, which is the one to be considered here, corresponds nearly to the French term crayon, though this includes also pencils made of differently-coloured earthy compositions. See CRAYON; DRAWING CHALKS.

The best black-lead pencils of this country are formed of slender parallelopipeds, cut out by a saw, from sound pieces of plumbago, especially such as have been obtained from Borrowdale, in Cumberland. (See PLUMBAGO). These parallelopipeds are generally enclosed in cases made of 'cedar wood,' though of late years they are also used alone, under the name of ever-pointed pencils, in peculiar pencil-cases, provided with an iron wire and screw, to protrude a minute portion of the plumbago beyond the tubular metallic case, in proportion as it is wanted. The wood commonly used for pencils, though called 'cedar,' is really a juniper, being usually obtained from the *Juniperus Virginiana.*

Pieces of plumbago sufficiently large to be thus employed are very rare, and the supply from the Cumberland mine can no longer be relied on. The mine has been closed for many years. In 1859 a company was formed for again working it, but failed to discover any plumbago of value. This year (1874) another attempt is being made to develope the mine. Many efforts have been made to utilise the smaller fragments of plumbago—as by grinding them, melting them with sulphur or antimony, and the like; but few of these have been attended with any success.

The late Mr. Brockedon was long occupied in seeking for some method which might enable him to employ the pure powder of black-lead without cementing it by any substance, which inevitably injures the quality. He endeavoured to render the powder coherent by submitting it to enormous pressure; but the different machines and apparatus he at first made use of for this purpose, however strongly they were made, were broken under the pressure, and his endeavours were thus unsuccessful, until the happy idea suggested itself of operating in a vacuum. But it was extremely difficult, if not impossible, to introduce under the receiver of an air-pump an apparatus for compressing the powder of graphite. Mr. Brockedon overcame this difficulty by an arrangement as simple as it is easily executed; for, after having compacted the powder by a moderate pressure, and thus reduced it to a certain size, he enclosed it in very thin paper glued over the whole surface. He then pierced it in one place with a small round hole permitting the escape of the air from within, when the block thus prepared was placed under an exhausted receiver, and the air having been removed, the orifice was closed with a little piece of paper (a small adhesive wafer was usually employed for this purpose), and in this state it was found that it might be left for twenty-four hours without injury. Being submitted to a regulated pressure once more, the different particles became agglomerated, and an artificial block of graphite (see GRAPHITE) was produced by simple pressure, as solid as the specimens obtained from the mine.

The artificial masses of plumbago thus obtained owed much of their character to the extreme fineness to which the plumbago was reduced by previous grinding under rollers. In this manner a great deal of useless plumbago is worked up into excellent black-lead pencils. The different degrees of darkness in drawing pencils should be secured by the selection of specimens of plumbago of varying degrees of density. It is, however, commonly obtained by combining, with the plumbago, sulphur, or sulphuret of antimony, and by subjecting the plumbago to the action of heat. In the commoner kinds of pencil a very heterogeneous mixture is employed; indeed, many pencils are little more than black chalks.

The pencil works at Keswick consist of a house of several stories, in the lower of which is a huge water-wheel turned by the Greta, outside being the cedar wood ready for use. The quantity of cedar consumed annually by the establishment is 4,000 cubic feet. These cedar logs are sawn into planks, and then a circular saw cuts the planks into smaller pieces, preparatory for the grooving-engine; this grooving-engine consists of two revolving saws, going at inconceivable speed; one saw cutting the slips of wood into narrow square rods, and the other making a groove along the rod and cutting to size at the same time; adjoining the grooving apparatus is a circular saw, cutting slips of cedar as covers to the grooved lengths.

The plumbago, if good, needs no refining; it is used precisely in the condition in which it leaves the mine. To ascertain its qualities each piece is scraped with the edge of a knife, besides being otherwise tested; and in proportion as there is no gritty particles in it, so is it the more valuable. Some pieces are harder, some a little darker in colour than others; and according to these peculiarities, they are employed for pencils of various hardness and shades. The whole knack of pencil-making seems to depend on the detection of these niceties in the bits of lead, and also, of course, in their honest adaptation to the varieties which are dealt out to the public. Plumbago of an impure kind is ground to powder; the grit, as far as possible, separated from it, and the cleansed material, mingled with a cohesive liquid, is dried and pressed into hard lumps for use. This process, however, is applied principally, if not exclusively, to the plumbago imported from India, and only in reference to pencils of the commonest sort. Pencils made with such stuff are valueless to artists; for independently of their want of tone, they are never altogether free from grit. The best pencil is one made from genuine Borrowdale lead, pure from the mine, and adapted by a skilful manufacturer to its assigned purpose. The mode of preparing the pieces of good plumbago for the pencil is very simple. All the bits, with their surface merely scraped, are glued to a board, in order to fix them in a position for being sawn. When so fixed they are brought under the action of a saw, which divides them into thin slices or scantlings. These slices are now handed to the fitter. This is an operative who, with a lot of grooved rods before him, sticks slices of the lead into grooves, snapping off each slice level with the surface, so as just to leave the groove properly filled. In the making of a single pencil, perhaps as many as three or four slice lengths are required; but however many, each slice is fitted exactly endlong with another, so as to leave no intervals. The rods being thus filled, are carried to the fastener-up. This person glues the cedar covers or slips over the filled rods; and having got a certain number arranged alongside of each other, he fixes them tightly together, and lays them aside to dry, When dried they are ready for being rounded. The rounding is done by an apparatus fixed to a bench, containing revolving planes or turning tools. Into this engine, rods are put one after another, and out they come as fast as the eye can follow them, rounded to a perfect nicety. By this simple and efficient machine a man will round from six hundred to eight hundred dozens of pencils in a day. After being rounded they get a smoothing with a plane, and then they are polished by being rubbed with a peculiar kind of fish-skin ; this latter operation being performed by girls. Being polished, the next step is to cut the rods into lengths with a circular saw, after which the lengths are respectively smoothed at the ends. Nothing now remains but to stamp the name of the maker, with the letters significant of their quality. The stamping-engine is as ingenious a piece of machinery as is in the establishment. Fed into it, the pencils are stamped in less than an instant of time. A girl will with this apparatus stamp two hundred pencils per minute. Gathered from a box below into which the pencils fall, they are carried away to be tied in bundles.

In the year 1795 M. Conté invented an ingenious process for making artificial black-lead pencils.

Pure clay, or clay containing the smallest proportion of calcareous or siliceous matter, is the substance which he employed to give aggregation and solidity, not only to plumbago-dust, but to all sorts of coloured powders. That earth has the property of diminishing in bulk and increasing in hardness, in proportion to the degree of heat it is exposed to, and hence may be made to give every degree of solidity to crayons. The clay is prepared by diffusing it in large tubs through clear river-water, and letting the thin mixture settle for two minutes. The supernatant milky liquor is drawn off by a syphon from near the surface, so that only the finest particles of clay are transferred into the second tub, upon a lower level. The sediment, which falls very slowly in this tub, is extremely soft and plastic. The clear water being run off, the deposit is placed upon a linen filter, and allowed to dry. It is now ready for use.

The plumbago must be reduced to a fine powder in an iron mortar, then put into a crucible, and calcined at a heat approaching to whiteness. The action of the fire gives it a brilliancy and softness which it would not otherwise possess, and prevents it from being affected by the clay, which it is apt to be in its natural state. The less clay is mixed with the plumbago, and the less the mixture is calcined, the softer are the pencils made of it; the more clay is used, the harder are the pencils. Some of the best pencils made by M. Conté were formed of two parts of plumbago and three parts of clay; others of equal parts. This composition admits of indefinite variations, both as to the shade and hardness—advantages not possessed by the native mineral.

The materials having been carefully sifted, a little of the clay is to be mixed with the plumbago, and the mixture is to be triturated with water into a perfectly uniform paste. A portion of this paste may be tested by calcination. If on cutting the indurated mass particles of plumbago appear, the whole must be further levigated. The remainder of the clay is now to be introduced, and the paste is to be ground with a muller upon a porphyry slab, till it be quite homogeneous, and of the consistence of thin dough. It is now to be made into a ball, put upon a support, and placed under a bell glass inverted in a basin of water, so as to be exposed merely to the moist air.

Small grooves are to be made in a smooth board, similar to the pencil parallelopipeds, but a little longer and wider, to allow for the contraction of volume. The wood must be boiled in grease, to prevent the paste from sticking to it. The above-described paste being pressed with a spatula into these grooves, another board, also boiled in grease, is to be laid over them very closely, and secured by means of screw-clamps. As the atmospheric air can get access only to the ends of the grooves, the ends of the pencil-pieces become dry first, and by their contraction in volume get loose in the grooves, allowing the air to insinuate further, and to dry the remainder of the paste in succession. When the whole piece is dried, it becomes loose, and might be turned out of the grooves. But before this is done, the mould must be put into an oven moderately heated, in order to render the pencil-pieces still drier. The mould should now be taken out, and emptied upon a table covered with cloth. The greater part of the pieces will be entire, and only a few will have been broken if the above precautions have been duly observed. They are all, however, perfectly straight, which is a matter of the first importance.

In order to give solidity to these pencils, they must be set upright in a crucible till it is filled with them, and then surrounded with charcoal-powder, fine sand, or sifted wood-ashes. The crucible, after having a luted cover applied, is to be put into a furnace, and exposed to a degree of heat regulated by the pyrometer of Wedgwood; which degree is proportional to the intended hardness of the pencils. When they have been thus baked, the crucible is to be removed from the fire, and allowed to cool with the pencils in it.

Should the pencils be intended for drawing architectural plans, or for very fine lines, they must be immersed in melted wax or suet, nearly boiling hot, before they are put into the cedar cases. This immersion is best done by heating the pencils first upon a gridiron, and then plunging them into the melted wax or tallow. They acquire by this means a certain degree of softness, are less apt to be abraded by use, and preserve their points much better.

When these pencils are intended to draw ornamental subjects with much shading, they should not be dipped as above.

Second Process for making Artificial Pencils, somewhat differing from the preceding.— All the operations are the same, except that some lamp-black is introduced along with the plumbago-powder and the clay. In calcining these pencils in the crucible, the contact of air must be carefully excluded, to prevent the lamp-black from being burned away on the surface. An indefinite variety of pencils, of every possible black tint, may thus be produced, admirably adapted to draw from nature.

Another ingenious form of mould is the following:—

Models of the pencil-pieces must be made in iron, and stuck upright upon an iron tray, having edges raised as high as the intended length of the pencils. A metallic alloy is made of tin, lead, bismuth, and antimony, which melts at a moderate heat. This is poured into the sheet-iron tray, and, after it is cooled and concreted, it is inverted, and shaken off from the model bar, so as to form a mass of metal perforated throughout with tubular cavities, corresponding to the intended pencil-pieces. The paste is introduced by pressure into these cavities, and set aside to dry slowly. When nearly dry, the pieces get so much shrunk that they may readily be turned out of the mould upon a cloth table. They are then to be completely desiccated in the shade, afterwards in a stove-room, next in the oven, and lastly ignited in the crucible, with the precautions above described.

M. Conté recommended the hardest pencils of the architect to be made of lead melted with some antimony and a little quicksilver.

In their further researches upon this subject, M. Conté and M. Humblot found that the different degrees of hardness of crayons could not be obtained in a uniform manner by the mere mixture of plumbago and clay in determinate doses. But they discovered a remedy for this defect in the use of saline solutions, more or less concentrated into which they plunged the pencils, in order to modify their hardness and increase the uniformity of their texture. The non-deliquescent sulphates were preferred for this purpose; such as sulphate of soda, &c. Even syrup was found useful in this way.

PENS, STEEL, AND OF OTHER METALS. As peculiar elasticity is required in these pens, now so commonly used, the best metal, made from either Dannemora- or hoop-iron, is selected and laminated into slips about 3 feet long and 4 inches broad, of a thickness corresponding to the desired thickness and flexibility of the pens. These slips are subjected to the action of a stamping-press, somewhat similar to that for making buttons. (See BUTTON; PLATED WARE.) The point destined for the nib is next introduced into an appropriate gauged hole of a little machine, and pressed into the semi-cylindrical shape; where it is also pierced with the middle slit and the lateral ones, provided the latter are to be given. The pens are now cleaned, by being tossed about among each other in a tin cylinder, about 3 feet long and 9 inches in diameter, which is suspended at each end upon joints to two cranks, formed one on each of two shafts. The cylinder, by the rotation of a fly-wheel, acting upon the crank-shafts, is made to describe such revolutions as agitate the pens in all directions, and polish them by mutual attrition. In the course of four hours several thousand pens may be finished upon this machine.

When steel pens have been punched out of the softened sheet of steel by the appropriate tool, fashioned into the desired form, and hardened by ignition in an oven and sudden quenching in cold water, they are best tempered by being heated to the requisite spring-elasticity in an oil-bath. The heat of this bath is usually judged of by the appearance to the eye; but this point should be correctly determined by a thermometer, according to the scale (see STEEL); and then the pens would acquire a definite degree of flexibility or stiffness, adapted to the wants and wishes of the consumers.

The following description of the pens made at the works of the late Joseph Gillott, Birmingham, will illustrate the entire manufacture:—

The steel is procured at Sheffield; it is cut into strips, and the scales removed by immersion in pickle composed of dilute sulphuric acid. It is passed through rollers, by which it is reduced to the necessary thickness; it is then in a condition to be made into pens, and is for this purpose passed into the hands of a girl, who is seated at a press, and who, by means of a bed and a punch corresponding, speedily cuts out the blank. The next stage is, piercing the hole which terminates the slit, and removing any superfluous steel likely to interfere with the elasticity of the pen; at this stage they are annealed in quantities in a muffle, after which, by means of a small stamp, the maker's name is impressed upon them. Up to this stage the future pen is a flat piece of steel: it is then transferred to another class of workers, who, by means of the press, make it concave, if a nib; and form the barrel, if a barrel-pen. Hardening is the next process: to effect this, a number of pens are placed in a small iron box and introduced into a muffle; after they become of a uniform deep red, they are plunged into oil; the oil adhering is removed by agitation in circular tin barrels. The process of tempering succeeds; and, finally, the whole are placed in a revolving cylinder with sand, pounded crucible, or other cutting substances, which finally brightens them to the natural colour of the material. The nib is ground with great rapidity by a girl, who picks it up, places it in a pair of suitable plyers, and finishes it with a single touch on a small emery-wheel. The pen is now in a condition to receive the slit, and this is also done by means of a press. A chisel or wedge with a flat side is fixed to the bed of the press; the descending screw has a corresponding chisel cutter, which passes down with the minutest accuracy; the slit is made; and the pen is completed. The last stage is colouring brown or blue; this is done by introducing the new pens into a revolving metal cylinder, under which is a charcoal stove, and watching narrowly when the desired tint is arrived at. The brilliancy is imparted by means of lac dissolved in naphtha; the pens are immersed in this, and dried by heat. Then follow the counting and selecting. Women are mostly employed in the manufacture, with skilled workmen to repair and set the tools. In this manufactory there are employed more than 500 hands, of which four-fifths are women. The manufactory has been established upwards of 50 years, and has been the means of introducing many improvements in the manufacture.

Since steel necessarily corrodes by the constant action of the acids in the ink, it has been thought that they would be protected by coating them with gold or silver; and this has been effected by the electrotype process. In most cases, however, the thin film of gold is rapidly removed, and the protection therefore afforded is small. The manipulatory details in the manufacture of gold and silver pens are so nearly similar to those above described, that it is thought unnecessary to repeat them. The best gold pens are tipped with a native alloy, which is a compound of osmium and iridium. See Osmiridium.

The importance of this manufacture will be best shown by Mr. Samuel Timmins's account of it in 'The Resources, Products, and Industrial History of Birmingham':—

'The number of actual makers of steel pens is 12. The number of men employed, 360; the number of women and girls, 2,050. The amount of horse-power employed may be estimated at 330, including, say, 50 employed in out-work rolling. The number of pens made weekly, 98,000 gross. The quantity of steel used weekly, 9½ to 10 tons. The value of pens per gross, 1½*d.* to 1*s.*; and of barrel-pens, from 7*d.* to 12*s.* per gross; some of the larger pens being very much higher, according to their size and finish.

'The increase of men and boys from 300 to 360, of women and girls from 1,550 to 2,050, of horse-power from 228 to 330, of steel used from 6½ to 10 tons, of pens made from 65,000 to 98,000 weekly, will sufficiently indicate the rapid development of the trade during the past sixteen years. These returns of the number of persons employed, amounting to 2,400 persons, do *not* include the large number employed in making the paper boxes and other accessories of the trade; and doubtless more than 2,000 persons are more or less directly connected with the steel-pen trade in Birmingham alone.

'One point relating to the cost of pens is very remarkable—the wonderfully low rate at which they are now produced. Thirty years ago, pens were sold, wholesale, at 5*s.* a gross, and now they are sold as low as 1½*d.* and 1¾*d.* per gross! When it is remembered that each gross requires 144 pieces of steel to go through at least twelve processes, the fact that 144 pens can be sold for 1½*d.* is a singular example of the results attainable by the division of labour and mechanical skill.

'Although most of the steel used for pens is produced in Sheffield, all the subsequent processes are carried on in Birmingham, which is now the head-quarters of the steel-pen trade. Two new factories had been established in France in 1849, in consequence of the high duties on English pens; and these factories (now six or seven) produce about 50,000 gross of pens per week, against 16,000 or 18,000 gross made in 1849. In Germany there are two factories, producing, however, very few pens. In America the high war-tariff has caused the establishment of four factories; and these, aided by skilled workmen from England, are producing about 10,000 gross of pens per week.

'Most of the processes of pen-making are performed by hand-presses, to cut out the blanks, to pierce the hole, to form the nib, to emboss the pattern, and to mark the name; self-acting machinery being used only for the commonest export pens.'

PEPERINO. Volcanic tufa: a light porous species of volcanic rock, so called on account of the peppercorn-like fragments of which it is composed.

PEPPER. (*Poivre*, Fr.; *Pfeffer*, Ger.) The pepper-tree (*Piper nigrum*) is cultivated in many parts of India, and to some extent in the West Indies. When the berries begin to change colour from green to red, they are collected, spread out, and dried in the sun. The stalks are separated by hand-rubbing, and then winnowing. The dry and shrivelled berries constitute the *black pepper*; the soundest grains are selected for *white pepper*. These are soaked in water until they swell and burst their corticle, which is afterwards separated by hand-rubbing and winnowing.

In McCulloch's 'Dictionary of Commerce' is a paper on the production of pepper, by Mr. Crawford, in which we find the following distribution:—

	lbs.
Sumatra (west coast)	20,000,000
Sumatra (east coast)	8,000,000
Islands in the Straits of Malacca	3,600,000
Malay Peninsula	3,733,333
Borneo	2,666,667
Siam	8,000,000
Malabar	4,000,000
Total	50,000,000

Pereira particularises the following kinds of pepper:—

1. *Malabar Pepper.*—The most valuable; a *brownish-black*.
2. *Penang Pepper.*—*Brownish-black*; but dusty. Sometimes used in England to manufacture white pepper.
3. *Sumatra Pepper.*—This is the cheapest sort. It is the black pepper of commerce. The heavier kinds are the most esteemed, and are known as *shot pepper*.
4. *Fulton's Decorticated Pepper.*—Black pepper, deprived of its husks by mechanical trituration.
5. *Bleached Pepper.*—Penang pepper bleached by chlorine.
6. *White Pepper*, described above.
7. *Tellicherry Pepper.*
8. *Common White Pepper.*—Comes from Penang by Singapore.

Pepper is stated to be adulterated with sago. This can always be detected by the microscope, the starch grains of sago being very much larger than those of pepper. Dr. Hassall has stated in the 'Lancet' that, although he frequently found pepper to be adulterated with linseed-meal, rice, and wheat-flour, yet, that out of forty-three samples obtained from various sources, he did not detect sago-meal in any.

Four pounds of black pepper yield only about one ounce of piperine, or 1-636th part. It is an insipid crystalline substance, insoluble in water, but very soluble in boiling alcohol, and is extracted at first along with the resin, which may be separated from it afterwards by potash. See PIPERINE.

PEPPER BETEL. The *Chavica betel* and the *C. Siriboa* yield the leaf which, mixed with slices of the betel nut (*Areca catechu*), is employed for mastication by many of the nations of the East. See BETEL.

PEPPER, JAMAICA. See PIMENTO.

PEPPER, LONG. *Chavica Roxburghii* (*Piper longum*). This shrub is cultivated in Bengal, and forms a considerable article of commerce all over India. The common long pepper is of a greyish-brown; it is cylindrical, and of about an inch in length.

PEPPERMINT. The *Mentha piperita*, a labiate herb, yielding preparations having stimulant and carminative qualities, such as peppermint-water, essence of peppermint, oil of peppermint, &c.

PEPSIN. The 'active principle,' or digestive 'ferment,' of gastric juice.

A preparation is sold as pepsin for coagulating milk. It is prepared by drying the glandular layer of a calf's or pig's stomach at a low temperature. Pepsin is employed advantageously in medicine. See Watts's 'Dictionary of Chemistry.'

PERCUSSION CAPS. The universal employment of the percussion cap in the place of the flint-lock has given rise to many most extensive manufactories devoted to their construction. Thin-rolled copper, as pure as possible, is selected. This is first cut into pieces called *blanks*. These are then punched up into the required shape.

They are charged by touching the bottom of each cap with a strong adhesive liquid, and before this hardens, the fulminating composition is dropped in. All that does not adhere is shaken out. The caps are varnished, and preserved for use. See FULMINATES.

PERFUMERY, ART OF, (*Parfumerie*, Fr.; *Wohlriechende Kunst*, Ger.) consists in the extraction of the odours of plants; isolating them—A and B—and in combining them with inodorous materials, such as grease, C; spirit, D; starch, E; soaps, F: also in the manufacture of cosmetics, G; dentifrices, pastes, tinctures, H; incense and pastils, I; pomades, oil, and other toilet-appendages, K; hair-washes, hair-dyes, and depilatories, L.

(A and B.) There are three distinct methods of procuring the odours of plants: 1st. By DISTILLATION. If cloves, cinnamon-bark, or the odorous leaves of plants or wood, be distilled, the fragrant principle contained therein rises with the steam, which being condensed, the otto, or essential oil, will be found floating upon the water. This process has already been described (see DISTILLATION; REFRIGERATION; OTTOS; OILS, VOLATILE; but can only be beneficially applied by the perfumer to the procuring of certain odours: from woods, such as santal and cedar; from leaves, such as patchouli and bay leaves; from various grasses, such as the lemon grass and citronella of Ceylon; from several seeds, such as carraway and nutmeg; and but to two or three flowers, such as orange-blossom, rose, and lavender. The various fragrant woods, seeds, and leaves are, however, almost as numerous as there are plants upon the earth, and as a consequence, the perfumer can have as great a variety of ottos by distilling for them.

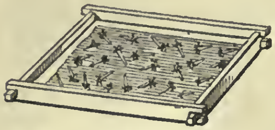
(C.) 2nd. ENFLEURAGE. When it is desired to obtain the odours of flowers, such as those of jasmin, acacia, violet, tuberose, jonquil, and numerous others, the process of distillation is inapplicable and useless, and that peculiar but simple method, termed 'Enfleurage,' must be adopted. This plan is founded on the fact, that greasy bodies readily absorb odorous particles, and will as freely part with them if in contact with pure alcohol. The operation of enfleurage is thus conducted at Messrs. Piesse and Lubin's laboratory of flowers, near Nice, in France.

Purification of the grease. A corps, or body grease, is first produced by melting together equal parts of deer- or beef-suet (the former is preferred), mutton-suet, and lard; it is then clarified thus:—Take 1 cwt. of grease, divide it into portions of about 2 lbs., place one of these in a mortar and well pound it; when it is well crushed, wash it with water repeatedly, so long, in fact, until the water is as clear, after withdrawing the grease, as before it was put in. The several lots of grease prepared in this way have now to be melted over a slow fire, adding thereto about 3 ounces of crystallised alum in powder and a handful of sea salt (common salt); now let the grease boil, but allow it to bubble for a few seconds only; then strain the grease through a fine linen into a deep pan, and allow it to stand to clear itself from impurities for about two or three hours. The clear grease is then again put into the melting vessel over a charcoal fire, adding thereto about three or four quarts of rose-water and half a pound of powdered gum benzoin; it is then allowed to boil gently, and all scum that rises carefully removed until it ceases to be produced. Finally, the grease is poured into deep pans to cool; when solid it is removed off the sedimentary water, and again being liquefied may be placed in store vessels for future use, where it may be kept for an indefinite period without change or becoming rancid. This purification of the grease gives employment to those engaged in the laboratory at a season when the flowers are not in bloom. M. Herman of Cannes, and M. Pilar of Grasse, prepare in this way during winter, together, one hundred and twenty thousand pounds of *perfectly inodorous grease.*

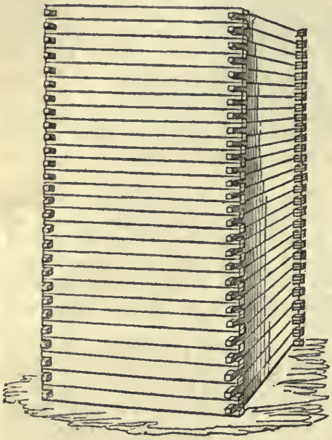
The growers of the flowers of course pay due attention to their cultivation, so as to produce an abundance of blossom in due season. Although it is not necessary that the flower-farmer should be a perfumery-factor, it is useful that the latter should have some knowledge of the former avocation, so as to be prepared for each harvest of flowers as they succeed each other, and when it is practicable to unite the occupations; better pecuniary results follow. At Cannes and Grasse, in France, which are separated from the frontier of Sardinia only by the river Var, and are distant from Nice about 30 miles, the entire population is more or less interested in this particular manufacture. The various flowers there cultivated do not come into blossom at one time, but in succession; so that there is ample time to attend to each in turn.

The enfleurage process is thus conducted:—Square frames, varying in size from 20 to 30 inches are made, in the centre of which is fixed a piece of stout glass as in *fig.* 1613. Each frame is $1\frac{1}{2}$ inch deep from the top edge to the glass, so that if two frames be placed together face to face, there is, as it were, a glass box with a wooden frame, having a depth of 3 inches between each glass. This affords ample room for the blossoms to lie between them without being crushed. In due season, that is, when the flowers begin to bloom, about half a pound of the purified grease is spread upon each side of the glass with a spatula or palate-knife. The gathered blossoms are then hand-sprinkled or broad-cast over the grease in one frame, and another frame is put over it so as to enclose the flowers. This operation is repeated as many times as there are flowers to spread over each. These frames are termed *Châsse*, which literally means 'Sash.' Now we are all familiar with window-sashes—that is, a glass with a frame round it—and such is in truth the Châsse used in the enfleurage process. Doubtless our window-'sash' is derived from the French. Châsse may also be rendered in English, 'a frame.' Enfleurage, then, is conducted upon a glass frame or sash. About every other day, or every third day, the spent flowers being thrown away, fresh ones are placed upon the grease; this manipulation being repeated so long as the plants yield blossoms, a time that varies from 1 to 2 months. After every addition of flowers, it will be observed that the grease increases in the fragrance of the flower with which it was sprinkled, and this continues till the enfleurage is complete, at which time the grease, now called 'Pomade,' is scraped off the sashes, put into vessels, then placed in hot water—a water-bath. By so doing the pomade is liquefied, but is not made hot enough to destroy its odour. By this treatment various extraneous matters, such as a few anthers of flowers, a stray bee, some pistils or loose part of the corolla, a wayward butterfly and moth, and such similar things, are removed, by pouring the clear pomade into the canisters through fine linen. When the pomade is cold enough it sets in these vessels, and is then fit for exportation or for ulterior uses. *Fig.* 1614 represents a pile of châsse.

1613



1614



3. Maceration. In some few instances better results are obtained by adopting the process of maceration, which consists in infusing the fresh flowers in liquefied grease. For this purpose, the purified grease is placed in a hot water-bath, that is, the vessel containing the grease is set in another of a larger size, in which water is kept warmed over a stove. In the French laboratories, this apparatus is known as the *bain marie*, salt being put into the water to increase its boiling-point. Every time fresh flowers are gathered, the spent ones are strained away, and the fresh flowers put into the partially-scented grease. In a few instances it is found advantageous to begin perfuming the grease by maceration, and to finally finish it by enfleurage; this is especially the case with violet pomade.

After the maceration is completed, that is, when there are no more flowers to be had, the grease must be kept steadily at a uniform degree of liquefaction, in order that friable portions of the flowers, &c., may subside, so that the fair pomade can be separated therefrom pure and unsullied. Oils are scented by enfleurage and maceration processes by a slight difference of mechanical arrangement. Thus, the sash, in lieu of glass, contains a wire-gauze, like a coarse wire-blind (*châsse en fer*); upon this gauze is laid a thick piece of fustian-like cotton fabric (*molleton du coton*), which has previously been steeped in the purest olive oil. Upon each molleton laid in the sash-frame the flowers are sprinkled in the same way as if it were for pomade, and the flowers are changed as often as possible. When the plants cease to bloom, each molleton is wrapped in a strong cord net, and placed in a hydraulic or other press, for the purpose of squeezing the fragrant oil away from it. Oils of tuberose, rose, violet, jonquil, acacia, and orange are thus prepared.

According to the length of time the enfleurage process occupies, and the quantity of flowers employed over the same grease, the pomade or oil bears numbers respectively. Thus we have No. 12 pomade, No. 18 oil, No. 24 pomade, indicating their relative strength of fragrance; that is, the quantity of flowers employed in their manufacture.

(D.) Scented Spirits are produced by four separate plans:—

1. By distilling alcohol with an otto, such as lavender otto, to produce spirit of lavender. For this purpose, and to produce the finest distillate, take

Oil of English lavender	8 ounces
Rectified spirit 60° o. p.	8 pints
Rose-water	1 pint

Mix the oil first with the spirit, then gradually add the water; finally, distil off eight pints for sale. This distillate is unalterable by age, remains perfectly white, and will keep good in any climate. A great variety of scented spirits are made in this way, of which Hungary water and Eau d'Arquebuzade are good examples, the different scent or flavour being imparted by varying the combination of essential oils.

2. All essential oils being soluble in alcohol, a ready way of producing some kinds of concentrated essences is to dissolve the fragrant essential oil in the spirit. Thus, for

Essence of Roses.

Take alcohol, 60° o. p.	1 gallon.
,, pure otto of roses	3 ounces.

The oil quickly dissolves at a summer heat; but, in cold weather, beautiful acicular crystals appear throughout the liquid. Innumerable other concentrated essences may be produced in a similar way; but the standard strength varies with the oil used. Thus, for every gallon of spirit employed we should use 2 ounces of oil of vitivert, 3 ounces of oil of patchouli, 6 ounces of oil of geranium, 8 ounces of otto santal, &c.

3. Tincturation. — Musk, orris-root, ambergris, tonquin-beans, castor, vanilla, civet, and a few other odorous substances, yield their odours to spirit by tincturation, that is, by putting the fragrant material into the spirit, and allowing it to remain there for a period till the alcohol has extracted all the scent. The standard strength of these tinctures should be: for one gallon of alcohol, 2 ounces of grain musk, 3 ounces of ambergris, 8 ounces of vanilla, 8 lbs. of orris-root, 1 lb. of tonquin-beans. The standard strength of these essences is regulated, like that of 'jewellers' gold,' by the selling price; but the above is that figuratively indicated as alone worthy of the 'hall-mark.'

4. Enfleurage Essences.—The great bulk of the fine quality perfumes are procured by extracting the fragrance from the enfleurage-made pomades and oils, by contact of fine alcohol with the grease or oil. The pomade is chopped up very fine and put into the spirit, and allowed to remain together for one month at a summer heat.

Supposing the finest, or No. 24, pomade or oil is used, the standard strength of these essences should be: for one gallon spirit rectified 60° over proof, of rose pomade or oil, 8 lbs.; of acacia, 6 lbs.; of orange-flower, 8 lbs.; of jasmin, tuberose, violet, jonquil, 7 lbs.

If oils be used, the spirit and oil require to be well shaken together daily, because the oils, by their greater specific gravity, sink out of contact with the spirit. By continual agitation, the oils will not require many hours to part with their fragrance, in consequence of the mechanical subdivision which they are capable of, and hence are more intimately blended for the time with the spirit.

In this way are obtained essences of tuberose, orange-flowers, violet, jonquil, rose, acacia, and jasmin. What are called 'bouquets' and 'nosegays' are mere mixtures of the above primitive odours. A few examples we now give:—

Her Majesty's Perfume.

Enfleurage rose.	1 pint.	Enfleurage tuberose	½ pint.
,, violet	1 ,,	Tincture orris.	¼ ,,
,, orange	½ ,,	,, vanilla	¼ ,,

Albion Nosegay.

Essence of rose.	1 pint.	Tincture musk	⅛ pint.
Enfleurage rose	1 ,,	,, castor	⅛ ,,
Tincture orris.	½ ,,	Essence of bergamot	¾ ounce.
,, vanilla	¼ ,,		

White Roses.

Enfleurage rose	1 pint.	Enfleurage jasmin.	¼ pint.
Essence of rose	1 ,,	Essence patchouli.	⅛ ,,
Enfleurage acacia	½ ,,		

Excelsior Perfume.

Enfleurage acacia	1 pint.	Tincture vanilla	$\frac{1}{2}$ pint.
„ orange	1 „	„ civet	$\frac{1}{4}$ „
„ jasmin	1 „	Oil of almonds	$\frac{1}{2}$ drachm.
Essence of rose	1 „		

Frangipanni's Scent.

Enfleurage violet	1 quart.	Tincture tonquin-beans	$\frac{1}{2}$ pint.
Tincture of orris	1 „	„ musk	$\frac{1}{4}$ „
„ vanilla	1 pint.	Essence santal-wood	$\frac{1}{4}$ „
Essence neroli	1 „	Essential oil of cloves	$\frac{1}{3}$ drachm.

St. Valentine's Nosegay.

Enfleurage acacia	1 quart.	Tincture balsam of Peru	$\frac{1}{4}$ pint.
„ jasmin	1 pint.	Essence, citron zeste	1 ounce.
„ jonquil	1 „	„ orange zeste	$\frac{1}{2}$ „
Spirit of rose	1 „		

Every perfumer has some special formula, so that scarcely two houses work exactly the same mixture; although the *predominating* essences may be recognised which gives each particular perfume some speciality, as the bergamot does in the Albion nosegay, and the patchouli does in the white roses of the above.

Hungary Water and *Eau de Cologne.*

These preparations have long possessed great celebrity, in consequence, chiefly, of the numerous virtues ascribed to them. They are resorted to by many votaries of fashion as a panacea against ailments of every kind. They are, however, nothing more than aromatised alcohol, and as such are agreeable companions to the toilet.

Eau de Cologne derives its name from the city of Cologne, on the Rhine, at which place there are annually manufactured about 4,000,000 bottles. Hungary water is said to take its name from one of the queens of Hungary, who is reported to have derived great benefit from a bath containing it, at the age of 75 years. This preparation contains rosemary, which is said to excite the mind to vigorous action.

As will be seen by the following recipes, these waters are similarly constituted and prepared:—

Eau de Cologne—best quality.

Rectified alcohol, 60° over proof	10 gallons.	Essential oil of rosemary	3 ounces.
Oil of neroli of orange	7 ounces.	„ orange zeste	16 „
		„ bergamot	3 „

Eau de Cologne—second quality.

Alcohol, 50° over proof	10 gallons.	Oil of lemon	5 ounces.
Oil of petit-grain orange	5 ounces.	„ bergamot	5 „
„ rosemary	4 „		

Hungary Water.

Rectified alcohol, 60° over proof	10 gallons.	Oil of rosemary	6 ounces.
Oil of neroli of lemon	15 ounces.	„ citron zeste	3 „
„ petit-grain of orange	5 „	„ neroli of orange	2 „

Very fine Eau de Cologne and Hungary water can be made by merely mixing the ingredients as indicated in the recipes; but it is far better to mix the citrine essences with the spirit, and then to distil the mixture, finally adding to the distillate the orange neroli and the rosemary.

Both these perfumes are preferred when made with grape-spirit, in lieu of corn-spirit. When, however, corn-alcohol can only be used, its fragrance is greatly improved by the addition of one drachm of acetic ether to every gallon of spirit employed.

(E.) Powders.

Inodorous powders, such as starch and talc, are rendered fragrant—

1. By mixing with them odorous flowers, such as orange-blossom, violet, broken

cloves, acacia-buds, &c, allowing them to remain together for 24 to 48 hours, then sifting away the powder from the spent flowers.

2. By the addition of certain ottos, such as rose, lavender, &c., first rubbing a small portion of starch or talc in a mortar with the otto, then mixing this strongly-scented portion with the remainder, by sifting the whole well together in a trough.

In this way is prepared

Rose-Scented Toilet-Powder.

Wheat-starch	14 lbs.
Rose-pink	1 ounce.
Otto of rose	¼ „

The rose-pink and the otto of rose are rubbed well with about 8 ounces of starch, and finally sifted with the remainder as above described.

3. By reducing some fragrant substance, such as cinnamon, nutmeg, or orris-root, to a fine powder, and mixing them with a given proportion of the inodorous starch. The violet-powder of commerce is a good example:—

Infants' Violet-Powder.

Starch of wheat	14 lbs.	Ess. oil of bergamot	½ ounce.
Orris-root powder	3 „	„ almond	¼ drachm.

Sachée Powders

consist entirely of odorous substances reduced to powder, mixed and sifted in various proportions.

Rose-Sachée Powder

consists of

Rose-leaves, ground	1 lb.	Cedar-wood dust	½ lb.
Santal-wood powder	½ „	Otto of rose	1 drachm.

After certain tinctures are made, there is found in the perfume-laboratory a vast quantity of residue, or spent material, such as musk-pods, vanilla, tonquin-beans, ambergris, civet, &c. These spent materials, although not strong enough to yield any perfume to spirit, are yet fragrant, and may be judiciously used in combination with a little otto to produce a good sachée, such as

Olla Podrida,

which consists entirely of spent materials well ground together, and a little otto rose and lavender rubbed in to increase and sweeten its odour.

Frangipanni Sachée.

Orris-root	1 lb.	Grain musk	1 drachm.
Rose-leaves	1 „	Civet	¼ „
Santal-wood	½ „	Otto rose	½ „
Tonquin-beans, ground	½ „		

The civet, the musk, and otto of rose, are to be rubbed well with a little of the orris, and then mixed with the other ingredients; it being understood that all the materials, rose-leaves, orris-root, and santal-wood, have been previously reduced to powder.

Some odorous materials are sold pure, such as patchouli herb, which is merely the leaves of the plant rubbed on a sieve to powder. Santal-wood and orris-root have to be reduced to powder at the drug-grinder's mill.

(F.) Scented Soaps.

Soaps are perfumed by two methods:—

1. By melting the soap in a hot water- or steam-bath, and then adding the scent when the soap is perfectly soft; various kinds and qualities of soap are used for this purpose.

Curd or tallow soap, palm-oil soap, cocoa-nut-oil or marine soap, olive-oil soap, yellow or rosin soap, potash (soft) soap. See Soap.

When mixed in different proportions, and melted and scented, they bear various fanciful names given to them by the makers, and in some instances indicating their perfume; such as almond and rose soap. No one soap made by the soap-makers appears to give entire satisfaction to the consumer: soaps of oil do not lather sufficiently, or with freedom enough; tallow soaps are too hard; rosin or yellow soap has an unpleasant odour; cocoa-nut soap, being too alkaline, acts upon the skin. The perfumers, therefore, to make a good body soap mix these in various proportions. Thus Piesse and Lubin prepare

Windsor-Castle Soap.

Curd soap	1 cwt.	Grain musk	½ ounce.
Marine soap	21 lbs.	Oil of cloves	of each 3 ounces.
Olive-oil soap	14 „	„ rosemary	
Pale yellow soap	7 „	„ thyme	
Otto carraway	8 ounces.	„ cassia	

The soap is sliced into thin slabs, and put into the steam-pan in proportions of what is termed 'a round,' that is, the slabs are placed perpendicularly all round the side of the pans, so as to be in contact with the metal. In about half an hour this soap will have melted, or 'run down.' Another round is then introduced, and so continued every half-hour, till the whole melting is finished.

The different soaps that are being melted must be put into the pan separately, because they do not all take the same time to liquefy: thus, we must have a round of curd, then a round of marine, then of curd again, varying each time or half-hour; but each round must be of the same sort; the mixture being rendered perfect by stirring the soap with a crutch, or tool like an inverted ⊥, with a long handle. When the melting is finished, the ottos and musk are added; then the soap is turned out into a cooling-frame.

The musk, before being put into the soap, has to be well rubbed in a mortar with a little water, and then passed through a sieve to remove extraneous matters. When new this soap has little fragrance, but when old its 'bouquet' is delightful: the alkaline reaction of soap improves the perfume of the musk.

Brown Windsor Soap

is made of various qualities, generally inferior; the brown colouring added to the soap disguising its *yellow* origin. The scents used for perfuming it are also generally of a common quality, although there are some honourable exceptions.

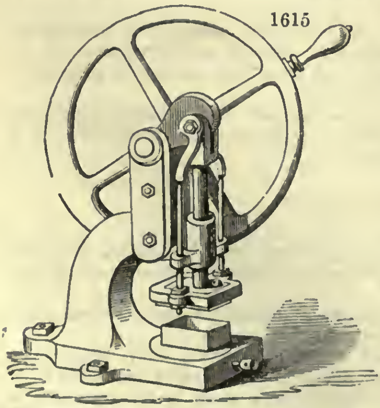
Glycerine Soap.

In consequence of the many virtues attributed to glycerine in a pure state, various soaps under the *name* of Glycerine Soap have been foisted upon the public. It is known to chemists that glycerine is one of the proximate elements of fatty bodies, and that during the saponification of grease it is eliminated as an educt. The better the soap, as a rule, the freer from glycerine. The presence of glycerine in soap is indicative that the soap is imperfectly made. To add glycerine to good soap is, in fact, to spoil the virtues of both articles.

Almond Soap

is made with a mixture of soaps such as is given above; and, when melted, is perfumed with 1 lb. of otto of almonds to every cwt. of soap used. Other fancy soaps are prepared in a similar way; the proportion of perfume regulating the retail price, or *vice versâ.*

1615



2. Soaps are also perfumed by the 'cold process,' as it is termed; that is, the soap is reduced to a state of fine division by shaving it up into a mortar, by putting the bars over an inverted cutting-plane. The best curd soap is generally selected for this purpose. After the soap is reduced to shavings, the scent is well incorporated, and then thoroughly beaten together with a heavy pestle. The soap is then moulded by the hand into lumps of about 4 ounces each, placed on racks to dry for a few days; when sufficiently firm, each lump is placed in the die-press or stamp (see *fig.* 1615) to give it the desired form and lettering. In this way are made all the finest scented soaps, of which we now give a few illustrations:—

Orange-Flower Soap.

Curd soap	7 lbs.	Essential oil of orange	2 oz.
Oil of neroli	2 oz.	Petit grain	½ oz.

Thibet-Musk Soap.

Grained musk	3 drachms.
Curd soap	7 lbs.

The musk is to be powdered with a little starch and sifted through lawn—a work of no little labour—before it is mixed with the soap. The alkaline reaction of soap is favourable to the development of the musk fragrance. It requires, however, fully three months to bring this soap to perfection, and the older it is the better.

Patchouli Soap.

Curd soap	7 lbs.
Essence of patchouli	1 oz.
Bergamot	2 oz.

Otto Rose Soap.

Curd soap (previously coloured with vermilion)	7 lbs.
Otto rose	1 oz.
Indian geranium	½ oz.
" santal	½ oz.

(G.) Cosmetics, or Toilet Appendages.

These are rather a numerous class of substances used to 'make up' artificial beauty and the deficiencies of natural imperfections. Whether this be strictly moral or otherwise is not our business to inquire. The practice is, however, sanctioned by its antiquity; and it is in the laboratory of the perfumer those things are made, which, as an old author upon the subject says, 'Can brighten the skin, give force to beauty, and take off the appearance of old age and decay.' There are preparations 'To prevent wrinkles;' 'To make the skin smooth, soft, and glossy;' 'To remove moulds, warts, and longing marks;' 'To improve the complexion, prevent freckles, blotches, and to whiten a tanned or sun-burnt skin;' 'To brighten the eye and increase the memory;' and numerous others, which our limits prevent detailing. We subjoin a few recipes, as examples:—

Milk of Pistachio Nuts, for improving the Complexion.

Spanish Pistachio nuts	4 ounces.
Violet-water	3¼ pints.
Spirit of neroli	¾ pint.
Palm soap, Green oil, Wax and spermaceti, each	1 ounce.

Dr. Startin, of Saville-row, gives the following recipe as 'an excellent cosmetic':—

Glycerine Lotion.

Orange-flower water	1 pint.
Pure glycerine	1 oz.
Biborate of soda (borax)	1 drachm.

Glycerine Jelly,

which is much approved of in winter seasons as a remedy for chapped hands, and for a dry skin, is made thus:—

Pure glycerine	2 oz.
White soft soap	½ oz.
Almond oil	1 lb.
Scented with otto thyme, otto cloves, and bergamot, each	½ drachm.

The soap and the glycerine are first perfectly blended, then the oil is gradually added, mixing the whole by constant trituration in a mortar; finally, the perfume is added.

Cold Cream of Roses.

This is justly a favourite and universal cosmetic.

Almond oil	1 lb.
Provence rose-water	1 lb.
White wax and spermaceti, each	1 oz.
Otto of roses	½ drachm.

Melt the wax and sperm in the oil, then gradually stir the running rose-water; when nearly finished add the scent.

(H.) Dentifrices, Pastes, &c.

Under the general title of Dentifrices, various scented tooth-powders, mouth-washes, tooth-pastes, breath-lozenges, are included in the perfumer's repertory.

Piesse and Lubin's Tooth-Powder.

Precipitated chalk	1 lb.
Orris-powder	1 lb.
Carmine	½ drachm.
Very fine powdered sugar	¼ lb.
Otto rose and neroli, each	1 drachm.

Opiate Tooth-Paste.

Honey	½ lb.
Precipitated chalk	½ lb.
Orris-powder	½ lb.
Tincture of opium and myrrh, each	¼ oz.
Essence, cloves, nutmeg, and rose, each	½ drachm.

(I.) Fumigating Perfumes.

The earliest records of 'sweet savours' show us that sweet smells were produced from throwing volatile and odorous resins on to a smouldering fire; and so much were they prized that they were considered worthy offerings to the Most High. The formula for incense for holy places is given in Exodus xxx. 34. The following is a pleasing incense:—

Santal wood in powder	1 lb.	Gum benzoin powder	½ lb.
Vitivert in powder	1 oz.	Grain musk	½ oz.
Cascarilla bark	½ lb.	Powdered nitre	2½ oz.

Ribbon of Bruges, for sweet fumigation.

Make a solution of saltpetre, *i.e.* nitrate of potassa, of 2 ounces to a pint of water; into this steep good undressed cotton tape, then hang up to dry; now steep it in the following tincture which has stood one month:—

Spirit	½ pint.	Myrrh	½ oz.
Musk	½ oz.	Orris	½ pin
Otto rose	1 drachm.	Benzoin	4 oz.

When dry it is fit for use; light it, blow out the flame, and as it smoulders, a fragrant vapour will rise into the air.

(K.) Fluids, Pomades.

Unguents for the hair are prepared in endless variety. The following are good examples:—

Philocome.

Enfleurage oil of any or mixed flowers	1 lb.
Virgin wax	3 oz. in summer;

or, in winter, one-third less.

Crystallised Oil.

Enfleurage oil of any flower	1 lb.
Spermaceti	2 oz.

Cool gradually.

Hungarian Pomade.

(*Pour moustache à la Crinoline.*)

White wax	1 lb.	Rose-water	1 pint.
Oil soap	½ lb.	Bergamot	1 oz.
Gum arabic	½ lb.	Thyme	1 drachm.

Hair-washes are for cleaning the head, and removing effete pomade.

Spirit	1 pint.
Marine soap	1 lb.

Melt the soap in the spirit in a bath, then add rose- or orange-water, ½ pint.

Athenian Hair-wash.

Rosemary-water	1 gallon.
Sassafras chips	$\frac{1}{4}$ lb.
Pearlash	2 oz.

Boil for half an hour; when cold, add spirit or Hungary-water, 1 pint.

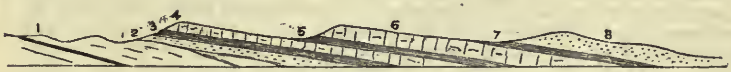
(L.) Several other products of the perfumer's laboratory, such as hair-dyes, fixateur, depilatory, court plaster, &c.; but these cannot be well taught by books.—S. P.

PERFUMERY, INDIAN. The natives place on the floor a layer of the scented flowers, about 4 inches thick and 2 feet square; cover them with a layer 2 inches thick of *Tel* or Sesamum-seed wetted; then lay on another 4-inch bed of flowers, and cover this pile with a sheet, which is pressed down by weights round the edges. After remaining in this state for 18 hours, the flowers are removed and replaced by a similar fresh layer, and the seeds are treated as before; a process which is repeated several times if a very rich perfumed oil be required. The sesamum-seeds thus embued with the essential oil of the plant, whether jasmine, bela, or chumbul, are placed in their swollen state in a press, and subjected to strong pressure, whereby they give out their bland oil strongly impregnated with the aroma of the particular flower employed. The oil is kept in prepared skins called *dubbers*, and is largely used by the Indian women. Attar of roses is extensively produced at Ghazepore, and is obtained by distillation.

PERIDOT. A jeweller's name for the transparent green chrysolite (olivine), cut as an ornamental stone. See CHRYSOLITE.

PERMIAN. The Permian rocks were so called by Sir Roderick Murchison, from the Government of Perm, in European Russia, where these rocks are largely developed. They had previously been termed the Lower New Red series. As, how-

1616



1. Coal-measures.

Permian rocks {
2. Red and variegated sandstone and conglomerates.
3. Marly shale, 'marl slate.'
4. Magnesian limestone, often sandy.
5. Red marl.
6. Thin bedded magnesian limestone.
7. Red marl.
}

8. New Red Sandstone.

ever, these strata have nothing in common with the New Red Sandstone, except occasionally colour, and as the magnesian limestone is often absent, the word 'Permian' now generally supersedes the older denomination. The Permian rocks form the uppermost member of the Palæozoic strata, lying, when the series is complete, on the Upper Coal Measures. They skirt the carboniferous rocks on the east uncomformably, from Nottinghamshire to the river Tyne; and where complete the section is as in *fig.* 1616, in Nottinghamshire and South Lancashire.

The sandstone, 2, contains plant remains, and the limestones, productas, spirifers, nautili, and other marine shells of Palæozoic types. It is from the Lower Limestone that the stone for building the Houses of Parliament was obtained. It forms frequently an excellent building stone, and may be obtained in places in blocks of great size. It is also extensively burned for lime.

Permian strata, believed to belong to the sandstone beds, No. 2, surround more or less the Lancashire, North and South Staffordshire, the Warwickshire, and the Shropshire coal-fields, &c. They are in places 1,000 feet thick, and consist chiefly of red marls, sandstones, and conglomerates. The Magnesian Limestone is generally absent in these districts; but thin bands of it occur in Lancashire, and in parts of Cumberland.

There are *magnesian limestones* in other formations, not to be confounded with those of Permian age.—A. C. R.

PERNAMBUCO WOOD. See BRAZIL WOOD.

PERRY is the fermented juice of pears, prepared in exactly the same way as CYDER.

PERSIAN BERRIES. See BERRIES, PERSIAN.

PERUVIAN BARK, or *Jesuits' Bark.* The products of several species of the *Cinchona.* For a knowledge of the medicinal properties of the Peruvian bark, and its value in curing intermittent fever, we are indebted to the Jesuit priests, who introduced it to Europe in 1632; but it was not commonly used till the latter part of the seventeenth century. The disulphate of quinine is largely prepared from this bark, of which we imported in 1873 as follows:—

	Quantity Cwts.	Value £
From France	1,110	7,845
„ Central America	1,228	12,280
„ New Granada	11,843	106,617
„ Ecuador	4,668	44,597
„ Peru	5,829	74,643
„ Chili	1,782	23,453
„ Brazil	146	1,387
„ Other countries	1,845	14,798
Total	28,451	285,620

Of which we re-exported 11,424 cwts. to the value of 71,304*l.*

PETALITE, from *πέταλον, a leaf.* The mineral in which lithia was first discovered by Arfvedson. Petalite occurs in the iron mine of Utö, Stockholm; near York, on the north coast of Lake Ontario; at Bolton, Mass., U.S.; and at Elba. Its composition is, according to Rammelsberg:—silica, 77·79; alumina, 18·58; lithia, 3·30; soda, 1·19 = 100·86.

PETROLEUM. (*Pétrole*, Fr.; *Steinöl*, Ger.) This term is applied to several fluid bituminous substances, found in a great number of different localities, in rocks of very dissimilar ages, and which were formerly known as Persian naphtha, or rock-naphtha. (See NAPHTHA.) As it, however, forms only one of a numerous class of analogous compounds, it will be convenient to take a general view of the whole class of bituminous minerals occurring in nature. Starting with the liquid compounds, which, as a rule are, in composition isomeric with olefiant gas, and may be represented by the formula C_nH_n, the diminution of hydrogen is accompanied by an increase of density, until we reach the more bituminous varieties of coal. The following table, by Dr. Sterry Hunt, represents the intermediate steps of this series; the analyses are computed with 24 equivalents of carbon, in order to compare them with cellulose, $C^{24} H^{20} O^{20}$:—

Liquid bitumens; general composition	$C^{24} H^{24}$.
„ „ Rangoon petroleum	$C^{24} H^{28}$.
Elastic bitumen or Elaterite; Derbyshire	$C^{24} H^{22} O^{0.3}$
Asphalt, Bastennes	$C^{24} H^{16} O^{0.7}$
„ Naples	$C^{24} H^{15} O^{2}$.
„ Mexico	$C^{24} H^{17} O^{2}$.
Idrialine	$C^{24} H^{8}$.
Albertite or Albert coal; New Brunswick	$C^{25} H^{16} O^{2}$.
Bituminous or resinous lignite	$C^{24} H^{15} O^{3}$.
Bituminous coal, extremes of composition	$\begin{cases} C^{24} H^{8} O. \\ C^{24} H^{10} O^{4}. \end{cases}$

From the above table, it will be seen that certain bitumens, such as Idrialine, differ but slightly in composition from bituminous coals, and in reality it is very difficult to draw a decided line between them. The questions as to whether certain Scotch cannel coals and the Albert coal of New Brunswick, are to be considered as coal or not, have been discussed at great lengths before courts of law, without leading to any satisfactory definition. Roughly speaking, the characters of fusibility and solubility in benzole and sulphide of carbon are to be relied on as distinguishing the solid bitumens from coals.

According to Boussingault, asphalt is a dark brown or pitchy-black substance, fusible at the temperature of boiling water. At lower temperatures, when perfectly solid, it breaks with a well-marked conchoïdal fracture. Hardness, 2; specific gravity 1·1 to 1·2. It becomes negatively electric by friction, giving out a strong and characteristic bituminous odour. When asphalt is treated with anhydrous alcohol, about 5 per cent. of a resin is extracted, which is called by Boussingault *Petrolete.* From the remaining 95 per cent. insoluble in alcohol, ether dissolves 70 per cent. of a black resin, giving a brown solution. The whole of the remaining 25 per cent. is soluble in rock-naphtha or ethereal oils, and has been termed *Asphaltene.* Its percentage composition is: carbon, 75·5; hydrogen, 9·9; and oxygen, 14·8 or approximately of the atomic formula, $C^{25} H^{20} O^{4}$, which, according to the preceding table, is intermediate between asphalt and elaterite.

Among the more important localities of bituminous matters, are the following:—Sandstones and limestones filled with asphalt, in greater or less abundance, of the age of the Molasse, or Middle Tertiary period, are found at Seyssel, in the French department of the Rhine; also in the Val de Travers, in Neocomian limestone. The bituminous sand of Bechelsbronn, in Alsace, which is of tertiary age, is about 7 feet thick, containing 2 per cent. of bitumen. Similar sands are found at Soultz-sous-Fôrets, and Schwabsweilier, in the same country. At Lobsann, also, in Alsace, Daubrée has described a freshwater tertiary limestone, which contains 10, 12, and even at times 18 per cent. of bitumen. Similar deposits exist in Otago, N.Z. Bitumen also occurs in sandstone in the Auvergne, in Central France.

Bitumen is occasionally found in mineral veins, as, for instance, at Dannemora and Filipstad, in Sweden, accompanying magnetite, and in the carboniferous limestone at Staunton Harold, in Leicestershire, in small veins associated with galena, copper-, and iron-pyrites. It also occurs in brown iron ores, at Markolden and Markoldendorf, near Hildesheim; and at Elligsér Brink, in Brunswick. An analogous mode of occurrence is furnished by *Hatchettine*, or mineral tallow, a beautiful pearly-white substance, almost identical with paraffin, which is found in the interior of nodules of clay-ironstone in the neighbourhood of Merthyr Tydfil. *Ozokerite* is a similar substance, of a darker colour, found in sandstones both in Scotland and in Galicia and Moldavia. *Idrialine* is remarkable as being a hydrocarbon, containing a minimum amount of hydrogen: it occurs in a bituminous schist, which contains cinnabar, at the great quicksilver mine of Idria, in Carniola. A remarkable substance, forming apparently a link between lignite and asphalt, has been described by Delesse. It is a brownish-black rock, of a very compact texture, found at Promina, in Austria, containing 59 per cent. of crystalline carbonate of lime, 9 per cent. of argillaceous matter, and 32 per cent. of a combustible substance, which is fusible but almost totally insoluble in benzine. When heated it gives off acid vapours, leaving only 3½ per cent. of coke. See Asphalt; Bitumen; Ozokerite.

The so-called *Pyropissite* of Kengott is another mineral intermediate in character between lignite and bitumen. It is a dark yellowish-grey, or brown, earthy, and friable substance, with a shining streak, of the specific gravity 0·9. When heated it gives off a dense white smoke, and melts to a pitchy mass. A waxy substance of a very complex composition may be extracted from it by digestion in ether, and Marchand obtained 62 per cent. of paraffin from the natural mineral by dry distillation. The principal localities are Gerstewitz near Weissenfels, and Helbra in Thuringia, where it forms a layer of 3½ feet in thickness, immediately above a seam of brown coal.

Dysodil is another bituminous mineral associated with brown coal, but this term appears to be applied to two different substances: one being an infusorial earth saturated with mineral tallow, found near Giessen, in Hesse-Darmstadt, while on the lower Rhine the term is applied to a lamellar brown coal. See Dysodil.

Turba, a very light material, greyish or brownish in colour and felty in texture, which ignites readily with a dense smoky flame, leaving the mass of the same dimensions as before, occurs in abundance at Camamú, province of Bahia, Brazil. Hartt (Hartt's 'Scientific Results of Agassiz's Journey to Brazil,' p. 262) states that it rests in a basin of gneiss whence the tertiary clays have been swept away; hence it appears to be of recent origin. In a section of 108 feet the turba intermingles with a series of arenaceous and argillaceous sandstones, alternating with bituminous clay, lignite, shale, and sometimes pure bitumen; it usually rests on limestone, a conjunction peculiar to petroleum and shales. Prof. Edwards considers the turba not a sub-aqueous deposit, as it contains no diatoms, and its enclosed fossils are wood, a few leaves, and fibres like fine roots. It has yielded from 50 to 100 gallons of oil per ton on distillation.

The Rev. Mr. Clarke of Sydney, N. S. W. ('Journ. Geol. Society,' vol. xxii. p. 447), speaks of the *Bournda deposit* near Cape Howe being probably of recent origin. Like the Brazilian deposit just described, this also consists of a series of clays and blackish mud, alternating with lignite. It, too, has been formed in a lake near the sea-beach. A white waxy substance like bog butter was found to the north of this last-described deposit some years ago. It yielded on distillation 8·6 per cent. of crude oil, which again yielded on subsequent distillations 35 per cent. of burning oil, lubricating oil, and paraffin.

Large deposits of petroleum and its associated minerals have been discovered along the course of the chalk of North Germany, at its junctions with the sands which cap it. Indications have been seen near Hamburg, Hesse-Darmstadt, Ruttsdam, and other places. On the banks of the Rhine a bed of *Albertite* is being worked for oil-making; it is said to yield 120 gallons to the ton in laboratory experiments. Principal Dawson now relegates Albertite from the class of gas-coals into that of the petroleums. (See 'Acadia,' 2nd ed.) See also Albertite.

Springs of mineral oil, or liquid petroleum, are found in almost all localities where bitumen or asphalt exists in quantity in the rocks; many of these localities have been known from time immemorial: such as, for instance, the Rangoon wells, and those of

Persia and the Caspian Sea. It is only within the last few years, however, that the largest source of supply in the north-eastern states of America and Canada have been developed, although the existence of petroleum in Pennsylvania (where it was collected and sold by the Seneca Indians, under the name of Seneca oil) has been known for a very long period. Many different bituminous formations are known at different horizons in the palæozoic rocks of America; in the Silurian series traces of the former existence of bitumen are afforded by the occurrence of shining anthracitic substances in cracks and fissures in the Quebec group, and its equivalent, the Calciferous sand-rock, at several localities in Eastern Canada and the State of New York. In the Trenton limestone, liquid petroleum is found in the chambers of the larger orthoceratites, some of these fossils containing at times several ounces of oil; and a spring yielding small quantities rises from the Utica slate on Great Manitoulin Island, on Lake Huron. A more important but as yet scarcely developed locality, probably at the top of the Silurian series, is in the peninsula of Gaspé, in the easternmost part of Canada. It is, however, from the Devonian rocks that the greatest quantities of petroleum are derived in America. At Oil Springs and Enniskillen, near Sarnia, Canada West, natural oil-springs occur upon the outcrop of the Corniferous limestone, or the overlying Hamilton shale, along the line of a broad and low anticlinal traversing the district in a nearly east-and-west line, both formations being generally covered by from forty to sixty feet of drift and alluvial clays and sands. At the Wyoming Company's wells, the overflow of the natural springs, rising through the superficial beds, have produced deposits of hardened and slightly elastic bitumen or asphalt, which are locally known as 'gum-beds.' They are somewhat irregular in thickness, varying from a few inches to two feet, and cover an area of about two acres. According to Delesse, this substance fuses at 180° Fahr. and contains 62½ per cent. of bitumen, soluble in benzole; 24·8 per cent. of organic matter, the remains of plants which have grown upon the present surface, and have become imbedded in the 'gum'; and 12·7 per cent. of clay and sand. The occurrence of these beds is instructive, as showing how bituminous rocks may be formed by the gradual drying-up and oxidation of liquid petroleum. When wells are sunk in the overlying clays and sands, there is usually found, at the junction with the shales, a bed of coarse gravel holding large quantities of oil of a treacly consistency and dark colour. This is the oil of the surface-wells, so called from their being situated entirely in superficial deposits, as distinguished from the rock-wells, which are bored into the Hamilton shales and Corniferous limestone strata below. It has a very offensive smell, but is actually of greater value than the more limpid product of the rock-wells, being sold without any further preparation as a lubricating medium for the axles of railway-carriages. The rock-wells are of two characters, namely, 'pumping' and 'flowing:' the former being mostly intermittent in their discharge, and requiring the aid of machinery to bring their contents to the surface, while in the latter the oil rises, like water in a true artesian well, above the level of the surface; the free discharge being, however, due not to hydrostatic pressure so much as to the elastic force of light carburetted hydrogen gas, which is almost always present in oil-wells. Unlike wells sunk for water, the gathering-ground of an oil-well is extremely local, being probably confined to a lenticular belt of porous rock in its immediate neighbourhood; and when this is exhausted, the supply fails: and unless the hole be bored deeper, on the chance of striking another vein in depth, it is abandoned for a fresh locality. The first great flowing-well at Enniskillen yielded 1,500 barrels when first struck, the greater part of which, for want of sufficient collecting vats, overflowed into the valley of the neighbouring brook, and was lost; but in a short time it was exhausted. The best wells in this locality, in July 1865, yielded about 100 barrels, or 4,000 gallons each, daily; but only five were in this category, the greater number not exceeding 10 or 20 barrels. The Wyoming Company's wells, 9 in number, sunk on the gum-beds, yielded from 5 to 6 barrels each, per day, at the same period. It was computed that the working expenses of a well, pumped by steam-power, could be covered by a yield of a single barrel daily. The conditions under which petroleum occurs in Pennsylvania, are somewhat similar to those observed in Canada, but on a somewhat higher geological horizon; the chief oil-bearing rocks being the sandstones, limestones, and slates, overlying the Hamilton and Genesee groups. The deepest wells in Oil Creek, the principal Pennsylvanian locality, are supposed to be in the Portage, while the shallower ones are in the Chemung group, both members of the Upper Devonian series. At the commencement of the year 1865, in the district of Oil Creek, Pennsylvania, 480 wells were already sunk, and 542 more were in progress of sinking, within an area of 5 square miles. Of these, 189 produced oil, the total estimated yield being 4,000 barrels, or 160,000 gallons daily. Some of the earlier wells, sunk in the year 1861, at first yielded from 600 to 3,000 and 4,000 barrels each, daily, but in no instance have these great yields been kept up for more than a few months: the maximum yield at the date alluded to appears to have been about 325 barrels. The MacKinley well, in the same locality, is noticeable on account of its uniformity of yield, amounting to between 50 and 60 barrels per diem, which production has been steadily maintained without pumping for nearly 3 years.

The uppermost Devonian or Catskill group has as yet given rise to no wells of any importance. The subcarboniferous or mountain limestone, and the lower carboniferous rocks of the United States are devoid of petroleum; but in England, traces of the presence of bitumen are found in the mountain limestone in Shropshire, at Castleton in Derbyshire, and at Staunton Harold in Leicestershire. In the lower coal-measures, oil-wells are found in Ohio and Virginia, and also in the upper coal-measures at Marietta, in the former state. A spring of actual petroleum was discovered some years ago in the coal-measures at Alfreton in Derbyshire; and while the supply lasted, it was employed in the manufacture of paraffin and lubricating oils.

In the secondary rocks, solid and liquid bitumen occur at many different points, but not in the extraordinary quantities that characterise the palæozoic rocks of America; among other localities may be mentioned Deestadt and Sickle, in Brunswick, where it occurs in the lias shales; and Edimissen and Odensee, in Hanover, where springs of petroleum rise from the middle beds of the Wealden series, which are also coal-bearing. In England, the lias jet-rock of Whitby, and the Kimmeridge shale of Dorsetshire, are examples of bituminous rocks belonging to the secondary period. The petroleum of California is derived from rocks of cretaceous, or perhaps tertiary age.

One of the most interesting of the tertiary petroleum districts is that of Galicia, on the northern slope of the Carpathians. This, according to Von Hochstetter, extends N.W.—S.E. for about 200 miles, along a line of fractures parallel to the main chain of mountains, through which fractures petroleum rises on account of the gaseous pressure below, and saturates the overlying brecciated rocks and sandstones, which are of eocene age. The wells actually sunk are square shafts, which often pass through a peculiar breccia of fragments of bituminous shale, angular pieces of asphalt, quartz grains, and flakes of mica, cemented by calc-spar. The rock generally is a sandy shale. In one of these wells, at 2 fathoms deep, the cracks of the rock were found to be filled with a white bitumen like Hatchettine, and in the third fathom petroleum appeared in drops, which filtered through the walls, and collected at the bottom of the shaft. The oil is so full of paraffin, that it is only when a certain quantity of water issues with it out of the rock, that any quantity is collected. Samples collected from five different localities varied in specific gravity from 0·803 to 0·920, the latter being surface-oils collected from a pool of water. The lighter varieties contain so much paraffin as to solidify at a temperature of 50° F. The relation between the West Galician oil, rising from eocene rocks, to that of Eastern Galicia, which is obtained from miocene strata, is similar to that existing between the Pennsylvanian and Canadian oils—the latter in either case being dark in colour, and less fluid than the former. The Wallachian oil is also dark coloured, and is associated with ozokerite or paraffin, in a similar manner to that of Galicia. Another and better-known deposit of petroleum in tertiary strata is that in the Island of Trinidad, which has been described at considerable length by Mr. G. P. Wall, in his 'Report on the Geology of Trinidad.'

The methods employed in America for boring oil-wells are usually of a very simple character, and do not differ very much from those used in this country for trial-borings in the coal-measures. As a rule, a rope is used for suspending the boring-bar, instead of rigid rods; the lower parts of the arrangement, known as the augur-bar and sinker-bar, weigh from 7 to 9 cwts., and are united by a simple gliding piece, called the 'jars,' which is, in fact, an application of the free-falling cutter used in deep borings in Europe. The detritus is removed by the shell- or sand-pump, in the ordinary way. A modification of Fauvelle's system, having hollow rods with a continuous discharge of the detritus, was at one time in use at Oil Springs, Canada West. The boring-bit has a hollow stem, the cutting edges being formed by three stout radiating pieces of steel. In the angle formed by these pieces, and their junction with the stem-brass, valves are inserted which allow the detritus to enter the rod through which it rises, and is discharged in jets at every fall of the cutter. The lifting of the borer is effected by toothed levers, similar to those of a safety-catch used in collieries, which fall together by their own weight, and take hold of the rod at the end of the stroke; and are released by tappets attached to the boring-frame or derrick, striking against their outer ends when the rod is at the top of its stroke. The boring is usually performed by steam-power, the upper end of the rope being secured to the outer arm of a vibrating or 'walking' beam, receiving motion by means of a strap and pulley from a small steam-engine of about 1 or 2 horse-power. When the boring is finished, the same arrangement is used to work the oil-pump. The use of the intermediate beam and driving-belt allows the boiler, which is usually of the common agricultural or portable form, to be kept at a safe distance from the stream of inflammable gas, accompanying the oil and water brought up. The mixed fluid lifted by the pump is received in large open vats, in which the separation takes place; the water being allowed to run off by a waste-pipe below, while the oil accumulates until a sufficient quantity has been collected for barrelling. The standard measure for petroleum is the barrel of 40 American or old wine-gallons, equal in weight to about 3 cwts.

From what has already been stated, it will be easily understood that petroleum varies considerably in composition and density, according to whether it be derived from shallow or deep wells, the former giving the darkest and heaviest products. The following are some of the chief properties of different American oils, according to Gesner:—Pennsylvanian petroleum is dark coloured, with a peculiar greenish lustre or fluorescence; by reflected light, the specific gravity varies from 0·782 to 0·820. When refined, the distillate yields from 75 to 85 per cent. of illuminating oil, giving off inflammable vapours at a temperature of from 110° to 116° F. The heavy oils produced in the distillation yield paraffin, or may be used for lubricating. The specific gravity of heavy natural or lubricating oil from Pennsylvania, is from 0·800 to 0·860.

Oil from Mecca, Ohio, which remains fluid at very low temperatures, has the specific gravity 0·890 to 0·910. The Canadian or Enniskillen petroleum is dark coloured, and has a peculiar and very offensive smell, but yields a larger quantity of burning oils than the Pennsylvanian; its specific gravity is from 0·860 to 0·880; that of the rectified burning-oil is 0·838. A sample of Californian petroleum, of the specific gravity 0·927, yielded the following products when refined:—

Illuminating oil	38 per cent.
Lubricating oil	48 ,, ,,
Pitch	10 ,, ,,
Water	4 ,, ,,

Another sample from California lost from 10 to 15 degrees by volume, yielding, on rectification:—

	Per cent.
Light oils	5
Burning oil	50
Light machine-oil	20
Heavy oil and paraffin	25

The bitumen of the gum-bed of Enniskillen yields 50 per cent. of volatile products by distillation; and the Rangoon tar contains about 10 or 11 per cent. of paraffin.

The refining of petroleum has already been noticed under NAPHTHA. The following is a sketch of the operation as performed at a small refinery at Oil Springs, Canada West. The crude oil, purchased from the proprietors of the wells, is stored in large underground tanks. For refining, wrought-iron stills are employed, having a capacity of 40 barrels, or 1,600 gallons; they are flat-bottomed, and are provided with man-holes, through which the black pitchy residue is removed. When the charge is introduced the still is closed, and the distillation is effected by a fire placed beneath. The charge takes about a week to work off; the distillate is collected in large wooden tubs, a small quantity of a thick greenish substance separating from it, which is returned to the still. The pitchy residue in the still is not subjected to any further treatment, but forms part of the fuel used in the next distillation. The liquid collected is mixed with from 5 to 10 per cent. of sulphuric acid, and agitated by rotatory paddles at a steam-heat, for the purpose of bleaching it. After this is done, the bleached oil is washed with water, the last faint traces of acid are neutralised with caustic potash, and it is finally deodorised with ammonia. When freshly prepared, the refined oil is without colour or smell; and when seen in large quantity, exhibits the extraordinary blue, or fluorescent rays of Professor Stokes in a striking manner. The loss in distillation is about 30 per cent.; the refined oil is packed in 40-gallon barrels made of oak, which, before they are used, are lined with an elastic cement resembling vulcanised india-rubber, the principal ingredients of which are glue and white lead, in order to prevent leakage through the joints of the staves.

The gigantic dimensions of the American petroleum trade may best be represented by the following statistics given in evidence, before a Select Committee of the House of Lords, in 1872:—

Exports from the United States during the years 1870 *and* 1871, *to London and several Continental ports, in gallons.*

	1870	1871
London	2,047,118	1,457,628
Bremen	10,162,399	12,356,572
Hamburg	4,456,226	5,780,459
Rotterdam	5,305,299	6,987,302
Königsberg and Stettin	2,665,677	5,600,978
Copenhagen	894,422	2,967,345
Genoa and Leghorn	2,515,926	3,109,142

The petroleum *Exports* of the United States for 1872 were as follow:—

During the year there had been exported 170,385,869 gallons; the most of it going to German ports. This, compared with 1871, is a decrease of over 5,000,000 of gallons; this decrease in a trade which naturally ought to increase being accounted for by the strenuous efforts which have been made to control the trade and prices by decreasing production at the wells. These efforts still continue, though they are looked upon as unsuccessful. The bulk of the export is made from New York and Philadelphia; the former having sent out 90,000,000, and the latter nearly 57,000,000 gallons during the year, leaving but 3 per cent. of the export for other ports. Philadelphia, compared with 1871, increased her export nearly 750,000 gallons; while that of New York was reduced nearly 5,000,000 of gallons. Owing to certain trade advantages in favour of Philadelphia, her export gradually increases at the expense of other ports. Year by year a larger portion of the petroleum shipped is refined oil; nearly 128,000,000 out of the 150,000,000 gallons sent in 1872 having been refined oil.

Total exports from United States to all parts of the world during the years—

	Gallons
1868	97,013,817
1869	100,780,158
1870	139,271,450
1871	154,877,377

The high prices of petroleum in Europe when first used as an illuminant, stimulated production to an extraordinary extent. This was also aided by the cheapness of manufacture; pumping, purification, and cooperage being very easy items. When Young's burning-oil sold retail at 3*s.* 6*d.* per gallon, and when 1*s.* 6*d.* was the lowest quotation looked on as possible, it was seriously doubted that the Americans could compete with British oil-makers at the lower figure. But several years' experience has shown how petroleum can be profitably exported at a price in Europe below this. In fact, the safest petroleum is now sold so low as to allow the working-man a light superior to gas at 1*d.* a night. Our statistics show how decrease in price has only stimulated activity in production. Notwithstanding the lull at the commencement of last season's trade, caused by a temporary combination amongst the well-owners, it heads the yield of all previous years. Though really coextensive with the area of the North American continent, petroleum is chiefly got in Pennsylvania, West Virginia, and Ohio, in the United States; as also in Western Canada. Its proximity to immense metallic deposits in many localities encourages the hope of its speedy use in metallurgy. Less than half of the crude material can be safely sold for lamps, but it would admirably answer this purpose. (See NAPHTHA, NATIVE.) Most of the refined material reaching Europe is obtained in county Venango in Pennsylvania, in the neighbourhood of Oil City, Titusville, Petroleum, Cherry Run, &c. There are now few or no flowing wells in the oil regions; but, owing to various circumstances, the oil-well owner can compete very favourably with the British mineral-oil maker. British crude shale-oil, in the most favourable circumstances, was manufactured at a prime cost of $3\frac{3}{4}$*d.* per gallon; now (1873) it costs nearly double. Pumping an oil-well should not cost more than $\frac{1}{2}$*d.* per gallon. The bore-holes which are made through the heavy honeycombed structure of the sandstones of Oil Creek, U.S., are from 3 to 4 inches in diameter, and frequently 500 or 600 feet deep, sometimes 800 feet deep. From many years' experience, the cost of sinking a bore-hole nearly 900 feet deep, and preparing everything to pump up the petroleum, is 4,000 to 5,000 dollars. Now in 1869 some of the best-yielding bore-holes gave much more than 250 to 300 barrels per day, but at the close of the year only one of these bore-holes continued yielding 200 barrels a day; whilst thirty were giving from 50 to 100 barrels per day. Assuming the Titusville standard of 43 gallons per barrel, it would cost 7,000*l.* sterling to fit up a shale-work giving the lowest yield; and the profits would be fractional compared with those of the oil-well. This competition has driven the crude-oil trade of Britain into the hands of large capitalists. But the oil-maker calculates on the gross profits of a large turn-over, and on his advantage over his Pennsylvanian competitor in having sulphate of ammonia, paraffin, and other ore-products. The enormous quantity of used petroleum-barrels in the British market is also a great source of profit.

As regards the origin of petroleum and analogous bituminous substances, there can be but little doubt that they are derived from the decomposition of organic matter in the rocks containing them. The changes forming part of the great series whereby organised structures, containing carbon, oxygen, and hydrogen, become altered into peat, lignite, coal, anthracite, and graphite, are too well known to be dwelt upon here at length; suffice it to say, that they consist in the abstraction of variable quantities of carbonic acid, water, and marsh-gas (C^2H^4). From the results of observations of the Geological Survey of Canada, Dr. Sterry Hunt, Mr. Wall, and others, it would appear that the separation of these hydrocarbons is the first stage of carbonaceous metamorphism, and that such substances when under favourable conditions—that is, when kept from the access of air, as in the cavities of limestones, or in sandstones or shales covered by impermeable beds—may be preserved intact; but when they are allowed to come to the surface (as, for instance, in rising through cracks and superficial gravels) oxidation takes place, the greater part of the hydrogen is removed, and ultimately asphalt and coaly substances are produced. That much of the petroleum of the older rocks may be derived from the decomposition of animal matter is evident by its presence in considerable amount in the cells of coral, in Corniferous limestone, which contains exclusively marine remains, and is not permeable to liquids from without. In peat and brown coal there is no difficulty in supposing that the decomposition of the plants has given rise to the various paraffin-like and other solid hydrocarbons which it contains. One particular class of these substances—namely, the resins, such as amber, retinite, &c.—may have existed in the tissues of the plants during their life, as they may all be paralleled with the gum-resins of living conifers. Perhaps the most remarkable among these bitumens is that called *Scheererite*, found in the brown coals of Uznach in Switzerland, and Eger in Bohemia; which, while resembling Hatchettine, has the composition of marsh-gas, showing the same relation to it that paraffin does to olefiant gas.

Another fact in support of the animal origin of some bitumens is that furnished by the bituminous odour evolved by nearly all very fossiliferous limestones, as, for instance, the Upper Silurian and Carboniferous limestones of England, which certainly contain no land-plants.

Another view, put forward by Dr. Senft, may be of use in explaining why in certain cases coals are produced and in others bituminous shales: it is, that the carbonaceous substance produced in peat-bogs has the power of absorbing and fixing carburetted and sulphuretted hydrogen. Now, supposing in a sea-bed the amount of decomposing organic matter, marine plants, molluscs, corals, &c., to be small as compared with the accompanying mineral matter (carbonate of lime, silica, clay, &c.), the hydrocarbons formed would be liable to escape, and remain isolated as petroleum. But, on the other hand, in the case of a great forest-growth or peat-bog decomposing under water, the hydrocarbons separated would be liable to be reabsorbed by the great excess of residual carbon present, and to be condensed, giving rise to bituminous coals. See NAPHTHA; PARAFFIN.

Petroleum Imports in 1873.

(For further information on this subject, consult Sterry Hunt's paper in 'American Journal of Science,' vol. xxxv. p. 158; *Senft, über Humus, Torf*, &c.; Gesner on 'Coal Oils'; and *Rammelsberg, Mineral-Chemie.*)

At the old rates of wages and coals, the crude oil yielded a moderate trade-profit in competition with petroleum; but this summer (1873) many British companies have considerably reduced their dividends. And the stability of our home trade will depend on increased economies in fuel, mining, and labour. On the other hand, the abundance of petroleum in America, and the ease with which it is obtained, will, unless new uses for the material are discovered, keep the trade only barely lucrative.

PE-TUN-TSE is the Chinese name for what is thought by geologists to be a partially-decomposed granite, used by them in the manufacture of their porcelain. It is analogous to our Cornish china-stone. See CHINA STONE; CLAY.

PETWORTH MARBLE. A shelly limestone, occurring in the Wealden strata, in the neighbourhood of Petworth, in Sussex. See SUSSEX MARBLE.—H. W. B.

PEWTER. (*Potier d'étain*, Fr.) Pewter is, generally speaking, an alloy of tin and lead, with a little antimony or copper, combined in several different proportions, according to the purposes which the alloy is to serve. The English pewterers distinguish three sorts, which they call *plate*, *trifle*, and *ley* pewter: the first and hardest being used for plates and dishes; the second for beer-pots; and the third for larger wine measures. The *plate pewter* has a bright silvery lustre when polished; the best is composed of 100 parts of tin, 8 parts of antimony, 2 parts of bismuth, and 2 of copper. The *trifle* is said by some to consist of 83 parts of tin, and 17 of antimony; but it generally contains a good deal of lead. The *ley pewter* is composed of 4 parts of tin and 1 of lead. The English ley pewter contains often much more than 20 per cent. of lead. As the tendency of the manufacturer is to put in as much of the cheap metal as is compatible with the appearance of his alloy in the market, and as an excess of lead may cause it to act poisonously upon all vinegars and many wines, the French Government appointed Fourcroy, Vauquelin, and other chemists, to ascertain by experiment the proper proportions of a safe pewter alloy. These commissioners found that 18 parts of lead might, without danger of affecting wines, &c., be alloyed with 82 parts of tin; and the French Government in consequence passed a law, requiring pewterers to use 83½ of tin in 100 parts, with a tolerance of error amounting to 1½ per cent. This ordonnance, allowing not more than 18 per cent. of lead at a maximum, has been extended to all vessels destined to contain alimentary substances. A table of specific gravities was also published, on purpose to test the quality of the alloy; the density of which, at the legal standard, is 7·764. Any excess of lead is immediately indicated by an increase in the specific gravity above that number.

Britannia metal, the kind of pewter of which English teapots are made, is an alloy of equal parts of brass, tin, antimony, and bismuth; but the proportions differ in different workshops, and in many much more tin is introduced. *Queen's metal* is said to consist of 9 parts of tin, 1 of antimony, 1 of bismuth, and 1 of lead; it serves also for teapots and other domestic utensils.

A much safer and better alloy for these purposes may be compounded by adding to 100 parts of the French pewter, 5 parts of antimony, and 5 of brass to harden it. Under TIN, will be found the description of an easy method of analysing its lead alloys.

The pewterer fashions most of his articles by casting them in brass moulds, which are made both inside and outside in various pieces, nicely fitted together, and locked in their position by ears and catches or pins of various kinds. The moulds must be moderately heated before the pewter is poured into them, and their surfaces should be brushed evenly over with pounce-powder (*sandarach*) beaten up with white-of-egg. Sometimes a film of oil is preferred. The pieces, after being cast, are turned and polished; and if any part needs soldering, it must be done with a fusible alloy of tin, bismuth, and lead.

It is the practice, however, in the metal works of Birmingham, to raise various articles, as tea-pots, milk-jugs, and the like, from the flat into their proper forms, by a process called SPINNING: this consists in bringing the sheet of pewter against a rapidly-revolving tool, by which, with a little dexterity on the part of the workman, it is gradually fashioned.

PHANTASMAGORIA. The phantasmagoria lanterns are a scientific form of magic lantern, differing from it in no essential principle. The images they produce are variously exhibited, either on opaque or transparent screens. The light may be a kind of solar lamp, but in most cases the oxyhydrogen or lime light is now employed. The manner in which the beautiful melting pictures called dissolving views are produced, as respects the mechanism employed,, deserves to be explained. The arrangement adopted in the instrument is the following:—Two lanterns of the same size and power, and in all respects exactly agreeing, are arranged together upon a little tray or platform. They are held fast to this stand by screws, which admit of a certain degree of half-revolving motion from side to side, in order to adjust the foci. This being done in such a manner that the circle of light of each lantern falls precisely upon the same spot upon the screen, the screws are tightened to the utmost extent so as to remove all possibility of further movement. The dissolving apparatus consists of a circular tin plate japanned in black, along three parts of the circumference of which a crescented aperture runs, the interval between the horns of the crescent being occupied by a circular opening, covered by a screwed plate, removeable at pleasure. This plate is fixed to a horizontal wooden axis, at the other end of which is a handle, by which the plate can be caused to rotate. The axis of wood is supported by two pillars connected with a flat piece which is secured to the tray. This apparatus is placed between the lanterns in such a manner that the circular plate is in front of the tubes of both, while the handle projects behind the lanterns at the back. The plate can, therefore, be turned round by means of the handle, without difficulty, from behind. A peg of wood is fixed into the axis, so as to prevent its effecting more than half a revolution. The widest part of the crescentic opening in the plate is sufficient to admit all the rays of the lantern before which it happens to be placed. On the plate being slowly turned half round, by means of the handle behind, the opening narrows until it is altogether lost in one of the horns of the crescent. The light of that lantern is gradually cut off as the aperture diminishes, until it is at length wholly shaded under the moveable cover occupying the interval between the horns of this crescentic opening. In proportion as the light is cut off from one, it is let on from the other tube, in consequence of the gradually-increasing size of the crescent revolving before it, until at length the widest part of this opening in the plate is presented before the tube of the second lantern, the first being, as we have seen, shaded. This movement being reversed, the light is cut off from the second lantern, and again let on from the first, and so on alternately. Thus while the screen always presents the same circle of light, yet it is derived first from one lantern, then from the next.

When in use a slider is introduced into each lantern. The lantern before the mouth of which the widest part in the opening in the plate is placed, exhibits the painting on the screen, the light of the other lantern being then hid behind the cover. On turning the handle, this picture gradually becomes shaded, while the light from the second lantern streams through the widening opening. The effect on the screen is the melting away of the first picture, and the brilliant development of the second, the screen being at no instant left unoccupied by a picture.

The principle involved in this apparently complex, but in reality simple mechanism, is, merely the obscuration of one picture and the throwing of a second in the same place on the screen. And it may be accomplished in a great variety of ways. Thus by simply placing a flat piece of wood, somewhat like the letter Z, on a point in the centre, so that alternately one or the other of the pieces at the end should be raised or depressed before the lanterns, a dissolving scene is produced. Or, by fixing a moveable upright shade, which can be pushed alternately before one or the other of the lanterns, the same effect is produced.

There are many individuals whose sole occupation consists in painting the minute scenes or slides used for the phantasmagoria lanterns. The perfection to which these paintings are brought is surprising, There are two methods by which the sliders now employed are produced. In one of these, the outline and detail are entirely the work of the artist's pencil. For pictures representing landscapes, or wherever a spirited painting is required, this is the exclusive method employed. The colours are rendered transparent by being ground in Canada balsam and mixed with varnish. The other method is a transfer process. The outlines of the subject are engraved on copper-plates, and the impression is received from these on thin sheets of glue, and is then transferred to a plate of glass, the impression being burnt in the same manner as is effected in earthenware. Sliders produced in this way receive the distinctive name of copper-plate sliders. The subject is merely represented in outline, it being left to the artist to fill up with the necessary tints, &c. The advantages of this method for the production of paintings of a limited kind are obvious. Photography on glass is now very largely employed to obtain pictures for the magic lantern.

Beechy's Trinoptric Lantern, which has been long manufactured by Mr. Abrahams of Liverpool, is an improvement on the ordinary phantasmagoria. The Bridgman Triple Lantern has recently been introduced.

PHENAKITE. A silicate of glucina. The Siberian crystals are occasionally cut for jewellery, and resemble rock crystal.

PHENAMEINE. See ANILINE VIOLET.

PHENICINE, *Phenicienne*, or *Phenyl Brown*. A colouring-matter produced by the action of nitro-sulphuric acid on phenylic alcohol (carbolic acid). Phenicine is an amorphous powder of a brown colour. It is sparingly soluble in water, but it dissolves readily in alcohol, ether, and acetic acid, also in the alkaline solutions, and in lime-water. The solution in an alkaline fluid is of a fine violet-blue, but it is changed to brown by the least excess of acid. It appears to be a mixture of two colouring-matters, one yellow, and the other black. Phenicine dyes silk and wool, like the aniline colours, without the intervention of a mordant. If a piece of silk or wool is dyed with phenicine, it acquires a fine garnet-red colour, on immersion in a solution of chromate of copper acidulated with sulphuric acid. Cotton being previously mordanted with tannin or stannate of soda may be dyed with phenicine of a deep purple colour, on being immersed in hot chromate of potash. The colour is, however, changed by alkalis, and destroyed by soap. See Carbolic Acid.

PHENOL. See Carbolic Acid.

PHENOL BLUE. Under certain circumstances, phenol gives rise to the formation of a blue colouring-matter, which is used to a certain extent in dyeing. This substance is known in commerce by the name of *azuline.* See Carbolic Acid.

PHORMIUM TENAX. New Zealand flax. From a Report of the Flax Commission appointed to examine into the preparation and value of the New Zealand flax, we learn that one general method of manufacture is adopted in the colony. This method has been thus described:—

'The green leaves are stripped by revolving-rollers with projecting beaters, travelling at a high rate of speed, which crush the epidermis against a fixed plate, so set as to allow room for the fibre to remain intact. The fibre, thus freed from the leaf of the plant, is washed by various methods, put on the ground or on lines to dry and bleach, finished by an arm or barrel-scutch, and when baled is ready for the market. No material alterations in the manufacturing processes have been made; but a more skilled labour and enlarged experience have improved the general quality of the fibre, so that it is more eagerly competed for in the London market as approaching nearer the appearance of Manilla hemp, and is, in fact, capable, in the opinion of competent judges, of being so prepared as to surpass it. The chief improvement recently introduced is the wet-scutching, by which the fibre is cleaned and softened, although it has not always been commercially successful; for, whilst local purchasers were ready to give 3*l.* per ton extra for the flax, the loss of fibre, by formation of an excessive amount of tow, and the additional expense of labour, increased the cost from 6*l.* to 10*l.*, so that the new process was abandoned. But, notwithstanding this, the Commissioners strongly recommend it for further trial. The mills are chiefly worked by steam-power; and good streams of water are also essential for the effectual washing of the fibre, which, when carefully prepared and neatly baled, fetches as much as from 17*l.* to 21*l.* per ton, although the ordinary price is about 15*l.* The cutting of the flax-leaves is an important point. In some fields an established vigorous plant, in suitable soil, will yield four good leaves for manufacture every year. The leaves are usually of twelve months' growth, and vary from 3 to 5 feet long. In some parts they are greatly injured by a small 'looper' caterpillar, about an inch in length, which eats quite through the fibre, in patches from $\frac{1}{2}$ an inch to 2 inches long, and $\frac{1}{4}$ of an inch broad. This insect comes to its full size, and is most numerous, in the month of December. Of the leaves, when cut, $5\frac{1}{2}$ tons yield one ton of fibre. They are mostly found after two years' growth to have passed their prime and begun to decay. The green strippings of the leaf form food for horses.'

The phormium fibre is largely used for rope-making. It is said that the New Zealand white rope when kept dry, lasts longer and wears 60 per cent. better than tarred rope of this material, and 34 per cent. better than Manilla-hemp fibre, but the effect of wetting with salt water acts injuriously upon the New Zealand rope, whilst the Manilla rope is said to be actually improved by the salting. The breaking-strain of Manilla-hemp rope being taken as 100, that of several varieties of New Zealand rope as at present exported varies from 53 to 84, with an average of 91. But samples of native-dressed New Zealand fibre ranged from 70 to 122, with an average of 91. During the year 1870 there were 161 mills in operation in the colony, with an aggregate of 342 stripping machines, employing 1,450 horse-power and 1,766 persons, and producing 4,457 tons of fibre. From April 1870 to May 1871, 36,008 bales of fibre were brought to London, in addition to which 87 were destroyed at sea; 1,546 bales of tow were also produced. The total value of the fibre, reckoning 6 bales to 1 ton, amounted to 140,506*l.*, the average price being 23*l.* 8*s.* per bale. See Fibres; Flax.

PHOSGENITE. Native chloro-carbonate of lead. See Lead.

PHOSPHATES. Combinations of phosphoric acid with metallic, earthy, or alkaline bases. A few only of these require notice in this work; all will be found described in Watts's 'Dictionary of Chemistry.'

Phosphate of Lime, or Acid Phosphate of Lime, is formed when bone-earth is treated with sulphuric acid. If bone-earth is digested with this acid for some time, and then water added, the clear solution filtered from the insoluble sulphate of lime will on evaporation yield crystals of phosphate of lime. Ground bones are frequently employed as a manure: their action depends in part upon the decomposed gelatine, but chiefly on the phosphate of lime, which they contain in the condition of a tribasic-phosphate. When, as for turnip-crops, a large supply of phosphoric acid is required, it is found advantageous to treat the bones with sulphuric acid, by which the triphosphate is converted into the acid phosphate of lime. The usual practice is to mix bone-dust with one-fourth of its weight of oil of vitriol, adding an equal quantity of water after each portion of acid; the mass is allowed to remain in a heap until quite dry. It is then sold as *superphosphate*, which is a mixture of the gelatinous portion of the bone with the acid phosphate and sulphate of lime. See APATITE; BONES; COPROLITE.

Phosphate of Magnesia enters into the composition of the bones of animals.

Amongst the native phosphates may be enumerated:—

Apatite. Phosphate of lime, the composition of which mineral is generally, phosphoric acid, 42·26; lime, 50·00; fluorine, 3·77. See APATITE.

Wagnerite. Phosphate of magnesia, with fluoride of magnesium.

Zwieselite. Phosphate of iron and manganese. See IRON.

Pyromorphite. Phosphate of lead. See LEAD.

Lazulite. Blue spar. See LAZULITE.

Turquoise. See TURQUOISE.

Vivianite. Blue iron earth or phosphate of iron. See IRON.

Libethenite. Phosphate of copper. See COPPER.

Ehlite. A hydrous phosphate of copper.

Wavellite. Sub-phosphate of alumina.

Childrenite, consists of phosphoric acid, 27·8; alumina, 14·4; protoxide of iron, 31·3; protoxite of manganese, 8·9; water, 17·6.

Phosphochalcite. Hydrous phosphate of copper.

Dufrenite. Green iron ore. Phosphoric acid, 28·0; peroxide of iron, 63·1; water, 8·9.

Uranite. Two varieties of this mineral are recognised: the one is a *copper-uranite*, known as *Torbnerite*, and consisting of a phosphate of uranium and copper; the other is a *lime-uranite*, known as *Autunite*, and composed of phosphate of uranium and lime.

Cryptolite. Phosphate of cerium.

Xenotime. Phosphate of yttria.

There are some other combinations which it is unnecessary to describe.

PHOSPHATIC NODULES. Concretions and nodules of phosphate of lime, which occur in layers chiefly in the Gault and Upper Greensand, and also in the Crag. They are now much used for artificial manure. See COPROLITES.

PHOSPHOR-BRONZE. Although the combination of phosphorus with copper, tin, zinc, and other alloys, dates a good way back, it is but yesterday since anything like a careful and skilful investigation of the physical properties of these combinations was undertaken.

The latest and most important of the experimental data as to the physical constants of phosphor-bronze which have been obtained are the following:—

Prussian Experiments.—By order of the Royal Prussian Ministry of Commerce experiments have been made with various sorts of phosphor-bronze. These experiments are carried on at the Royal Academy of Industry at Berlin. The object of these experiments is to ascertain the qualities and capacities of the metal whilst under heavy strain, and especially the comparative resistance to often-repeated strains, whether tensile or inflecting. The first bar of phosphor-bronze fixed on the stretching machine was tried under a constant strain of 10 tons per square inch, and resisted 408,230 pulls of this amount. A bar of ordinary bronze broke even before the strain of 10 tons per square inch had been attained. A second bar of phosphor-bronze was tried under a strain of 12½ tons per square inch; and under this high strain withstood 147,850 pulls. Yet more favourable results have been obtained on a machine by which the test-bar is repeatedly bent up to 40,000 times per day. A bar of phosphor-bronze whilst under 10 tons of strain per square inch resisted 862,980 bends, while best gun-metal broke after 102,650 bends. Another bar of phosphor-bronze under 9 tons strain per square inch is being tested, and has at present resisted 1,260,000 bends.

Austrian Experiments.—At the Imperial Austrian Polytechnic Institution in Vienna, experiments were executed by Professor R. Jenney with phosphor-bronze bars, showing the following results:—

Degree of elasticity	Resistance at point of elasticity	Resistance at point of rupture
9875	13·74 kilos. per sq. millimeter or 19,857 lbs. per square inch	40·40 kilos. per sq. millimeter or 58,383 lbs. per square inch

In the Imperial Arsenal at Vienna, experiments were made by Colonel Uchatius, giving the following results:—

	Absolute resistance	Point of elasticity	Stretch in percentage
			per cent.
Phosphor-bronze	5,660 kilos. per sq. c. m. or 81,795 lbs. per sq. inch	3,800 kilos. per sq. c. m. or 54,915 lbs. per sq. inch	1·6
Krupp's cast steel as used for guns	5,000 kilos. per sq. c. m. or 72,258 lbs. per sq. inch	1,000 kilos. per sq. c. m. or 14,450 lbs. per sq. inch	11·0
Ordnance bronze	2,200 kilos. per sq. c. m. or 31,792 lbs. per sq. inch	385 kilos. per sq. c. m. or 5,562 lbs. per sq. inch	15·0

Experiments on the capacity of phosphor-bronze to resist the oxidation of sea-water: Best English copper-sheets lost during six months immersion in sea-water 3·058 per cent. Phosphor-bronze sheets lost only 1·158 per cent.

To these may be subjoined the following results obtained by Messrs. Montefiore:—

Belgian Experiment.—Ordinary bronze always contains a larger or smaller amount of oxide in suspension. This has been contested by various authorities, as it was not possible to prove the presence of oxide of tin in the bronze by analysis, the oxide not being reduced by hydrogen at the temperatures which can be produced in laboratories.

By a longer series of experiments Messrs. Montefiore and Küntzel have now definitely proved the presence of oxide of tin and sub-oxide of copper. The presence of oxide greatly lessens the tenacity, elasticity, and tensile strength of the bronze. Various experiments were made in this direction. They melted shavings of old bronze and cast a bar thereof at 1,525° Cent. The remaining liquid bronze was stirred with a wooden stick (poled) and a second bar cast at 1,668° Cent. The remaining metal was deoxidised with phosphorus and a bar then cast at 1,614°. Then three castings were thus made out of the same crucible and in the same manner into three iron moulds. The results were as follow:—

Nature of the bronze	Absolute resistance	Elastic resistance	Lengthening until rupture	Diminution of section
			per cent.	per cent.
Old bronze . . .	1613	1209	2	3·2
,, poled . .	1755	1244	2·8	3·2
,, deoxidised ,, with phosphorus	2384	1356	6·8	6·7

Thus by the entire reduction the old bronze has tripled its tenacity and considerably augmented its absolute resistance.

Messrs. Alex. Dick and Co. have very recently established at Blackfriars Road London, a special foundry for phosphor-bronze casting, and have also made arrangements in Birmingham for the production of sheets, wire, &c.

The Table on p. 556 shows the results of Experiments to ascertain the Tensile Strength and the Resistance to Torsion of various Wires received from A. Dick, Esq., and made by Mr. David Kircaldy, of the testing and experimental works in Southwark.

PHOSPHORIC ACID exists abundantly in the mineral kingdom: it is found in several of the igneous rocks, in combination chiefly with lime. In the vegetable kingdom, it is discovered in the ashes of many plants, and it forms a large and important portion of the animal kingdom. *Anhydrous phosphoric acid*, is the acid formed by the vivid combustion of phosphorus. *Monabasic* or *metaphosphoric acid*, commonly known as glacial phosphoric acid, is now much employed in England, though for some time it did not attract the attention which it deserves in the arts and manufactures of this country. For many of the wants of the dyer, the calico-printer, the enameller, and even in the purification of some oils and fat, the glacial phosphoric acid has much to recommend it over any of the common acids at present in use. Nor need its price prove an obstacle to its introduction as a practical agent. Finely ground bone-ash, digested with a due proportion of oxalic acid and water, readily yields a solution of phosphoric acid, which requires only to be evaporated in a proper vessel to furnish at once this useful article. (*Ure.*) Unlike sulphuric and other strong acids, it is not decomposed by organic matter; and might hence be employed with great advantage in the precipitation of carmine and other delicate vegetable colours, as well as for

more general purposes. Some experiments have also shown that, combined with alumina and a little boracic acid, it is capable of producing a glaze for earthenware of extreme beauty and durability, in addition to its perfectly innocuous character and power of improving the colours imparted by most metallic oxides when applied to earthenware.

Another method of forming this monobasic acid is the following: one part of phosphorus is cut into small pieces, and introduced into a retort connected with a receiver, and containing thirteen parts of nitric acid, sp. gr. 1·2. The retort is moderately heated on a sand-bath, and the nitric acid which distils over returned to it from time to time until the phosphorus has disappeared. The greater part of the nitric acid is then distilled off, and the residual liquor evaporated so long as any water is evolved upon cooling: the phosphoric acid is a colourless glass, which dissolves slowly in water.

PHOSPHORITE. Concretionary and massive apatite. See APATITE.

PHOSPHORUS. (The following detailed description of the manufacture of phosphorus is left in Dr. Ure's own words, it being a good example of his descriptive powers when applied to scientific manufactures.) This interesting simple combustible being an object of extensive consumption, and therefore of a considerable chemical manufacture, I shall describe the requisite manipulations for preparing it at some detail. Put 1 cwt. of finely-ground bone-ash, such as is used by the assayers, into a stout tub, and let one person work it into a thin pap with twice its weight of water, and let him continue to stir it constantly with a wooden bar, while another person pours into it, in a uniform but very slender stream, 78 lbs. of concentrated sulphuric acid.

The heat thus excited in the dilution of the acid, and in its reaction upon the calcareous base, is favourable to the decomposition of the bone phosphate. Should the resulting sulphate of lime become lumpy, it must be reduced into a uniform paste, by the addition of a little water from time to time. This mixture must be made out of doors, as under an open shed, on account of the carbonic acid and other offensive gases which are extricated. At the end of 24 hours the pap may be thinned with water, and if convenient, heated, with careful stirring, to complete the chemical change, in a square pan made of sheet-lead, simply folded up at the sides. Whenever the paste has lost its granular character, it is ready for transfer into a series of tall casks, to be further diluted and settled, whereby the clear superphosphate of lime may be run off by a syphon from the deposit of gypsum. More water must then be mixed with the precipitate, after subsidence of which the supernatant liquor is again to be drawn off. The skilful operator employs the weak acid from one cask to wash the deposit in another, and thereby saves fuel and evaporation.

The collected liquors being put into a leaden, or preferably a copper pan, of proper dimensions, are to be concentrated by steady ebullition, till the calcareous deposit becomes considerable; after the whole has been allowed to cool, the clear liquor is to be run off, the sediment removed, and thrown on a filter. The evaporation of the clear liquor is to be urged till it acquires the consistence of honey. Being now weighed, it should amount to 37 pounds. One fourth of its weight of charcoal in fine powder, that is, about 9 pounds, is then to be incorporated with it, and the mixture is to be evaporated to dryness in a cast-iron pot. A good deal of sulphurous acid is disengaged along with the steam at first, from the reaction of the sulphuric acid upon the charcoal, and afterwards some sulphuretted hydrogen. When the mixture has become perfectly dry, as shown by the redness of the bottom of the pot, it is to be allowed to cool, and packed tight into stoneware jars, fitted with close covers, till it is to be subjected to distillation. For this purpose, earthen retorts of the best quality, and free from air-holes, must be taken, and evenly luted over the surface with a compost of fire-clay and horse-dung. When the coating is dry and sound, the retort is to be two-thirds filled with the powder, and placed upon proper supports in the laboratory of an air furnace, having its fire placed not immediately beneath the retort, but to one side, after the plan of a reverbatory; whereby the flame may play uniformly round the retort, and the fuel may be supplied as it is wanted, without admitting cold air to endanger its cracking. The gallery-furnace of the Palatinate (see MERCURY) will show how several retorts may be operated upon together, with one fire.

To the beak of the retort, properly inclined, the one end of a bent copper-tube is to be tightly luted, while the other end is plunged not more than one quarter of an inch beneath the surface of water contained in a small copper or tin trough placed beneath, close to the side of the furnace, or in a wide-mouthed bottle. It is of advantage to let the water be somewhat warm, in order to prevent the concretion of the phosphorus in the copper-tube, and the consequent obstruction of the passage. Should the beak of the retort appear to get filled with solid phosphorus, a bent rod of iron may be heated and passed up the copper-tube, without removing its end from the water. The heat of the furnace should be most slowly raised at first, but afterwards equably maintained in a state of bright ignition. After 3 or 4 hours of steady firing, carbonic acid and sulphurous acid gases are evolved in considerable abundance, provided the materials had not been well dried in the iron pot; then sulphuretted hydrogen makes its appearance, and next phosphuretted hydrogen, which last should continue during the whole of the distillation.

The firing should be regulated by the escape of this remarkable gas, which ought to be at the rate of about 2 bubbles per second. If the discharge comes to be interrupted, it is to be ascribed either to the temperature being too low, or to the retort getting cracked; and if upon raising the heat sufficiently no bubbles appear, it is a proof that the apparatus has become defective, and that it is needless to continue the operation. In fact, the great nicety in distilling phosphorus lies in the management of the fire, which must be incessantly watched, and fed by the successive introduction of fuel, consisting of coke with a mixture of dry wood and coal.

We may infer that the process approaches its conclusion by the increasing slowness with which gas is disengaged under a powerful heat; and when it ceases to come over, we may cease firing, taking care to prevent reflux of water into the retort, from condensation of its gaseous contents, by admitting air into it through a recurved glass tube or through the lute of the copper adapter.

The usual period of the operation upon the great scale is from 24 to 30 hours. Its theory is very obvious. The charcoal at an elevated temperature disoxygenates the phosphoric acid with the production of carbonic acid gas at first, and afterwards carbonic oxide gas, along with sulphuretted, carburetted, and phosphuretted hydrogen, from the reaction of the water present in the charcoal upon the other ingredients.

The phosphorus falls down in drops, like melted wax, and concretes at the bottom of the water in the receiver. It requires to be purified by squeezing in a shamoy leather bag, while immersed under the surface of warm water, contained in an earthen pan. Each bag must be firmly tied into a ball form, of the size of the fist, and compressed under the water heated to 130°, by a pair of flat wooden pincers, like those with which oranges are squeezed.

The purified phosphorus is moulded for sale into little cylinders, by melting it at the bottom of a deep jar filled with water, then plunging the wider end of a slightly tapering but straight glass tube into the water, sucking this up to the top of the glass, so as to warm it, next immersing the end in the liquid phosphorus, and sucking it up to any desired height.

The tube being now shut at bottom by the application of the point of the left index, may be taken from the mouth and transferred into a pan of cold water to congeal the phosphorus; which then will commonly fall out of itself, if the tube be nicely tapered, or may at any rate be pushed out with a stiff wire. Were the glass tube not duly warmed before sucking up the phosphorus, this would be apt to congeal at the sides before the middle be filled, and thus form hollow cylinders, very troublesome and even dangerous to the makers of phosphoric match-bottles. The moulded sticks of phosphorus are finally to be cut with scissors under water to the requisite lengths, and put up in phials of a proper size; which should be filled up with water, closed with ground stoppers, and kept in a dark place. For carriage to a distance, each vial should be wrapped in paper, and fitted into a tin-plate case.

Phosphorus has a pale yellow colour, is nearly transparent, brittle when cold, soft and pliable, like wax, at the temperature of 70° F., crystallising in rhombo-dodecahedrons out of its combination with sulphur, and of specific gravity 1·77. It exhales white fumes in the air, which have a garlic smell, appear luminous in the dark, and spontaneously condense into liquid phosphorus acid. Phosphorus melts in close vessels, at 95° F., into an oily-looking colourless fluid; begins to evaporate at 217·5°, boils at 554°, and if poured in the liquid state into ice-cold water, it becomes black, but resumes its former colour when again melted and slowly cooled. It has an acrid disagreeable taste, and acts deleteriously in the stomach, though it has been administered as a medicine by some of the poison-doctors of the present day. It takes fire in the open air at the temperature of 165°, but at a lower degree if partially oxidised, and burns with great vehemence and splendour.

PHOSPHORUS, AMORPHOUS, or **RED PHOSPHORUS.** If a stick of phosphorus be put into an hermetically-closed tube and exposed to the action of the spectrum, one end will become *white*, and the other *red*. It may be prepared also by exposing phosphorus for a long time in an atmosphere quite free of oxygen or moisture, to a temperature of 470° F. At this temperature the phosphorus fuses; it remains for some time colourless, and then gradually becomes red and opaque. Amorphous phosphorus was investigated by Dr. Schrötter, of Vienna. The apparatus for making it consists of a double iron pan; the intermediate space between the two contains a metallic bath of an alloy of tin and lead; with a cast-iron cover to the inner vessel, fitted to the top end by means of a screw, and fastened to the outer vessel by screw-pins. In the interior iron pan a glass vessel is fitted, in which the phosphorus to be operated upon is placed. From this inner vessel a tube passes, and is dipped into water to serve as a safety-valve. A spirit lamp is applied under that pipe if necessary, to prevent it being clogged with phosphorus. The phosphorus to be converted is first of all melted, and then cooled under water, and dried as much as possible. A fire is now made under the other vessel, and the temperature raised to such a degree as to drive off the air, &c. The temperature has to be gradually raised, until bubbles escape at the end of the pipe, which take fire as they enter the air, and the heat may soon rise in the bath till it be 470° F. This temperature must be maintained for a certain time to be determined by experience: the apparatus may then be allowed to cool. The converted phosphorus is difficult to detach from the glass. It is to be levigated under water, and then drained in a bag. The phosphorus when moist should be spread thinly on separate shallow trays of sheet iron or lead, so placed alongside each other as to receive the heat of steam, and lastly, of chloride of calcium, or of sand, till the phosphorus, having been frequently stirred, shows no more luminous vapour. The operator should have water at hand to quench any fire that might arise. It is then to be washed till the water shows no trace of acid. Should the resulting phosphorus contain some of the unconverted article, this may be removed by bisulphide of carbon. Thus, heat alone effects the transmutation. It is identical in composition with ordinary phosphorus, and may be reconverted into it without loss of weight, and that merely by change of temperature. This substance remains unaltered in the atmosphere, is insoluble in bisulphide of carbon, in alcohol, ether, and naphtha. It requires a heat of 260° Cent. to restore it to the ordinary state, and it is only at that heat that it begins to take fire in the open air. It is not luminous in the dark at any ordinary temperature. When perfectly dry, amorphous phosphorus is a scarlet or carmine powder, which becomes darker when heated. On the large scale it is prepared in dark masses of a red or dark brown colour. The great advantages of this singular condition of phosphorus are, that it does not appear to affect those persons who are employed in the manufacture of lucifer-matches with the loathsome disease which the use of the ordinary phosphorus produces. See Lucifer-Matches.

PHOSPHORUS MATCHES. See Lucifer-Matches.

PHOSPHORUS PASTE, *for the Destruction of Rats and Mice.* The Prussian Government issued an ordonnance on April 27, 1843, directing the following composition to be substituted for arsenic, for destroying rats and mice; enjoining the authorities of the different provinces to communicate, at the expiration of a year, the results of the trials made with it, with the view of framing a law on this subject.

The following is the formula for this paste:—

Take of phosphorus 8 parts, liquefy it in 180 parts of lukewarm water; pour the whole into a mortar, add immediately 180 parts of rye-meal; when cold, mix in 180 parts of butter melted, and 125 parts of sugar. If the phosphorus is in a finely-divided state, the ingredients may be all mixed at once without melting them. This mixture will retain its efficacy for many years, for the phosphorus is preserved by the butter, and only becomes oxidised on the surface. Rats and mice eat this mixture with avidity; after which they swell out, and soon die. Several similar preparations are now made in this country for the destruction of vermin.

PHOTO-GALVANOGRAPHY. A name given to a process invented by Mr. Pretsch, for producing engravings from photographs, by the application of the *galvano-plastic* process. It is not now employed, although great efforts were made to introduce it to the public. The principles involved are sufficiently described in the article on Photographic Engraving.

PHOTOGEN. Syn. *Paraffin Oil.* A term which has recently found its way into commerce, to designate certain oils or naphthas for illuminating purposes. It is generally prepared from shales, brown coals, or cannels. Boghead coal, and the numerous varieties of inflammable shales which more or less resemble it, are specially adapted for the preparation of photogen. The chief physical difference between photogen and ordinary coal-oils of the same boiling-point, is the specific gravity, with which the former varies from 0·820 to 0·830, whereas common coal-naphtha never has a less density than 0·850. It is true that photogen may be obtained of as high a density as 0·900, but then it will be of an excessively high boiling-point, and, in all probability, saturated with paraffin.

The light oil known as photogen may be obtained from common bituminous coals by distilling them at a lower temperature than is employed in gas-works. To obtain the maximum amount of photogen from coal, the temperature should not be much above 700° Cent.

Preparation.—The coals, broken into small pieces (the smaller the better), are to be heated in vertical or horizontal iron retorts, the tar being received through a very wide worm into large tanks. Some manufacturers use vertical, and others horizontal retorts; it is also common to distil the coals by the heat produced by their own combustion. If the latter process be employed, the arrangements for condensing the product must be very perfect, or great loss will be sustained, owing to the air which supports the combustion carrying away a considerable quantity of the hydrocarbons. This power of air to saturate itself with vapours is of great importance in the economy of all processes where the distillation of one portion of substance is carried on by the heat evolved by the combustion of another. It is not uncommon in practice, where the cylinders are horizontal, to place the coal or other matters to be distilled in semicylindrical trays, which are capable of being inserted into the retorts, and also of being removed to make way for another charge at the completion of the operation.

The tar obtained by any of the above processes is to be redistilled: the lighter portions form (when purified by means of sulphuric acid and alkalis) the fluid known in commerce as 'Boghead naphtha.' (See Naphtha, Boghead.) In Germany and some other places, it is usual to divide the distillate from the tar into two portions, one being for the preparation of photogen, and the other for 'solar oil.' This division is made as the fluid runs from the still; the more volatile constituting the photogen, and the less the solar oil.

The process of purification is the same in both cases, namely, alternate treatments with concentrated sulphuric acid to remove the highly-coloured and odorous constituents of the crude distillate, and washing with an alkali to remove carbolic acid and its congeners; also that portion of sulphuric acid which remains suspended in the naphtha, and the sulphurous acid produced by the decomposition of a portion of the sulphuric acid by the carbon of certain easily-decomposed organic matters in the crude distillate. This decomposition of the sulphuric acid happens thus:—

$$2SO^3HO + C = 2SO^2 + 2HO + CO^2$$
$$(\mathbf{2H^2SO^4 + C = 2SO^2 + 2H^2O + CO^2}).$$

There is another advantage in the treatment of the fluid by alkalis, inasmuch as some sulphide of hydrogen, and probably other fœtid sulphur-compounds, is decomposed and the resulting products removed.

In preparing photogen from any of the sources enumerated, much must be left to the discretion of the manufacturer, both as regards the apparatus and the chemical processes. In some instances the solar oil and photogen are with advantage prepared separately; but in this country it is more usual to mix the heavy and light oils together, so as to produce a fluid of medium density and volatility. It must be remembered that while the more volatile hydrocarbons confer extreme inflammability and fluidity, they are at the same time more odorous than the less volatile portion of the distillate, which is the true paraffin oil.

The more odorous impurities in photogen appear to be easily susceptible of oxidation. This is evident from the facility with which foully-smelling photogen loses its offensive odour in contact with bichromate or manganate of potash, or even animal charcoal. Their exposure to air even greatly improves the odour, and a recently-distilled photogen, which is very unpleasant, becomes comparatively sweet if kept in tanks or barrels for a few days. The same thing happens with many essential oils, such as those of peppermint, cloves, &c. The presence of sulphurous acid in photogen may be instantly detected by shaking a little in a test-tube with a few drops of a very weak solution of bichromate of potash; if sulphurous acid be present, a portion of the chromic acid will be reduced to green oxide, which will instantly betray the presence of the reducing agent alluded to.

Photogen often shows the phenomenon of dichroism; but the more it is purified by acids, the more feebly is the coloration by reflected light observed, and if the less volatile portion of the distillate be rejected, the property alluded to will not be perceived.

In distilling the heavy oils or tars produced by distilling Boghead coal or other photogen-yielding substances, it is particularly to be observed that the worms or other tubes proceeding from the stills, if of too small diameter, are liable to become choked up with paraffin; this, if unobserved, might lead to serious results. It is very convenient to have a steam-pipe inserted into the worm-tubes or condensing-tanks, to enable the water to be heated to such a point as to melt any solid matters in the worms, and allow them to be washed into the recipient by the fluids distilling over.

The following Table by Wagenmann will be found of great importance to those who are interested in the commercial value of the different varieties of coals and bitumens as sources of illuminating oils :—

Name	Locality	Tar per cent.	Specific gravity	Crude oil sp. gr. from 0·700 to 0·950	Crude oil sp. gr. from 0·850 to 0·900	Crude paraffin

None of the cannel or bituminous coal, shales, or other substances used for yielding burning fluids by distillation, give distillates of such purity and freedom from odour, as Rangoon tar. The more volatile portion of the distillate from the latter has obtained in commerce the absurd name of Sherwoodole; it is used instead of coal-benzole for removing grease, &c. The paraffin obtained from Rangoon tar has a greater value for commercial purposes than that from Boghead coal, inasmuch as it has a higher melting-point, which renders it better adapted for candles. The following are the melting-points of various samples of paraffin :—

	Melting-point. Fahr.
Boghead-coal paraffin	114°
,, ,, another specimen	108
The last, after being distilled	108
Turf paraffin	116
Bituminous-coal paraffin, prepared by Atwood's process .	110
Rangoon-tar paraffin	140

It is curious to observe the effect of light upon photogen. Some samples of extremely dark colour, when exposed to its influence for a few days, become as completely bleached as animal oils would under these circumstances. At the same time, as we have before hinted, the odour becomes much improved. A photogen of good quality has by no means a repulsive odour, but if much of the more volatile constituents be present, it is impossible to avoid its being disagreeable if spilled about. The less volatile hydrocarbons have comparatively little odour. It should not be too inflammable, that is to say, it must not take fire on the approach of a light. If it does, it is owing to the more volatile portion not having been sufficiently removed. See Paraffin for a description of its manufacture.

PHOTOGRAPHIC ENGRAVING. The first who appears to have had any idea of engraving by the influence of sunlight was Nicephore Nièpce. According to M. Aimé Girard, the first proof taken by him by means of this process bears date 1827. This process was very simple: it consisted in spreading a thin layer of bitumen of Judæa upon a copper- or pewter-plate, which was then placed in the camera obscura, where it was allowed to remain some hours, until the bitumen had received the impression of the external objects towards which the lens had been directed. On withdrawing the plate, it was submitted to the action of the essential oil of lavender, which dissolved those portions of the bitumen not acted upon by the light, leaving the metal bare, while the remaining bitumen produced the design. Passing the plate afterwards through an acid solution, the acid acted on the metallic plate, while the other parts were preserved by the protecting varnish.

Six years later, that is, in 1839, M. Daguerre made his discovery of the 'Daguerreotype' public. In the meantime, he had considerably improved on Nièpce's process; but although many, and some tolerably successful, attempts were made to engrave the pictures produced by these processes, none were quite successful.

The next process to which we shall refer is that of M. Fizeau. He took a Daguerreotype plate, and submitted it to the action of a mixture of nitric, nitrous, and hydrochloric acids, which did not affect the whites of the picture but attacked the blacks with a resulting formation of adherent chloride of silver, which speedily arrested the action of the acid. This he removed by a solution of ammonia, and the action of the acid was continued. This process he continued until a finely-engraved plate was the result; but the lines of this plate were not deep enough to allow of many prints being taken from it. To remedy this, he covered the plate with some drying oil, and then, wiping it from the surface, left it to dry in the hollows. He afterwards submitted the plate to an electro-chemical process which covered the raised parts with gold, leaving the hollows, in which the varnish remained, untouched. On the completion of the gilding, the varnish was removed by means of caustic potash, and the surface of the plate, covered with *grains de gravure*, producing what is technically termed an *aquatint* ground, and the deepening of the lines was proceeded with by means of the acid. The Daguerreotype plate was by these means converted into an engraved plate, but as it was silver it would have worn out very soon; to obviate which an impression was taken on copper by the electro-chemical process, which could of course be renewed when it showed signs of wear.

M. Claudet and Mr. Grove both produced some very good engravings on the Daguerreotype plate, but these processes have proved rather curious than useful.

On October 29, 1852, Mr. Fox Talbot patented a process, which was similar to a process previously used by MM. Pretsch and Poitevin, as regards the substance first employed, viz. a mixture of bichromate of potash and gelatine; but the remaining portion of the process was conducted on the same principle, though in a different manner, to that of M. Fizeau.

Mr. Mungo Ponton discovered the use of the bichromate of potash as a photographic agent; and Mr. Robert Hunt subsequently published a process, called the 'Chromotype.' In both these processes the peculiar property of the chromic acid, liberated under the action of sunshine, to combine with organic matter, was pointed out. MM. Pretsch, Poitevin, and Talbot, only availed themselves of this previous discovery, and in each instance gelatine was rendered insoluble by the decomposition of the bichromate of potash under the influence of *actinic* power. By dissolving off the still soluble portions of the gelatine, either metal could be precipitated by the voltaic battery, or an etching produced.

In 1853 M. Nièpce de St. Victor, the nephew of Nicephore Nièpce, took up his uncle's plan, and with the assistance of M. Lemaitre, who had also assisted his uncle, endeavoured to perfect it; but, though he modified and improved it, his success was not very great—it was always found necessary to have the assistance of an engraver to complete the plate.

After this many others, among whom may be enumerated MM. Lerebours, Lemercier, Barreswil, Davanne, and, finally, Poitevin, endeavoured to obtain a design by similar means on stone. The last appears to have succeeded. His method is based on the chemical action of light on a mixture of gelatine and bichromate of potash, as above. This mixture, which when made is perfectly soluble in water, becomes insoluble after exposure to the light. His mode of proceeding is as follows:—

He spreads the mixture on the stone, and, after drying, lays the negative upon it, and exposes it to the light. After a suitable exposure the negative is removed, and the portions not acted upon by the light are washed away with water, and the design remains with the property of taking the ink like an ordinary lithographic crayon. The stone is then transferred to the press, and proofs taken in the usual way. It is said that pictures have been obtained from the stone after 900 copies had been pulled.

The process of M. Charles Négre was more complicated than the preceding, but yielded superior results. His process was not unlike that of M. Fizeau.

Mr. Fox Talbot thus describes his process of *Photoglyphic Engraving*:—

'I employ plates of steel, copper, or zinc, such as are commonly used by engravers. Before using a plate its surface should be well cleaned; it should then be rubbed with a linen cloth dipped in a mixture of caustic soda and whiting, in order to remove any remaining trace of greasiness. The plate is then to be rubbed dry with another linen cloth. This process is then to be repeated; after which, the plate is in general sufficiently clean.

'In order to engrave a plate, I first cover it with a substance which is sensitive to light. This is prepared as follows:—

'About a quarter of an ounce of gelatine is dissolved in eight or ten ounces of water, by the aid of heat. To this solution is added about one ounce, by measure, of a saturated solution of bichromate of potash in water, and the mixture is strained through a linen cloth. The best sort of gelatine for the purpose is that used by cooks and confectioners; in default of this, isinglass may be used, but it does not answer so well. This mixture of gelatine and bichromate of potash keeps good for several months, owing to the antiseptic and preserving power of the bichromate. It remains liquid and ready for use at any time during the summer months; but in cold weather it becomes a jelly, and has to be warmed before using it: it should be kept in a cupboard or dark place. The proportions given above are convenient, but they may be considerably varied without injuring the result.

'The engraving process should be carried on in a partially-darkened room, and is performed as follows:—

'A little of this prepared gelatine is poured on the plate to be engraved, which is then held vertical, and the superfluous liquid allowed to drain off at one of the corners of the plate. It is held in a horizontal position over a spirit-lamp, which soon dries the gelatine, which is left as a thin film, of a pale yellow colour, covering the metallic surface, and generally bordered with several narrow bands of prismatic colours. These colours are of use to the operator, by enabling him to judge of the thinness of the film: when it is very thin, the prismatic colours are seen over the whole surface of the plate. Such plates often make excellent engravings; nevertheless, it is perhaps safer to use gelatine films, which are a little thicker. Experience alone can guide the operator to the best result. The object to be engraved is then laid on the metal plate, and screwed down upon it in a photographic copying-frame. Such objects may be either material substances, as lace, the leaves of plants, &c., or they may be engravings, or writings, or photographs, &c. &c. The plate bearing the object upon it is then to be placed in the sunshine, for a space of time varying from one to several minutes, according to circumstances; or else it may be placed in common daylight, but of course for a long time. As in other photographic processes, the judgment of the operator is here called into play, and his experience guides him as to the proper time of exposure to the light. When the frame is withdrawn from the light, and the object removed from the plate, a faint image is seen upon it—the yellow colour of the gelatine having turned brown wherever the light has acted.

'When the plate bearing the photographic image is removed from the copying frame, I spread over its surface, carefully and very evenly, a little finely-powdered gum copal. It is much easier to spread this resinous powder evenly upon the surface of the gelatine, than it is to do so upon the naked surface of a metal plate. The chief error the operator has to guard against is that of putting on too much of the powder: the best results are obtained by using a very thin layer of it, provided it is uniformly distributed. If too much of the powder is laid on it, it impedes the action of the etching liquid. When the plate has been thus very thinly powdered with copal, it is held horizontally over a spirit-lamp in order to melt the copal; this requires a considerable heat. It might be supposed that this heating of the plate, after the formation of a delicate photographic image upon it, would disturb and injure that image; but it has no such effect. The melting of the copal is known by the change of colour, The plate should then be withdrawn from the lamp, and suffered to cool. This process may be called the laying an aquatint ground upon the gelatine, and I believe it to be a new process. In the common mode of laying an aquatint ground, the resinous particles are laid upon the naked surface of the metal, before the engraving is commenced. The gelatine being thus covered with a layer of copal, disseminated uniformly and in minute particles, the etching liquid is to be poured on. This is prepared as follows:—Muriatic acid, otherwise called hydrochloric acid, is saturated with peroxide of iron as much as it will dissolve with the aid of heat. After straining the solution, to remove impurities, it is evaporated till it is considerably reduced in volume, and is then poured off into bottles of a convenient capacity; as it cools, it solidifies into a brown semi-crystalline mass. The bottles are then well corked-up, and kept for use. I shall call this preparation of iron by the name of "perchloride of iron." It is a substance very attractive of moisture.

'Water dissolves an extraordinary quantity of it, sometimes evolving much heat during the solution. I find that the following is a convenient way of proceeding:—

'A bottle (No. 1) is filled with a saturated solution of perchloride of iron in water. A bottle (No. 2) with a mixture consisting of five or six parts of the saturated solution and one part of water. And a bottle (No. 3) with a weaker liquid, consisting of equal parts of water and the saturated solution. Before attempting an engraving of importance, it is almost essential to make preliminary trials, in order to ascertain that these liquids are of the proper strength. I have already explained how the photographic image is made on the surface of the gelatine, and covered with a thin layer of powdered copal or resin, which is then melted by holding the plate over a lamp. When the plate has become perfectly cold, it is ready for the etching process, which is performed as follows:—A small quantity of the solution in bottle No. 2, viz. that consisting of five or six parts of saturated solution to one of water, is poured upon the plate, and spread with a camel's-hair brush evenly all over it. It is not necessary to make a wall of wax round the plate, because the quantity of liquid employed is so small that it has no tendency to run off the plate. The liquid penetrates the gelatine wherever the light has not acted on it, but it refuses to penetrate those parts upon which the light has sufficiently acted. It is upon this remarkable fact that the art of photoglyphic engraving is mainly founded.'

Photographic engraving has not, up to the present time (1874), been successfully introduced into the arts. Many especially interesting processes have been devised; and on the small scale, with the proper amount of care, they have been all that is desirable; but, when it has been attempted to apply the process on the larger scale, it has either failed entirely, been uncertain in its results, or too costly for the general public.

PHOTOGRAPHIC PRINTING. Numerous experiments have been made for the purpose of preparing surfaces upon which pictures could be obtained by the action of sunshine, or on to which photographic pictures could be transferred.

Most of the processes are founded on the peculiar action of the solar rays upon the bichromate of potash dissolved in a solution of gelatine. It is not possible in a work of this class to do more than deal with the general principles involved. In the last edition, Woodbury's relief-printing was alone described. A portion of that description is retained.

The process is thus described:—A sheet of talc (mica) of the size required is affixed with gum or water to a plate of glass, and placed on a levelling stand; some bichromatised gelatine is then poured on its surface to form an even coating. When quite dry, the talc by means of a knife is removed, the exposed surface carefully cleaned, and placed in contact with the negative that is to be reproduced. The gelatine is protected by a piece of blotting-paper, then covered with a glass to ensure uniform pressure and close contact between the talc and the negative. After exposure to the sun for an hour, the film must be placed face upwards in a dish of hot water; this will dissolve all the gelatine unacted upon by the sun, leaving a picture in relief, the parts most acted on standing in highest relief. When no more gelatine will dissolve, the film is dried by heat to a certain stage, then naturally.

The metallic intaglio is produced in the following manner:—The gelatine relief, with a clean sheet of metal composed of type-metal and lead placed on it, is submitted to hydraulic pressure. As it is of the greatest importance that it should be kept perfectly flat, a sheet of steel of sufficient thickness to prevent its bending or yielding when in the press, is placed under the talc, and a similar one on top of the metal. The amount of pressure varies with the softness of the metal employed, but the approximate amount may be stated as 4 tons to the square inch. This process does not in the least injure the gelatine mould, which will serve many times.

The process of printing from the metal mould is conducted in the following manner:—The press is made in the form of a very shallow box with a winged lid. In the bottom of the box is placed a plate of thick glass (resting on four screws), and in the lid is a similar plate. The mould is placed face upwards on the glass in the box, and raised by means of the screws to come in contact with the glass lid when closed. A small quantity of ink is then placed on the middle of the mould, the sheet of paper is laid on the top of the ink, and the lid being closed, the ink spreads out between the paper and the mould, filling up the cavities in the latter, the superfluous portion escaping over the edges. The lid should remain closed until the ink is sufficiently set to allow of its being removed with the paper. The conditions required in the ink are fluidity with rapid setting, transparency, and facility for the removal from the mould, with perfect adherence to the paper. All these are found in gelatine, to which any colouring-matter may be added. The ink must be kept warm, the heat and strength being such as to ensure its setting in a reasonable time; the mould should be slightly moistened with oil to prevent the ink adhering to it.

After remaining in the box for about a minute the paper is removed, taking with it the mass of gelatine, which at this stage forms a picture in relief (hence the name of this process, *relief-printing*), but as it dries, this peculiarity gradually disappears, and when it is quite dry not a trace of it is left. One operator may work several of these presses at the same time, and by so doing he may produce from 150 to 200 prints per hour. The print is fixed by immersing it for a short time in a solution of alum, which renders it impervious to moisture and improves its mechanical condition.

Mr. Walter Bentley Woodbury obtained two patents for modified forms of his process in 1870 and in 1872, for sundry improvements in the '*Woodbury Type*;' his latest process being the following one, quoted from the Specification of his process, dated December 4, 1872:—

'In place of using a thin film of collodion (as is generally used in the process called 'Woodbury type') to hold the gelatine of the relief, I proceed as follows:—I first rub over a sheet of plate-glass with French chalk or ox gall, and then coat with the bichromatised gelatine solution as now used. When this is dried and ready for use, I expose the side that was next to the glass for a few seconds to daylight before exposing it under the negative. This has the effect of causing a thin film of the gelatine to become insoluble, which after subsequent exposure under the negative will not wash away, but form a support for the photographic image afterwards impressed, thus doing away with the expense and trouble of the double coatings as now practised. When the gelatine relief is dried in the ordinary way I take a thin sheet of tin foil (same size as the gelatine relief), and attach it by gum or other adhesive substance around the edges to the gelatine relief. I now lay on the back of this a stout sheet of plate-paper, and pass the whole through an ordinary rolling press; the tin foil is by this means impressed into all the details of the relief, but in that state it would be useless to print from. I then proceed as follows:—A shallow metal box is filled with a composition of shellac and asphalt which on warming becomes soft, but hardens on cooling; this box is placed on a hot plate until the composition it contains softens; it is then placed on the lower plate of the ordinary Woodbury printing-press, the foil and relief laid on it, the press closed and the pressure applied by the under screw. When the composition has hardened the tin foil adheres to it, and I remove the gelatine relief from the foil, and use the foil-backed mould to print from. In place of fixing the proofs by alum or other substance of a like nature I varnish the proofs with an ordinary varnish composed of shellac and alcohol, which gives the print the effect of a photograph on albumenised paper, at the same time protecting the surface from moisture. I also sometimes use the composition above named without the foil as a printing-mould direct, and when sufficient numbers have been printed the box holding the composition is again heated, and can be used over and over again. The third part of my invention consists in an improved method of printing Woodbury type by machinery. This I accomplish as follows:—Out of a solid block of iron I have turned a cylindrical hole in which is made to fit very loosely a cylinder of soft metal, having a taper or conical hole through it lengthwise. Between the interior of the steel block and the soft metal cylinder I insert the gelatine reliefs, then by means of a taper or wedge-shaped spindle (roughened) I drive by hammering or by pressure the soft metal against the iron cylinder, thus impressing the relief on the outside of the metal cylinder, the taper spindle at the same time forming a shaft for the cylinder to be used in the process of printing. I then mount this roller bearing the relief in vertical slots in a frame having a bed of plate-glass on which the paper rests, the roller resting on the glass by its own weight and being dragged round by the paper itself, or in place of the glass plate I allow the soft metal to lie on another fixed or moveable roller of metal or glass. The latter may be hollow so as to reduce its temperature in hot weather by a stream of cold water running through it.'

Mr. Joseph Wilson Swan, of Newcastle, was a very zealous worker. He combined with the bichromated gelatine carbon or other colouring-matter. The intermediate stages of the process were as in other of the chromotype processes, and the coloured gelatine was made to receive a printing ink, and impressions were taken therefrom. In 1865 he improved his process as follows:—When the image is produced by means of a negative that is employed to produce an impression of the sensitive gelatinous tissue, previous to its development the tissue is mounted upon a surface of glass, and the uncoated surface of the glass is placed towards the light. Warm water is used to dissolve the soluble portions of the gelatinous coating, and thus to develop the image. The plate bearing this image is surrounded with a rim, hardened by means of a protosalt of iron or of sulphate of alumina. The surface is coated with silver while wet and electrotyped in copper, and from this plate with proper precautions any number of copies can be printed off. In 1872 Mr. Swan informed the writer that the process had been much improved, particularly in the transfer part of the process. The tissue, after being impressed by the solar action in the printing-frame, is now attached to the surface on which the development of the pictures is effected *without the aid of any cementing material*, and *without the employment of a press.* The natural adhesiveness of the tissue itself, aided as it is by atmospheric pressure and capillary attraction, obtains a very perfect attachment of the tissue to either a plate of glass or metal or to insoluble gelatinised or insoluble coagulated albumenised paper. In practice the tissue is transferred for development (by warm water) to a zinc plate *when it is required to be re-transferred to paper* (to procure reversal), and when the re-transfer is not required the tissue is at once transferred to (and the picture developed upon) paper faced with some insoluble material such as named, or lac. Mr. Johnson, who has latterly done much in the improvement of the process in connection with the points referred to, and who works in conjunction with the Autotype Company, prefers to use a paper faced with lac, decolourised of course. This process has been largely developed as the '*autotype process*' and many very fine productions are now being regularly published.

Numerous modifications of these processes have from time to time been brought under the notice of the public. Mr. Duncan Campbell Dallas, amongst others, patented the following process, known as the *Dallastype* :—

The design is photographed or drawn upon a glass plate in a medium that intercepts the actinic rays. Over the design a solution of bichromatised gelatine is poured, and when the coating thus formed is sufficiently dry, the uncoated side is exposed to the light. The parts not acted upon by light are then softened and caused to swell by treatment with cold water; this is poured off and the design is repeatedly washed with warm water till the design is free from the gelatinous mixture and allowed to dry. A mould is then taken of the surface by electrotyping, by casting, or by pressure.

Further information relative to processes of this character must be sought in the numerous Specifications of Patents which exist. The process of Photozincography will be found under its special heading. See PHOTOZINCOGRAPHY.

PHOTOGRAPHY. (From *φῶς*, *phōs*, *phōtos*, light; *γραφή*, *graphé*, a writing or a description.) The art of producing pictures by the agency of sunshine, acting upon chemically-prepared papers.

There are certain chemical compounds, and especially some of the salts of silver, which are rapidly decomposed by the influence of the sunshine, and, though more slowly, by ordinary daylight, or even by powerful artificial light. As the extent to which the decomposition is carried on, depends upon the intensity of radiation proceeding from the object, or passing through it, accordingly as we are employing the reflected or the transmitted rays, it will be obvious that we shall obtain very delicate gradations of darkening, and thus the photograph will represent in a very refined manner all those details which are rendered visible to the eye by light and shadow.

There are two methods by which photographs can be taken: the first and simplest is by *super-position*, but this is applicable only to the copying of engravings or of such botanical specimens as can be spread out upon paper, and objects which are entirely or in part transparent. The other method is by throwing upon the prepared paper the image obtained by the use of a lens fitted into a dark box—the *camera obscura*.

To carry out either of these methods certain sensitive surfaces must be produced; these therefore claim our first attention:—The artist requires—

1. Nitrate of silver. 2. Ammonia nitrate of silver. 3. Chloride of silver. 4. Iodide of silver. 5. Bromide of silver. These five chemical compounds may be regarded as the agents most essential in the preparation of photographic surfaces.

1. NITRATE OF SILVER. The crystallised salt should, if possible, always be procured. The fused nitrate, which is sold in cylindrical sticks, is liable to contamination. A preparation is sometimes sold for nitrate of silver, at from 6*d.* to 9*d.* the ounce less than the ordinary price, which may induce the unwary to purchase it. This reduction of price is effected by fusing with the salt of silver a proportion of some cupreous salt, generally the nitrate, or nitrate of potash. This fraud is readily detected by observing if the salt becomes moist on exposure to the air,—a very small admixture of copper rendering the nitrate of silver deliquescent. The evils to the photographer are, want of sensibility upon exposure, and the perishability (even in the dark) of the finished drawing.

The most simple kind of photographic paper is that washed with the nitrate of silver only; and for many purposes it answers well, particularly for copying lace or feathers; and it has this advantage that it is perfectly fixed by well soaking in *pure* warm water.

The best proportions in which this salt can be used are 60 grains of it dissolved in a fluid ounce of water. Care must be taken to apply it equally, with a quick but steady motion, over every part of the paper.

By dissolving the nitrate of silver in common rectified spirits of wine instead of water, we produce a tolerably sensitive nitrated paper, which darkens to a very beautiful chocolate-brown.

2. Ammonia Nitrate of Silver. Liquid ammonia is to be dropped carefully into nitrate of silver; a dark oxide of silver is thrown down; if the ammonia-liquor is added in excess, this precipitate is redissolved, and we obtain a perfectly colourless solution. Paper washed with this solution is more sensitive than that prepared with the ordinary nitrate.

3. Chloride of Silver. This salt is obtained most readily by pouring a solution of common salt, *chloride of sodium*, into a solution of nitrate of silver. It then falls as a pure white precipitate, which changes colour in diffused daylight.

Chloridated papers are formed by producing a chloride of silver on their surface, by washing the paper with the solution of chloride of sodium, or any other chloride, and when the paper is dry, with the solution of nitrate of silver.

The most sensitive paper.—Chloride of sodium, 30 grains to 1 ounce of water; nitrate of silver, 120 grains to 1 ounce of distilled water.

The paper is first soaked in the saline solution, and after being carefully wiped with linen, or pressed between folds of blotting-paper and dried, it is to be washed twice with the solution of silver, drying it by a warm fire between each washing. This paper is very liable to become brown in the dark. Although images may be obtained in the camera obscura on this paper by about half an hour's exposure, they are never very distinct, and may be regarded as rather curious than useful.

Less sensitive paper for copies of engravings or botanical specimens.—Chloride of sodium, 25 grains to 1 ounce of water; nitrate of silver, 99 grains to 1 ounce of distilled water.

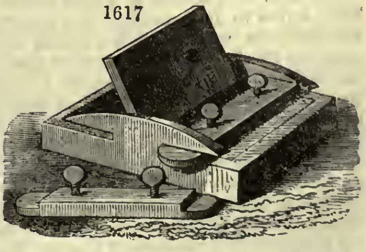
Common sensitive paper for copying lace-work, feathers, &c.—Chloride of sodium, 20 grains to 1 ounce of water; nitrate of silver, 60 grains to 1 ounce of distilled water. This paper keeps tolerably well, and, if carefully prepared, may always be depended upon for darkening equally.

4. Iodide of Silver. This salt was employed very early by Talbot, Herschel, and others, and it enters as the principal agent into Mr. Talbot's calotype-paper (see Calotype). Paper is washed with a solution of the iodide of potassium, and then with nitrate of silver. By this means papers may be prepared which are exquisitely sensitive to luminous influence, provided the right proportions are hit; but, at the same time, nothing can be more insensible to the same agency than the pure iodide of silver. A singular difference in precipitates, to all appearance the same, led to the belief that more than one definite compound of iodine and silver existed; but it is now proved that pure iodide of silver will not change colour in the sunshine, and that the quantity of nitrate of silver in excess regulates the degree of sensibility. Experiment has proved that the blackening of one variety of iodated paper, and the preservation of another, depends on the simple admixture of a very minute excess of the nitrate of silver.

5. Bromide of Silver. Bromide is the most sensitive to light of all the salts of silver. To prepare a highly sensitive paper of this kind, select some sheets of superior glazed post, and wash it on one side only with bromide of potassium (40 grains to 1 ounce of distilled water) over which, when dry, pass a solution of 100 grains of nitrate of silver in the same quantity of water. The paper must be dried as quickly as possible without exposing it to too much heat; then again washed with the silver-solution, and dried in the dark. Such are the preparations of an ordinary kind, with which the photographer will proceed to work.

The most simple method of obtaining sun-pictures is that of placing the objects to be copied on a piece of prepared paper, pressing them close with a piece of glass, and exposing the arrangement to sunshine: all the parts exposed darken, while those covered are protected from change, the resulting picture being *white* upon a *dark ground*.

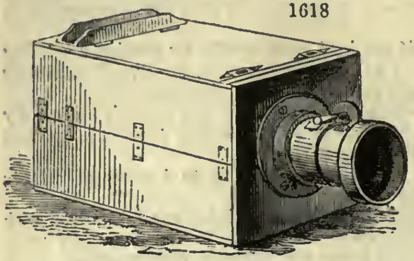
1617



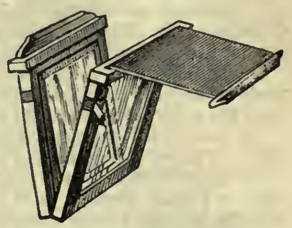
For the multiplication of photographic drawings, it is necessary to be provided with a frame and glass, called a *copying frame*. The glass must be of such thickness as to resist considerable pressure, and it should be selected as colourless as possible, great care being taken to avoid such as have a tint of yellow or red, these colours preventing the permeation of the most efficient rays. *Fig.* 1617 represents the frame, showing the back, with its adjustments for securing the close contact of the paper with every part of the object to be copied.

Having placed the frame face downwards, carefully lay out on the glass the object to be copied, on which place the photographic paper very smoothly. Having covered this with the cushion, which may be either of flannel or velvet, fix the back, and adjust it by the bar, until every part of the object and paper are in the closest possible contact; then turn up the frame and expose to sunshine.

1618



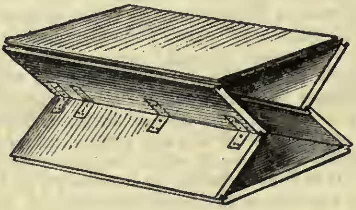
1619



It should be here stated, once for all, that such pictures, howsoever obtained, are called *negative photographs* ;—and those which have their lights and shadows correct as in nature—dark upon a light ground—are *positive photographs*. The mode of effecting the production of a *positive* is, having, by fixing, given permanence to the negative picture, it is placed, face down, on another piece of sensitive paper, when all the parts which are white on the first, admitting light freely, cause a dark impression to be made on the second, and the resulting image is correct in its lights and shadows, and also as it regards right and left.

For obtaining pictures of external nature, the Camera Obscura of Baptista Porta is employed.

1620



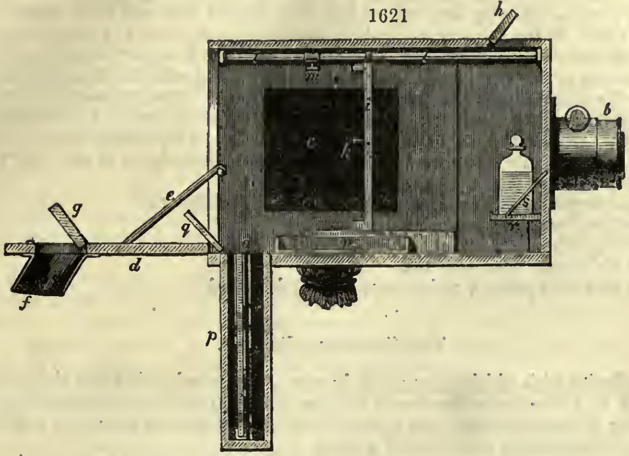
The figures (*figs.* 1618, 1619, 1620) represent a perfect arrangement, and, at the same time, one which is not essentially expensive. Its conveniences are those of folding (*fig.* 1620), and thus packing into a very small compass, for the convenience of travellers.

Fig. 1618 exhibits the instrument complete. *Fig.* 1619 shows the screen in which the sensitive paper is placed, the shutter being up and the frame open that its construction may be seen.

Camera obscuras of a more elaborate character are constructed, and many of exceeding ingenuity, which give every facility for carrying on the manipulations out of doors.

Fig. 1621 is a section of a very useful instrument, and *fig.* 1622 its external form. With a view to its portability it is constructed so as to serve as a packing-case for all the apparatus required. *a* is a sliding door, which supports the lens. *b*, *c*, *c* are side-openings fitted with cloth-sleeves to admit the operator's arms. *d* is a hinged door at the back of the camera, which can be supported like a table by the hook *e*. *f* is the opening for looking into the camera during an operation. This opening is closed when necessary by the door *g*, which can be opened by the hand passed into the camera through the sleeves *c*. The yellow-glass window which admits light into the camera during an operation is under the door, *h*. *i* is the sliding frame for holding the focussing glass, or the frame with the prepared glass, either of which is fastened to the sliding frame by the check, *k*. The frame slides along the rod, *l l*, and can be fitted to the proper focus by means of the step *m*. *n* is the gutta-percha washing-tray. *o* is an opening in the bottom of the instrument near the door, to admit the well, *p*, and which is closed when the well is removed by the door. The well is divided into two cells, one of which contains the focussing glass, and the other the glass trough, each in a frame adapted to the sliding frame, *i*. On each side of the sliding door that supports the lens, *a*, there is within the camera a small hinged-table, *r*, supported by a bracket, *s*.

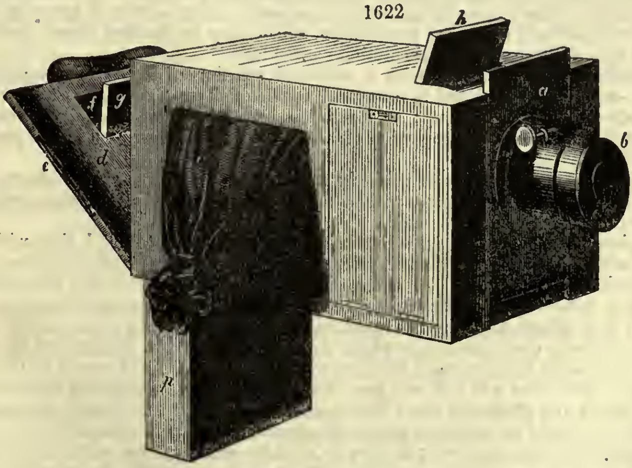
1621



These two tables serve to support the bottles that contain the solutions necessary to be applied to the glass plate after its exposure to the lens.

For supporting any of these camera obscuras, tripod stands are employed; these are now made in an exceedingly convenient form, being light, at the same time that

1622



they are sufficiently firm to secure the instrument from any motion during the opera tion of taking a picture.

The true photographic artist, however, will not be content with a camera obscura of this or any other kind. He will provide himself with a tent, in which he may be able to prepare his plates, and subsequently to develop and to fix his pictures. Many kinds of tent have been brought forward; but we have not seen any one which unites perfectly all that can be desired, within a limited space, and which possesses the great recommendation of lightness.

Smartt's photographic tent, however, appears to meet nearly all the conditions required. In this tent an endeavour has been made to obviate many of the inconveniences complained of, especially as to working space, firmness, simplicity, and portability. It is rectangular in form, is 6 feet high in the clear, and 3 feet square, affording table space equal to 36 inches by 18 inches, and ample room for the operator to manipulate with perfect ease and convenience. The table is made to fold up when not in use; and in place of the ordinary dish for developing, a very efficient and portable tray is provided, made of india-rubber cloth, having its two sides fixed and rigid, and its two ends moveable; it thus folds up into a space but little larger than one of its sides. The working space of the table is economised thus:—a portion of it is occupied in the way just described: the silver-bath is suspended from the *front* of the table, and rests upon a portion of the framework of the tent. This arrangement leaves ample space on the table for manipulating the largest-sized plates. The collodion pourer, the plate-developing holder, the developing cups, and the water-bottle, have all special points in construction. The entire weight of the tent is 20 lbs., and it is easily erected or taken down by one person. Many improvements have been introduced in this tent, which now render it nearly perfect.

The processes of most importance may be divided as follow:—

1. The *Copying* process, already described.
2. The *Daguerreotype*. See DAGUERREOTYPE.
3. The *Calotype*. See CALOTYPE.
4. The *Collodion* process, which must now be described

THE COLLODION PROCESS.

The difficulty with which we are met in any attempt to describe this photographic process is, that it is almost hopeless to find two photographers who adopt precisely the same order of manipulation; and books almost without number have been published, each one recommending some special system.

By general consent the discovery of the collodion process, as now employed, is given to the late Mr. Scott Archer. It will, therefore, be considered quite sufficient to give the details of his process, which has really been but little improved on since its first introduction.

To prepare the collodion. Thirty grains of gun-cotton should be taken and placed in 18 fluid ounces of rectified sulphuric ether, and then 2 ounces of alcohol should be added, making thus 1 imperial pint of the solution. The cotton, if properly made, will dissolve entirely; but any small fibre which may be floating about should be allowed to deposit, and the clear solution poured off.

To iodise the collodion. Prepare a saturated solution of iodide of potassium in alcohol—say 1 ounce, and add to it as much iodide of silver, recently precipitated and well washed, as it will take up: this solution is to be added to the collodion, the quantity depending on the proportion of alcohol which has been used in the preparation of the collodion.

Coating the plate. A plate of perfectly smooth glass, free from air-bubble or striæ, should be cleaned very perfectly with a few drops of ammonia on cotton, and then wiped with a very clean cotton cloth.

The plate must be held by the left hand perfectly horizontal, and then with the right a sufficient quantity of iodised collodion should be poured into the centre, so as to diffuse itself equally over the surface. This should be done coolly and steadily, allowing it to flow to each corner in succession, taking care that the edges are well covered; then gently tilt the plate, that the superfluous fluid may return to the bottle from the opposite corner to that by which the plate is held. At this moment the plate should be brought into a vertical position, when the diagonal lines caused by the fluid running to the corner will fall one into the other, and give a clear flat surface. To do this neatly and effectually some little practice is necessary, as in most things; but the operator should by no means hurry the operation, but do it systematically, at the same time not being longer over it than is actually necessary, for collodion being an ethereal compound evaporates rapidly. Many operators waste their collodion by imagining it is necessary to perform this operation in great haste; but such is not the case, for an even coating can seldom be obtained if the fluid is poured on and off again too rapidly; it is better to do it steadily, and submit to a small loss from evaporation. If the collodion becomes too thick, thin it with the addition of a little fresh and good ether.

Exciting the plate. Previous to the last operation, it is necessary to have the bath ready, which is made as follows:—

Nitrate of silver	30 grains.
Distilled water	1 ounce.

Dissolve and filter.

The quantity of this fluid *necessary* to be made must depend upon the *form of trough to be used*, whether horizontal or vertical, and also upon the size of the plate. With the vertical trough a glass dipper is provided, upon which the plate rests, preventing the necessity of any handle or the fingers going into the liquid. If however, the glass used is a little larger than required, this is not necessary. Having then obtained one or other of these two, and filtered the liquid previously, the plate, free from any particle of dust, &c., is to be *immersed steadily and without hesitation*; for if a pause should be made in any part, a line is sure to be formed, which will print in a subsequent part of the process.

The plate being immersed in the solution must be kept there a sufficient time for the liquid to act freely upon the surface, particularly if a negative picture is to be obtained. *As a general rule, it will take about two minutes, but this will vary with the temperature of the air at the time of operating, and the condition of the collodion.* In cold weather, or indeed anything below 50° Fahr. the bath should be placed in a warm situation, or a proper decomposition is not obtained under a very long time. Above 60° the plate will be certain to have obtained its maximum of sensibility by two minutes' immersion, but below this temperature it is better to *give a little extra time.*

To facilitate the action, let the temperature be what it may, the plate must be lifted out of the liquid two or three times, which also assists in getting rid of the ether from the surface, for unless this is thoroughly done a uniform coating cannot be obtained; *but on no account should it be removed until the plate has been immersed about half a minute*, as marks are apt to be produced if removed sooner.

The plate is now ready to receive its impression in the camera obscura. This having been done, the picture is to be developed.

The development of the image. To effect this the plate must be taken again into the dark room, and with care removed from the slide to the levelling stand.

It will be well to caution the operator respecting the removal of the plate. Glass, as before observed, is a bad conductor of heat; therefore, if in taking it out we allow it to rest on the fingers at any one spot too long, that portion will be warmed through to the face, and as this is not done until the developing solution is ready to go over, the action will be more energetic at those parts than at others, and consequently destroy the evenness of the picture. We should, therefore, handle the plate with care, as if it already possessed too much heat to be comfortable to the fingers, and that we must therefore get it on the stand as soon as possible.

Having then got it there, we must next cover the face with the developing solution. This should be made as follows:—

Pyrogallic acid	5 grains.
Glacial acetic acid	40 minims.
Distilled water	10 ounces.

Dissolve and filter.

Mr. Delamotte employs

Pyrogallic acid	9 grains.
Glacial acetic acid	2 drachms.
Distilled water	3 ounces.

Now, in developing a plate, the quantity of liquid taken must be in proportion to its size. A plate measuring 5 inches by 4 will require half an ounce; less may be used, but it is at the risk of stains; therefore we would recommend that half an ounce of the above be measured out, into *a perfectly clean measure*, and to this from 8 to 12 drops of a 50-grain solution of nitrate of silver be added.

Pour this quickly over the surface, taking care not to hold the measure too high, and not to pour all on one spot, but having taken the measure properly in the fingers, begin at one end, and carry the hand forward; immediately blow upon the face of the plate, which has the effect not only of diffusing it over the surface, but causes the solution to combine more equally with the damp surface of the plate; it also has the effect of keeping any deposit that may form in motion, which if allowed to settle, causes the picture to come out mottled. A piece of white paper may now be held under the plate, to observe the development of the picture: if the light of the room is adapted for viewing it in this manner, well; if not, a light must be held below, but in either case arrangements should be made to view the plate easily whilst under the operation: a successful result depending so much upon obtaining sufficient development without carrying it too far.

As soon as the necessary development has been obtained, the liquid must be poured off, and the surface washed with a little water, which is easily done by holding the plate over a dish, and pouring water on it; taking care, both in this and a subsequent part of the process, to hold the plate horizontally, and not vertically, so as to prevent the coating being torn by the force and weight of water.

Protosulphate of iron, which was first introduced as a photographic agent in 1840 by Mr. Robert Hunt, may be employed, instead of the pyrogallic acid, with much advantage. Generally the collodion portraits are now developed by the iron salt. The following are the best proportions:—

Protosulphate of iron	1 ounce.
Acetic acid	12 minims.
Distilled water	1 pint.

This is used in the same manner as the former solutions.

Fixing of image. This is simply the removal of iodide of silver from the surface of the plate, and is effected by pouring over it, after it has been dipped into water, a solution of hyposulphite of soda, made of the strength of 4 ounces to 1 pint of water. At this point daylight may be admitted into the room, and indeed we cannot judge well of its removal without it. We then see by tilting the plate to and fro the iodide gradually dissolve away, and the different parts left more or less transparent, according to the action of light upon them.

It then only remains to thoroughly wash away every trace of the hyposulphite of soda, for should any salt be left, it gradually destroys the picture. The plate should therefore either be immersed with great care in a vessel of clean water, or what is better, water poured gently and carefully over the surface. After this it must be placed upright to dry or be held before a fire.

The fixing processes. The most important part of Photography, and one to which the least attention has been paid, is the process of rendering permanent the beautiful images which have been obtained. Nearly all the fine photographs with which we are now familiar are not permanent. This is deeply to be regretted, especially as there appears to be no necessity for their fading away. In nearly all cases the fading of a photograph may be referred to carelessness; and it is not a little startling, and certainly very annoying, to hear a very large dealer in photographic pictures declare that the finest pictures by the best photographers are the first to fade. This is, no doubt, to be accounted for by the demand which there is for their pictures, leading to a fatal rapidity in the necessary manipulatory details.

There is no necessity for a photograph to fade if kept with ordinary care. It should be at all events as permanent as a sepia drawing. Hyposulphite of soda is the true fixing agent for any of the photographic processes, be they Daguerreotype, calotype, collodion, or the ordinary process for producing positive prints. It should be understood, whichever of the salts of silver are employed, that by the action of the solar rays either oxide of silver or metallic silver is produced, and the unchanged chloride, iodide, or bromide can be dissolved out by the use of the *hyposulphite of soda.*

The photographic picture on paper, on metal, or on glass, is washed with a strong solution of the hyposulphite of soda, and the silver salt employed combines with it, forming a peculiarly sweet compound, the hyposulphite of silver; this is soluble in water, and hence we have only to remove it by copious ablutions. The usual practice is to place the pictures in trays of water and to change the fluid frequently. In this is the danger, and to it may be traced the fading of nine-tenths of the pictures prepared on paper.

Paper is a mass of linen or cotton fibre; howsoever fine the pulp may be prepared, it is still full of capillary pores, which, by virtue of the force called capillarity, holds with enormous tenacity a large portion of the solid contents of the water. If we make a solution of a known strength of the hyposulphite of soda, and dip a piece of paper into it, it will be found to have lost more of the salt than belongs to the small quantity of water abstracted by the paper. Solid matter in excess has been withdrawn from the solution. So a photographic picture on paper holds with great tenacity one or other of the hyposulphites. By soaking there is of course a certain portion removed, but it is not possible by any system of soaking to remove it all.

The picture is, however, prepared in this manner, and slowly, but surely, under the combined influences of the solar rays and atmospheric moisture, the metallic silver loses colour, *i. e.* the photograph fades.

The only process to be relied on demands that every picture should be treated separately. First, any number may be soaked in water, and the water changed; by this means the excess of the hyposulphite of silver is removed. Then each picture must be taken out and placed upon a slab of porcelain or glass, and being fixed at a small angle, water should be allowed to flow freely over and off it. Beyond this, the operator should be furnished with a piece of soft sponge, and he should maintain for a long time a dabbing motion. By this mechanical means he disturbs the solid matter held in the capillary tubes, and eventually removes it. The labour thus bestowed is rewarded by the production of a permanent picture, not to be secured by any other means.

A process has recently been introduced (1874) which is highly spoken of. It consists essentially in mixing recently-precipitated bromide of silver with very pure gelatine. This creamy, semi-opaque mixture is poured on glass-plates, and these are dried with application of moderate heat in perfect darkness. The plates are rendered highly sensitive in the usual manner. It is said that in good light a portrait can be taken in five seconds.

PHOTOMETRY. The measurement of light, or of illuminating power. See ILLUMINATION.

PHOTO-SCULPTURE. The following description of this art is written by the late M. A. Claudet, F. R. S., who most successfully practised it:—'This beautiful application of photography is called Photo-sculpture, and is the invention of M. Willème, an eminent French sculptor. Before explaining how M. Willème was led to this discovery, let me remind you that photography itself was invented by painters of talent—by artists who, while using the camera obscura for studying the subject of their intended pictures, were struck with the beauty of those natural representations. In contemplating them they naturally desired that the pictures could be permanently fixed. Considering that these pictures were formed by the light reflected from the objects, they essayed to fix them by availing themselves of the known scientific fact that light had the property of blackening certain chemical compounds. The flash of that idea was enough; their genius and perseverance solved the problem, and they created that art which they desired so much—photography. A similar and no less instructive story may be told of photo-sculpture. M. Willème was in the habit, whenever he could procure photographs of his sitters, of endeavouring to communicate to the model the correctness of those unerring types. But how should he raise the outlines of flat pictures into solid form? Yet these single photographs, such as they were, could serve him to measure exactly profile outlines. He could indeed, by means of one of the points of a pantograph, follow the outline of a photograph, while with the other point directed on the model, he ascertained and corrected any error which had been communicated to his work during the modelling. What he could do with one view or one single photograph of the sitter, he might do also with several other views if he had them. This was sufficient to open the inquiry of an ingenious mind. He saw at once that if he had photographs of many other profiles of the sitter, taken at the same moment, by a number of camera obscuras placed round, he might alternately and consecutively correct his model by comparing the profile outline of each photograph with the corresponding outline of the model. Such was the origin of a marvellous and splendid discovery. But it soon naturally occurred to him, that instead of correcting his model when nearly completed, he had better work with the pantograph upon the rough block of clay, and cut it out gradually all round in following one after the other the outline of the photographs. Now supposing that he had twenty-four photographs, representing the sitter in as many points of view (all taken at once), he had but to turn the block of clay after every operation $\frac{1}{24}$th of the base upon which it is fixed, and to cut out the next profile, until the block had completed its entire revolution, and then the clay was transformed into a perfect solid figure of the twenty-four photographs; the statue of the bust was made. When this is once explained, everyone must be struck with admiration at the excellence of the process. It is so sure, and so simple, that we are surprised it has not been thought of before.'

PHOTOZINCOGRAPHY. This is the name given by Major-General Sir Henry James, R.E., Director of the Ordnance Survey, who has thus described the process:—

'For the purpose of producing rapidly and in large numbers, fac-similes of plans, drawings, written and printed documents, &c., of the same size as the originals, or to any required lesser scale, the present Director of the Ordnance Survey successfully introduced in 1859, a method combining the accuracy of photography with the facility of printing from zinc-plates, and named the process Photozincography. It is now extensively used at Southampton for supplying the public, at a low cost, with fac-similes of some of the most interesting and valuable State papers that are preserved among the national manuscripts of the United Kingdom.

'The fac-similes being in ink of which carbon is the basis, are not liable to fade, like photographic prints in silver; for although the silver is coated with a film of gold in the toning bath, it slowly yields to atmospheric influences, and to the long-continued action of small traces (almost impossible to eradicate) of substances employed in the manipulation.

'In the process of zincography a tracing of the document is made in a greasy ink, and applied to a zinc-plate, from which any desired number of impressions may be printed; but in photozincography a photograph is prepared in such a manner that it may be transferred to a zinc-plate, the prints from which are free therefore from any error of the draughtsman's hand.

'In copying maps, engravings, manuscripts, &c., a negative of the object is taken on a glass-plate, and the silver deposit blackened with corrosive sublimate and ammonium hydrosulphate; a sun-print is taken from the negative on paper, coated with gelatine and bichromate of potass, which surface when exposed to the influence of light, is insoluble in water at a moderately high temperature.

'The print is uniformly covered all over with greasy transfer ink, and afterwards washed with warm water to dissolve the gelatine unacted upon by light, and so carry away the ink upon it, which now remains only on the insoluble portions. In this way a print in a greasy carbon ink is prepared, which has both the appearance and the properties of an ordinary tracing in lithographic ink, and can be transferred to zinc or stone in the usual manner.

'The paper used for the carbon print should be tough, free from loose fibres, and have a surface that will remain almost undisturbed when saturated with water, and subjected to gentle friction. The double-elephant bank-post manufactured by Cowan and Sons, Cannon Street, London, answers these requirements, and has been found more suitable than any other paper that has been tried at Southampton.

'The sensitizing solution is made by dissolving gelatine in hot water, and adding potassium bichromate in solution in the following proportions:—

Nelson's best patent fine gelatine	3 ozs.
Potassium bichromate	2 „
Hot water	50 „

The mixture must be made and preserved in the dark.

'When used for coating the paper, it is put into a flat dish and kept at a temperature of about 100° Fahr., by means of a water-bath; the paper is floated on its surface for two or three minutes, then hung up to dry by two corners, floated again for a shorter period, but at a lower temperature, so as not to remove the first coating, and dried in a reversed position; by this double application, with the aid of a high temperature maintained during the act of drying, a uniform surface is obtained.

'The coated paper, which is very sensitive to light, is then smoothed by being passed through a lithographic press, and may be used any time within a week of its preparation, but the best results in making copies of maps, engravings, manuscripts, &c., are obtained when the sensitized paper has not been kept longer than two or three days; after a week the paper becomes useless, it being almost impossible to clear the ink from the ground of the print on account of the uniform reduction of a portion of the potassium bichromate. The sensitizing mixture may be preserved for further use for a considerable length of time, if kept in an opaque vessel, free from organic matter, and in a dark room; an earthenware jar is a convenient receptacle, as the mixture when cold becomes a jelly, and the jar can be put in hot water without injury, so as to melt its contents when required for preparing more paper.

'The time required to obtain a suitable sun-print on the prepared paper varies perhaps from one to twenty minutes, with the amount of light, the age of the paper, and the condition of the negative; it may generally be known by the exposed portions of the yellow bichromate surface becoming a dark olive colour; the printing should then be stopped, and the paper coated with transfer ink. Paper recently prepared requires rather longer exposure than that two or three days old, as, if the latter be darkly printed, it is almost impossible to wash off the superfluous ink.

'To make the transfer ink, 3 ounces of Burgundy pitch are melted in an iron saucepan, ½ an ounce of white wax, and ½ an ounce of palm-oil are added, and then by degrees 1 ounce of finely-powdered bitumen of Judæa; the mixture is stirred and heated over a fire until it commences to burn; after the flame is extinguished by the lid of the saucepan, 8 ounces of best lithographic printing ink, rubbed up with 4 ounces of middle lithographic varnish are gradually added, and when uniformly mixed, the composition is ground in small portions on a hot slab with a stone muller.

'When this ink is required for use, a little of it is spread upon a stone and thinned with turpentine, according to the consistency required for the nature of the work about to be transferred. To coat the paper, a lithographic stone is uniformly inked with a printing roller charged with the composition, the sun-print is laid face downwards on the stone, and passed through a lithographic press in a dark room; it is detached from the stone, reversed in position, and passed through the press a second time to ensure a sufficient and uniform coating of ink. After the print has been inked, it is floated face upwards on water at about 90° Fahr., for a few minutes, when by an unequal swelling of the gelatine the detail of the image can be distinguished. To prevent stains, that would inevitably spoil fine work, it is necessary that no water be allowed to fall upon the face of the print while it is floating. After a few minutes, the paper is raised from the surface of the water, and laid evenly, with the inked face uppermost, on a slightly-inclined surface of glass or earthenware, and a fine soft sponge dipped in tepid water is repeatedly passed over it with a light hand, plenty of water being used; this removes the gelatine and bichromate that have not been affected by light, and they carry off with them the ink that was on their surface, leaving it only on the parts of the print that have been rendered insoluble. Very gentle friction should be used, and during the process of sponging, the print should be soaked face downwards in warm water for a few minutes, to assist in loosening the ink and removing the gelatine. Soaking in this manner, for some little time, has a great effect in preventing blemishes, in lessening the amount of friction which is sometimes liable to break up the finer parts of the print, and in the case of sensitive paper, over-exposed to light, of improving the resulting transfer. When the chromo-carbon print is sharp and clear, it should be well washed with tepid water so as to remove every trace of soluble gelatine, as if any intervened between the inky surface and the zinc plate (or lithographic stone) with which it is to be pressed in contact, there would be a flaw in the transfer. After this washing, the print is dried and transferred to zinc or stone, in the same way as an ordinary tracing in lithographic ink, only from the ink not having been long exposed to the atmosphere, it is seldom necessary to pass it more than once through the press.

'The same number of impressions can be obtained as if the transfer had been effected by means of a tracing in greasy ink.

'In reproducing a large-sized map by photozincography, a series of rectangles are drawn on it suitable to the size of the camera, and negatives are taken which shall overlap each portion, the chromo-carbon prints from these being joined together before they are transferred to the zinc-plate. To ensure a good result, the negatives should be as nearly as possible of uniform density, the prints finished with a corresponding thickness of ink on their surfaces, and the joining effected by cutting away the overlapping portions in such a manner as not to interfere with the names or prominent objects on the map. In this way photozincographs exceeding 3 feet in length by 2 feet in breadth have been successfully prepared.

'Photozincography has also been applied to the representation of buildings, natural objects, scenery, &c., with more or less success, according to the strength of the contrasts of light and shade presented by the object; the difficulty being to obtain fine gradations of shade or half-tone. In this application of the art, the glass negatives taken are left in the same condition as they would be used for making ordinary silver prints of views and scenery, for if they were intensified with corrosive sublimate and ammonium hydro-sulphate, as described in copying maps and engravings (where sharp lines are required), all gradations of shade would be destroyed.

'Chromo-carbon prints are made from these negatives in the manner before described, and transferred to zinc, the only difference in their preparation being that the paper coated with bichromate and gelatine is kept from four to five days after preparation before being printed upon, and the transfer-ink is a little more burnt, when being prepared, than the ink that is used for prints without gradations of shade; considerable experience is necessary in washing the prints so as to bring out the full effect of the shadows, and much of the success of the process also depends on the skill and care of the zinc-printer. An application of glycerine to the zinc-plate is found to assist materially in keeping the transfer clean, and preventing the fine portions from being clogged with ink; 1 ounce of glycerine is added to 1 pint of freshly-dissolved gum Arabic of the usual consistency, made neutral to test-paper by the addition of lime-water, and 2 ounces of this mixture added to 12 ounces of water are used for wiping over the surface of the plate; the addition of the glycerine seems to keep the surface moist for a longer time than the simple application of water, and renders the roller less liable to 'catch.' Glycerine is also used in this manner in ordinary zincographic printing, when a very large number of impressions are required from a plate.

'Photozincographic views of natural objects generally have a better effect when printed on tinted and enamelled paper than on an ordinary white ground, and paper so coated adds materially, by lifting the ink better than a plain surface, in keeping the transfer in good condition on the zinc. A paper of an agreeable tint may be prepared with the following composition:—

Size melted in 10 pints of water	20 oz.
Zinc white, ground in water and weighed wet	14 lbs.
Oxide of iron	3 oz.
Chrome yellow	200 grains.
Vermilion	30 „

'The mixture is brushed while warm over the paper, any streaks being obliterated with a flat camel's-hair brush; and when the coating is dry, a second layer is applied in a similar manner.'

PHTHALIC ACID. A crystallised substance produced by the action of nitric acid on rubian. See MADDER.

PHYTOGRAPHY. See NATURE-PRINTING.

PIASSABA FIBRE, obtained from the *Attalea funifera*, and used in Brazil for rope-making. It is this palm which also yields Coquilla nuts.

PICAMARE. A colourless oil in wood-tar, discovered by Reichenbach. See DISTILLATION, DESTRUCTIVE; NAPHTHA; PYROXILIC SPIRIT.

PICKLES are various kinds of vegetables and fruits preserved in vinegar. The preparation of pickles belongs rather to a book on cookery. The peculiar and beautiful green colour which has been frequently imparted to pickles is due in nearly all cases to the use of a salt of copper. This is in the highest degree injurious, and cannot be too strongly deprecated. The presence of copper may be detected by putting the blade of a perfectly clean knife, or still better, a polished piece of soft iron, into the suspected pickle; it will, if copper be present, become coated in a short time with a cupreous film. It is satisfactory to find that most of our large pickle-manufacturers are content to sacrifice the colour, at one time so much looked to; and they now furnish the public with pickles which are free from any metallic contamination.

PICOLINE, $C^{12}H^{7}N$ (**$C^{6}H^{7}N$**). A nitryle base, isomeric with aniline, discovered by Anderson in coal-naphtha and bone-oil. It is also contained in the shale-naphtha and crude chinoline.

PICRIC ACID. One of the products of the action of nitric acid upon phenol: it may also be obtained from a considerable number of other organic compounds, amongst which may be mentioned an Australian resin, from *Xanthorrhœa hastilis* (Stenhouse), salicin, indigo, &c; but the best source is undoubtedly impure phenol, or even the coal-tar oils that distil at 180° and 200° Cent. (Laurent). See CARBOLIC ACID.

The reaction between nitric acid and phenol is very violent. It is therefore necessary to observe many precautions when operating upon considerable quantities of material. When the first violent action has ceased, fresh quantities of nitric acid are added, and the mixture is heated in order to facilitate the reaction. On allowing the mixture to cool, after having added water, a yellowish, very bitter mass is obtained, which is washed with water in order to remove the excess of nitric acid. This mass consists of impure picric acid, and treated with cold or hot water, it furnishes solutions which, when filtered, may be employed for the ordinary processes of dyeing.

It is, however, preferable to purify the acid and to prepare it in the crystallised condition.

For this purpose two processes may be employed. The yellow mass may be extracted by boiling water sufficiently acidulated with sulphuric acid to render comparatively insoluble the yellow resinous matters. (These yellow matters are produced by an incomplete transformation, partly of the phenol, but principally of the neutral oils, and other foreign matters accompanying it, and which have also been attacked by the nitric acid.) The picric acid crystallises from the solution (the more easily for being acidulated with sulphuric acid), and is deposited in the form of crystalline plates of a light yellow colour. But these crystallisations cause the loss of a considerable quantity of substance, and by no means eliminate completely the yellow tarry matter. It is therefore better to convert the impure acid into a salt which may be easily purified, and afterwards to precipitate the acid from it. The picrate of potassium is very applicable for this purification, as it is only slightly soluble in cold water, whilst it is readily soluble in boiling.

But in operating upon a large scale, the filtration of large quantities of the salt becomes extremely difficult, as the liquids, even when boiling and contained in heated funnels, have a great tendency to crystallise on the filters, which then become choked.

Several manufacturers therefore adopt another process, which consists in saturating a boiling solution of picric acid with carbonate of soda, excess being avoided, for fear of dissolving the yellow resinous matter. The boiling matters are filtered to separate this resin, and to the filtrate a further quantity of carbonate of soda is added. This causes the bulk of the picrate of soda to crystallise out, as this salt is nearly insoluble in solutions containing an excess of alkaline carbonate. The small quantity of picrate still remaining in the mother-liquors may be precipitated by the addition of a salt of potassium.

The crystallised picrate of soda thus obtained is then dissolved, and its boiling solution is decomposed by an excess of sulphuric acid. The picric acid thus separated being very insoluble in the mother-liquors containing the acid sulphate of soda, crystallises almost entirely on cooling; when drained, washed with a little cold water, and pressed, it is almost chemically pure.

Picric acid is used for dyeing silk and wool of a yellow colour. Its colouring power is very considerable, and it exhibits a great affinity for nitrogenised substances. The colour resists the action of light very well, but it is somewhat affected by washing, particularly with soap. It is rendered more stable by mordanting the material with alum.

Cotton, hemp, and flax, do not show any affinity for picric acid. The acid may therefore be employed to distinguish silk and wool from cotton and flax. For this purpose it is only necessary to plunge the tissue in a boiling solution of picric acid, and then wash in water. The silk and wool will assume an intense yellow colour, whilst the cotton and flax remain perfectly colourless.

The use of picric acid for dyeing purposes was first suggested by M. Guinon of Lyons, in 1845.

Picric acid, under the influence of reducing agents, produces other colouring-matters; treated with ferrous salt and an alkali, for example, it produces a red acid (Wöhler's nitro-hæmatic acid). Under the influence of cyanide of potassium, again, it gives rise to a purple potassium salt (Mr. Hlasiwetz's isopurpurate of potassium). This purpurate, treated with an ammoniacal salt, prôduces an ammonaical compound, which, when applied to dyeing, acts like the murexide of uric acid, giving, in fact, precisely the same tints. Under the influence of chloride of tin, picric acid may even produce, blue, purple, and red colouring-matters; but the nature of these substances is very little known, and not one of them has as yet (1862) received any practical application.—*Hofmann.*

Instead of free picric acid, the alkaline picrates have been used in dyeing. This practice is to be condemned since these salts are highly explosive, and are indeed used on the Continent as explosive agents. Picrate gunpowder is prepared, in which picrate of potash replaces saltpetre. Picrate of ammonia enters into the composition of many coloured fires. The isopurpurate of potash mentioned above is now used as a dye under the French name of *Grénat soluble.*

PICROMEL is the name given by M. Thénard to a black bitter principle which he supposed to be peculiar to the bile. MM. Gmelin and Tiedemann have since called its identity in question.

PICROTOXIN (*Picrotoxic acid*) is an intensely bitter poisonous vegetable principle, extracted from the seeds of the *Menispermum cocculus* (Cocculus Indicus). It crystallises in small white needles, dissolving in boiling water and in alcohol. It does not combine with acids, but forms combinations with alkalis.

PIETRA DURA. Ornamental work, executed in coloured stones, representing flowers, fruits, birds, and the like. The Florentine work and the inlaid marble work of Derbyshire are of this character.

PIG IRON. See Iron.

PIGMENTS. See Colours; Paints.

PIMENTO. (*Myrtus pimenta*, Linn.; *Eugenia pimenta*, De Candolle.) Allspice, or Jamaica pepper. This plant is cultivated in Jamaica in regular *Pimento walks.* The full sized-fruit is gathered green and sun dried, during which process it is frequently immersed. It is sent to the English market in bags of 1 cwt. each. This fruit consists, according to Bonastre's complicated analysis, of:—

	Shells or capsules	Kernels.
Volatile oil	10·0	5·0
Green oil	8·4	2·5
Concrete oil	0·9	1·2
Extract containing tannin	11·4	39·8
Gummy extract	3·0	7·2
Brown matter dissolved in potash	4·0	8·0
Resinous matter	1·2	3·2
Sugar, uncrystallised	3·0	8·0
Gallic and malic acids	0·6	1·6
Vegetable fibre	50·0	16·0
Ashes charged with salts	2·8	1·9
Moisture and loss	4·1	4·8

PINANG, or Betel Nut. See Areca.

PINCHBECK. A yellow metal, composed of 3 ozs. of zinc to 1 lb. of copper. See Alloys; Brass.

PINCOFFIN, or *Alizarine commerciale*.—Under these names, some years ago, Messrs. Pincoff and Co., of Manchester, brought into the market a garancin which yields very fine violet tints without requiring clearing. The other colours obtained with it are equally satisfactory. Pincoffin is a garancin prepared, and more especially washed, with the greatest care. It is made as neutral as possible, and then exposed to a heat above 100° C., by means of high-pressure steam. Under these circumstances, a certain quantity of brown colouring-matter is destroyed or rendered inert, and the dried product immediately yields fine tints.

PINE-APPLE YARN and **CLOTH.** In Mr. Zincke's process, patented in December 1836, for preparing the filaments of this plant, the *Bromelia Ananas*, the leaves being plucked, and deprived of the prickles round their edges by a cutting instrument, are then beaten upon a wooden block with a wooden mallet, till a silky-looking mass of fibres is obtained, which are to be freed by washing from the green fecula. The fibrous part must next be laid straight, and passed between wooden rollers. The leaves should be gathered between the time of their full maturity and the ripening of the fruit. If earlier or later, the fibres will not be so flexible, and will need to be cleared by a boil in soapy water for some hours, after being laid straight under the pressure of a wooden grating, to prevent their becoming entangled. When well washed and dried, with occasional shaking out, they will now appear of a silky fineness. They may be then spun into porous rovings, in which state they are most conveniently bleached by the ordinary methods.

PINES. A numerous family of cone-bearing timber trees. The wood, which is extensively used, is imported under the names of American, Baltic, Dantzic, Memel, Norway, and Riga timber, Swiss deals, &c. The New Zealand pine, called also the Cowdie or Kaurie (the *Dammara Australis*), is not a true pine.

The Pinus sylvestris. The wild pine, or Scotch fir, yields the yellow deal.

The Abies excelsa. The Norway spruce-fir, the white deal. See Abies.

The Abies picea. The silver fir, a whitish deal, much used for flooring.

The Larix Europæa. The larch. This wood is much employed in Switzerland.

The Pinus strobus. The Weymouth pine, is much used in the Northern United States.

The Pinus Australis. The southern pine, yellow pine, or pitch pine. Of this wood nearly all the houses of the Southern United States are built. It is imported into Liverpool as the Georgia pitch pine.

There are numerous others, as the American larch, the balm-of-Gilead fir, the spruce-firs, &c., which are employed in various districts for ship and house building, but they scarcely require any special notice here.

PINEY TALLOW is a concrete fat obtained by boiling with water the fruit of the *Vateria indica*, a tree common upon the Malabar coast. It seems to be a substance intermediate between tallow and wax; partaking of the nature of stearine. It melts at 97½° F., is white or yellowish, has a spec. grav. of 0·926; is saponified by alkalis, and forms excellent candles. Dr. Benjamin Babington, to whom we are indebted for all our knowledge of piney tallow, found its ultimate constituents to be, 77 of carbon, 12·3 of hydrogen, and 10·7 of oxygen. See Oils.

PIN MANUFACTURE. (*Fabrique d'épingles*, Fr.; *Nadelfabrik*, Ger.) A pin is a small bit of wire, commonly brass, with a point at one end and a spherical head at the other. In making this little article, there are no less than fourteen distinct operations:—

1. *Straightening the wire.* The wire, as obtained from the drawing-frame, is wound about a bobbin or barrel, about 6 inches diameter, which gives it a curvature that must be removed. The straightening engine is formed by fixing 6 or 7 nails upright in a waving line on a board, so that the void space measured in a straight line between the first three nails may have exactly the thickness of the wire to be trimmed; and that the other nails may make the wire take a certain curve line, which must vary with its thickness. The workman pulls the wire with pincers through among these nails, to the length of about 30 feet, at a running draught; and after he cuts that off, he returns for as much more; he can thus finish 600 fathoms in the hour. He next cuts these long pieces into lengths of 3 or 4 pins. A day's work of one man amounts to 18 or 20 thousand dozen of pin-lengths.

2. *Pointing*, is executed on two iron or steel grindstones, by two workmen, one of whom roughens down, and the other finishes. Thirty or forty of the pin wires are applied to the grindstone at once, arranged in one plane, between the two forefingers and thumbs of both hands, which dexterously give them a rotatory movement.

3. *Cutting these wires into pin-lengths.* This is done by an adjusted chisel. The intermediate portions are handed over to the *pointer*.

4. *Twisting of the wire for the pin-heads.* These are made of a much finer wire, coiled into a compact spiral, round a wire of the size of the pins, by means of a small lathe constructed for the purpose.

5. *Cutting the heads.* Two turns are dexterously cut off for each head, by a regulated chisel. A skilful workman may turn off 12,000 in the hour.

6. *Annealing the heads.* They are put into an iron ladle, made red-hot over an open fire, and then thrown into cold water.

7. *Stamping or shaping the heads.* This is done by the blow of a small ram, raised by means of a pedal lever and a cord. The pin-heads are also fixed on by the same operative, who makes about 1,500 pins in the hour, or from 12,000 to 15,000 per diem, exclusive of one-thirteenth, which is always deducted for waste in this department, as well as in the rest of the manufacture. Cast heads, of an alloy of tin and antimony, were introduced by patent, but never came into general use.

8. *Yellowing or cleaning the pins*, is effected by boiling them for half an hour in sour beer, wine lees, or solution of tartar; after which they are washed.

9. *Whitening or tinning.* A stratum of about 6 pounds of pins is laid in a copper-pan, then a stratum of about 7 to 8 pounds of grain tin; and so alternately till the vessel be filled; a pipe being left inserted at one side, to permit the introduction of water slowly at the bottom, without deranging the contents. When the pipe is withdrawn, its space is filled up with grain tin. The vessel being now set on the fire, and the water becoming hot, its surface is sprinkled with 4 ounces of cream of tartar; after which it is allowed to boil for an hour. The pins and tin grains are, lastly, separated by a kind of cullender.

10. *Washing the pins*, in pure water.

11. *Drying and polishing them*, in a leather sack filled with coarse bran, which is agitated to and fro by two men.

12. *Winnowing*, by fanners.

13. *Pricking the papers*, for receiving the pins.

14. *Papering*, or fixing them in the paper. This is done by children, who acquire the habit of putting up 36,000 per day.

The pin manufacture is one of the greatest prodigies of the division of labour; it furnishes 12,000 articles for the sum of three shillings, which have required the united diligence of fourteen skilful operatives.

The above is an outline of the mode of manufacturing pins by hand labour; but several beautiful inventions have been employed to make them entirely, or in a great measure, by machinery; the consumption for home sale and export amounting to 15 millions daily, for this country alone. A detailed description of it will be found in the 9th volume of 'Newton's London Journal.' The following outline will give the reader an idea of the structure of Mr. L. W. Wright's ingenious machine for pin-making:—

The rotation of a principal shaft mounted with several cams gives motion to various sliders, levers, and wheels, which work the different parts. A slider pushes pincers forwards, which draw wire from a reel, at every rotation of the shaft, and advance such a length of wire as will produce one pin. A die cuts off the said length of wire by the descent of its upper chap; the chap then opens a carrier, which takes the pin to the pointing apparatus. Here it is received by a holder, which turns round, while a bevel-edged file-wheel rapidly revolves, and tapers the end of the wire to a point. The pin is now conducted by a second carrier to a finer file-wheel, in order to finish the point by a second grinding. A third carrier then transfers the pin to the first heading die, and by the advance of a steel-punch the end of the pin wire is forced into a recess, whereby the head is partially swelled out. A fourth carrier removes the pin to a second die, where the heading is perfected. When the heading-bar retires, a forked lever draws the finished pin from the die, and drops it into a receptacle below.

The following is a further detail of this very interesting manufacture:—

In pin-making the wire is brass, (a compound of copper and zinc): it is reduced by the ordinary process of wire-drawing to the requisite thickness: in this process it is necessarily curved. To remove this it is re-wound, and pulled through between a number of pins arranged at the draw or straightening bench; it is then cut into convenient lengths for removal, and finally reduced to just such a length as will make two pins. The pointing is done upon steel mills (revolving wheels), the circumference of which is cut with teeth, the one fine, the other coarse. Thirty or forty lengths are packed up at once, and, as in needle-making, the cast of hand given by the workman makes them revolve, and the whole are pointed at once; the same operation is performed with the other end. The process of heading is next performed as follows: a number of the pointed wires now cut in two, are placed in the feeder of the machine; one drops, is firmly seized, and by means of a pair of dies, a portion of the metal is forced up into a small bulb; by a beautifully simple and automatic arrangement, it is passed into another, when a small horizontal hammer gives it a sharp tap, which completes the head. The white colour is produced by boiling in a solution of cream of tartar and tin. They are then dried, and passed into the hands of the wrappers-up. The preparation for marking the paper is peculiar, and is done by means of a moulded piece of wood, the moulds corresponding to those portions which represent the small folds of paper through which the pins are passed, and thereby held. The pins are then taken to the paperers, who are each seated in front of a bench, to which is attached a horizontally-hinged piece of iron, the edge of which is notched with a corresponding number of marks to the number of pins to be stuck; the small catch which holds together the two parts of the iron is released, the paper introduced, and a pin inserted at every mark; the paper is then released, and the task of examination follows, which is the work of a moment. The paper of pins is held so that the light strikes upon it: those defective are immediately detected by the shade, are taken out, and others substituted in their stead. An ancient edict of Henry VIII. held that 'no one should sell any pins but such as were double-headed, or the heads soldered fast on.'

An improved pin has been introduced, in which iron or steel wires have been employed. The iron or steel wire employed should be very round, and, to protect it from rust, it should, at the last drawing, be lubricated by means of a sponge saturated with oil, placed between the draw-plate and reel.

The following is the process adopted with these:—The wire being cut into pins and these headed and pointed, all according to the usual methods, the pins are thrown into a revolving cylinder of wood containing a bath of soap-and-water in a hot state. It is of the capacity of about 9½ gallons, but should not contain more than about 1½ gallon of water, with about 2 ounces of soap dissolved therein, as this quantity will be sufficient for the treatment of about 13½ lbs. weight of pins at a time. The cylinder, when thus charged, is made to revolve for about a quarter of an hour; at the expiration of which time the pins are found free from the oil with which they were previously coated, and also very much smoothed and polished by their rubbing one against the other.

The pins are next dried by transferring them to another cylinder partially filled with well-dried sawdust (preferring for the purpose the sawdust of poplar wood), and causing this cylinder to revolve for about ten minutes; or, instead of employing a cylinder of this description, the pins may be thrown into a bag or bags partially filled with sawdust, and the requisite friction produced by swinging or rolling these bags about for the same length of time.

Into a glass or stone vase, there are put about 1½ gallon of salt water, $\frac{7}{10}$ths of a pound of sulphuric acid, $\frac{6}{100}$ lb. of salt of tin, $\frac{6}{100}$ lb. of crystallised sulphate of zinc, and 100 grs. of pure sulphate of copper. This mixture is left to work for about 24 hours, so that the salts and sulphates may be properly dissolved.

The mixture, prepared as directed, is introduced into another revolving cylinder, and pins about 13½ lbs. weight are thrown into the midst of it. The cylinder is then caused to revolve for about half an hour, which serves at once to remove any verdigris from the pins, to impart a high polish to them, and to give a beginning to the copper-coating process. At the end of the half hour or thereabouts, 232 grs. of crystallised sulphate of copper in coarse powder, and 150 grs. of crystallised sulphate of zinc, previously dissolved in soft water, are added to the mixture in the cylinder, and the whole again agitated for about a quarter of an hour. The pins are by this operation not only completely coated, but acquire a very considerable degree of polish. The copper liquors being drawn off, the pins are washed with cold water in the rotating cylinder, and afterwards in a tub with soap-and-water out of contact with air, where they are well shaken. The contents of the tub are then emptied into a wooden strainer, having a perforated bottom of tin-plate iron. The pins are finally dried by agitation with dry sawdust.

The tinning and blanching are performed by laying the pins upon plates of very thin tin placed one above another, in a tinned copper boiler containing a solution of about 4¾ lbs. of crude tartar or cream of tartar, in about 22 gallons of water, and then setting the whole to boil for about 12 hours. The tartar solution should be prepared at least 24 hours previously. A little more cream of tartar improves the brilliancy of the pins.

PINUS. See PINES.

PIPECLAY. A hydrous silicate of alumina, found in Devonshire and some other parts, used in the manufacture of tobacco-pipes. See CLAY.

PIPERDINE. A volatile base, discovered by Anderson, by acting with potash on the product of the action of nitric acid on piperine. It may also be procured by treating piperine with potash. It has been chiefly studied by Cahours.

PIPERINE is a crystalline principle extracted from black pepper, by means of alcohol. It is colourless, has hardly any taste, fuses at 212° F.; is insoluble in water, but soluble in acetic acid, ether, and most readily in alcohol.

PIPESTONE. A variety of clay slate. See CATLINITE.

PISOLITE. The peastone. See LIMESTONE.

PISOLITIC IRON ORE. An ore made up of small nodules, like peas. See IRON.

PITA HEMP. The fibre of the American aloe (*Agave Americana*), used for textile fabrics, and in paper-making.

PITCHBLENDE. An ore of uranium. See URANIUM.

PITCH, MINERAL, is the same as BITUMEN and ASPHALT, which see.

PITCH *of wood-tar* (*Poix*, Fr.; *Pech*, Ger.) is obtained by boiling tar in an open iron pot, or in a still, till the volatile matters are driven off. Pitch contains pyroligneous resin along with colophony (common rosin), but its principal ingredient is the former, called by Berzelius *pyretine.* It is brittle in the cold, but softens and becomes ductile with heat. See TAR.

PITCHSTONE. A volcanic rock resembling obsidian, but having a pitchy rather than a glassy lustre.

PIT-COAL. See COAL.

PITTACAL, from two Greek words, signifying *fine pitch*, is one of the principles detected in wood-tar by Reichenbach. It is obtained by adding baryta-water to a solution of *picamar*, or of oil of tar deprived of its acid, when the pittacal falls. It is a dark blue solid substance, somewhat like indigo, and assumes a metallic lustre on friction. It is void of taste and smell, not volatile; carbonises at a high heat without emitting an ammoniacal smell; is soluble or rather very diffusable in water; gives a green solution, with a cast of crimson, in sulphuric acid, with a cast of red-blue in muriatic acid, and with a cast of aurora-red in acetic acid. It is insoluble in alkalis, and in alcohol and ether. It dyes a fast blue upon linen and cotton goods with tin and aluminous mordants.

PLAGIOCLASE. See FELSPAR.

PLANE TREE. The *Platanus occidentalis*, one of the largest of the American trees. The wood of the plane tree is much used for quays; it is also employed for musical instruments, and for other works requiring a clean light-coloured wood. The False Plane, or Sycamore, is one of the Maple family (*Acer pseudo-platanus*).

PLANTAIN. See BANANA.

PLASMA. A translucent chalcedony, of a greenish colour and a glittering lustre.

PLASTER. See MORTAR.

PLASTER OF PARIS. See ALABASTER and GYPSUM.

PLASTIC CLAY. Any clay which, when in a moist state, may be kneaded between the fingers, and admits of being moulded into a definite form.

Plastic clay is not confined to any particular strata, but is found in secondary and tertiary formations, and also in deposits derived from the decomposition of other rocks. In geological nomenclature, however, the term Plastic Clay is applied to those portions of the Lower Tertiary or Eocene strata which intervene between the Chalk and the London clay, in consequence of some of the beds of clay of which they are composed being of a plastic nature. Some of the earliest pottery made in the country was manufactured from these clays, dug up at Crendle Common, near Cranborne, in Dorsetshire, where, as well as at Newport in the Isle of Wight, Fareham in Hants, &c., the clay is still dug and converted into pottery. The clay from the Plastic Clay series is generally of a bright brick-red colour, frequently mottled with white, but sometimes (as at Crendle) it is dark purple or nearly black towards the lower part, and this clay is said to be the best as regards quality. The clays of the Plastic Clay burn to a red colour, and are manufactured into bricks, tiles, flower-pots, and other coarse pottery.—H. W. B.

The Plastic Clay series, between the Thanet Sand and the London Clay, is now generally known by Mr. Prestwich's name of the Woolwich and Reading beds.

PLATE-CLEANING. Boil 30 grms. of finely-powdered and calcined hartshorn in a quart of water, and while on the fire put as many silver articles in the vessels used for boiling as it will hold, and leave them there for a short time; then withdraw them, and dry them over the fire; continue this until all the articles have been treated in the same manner; then introduce into the hartshorn-water clean woollen rags, and allow them to remain until saturated, after which dry them, and use them for polishing the silver. This is also the best substance for cleaning locks and brass handles of room-doors. When the silver articles are perfectly dry, they must be carefully rubbed with a soft leather. This mode of cleaning is excellent, and much preferable to the employment of any powder containing mercury, as mercury has the effect of rendering the silver so brittle as to break on falling.

PLATE GLASS. See GLASS.

PLATED MANUFACTURE. (*Fabrique de plaqué*, Fr.; *Silber Plattirung*, Ger.) The silver in this case is not applied to ingots of pure copper, but to an alloy consisting of copper and brass, which possesses the requisite stiffness for the various articles.

The furnace used for melting that alloy, in black-lead crucibles, is a common air-furnace, like that for making brass. See BRASS.

The ingot-moulds are made of cast iron, in two pieces, fastened together; the cavity being of a rectangular shape, 3 inches broad, 1½ thick, and 18 or 20 long. There is an elevated mouth-piece or gate, to give pressure to the liquid metal, and secure solidity to the ingot. The mould is heated till the grease with which its cavity is besmeared merely begins to smoke, but does not burn. The proper heat of the melted metal for casting, is when it assumes a bluish colour, and is quite liquid. Whenever the metal has solidified in the mould, the wedges that tighten its rings are driven out, lest the shrinkage of the ingot should cause the mould to crack.

The ingot is now dressed carefully with the file on one or two faces, according as it is to be single- or double-plated. The thickness of the silver plate is such as to constitute one fortieth of the thickness of the ingot; or when this is an inch and a quarter thick, the silver plate applied in one thirty-second of an inch; being by weight a pound troy of the former, to from 8 to 10 pennyweights of the latter. The silver, which is slightly less in size than the copper, is tied to it truly with iron wire, and a little of a saturated solution of borax is then insinuated at the edges. This salt melts at a low heat, and excludes the atmosphere, which might oxidise the copper, and obstruct the union of the metals. The ingot thus prepared is brought to the plating furnace.

The furnace has an iron door with a small hole to look through; it is fed with coke laid upon a grate at a level with the bottom of the door. The ingot is placed immediately upon the coke, the door is shut, and the plater watches at the peep-hole the instant when the proper soldering-temperature is attained. During the union of the silver and copper, the surface of the former is seen to be drawn into intimate contact with the latter, and this species of *riveting* is the signal for removing the compound bar instantly from the furnace. Were it to remain a very little longer, the silver would become alloyed with the copper, and the plating be thus completely spoiled. The adhesion is, in fact, accomplished here by the formation of a film of true silver-solder at the surfaces of contact.

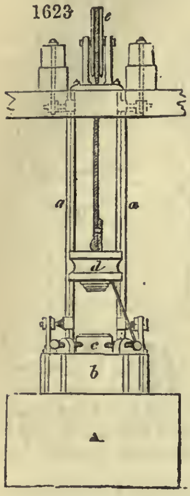
The ingot is next cleaned, and rolled to the proper thinness between cylinders, as described under MINT; being in its progress of lamination frequently annealed on a small reverberatory hearth. After the last annealing, the sheets are immersed in hot dilute sulphuric acid, and scoured with fine Calais sand; they are then ready to be fashioned into various articles.

In plating copper-wire, the silver is first formed into a tubular shape, with one edge projecting slightly over the other; through which a red-hot copper cylinder being somewhat loosely run, the silver edges are closely pressed together with a steel burnisher, whereby they get firmly united. The tube thus completed is cleaned inside, and put on the proper copper rod, which it exactly fits. The copper is left a little longer than its coating tube, and is grooved at the extremities of the latter, so that the silver edges, being worked into the copper groove, may exclude the air from the surface of the rod. The compound cylinder is now heated red-hot, and rubbed briskly over with the steel burnisher in a longitudinal direction, whereby the two metals get firmly united, and form a solid rod, ready to be drawn into wire of any requisite fineness and form; as flat, half-round, fluted, or with mouldings, according to the figure of the hole in the draw-plate. Such wire is much used for making bread-baskets, toast-racks, snuffers, and articles combining elegance with lightness and economy. The wire must be annealed from time to time during the drawing, and finally cleaned, like the plates, with dilute acid.

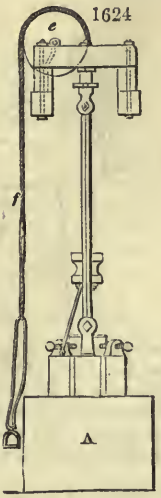
Formerly the different-shaped vessels of plated metal were all fashioned by the hammer; but every one of simple form is now made in dies struck with a drop-hammer or stamp. Some manufacturers employ 8 or 10 drop machines.

Figs. 1623 and 1624 are two views of the stamp: A is a large stone, the more massy the better; *b*, the anvil on which the die, *c*, is secured by four screws, as shown in the ground plan, *fig.* 1625. In *fig.* 1623, *a a* are two upright square prisms, set diagonally with the angles opposed to each other; between which the hammer or drop, *d*, slides truly, by means of nicely-fitted angular grooves or recesses in its sides. The hammer is raised by pulling the rope, *f*, which passes over the pulley, *e*, and is let fall from different heights, according to the impulse required. Vessels which are less in diameter at the top and bottom than in the middle, must either be raised by the stamp in two pieces, or raised by a hand-hammer. The die is usually made of *cast* steel. When it is placed upon the anvil, and the plated metal is cut into pieces of proper size, the top of the die is then surrounded with a lute, made of oil and clay, for an inch or two above its surface; and the cavity is filled with melted lead. The under face of the stamp-hammer has a plate of iron, called the *licker-up*, fitted into it, about the area of the die. Whenever the lead has become solid, the hammer is raised to a

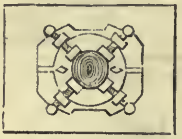
1623



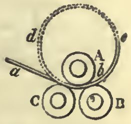
1624



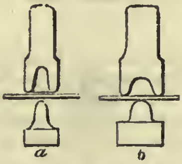
1625



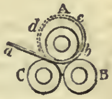
1628



1626



1627

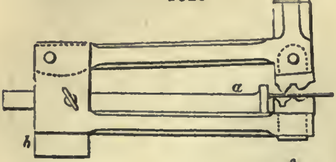


certain height, and dropped down upon it; and as the under face of the licker-up is made rough like a rasp, it firmly adheres to the lead, so as to lift it afterwards with the hammer. The plated metal is now placed over the die, and the hammer, mounted with its lead, is let fall repeatedly upon it, till the impression on the metal is complete. If the vessel to be struck be of any considerable depth, two or three dies may be used of progressive sizes in succession. But it occasionally happens that when the vessel has a long conical neck, recourse must be had to an auxiliary operation, called *punching*. See the embossing punches, *fig.* 1626. These are made of cast steel, with their hollows turned out in the lathe. The pieces, *a b*, are of lead. The punching is performed by a series of these tools, of different sizes, beginning with the largest, and ending with the least. By this means a hollow cone, 3 or 4 inches deep, and 1 inch in diameter, may be raised out of a flat plate. These punches are struck with a hand-hammer also, for small articles of too great delicacy for the drop. Indeed, it frequently happens that one part of an article is executed by the stamp and another by the hand.

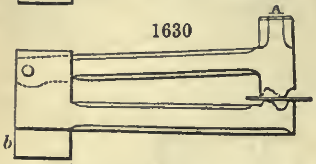
Cylindrical and conical vessels are mostly formed by bending and soldering. The bending is performed on blocks of wood, with wooden mallets; but the machine so much used by the tin-smiths, to form their tubes and cylindric vessels (see the end sections, *figs.* 1627, 1628), might be employed with advantage. This consists of 3 iron rollers fixed in an iron frame. A, B, C, are the three cylinders, and *a, b, c, d*, the riband or sheet of metal passed through them to receive the cylindrical or conical curvature. The upper roller, A, can be raised or lowered at pleasure, in order to modify the diameter of the tube; and when one end of the roller is higher than the other the conical curvature is given. The edges of the plated cylinders or cones are soldered with an alloy composed of silver and brass. An alloy of silver and copper is somewhat more fusible; but that of brass and silver answers best for plated metal, the brass being in very small proportion, lest the colour of the plate be affected. Calcined borax mixed with sandiver (the salt skimmed from the pots of crown glass) is used along with the alloy, in the act of soldering. The seam of the plated metal being smeared with that saline mixture made into a pap with water, and the bits of laminated solder, cut small with scissors, laid on, the seam is exposed to the flame of an oil blowpipe, or to that of charcoal urged by bellows in a little forge-hearth, till the solder melts and flows evenly along the junction. The use of the sandiver seems to be to prevent the iron wire that binds the plated metal tube from being soldered to it.

Mouldings are sometimes formed upon the edges of vessels, which are not merely ornamental, but give strength and stiffness. These are fashioned by an instrument called a *swage*, represented in *figs.* 1629, 1630. The part A lifts up by a joint, and the metal to be *swaged* is placed between the dies, as shown in the figures; the tail, *b*, being held in the jaws of a vice, while the shear-shaped hammer rests upon it. By striking on the head, A, while the metal plate is shifted successively forwards, the beading is formed. In *fig.* 1629, the tooth, *a*, is a guide to regulate the distance be-

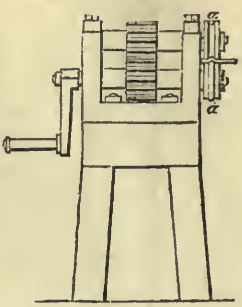
1629



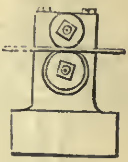
1630



1631



1633



1632

tween the bead and the edge. A similar effect is produced of late years in a neater and more expeditious manner by the rollers, *figs.* 1631, 1633. *Fig.* 1632 is a section to show the form of the bead. The two wheels *a, a, fig.* 1631, are placed upon axes, two of which are furnished with toothed pinions in their middle; the lower one being turned by the handle, gives motion to the upper. The groove in the upper wheel corresponds with the bead in the lower, so that the slip of metal passed through between them assumes the same figure.

The greatest improvement made in this branch of manufacture is the introduction of silver edges, beads, and mouldings, instead of the plated ones, which from their prominence had their silver surface speedily worn off, and thus assumed a brassy look. The silver destined to form the ornamental edging is laminated exceedingly thin; a square inch sometimes weighing no more than 10 or 12 grains. This is too fragile to bear the action of the opposite steel dies of the swage above described. It is necessary, therefore, that the sunk part of the die should be steel, and the opposite side lead, as was observed in the stamping; and this is the method now generally employed to form these silver ornaments. The inside shell of this silver moulding is filled with soft solder, and then bent into the requisite form.

The base of candlesticks is generally made in a die by the stamp, as well as the neck, the dish part of the nozzle or socket, and the tubular stem or pillar. The different parts are united, some with soft and others with hard solder. The branches of candlesticks are formed in two semi-cylindrical halves, like the feet of tea-urns. When an article is to be engraved on, an extra plate of silver is applied at the proper part, while the plate is still flat, and fixed by burnishing with great pressure over a hot anvil. This is a species of welding.

The last finish of plated goods is given by burnishing tools of bloodstone, fixed in sheet-iron cases, or hardened steel, finely polished.

The ingots for lamination might probably be plated with advantage by the delicate pressure process employed for silvering copper-wire.

For the processes of Electro-plating, see ELECTRO-METALLURGY.

PLATINUM (*Sym.* Pt., *At. wt.* 98·5). A metal of a greyish-white colour, harder than silver, and of about double its density, being of specific gravity 21. It is so infusible, that no considerable portion of it can be melted by the strongest heats of our furnaces. It is unchangeable in the air and water; nor does a white heat impair its polish. The only acid which dissolves it is the nitro-muriatic.

Native Platinum in the natural state is never pure, being alloyed with several other metals. It occurs only under the form of grains, which are usually flattened, and resemble in shape the gold *pepitas.* Their size is in general less than linseed, although in some cases they equal hemp-seed, and, occasionally, peas. One piece brought from Choco, in Peru, and presented to the Cabinet of Berlin by M. Humboldt, weighs 882½ grains, or more than 2 oz. avoirdupois. A lump of native platinum is in the Royal Museum of Madrid, which was found in 1814 in the gold mine of Condoto, province of Novita, at Choco. Its size is greater than a turkey's egg (about 2 inches one diameter, and 4 inches the other), and its weight 11,641 grains. In 1827 a specimen was found in the Ural Mountains which weighed 11·57 pounds troy; the largest yet obtained being in the Demidoff Cabinet, and weighing 21 pounds.

The colour of the grains of native platinum is generally a greyish white, like tarnished steel. The cavities of the rough grains are often filled with earthy and ferruginous matters, or sometimes with small grains of magnetic oxide of iron, adhering to the surface of the platinum grains. Their specific gravity is also much lower than that of forged pure platinum; varying from 15 in the small particles, to 18·94 in Humboldt's large specimen. This relative likeness is owing to the presence of iron, copper, lead, and chromium, besides its other metallic constituents, palladium, osmium, rhodium, and iridium.

Its main localities in the New Continent are the three following districts:—

At Choco, in the neighbourhood of Barbacoas, and generally on the coasts of the South Sea, or on the western slopes of the Cordillera of the Andes, between the 2nd and the 6th degrees of north latitude. The gold-washings that furnish most platinum are those of Condoto, in the province of Novita; those of Santa Rita, or Viroviro, of Santa Lucia, of the ravine of Iro, and Apoto, between Novita and Taddo. The deposit of gold and platinum grains is found in alluvial ground, at a depth of about 20 feet. The gold is separated from the platinum by picking with the hand, and also by amalgamation; formerly, when it was imagined that platinum might be used to debase gold, the grains of the former metal were thrown into the rivers, through which mistaken opinion an immense quantity of it was lost.

Platinum grains are found in Brazil, but always in the alluvial lands that contain gold, particularly in those of Matto-Grosso. The ore of this country is somewhat different from that of Choco. It is in grains, which seem to be fragments of a spongy substance. All the particles are nearly globular, exhibiting a surface formed of small spheroidal protuberances strongly cohering together, whose interstices are clean, and even brilliant. This platinum includes many small particles of gold, but none of the magnetic iron-sand or of the small zircons which accompany the Peruvian ore. It is mixed with small grains of native palladium, which may be recognised by their fibrous or radiated structure and particularly by their chemical characters.

Platinum grains are found in Hayti, or Saint Domingo, in the sand of the river Jacky, near the mountains of Sibao. Like those of Choco, they are in small brilliant grains, as if polished by friction. The sand containing them is quartzose and ferruginous. This native platinum contains, like that of Choco, chromium, copper, osmium, iridium, rhodium, palladium, and probably titanium. Vauquelin could find no gold among the grains.

Platinum is largely produced in the Russian territories, in the auriferous sands of Kuschwa, 250 wersts from Ekaterinbourg, and consequently in a geological position which seems to be analogous to that of South America. It also occurs at Nischne-Tagilsk and Goroblagodat, in the Ural, in alluvial and drift material.

These auriferous sands are, indeed, almost all superficial; they cover an argillaceous soil, and include, along with gold and platinum, *débris* of dolerite (a kind of basalt) magnetic iron-ore, grains of corundum, &c. The platinum grains are not so flat as those from Choco, but they are thicker; they have less brilliancy, and more of a leaden hue. This platinum, by M. Laugier's analysis, is similar in purity to that of Choco; but the leaden-grey grains, which were taken for a mixture of osmium and iridium, are merely an alloy of platinum, containing 25 per cent. of these metals. In Russia platinum has been formed into coins of eleven and twenty-two roubles each; and this country affords annually about 800 cwts. of platinum, which is nearly ten times the amount from other parts of the world.

Platinum has also been found in Borneo, in California, in North Carolina, in Canada, in Australia, in the sands of the Rhine, and in Co. Wicklow, Ireland.

M. Vauquelin found nearly 10 per cent. of platinum in an ore of argentiferous copper, which was transmitted to him as coming from Guadalcanal, in Spain. This would be the only example of platinum existing in a rock and in a vein. The same thing has not again been met with, even in other specimens from Guadalcanal.

Platinum has been known in Europe only since 1748, though it was noticed by Ulloa in 1741. It was compared at first to gold; and was, in fact, brought into the market under the name of white gold. The term 'platinum,' however, is derived from the Spanish word *plata*, silver, on account of its resemblance in colour to that metal.

The whole of the platinum ore from the Urals is sent to St. Petersburg, where it is, or formerly was, treated by the following simple process:—

One part of the ore is put into open platina vessels, capable of containing from 6 to 8 lbs., along with 3 parts of muriatic acid at 25° B. and 1 part of nitric acid at 40°. Thirty of these vessels are placed upon a sand-bath covered with a glazed dome with moveable panes, which is surmounted by a ventilating chimney to carry the vapours out of the laboratory. Heat is applied for 8 or 10 hours, till no more red vapours appear: a proof that the whole nitric acid is decomposed, though some of the muriatic remains. After settling the supernatant liquid is decanted off into large cylindrical glass vessels, the residuum is washed, and the washing is also decanted off. A fresh quantity of nitro-muriatic acid is now poured upon the residuum. This treatment is repeated till the whole solid matter has eventually disappeared. The ore requires for solution from 10 to 15 times its weight of nitro-muriatic acid, according to the size of its grains.

The solutions thus made are all acid: a circumstance essential to prevent the iridium from precipitating with the platinum, by the water of ammonia, which is next added. The deposit being allowed to form, the mother-waters are poured off; the precipitate is washed with cold water, dried, and calcined in crucibles of platinum.

The mother-waters and the washings are afterwards treated separately; the former being concentrated to one-twelfth of their bulk in glass retorts; on cooling, they let fall the iridium in the state of an ammoniacal chloride, constituting a dark purple powder, occasionally crystallised in regular octahedrons. The washings are evaporated to dryness in porcelain vessels; the residuum is calcined and treated like fresh ore; but the platinum it affords needs a second purification.

For agglomerating the platinum, the spongy mass is pounded in bronze mortars; the powder is passed through a fine sieve, and put into a cylinder of the intended size of the ingot. The cylinder is fitted with a rammer, which is forced in by a coining press, till the powder is much condensed. It is then turned out of the mould, and baked 36 hours in a porcelain kiln, after which it may be readily forged, if it be pure, and may receive any desired form from the hammer. It contracts in volume from 1-6th to 1-5th during the calcination.

The method ordinarily used for the extraction of platinum is that originally proposed by Dr. Wollaston. The ore is treated first with nitric and then with hydrochloric acid, to remove those metals which are readily soluble, and is afterwards digested in dilute aqua regia at a moderate heat. To the solution of platinum thus obtained, a solution of sal-ammoniac is added, when the platinum is precipitated in the form of a yellow salt—the double chloride of platinum and ammonium. This salt, when washed, is heated to redness, whereby the chlorine and ammonia are expelled, whilst a mass of *spongy platinum* is obtained. The sponge is worked into a paste with water, and, having been subjected to powerful pressure and dried, is carefully heated to whiteness in a wind-furnace and forged into an ingot. The platinum at a high temperature may be welded like iron.

For Dr. Wollaston's process, see *Philosophical Transactions*, 1829, Part I.

Great improvements in refining platinum have been introduced by Messrs. Deville and Debray. In a furnace, composed of blocks of lime, the platinum is fused by means of the oxyhydrogen flame, when the osmium present is expelled as tetroxide, while the silica forms a slag by combining with the lime.

The same chemists effect the purification of platinum by fusing the ore with galena in a reverberatory furnace. The metallic lead from the galena alloys with the platinum, whilst the iridosmine present in the ore is unattacked, and sinks, by its great density, to the bottom of the bath. The alloy of lead and platinum is then drawn off, and the lead removed by cupellation.

Platinum furnishes most valuable vessels to both analytical and manufacturing chemists. Boilers and stills of platinum used in the manufacture of oil of vitriol are constructed of large size and at great cost. The metal is malleable, and may be beaten out into leaves of extreme thinness. Dr. Wollaston succeeded in obtaining a wire not exceeding the two-thousandth of an inch in diameter. A wire of this metal of $\frac{1}{10}$th inch in diameter will support a weight of 361 lbs.

In 1828 a platinum coinage was commenced in Russia, but was discontinued in 1845.

This metal is applied to porcelain by two different processes: sometimes in a rather coarse powder, applied by the brush, like gold, to form ornamental figures; sometimes in a state of extreme division, obtained by decomposing its nitro-muriatic solution, by means of an essential oil, such as rosemary or lavender. In this case, it must be evenly spread over the whole ground. Both modes of application give rise to a steely lustre.

The properties possessed in common by gold and platinum have several times given occasion to fraudulent admixtures, which have deceived the assayers. M. Vauquelin having executed a series of experiments to elucidate this subject, drew the following conclusions:—

If the platinum do not exceed 30 or 40 parts in the thousand of the alloy, the gold does not retain any of it when the parting is made with nitric acid in the usual way; and when the proportion of platinum is greater, the fraud becomes manifest, 1st, by the higher temperature required to pass it through the cupel, and to form a round button; 2nd, by the absence of the lightning, fulguration, or coruscation; 3rd, by the dull white colour of the button and its crystallised surface; 4th, by the straw-yellow colour which platinum communicates to the aquafortis in the parting; 5th, by the straw-yellow colour, bordering on white, of the cornet after it is annealed. If the platinum amounts to one fourth of the gold, we must add to the alloy at least 3 times its weight of fine silver, laminate it very thin, anneal somewhat strongly, boil it half an hour in the first aquafortis, and at least a quarter of an hour in the second, in order that the acid may dissolve the whole of the platinum.

Were it required to determine exactly the proportions of platinum contained in an alloy of copper, silver, gold, and platinum, the amount of the copper may be found in the first place by *cupellation*; then the respective quantities of the three other metals may be learned by the processes founded, 1, upon the property possessed by sulphuric acid of dissolving silver without affecting gold or platinum; and, 2, upon the property of platinum being soluble in nitric acid, when it is alloyed with a certain quantity of gold and silver.

Platina, wrought and unwrought, imported in 1873.

	Ounces troy	Value
From Russia	39,284	£51,642

„ Other countries	6,157	9,580
Total	56,981	72,764

PLATINUM, ALLOYS OF. This metal will alloy with iron; the alloy is malleable and possesses much lustre. Copper and platinum in certain proportions form a brilliant alloy. Silver is much hardened by platinum: although platinum is not soluble in nitric acid, it will, when alloyed with silver, dissolve in that acid. An alloy of platinum and iridium is harder than platinum, and withstands the action of nitro-hydrochloric acid.

Some other alloys are known, but none of them are employed in the arts.

PLATINUM BLACK. This interesting preparation, which so rapidly oxidises alcohol into acetic acid, &c., by what has been called catalytic or contact action, is most easily prepared by the following process devised by M. Bœttger:—The insoluble powder of potassio-chloride or ammonio-chloride of platinum is to be moistened with sulphuric acid (oil of vitriol), and a bit of zinc is to be laid in the mixture. The platinum becomes reduced to a black powder, which is to be washed first with hydrochloric acid, and then with water. The fineness of this powder depends upon that of the saline powders employed to make it; so that if these be previously finely ground, the platinum black will be also very fine, and proportionally powerful as a chemical agent.

The following method of preparing igniferous black platinum, proposed by Descotil, has been recommended by M. Döbereiner:—

Melt platinum ore with double its weight of zinc; reduce the alloy to powder, and treat it first with dilute sulphuric acid, and next with dilute nitric acid, to oxidise and dissolve out all the zinc, which is somewhat difficult to do, even at a boiling-heat. The insoluble black-grey powder contains some osmide of iridium, united with the crude platinum. This compound acts like simple platinum black, after it has been purified by digestion in potash-lye, and washing with water. Its oxidising power is so great as to transform not only formic acid into the carbonic, and alcohol into vinegar, but even some osmic acid, from the metallic osmium. The above powder explodes by heat like gunpowder.

When the platinum black prepared by means of zinc is moistened with alcohol, it becomes incandescent, and emits osmic acid; but if it be mixed with alcohol into a paste and spread upon a watch-glass, nothing but acetic acid will be disengaged; affording an elegant means of diffusing the odour of vinegar in an apartment.

A yet more simple method of preparing the platinum black than either of those is the following:—Protochloride of platinum is dissolved in a concentrated solution of potash with the aid of heat; then alcohol is added by degrees, constantly stirring the solution. The platinum is precipitated as a black powder, which is boiled successively with alcohol, hydrochloric acid, and potash-water.

PLATINUM, FULMINATING. An explosive compound, obtained by adding acetic acid, in excess, to a solution of chloride of platinum and ammonium in caustic soda. It may also be prepared by precipitating sulphate of platinum with excess of ammonia.

PLATINUM, SALTS OF. The salts of platinum being rarely employed in the arts or manufactures, the reader is referred for them to Watts's 'Dictionary of Chemistry.'

PLATINUM, SPONGY. A loose porous form of metallic platinum, obtained by heating the double chloride of platinum and ammonium.

PLATINUM YELLOW. A pigment prepared from platinum, by oxidation with acids, is sold under this name.

PLUMBAGO, commonly called Black Lead; the name *plumbago*, and its common one, being derived from the fact of this mineral resembling lead in its external appearance. See GRAPHITE, for its mineralogical and chemical characters. In this country plumbago has been found most abundantly in Cumberland. The mountain at Borrowdale, in which the black lead is mined, is nearly 2,000 feet high, and the entrance to the mine is about 1,000 feet below its summit. This valuable mineral became so common a subject of robbery about a century ago, as to have enriched, it was said, a great many persons living in the neighbourhood. Even the guard stationed over it by the proprietors was of little avail against men infuriated with the love of plunder; since in those days a body of miners broke into the mine by main force, and held possession of it for a considerable time.

The treasure was then protected by a building, consisting of four rooms upon the ground-floor; and immediately under one of them is the opening, secured by a trap-door, through which alone workmen could enter the interior of the mountain. In this apartment, called the dressing-room, the miners change their ordinary clothes for their mining-dress. At one time as much as 100,000*l.* was realised from the Borrowdale mine in a year, the Cumberland plumbago selling at 45*s.* per pound. This mine has not, however, been worked for many years. The last great discovery, stated to have been about 30,000*l.*'s worth, has been hoarded by the proprietors, a small quantity only being sold every year; but it is now generally understood to be exhausted. Some few years since the Borrowdale Black Lead Mine was inspected by three experienced miners, but their report was far from encouraging: notwithstanding this, a new company is formed to work the mine (1874); they have found small quantities of plumbago, and the report is that the appearances are very promising.

This plumbago in Borrowdale is found in 'nests' in a trap rock, partially decomposed, which runs through the clay-slate. In Glenstrathfarrar in Inverness it is found in gneiss; and at Craigman in Ayrshire it occurs in coal-beds which have been formed in contact with trap. In Cornwall plumbago has been discovered in small lumps in the Elvan courses (see ELVAN); and on the northern coast of that county, small pieces are picked out of the clay-slate rocks, where it has been exposed by the wearing-down of the cliffs. At Arendal, in Norway, it occurs with quartz.

Plumbago occurs in Finland. Large quantities are brought from Ceylon and the East Indies. Some considerable portions are obtained from Canada.

Plumbago is sometimes formed in considerable quantities in the beds of blast furnaces, especially at Cleator Moor, and is known to the workmen as 'kish.'

Mr. Brodie purifies plumbago by mixing it in coarse powder, in an iron vessel, with twice its own weight of commercial sulphuric acid, and seven per cent. of chlorate of potash, and heats the whole over a water-bath until chloric oxide ceases to be evolved. By this means the compounds of iron, lime, and alumina present are rendered for the most part soluble, and the subsequent addition of a little fluoride of sodium to the acid mixture will decompose any silicates which may remain, and volatilise the silica present. The mass is now washed with abundance of water, dried, and heated to redness. This last operation causes the grains of the plumbago to exfoliate. The mass swells up in a surprising manner, and is reduced to a state of very minute division. It is then levigated, and obtained in a state of great purity, ready to be compressed by the method of Brockedon. See PENCILS.

Plumbago imported in 1873.

	Tons	Value

PLUSH (*Panne*, *Peluche*, Fr.; *Wollsammet*, *Plüsch*, Ger.) is a textile fabric, having a sort of velvet nap or shag upon one side. It is composed regularly of a woof of a single woollen thread, and a two-fold warp, the one, wool of two threads twisted, the other, goat's- or camel's-hair. There are also several sorts of plush made entirely of worsted. It is manufactured, like velvet, in a loom with three treadles; two of which separate and depress the woollen warp, and the third raises the hair-warp, whereupon the weaver, throwing the shuttle, passes the woof between the woollen and hair-warp; afterwards, laying a brass brooch or needle under that of the hair, he cuts it with a knife (see FUSTIAN) destined for that use, running its fine slender point along in the hollow of the guide brooch, to the end of a piece extended upon a table.

POAKE. A name amongst peltmongers for the collected waste arising in the preparation of skins: it is used for manure.

POIL DE CACHEMIRE. See ANGORA; CASHMERE.

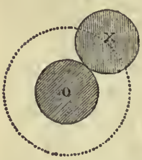
POINT NET is a style of lace formerly much in vogue, but now superseded by the bobbin net manufacture.

POLARISATION OF LIGHT. It is not the purpose of the present work to deal with any of the peculiar phenomena of the physical powers, except so far as they are involved in any of the processes of manufacture. Polarised light is employed in the sugar refinery; it therefore is necessary that some short account should be given of the phenomena so called, and of the methods of rendering them available to useful ends.

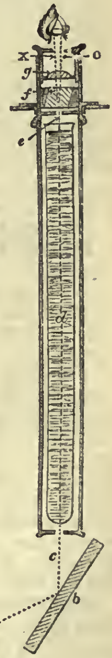
Under the term *Polarisation of Light* is comprehended a variety of very singular phenomena, which it is exceedingly difficult to explain within the space which can be devoted to this article. For anything like an exact description of these peculiar and striking phenomena, the reader is referred to works devoted specially to this branch of science. For our purpose it will be sufficient to state that if a ray of light is reflected from a plate of glass placed at an angle of about 56°, it will be found to have undergone a remarkable change. If the reflected ray of light is looked at through a thin slice of *Tourmaline*, it will be found that while the ray is seen, when the reflecting plate is in one position, it can no longer be seen through the transparent crystal if the glass-plate is turned round 90°, or if the crystal is turned to the same extent; although an ordinary ray of light is seen with equal intensity in whatever position the crystal may be held.

The ray of light by reflection, at or about the above-named angle, appears to have assumed the position of a polar body, *i.e.*, a body having dissimilar sides, or it may be, that the mode of motion has been altered by the reflection at the polarising angle. Light can be polarised by refraction equally as well as by reflection.

1635



1634



Under some circumstances, the condition of *Circular Polarisation* is produced. (See Pereira's *Lectures on Polarised Light.*) We do not attempt to explain this. The phenomena alone are all we have now to deal with. An instrument called a *Polariscope* is constructed upon the principles shown in the accompanying figure (*fig.* 1634).

If a ray of common light, *a*, be polarised by falling upon a glass, *b*, at an angle of 56° 45″, the plane-polarised ray *c*, is obtained. If this ray is transmitted through a pure solution of crystallisable cane-sugar, and the ray as it emerges, *e*, be analysed by a double-refracting rhomb of Iceland spar, *f*, two coloured images are perceived, as shown in *fig.* 1635. One, *o*, is caused by ordinary refraction, and the other, *x*, by extraordinary refraction. *g* (*fig.* 1634) is a lens to produce a well-defined image. The colours of these images are complementary; that is, when one is *red* the other is *green*, when one is *yellow* the other is *violet*, when one is *blue* the other is *orange*. By rotating the 'analyser,'—the rhomb of Iceland spar,—the colours change. If the rotation be right-handed, that is, as we turn a screw or cork-screw to make it enter, the sequence of colours is *red, orange, yellow, green, blue, indigo,* and *violet, red.* It will be understood that by rotating the rhomb of Iceland spar, the extraordinary ray revolves around the ordinary ray, each undergoing a change of colour. The sequence of the ordinary image being given above, and the complementary colours named, it will be seen that the sequence of colours on the extraordinary image will be *green, blue, indigo,* and *violet, red, orange, yellow, green.* In one complete revolution of the analyser each of the colours of the spectrum occurs twice for each image. The polariscope is now used for both the qualitative and quantitative analysis of sugar. Indeed, the minutest difference in chemical character and physical constitution can be readily detected by this instrument. See SUGAR.

POLISHING-SLATE. A grey or yellow slate composed of microscopic infusoria. It is found abundantly in the coal-measures of Bohemia, and in the Auvergne.

POLYCHROMATE. (*Æsculine.*) A compound from which a variety of colours may be prepared.

A great many vegetables give, when treated with hot water, a solution which appears yellow by transmitted light, but blue by reflected light. The inner bark of the horse-chestnut is a peculiar example of this. See FLUORESCENCE.

POLYHALITE. A sulphate of potash, lime, and magnesia, occurring in many salt mines, as at Stassfurt in Prussian Saxony.

POLYTYPE. A polytype is a cast of a woodcut taken in soft metal by a process now nearly discarded in favour of electrotyping.

POMADE DIVINE. See Balsam of Peru.

POOLEY MUNGU. Another name for Musta-paat (*Hibiscus cannabinus.*)

POPLAR. (*Peuplier*, Fr.; *Pappel*, Ger.) The wooden polishing wheels of the glass-grinder are made from horizontal sections of the stem of this tree. It is used in the manufacture of toys, but not for many other purposes.

POPLIN. A stuff made of silk and worsted, manufactured in Ireland. The Irish poplins are either watered, brocaded, or tissued: poplins are also made at Norwich.

POPPY OIL. Much used in painting. See Oils.

PORCELAIN. See Pottery.

PORCELAIN CLAY. See Clay.

PORCELAIN JASPER. Clay which has been vitrefied by the igneous rocks.

PORCELLANOUS SHELLS. See Shells.

PORPEZITE. A native alloy of gold and palladium, which occurs to some extent in the mines of Gongo Soco in Brazil.

PORPOISE OIL. See Oils.

PORPORINO. An Italian glass.

PORTER is a malt liquor, so called from being for a long period the favourite beverage of the porters of London, and indeed confined exclusively to this class of the workpeople of the metropolis. It is characterised by its dark brown colour, its transparency, its moderately bitter taste, and peculiar aromatic flavour. At first the essential distinction of porter arose from its wort being made with highly-kilned brown malt, while other kinds of beer and ale were brewed from a paler article; but of late years, the taste of the public having run in favour of sweeter and lighter beverages, the actual porter is brewed with a less proportion of brown malt, is less strongly hopped, and not allowed to get hard by long keeping in huge ripening tuns. Some brewers colour the porter with burnt sugar; but in general the most respectable concentrate a quantity of their first and best wort to an extract, in an iron pan, and burn this into a *colouring* stuff, whereby they can lay claim to the merit of using nothing in their manufacture but malt and hops. Porter is now brewed in large quantities in other cities besides London, especially in Dublin. See Beer.

PORTLAND ARROWROOT. See Arrowroot.

PORTLAND CEMENT is so called because it resembles in colour the Portland stone. It is prepared by calcining a mixture of the clayey mud of the Thames with a proper proportion of chalk. They make equally good cement in other parts of England and France by mixing chalk or marl with other clays. The materials are reduced to fine powder, and intimately mixed, with the addition of water. The resulting paste is moulded into bricks, which are dried and burned. It is of importance that the heat in calcining be sufficiently elevated, otherwise the carbonic acid and water may be expelled, without that reaction between the lime and clay which is required for the production of a cement. It is necessary to employ a white heat, which shall agglutinate and frit the mixture. After this operation the material is assorted, and the portions which are scorified by too much heat, as well as those insufficiently calcined, being set aside, the cement is pulverised for use. It is often advantageous to grind to powder the native mixtures of limestone and clay before burning them, in order to ensure homogeneousness. It will also be seen that calcination at a very high temperature is frequently required to develop the hydraulic character of limestones; the greater the temperature employed, the more slow is the solidification of the cement, but the harder does it become. See Cements.

PORTLAND STONE. An oolitic limestone, immediately underlying the Purbeck strata; so called in consequence of its development in the island of Portland, situated off the southern coast of Dorsetshire.

St. Paul's Cathedral, and many of the public buildings of this country, have been built of stone from Portland, and it is still obtained from numerous quarries on the island for transmission to other places, and formerly for the breakwater.

The quarries from which the stone used for building St. Paul's Cathedral was obtained were situated at the northern extremity of the island, but have been long abandoned in consequence of the stone being somewhat harder and more difficult to work than that met with in other parts of the island. The principal beds of stone quarried in the Isle of Portland are called, in descending order, *roach* or *roche*, *rubbly bed*, and *whit* (*i.e.* white) or *best* bed. These beds vary much in thickness, but they may be stated to average five and six feet respectively; some reaching fifteen feet.

The roach affords large blocks of a hard and durable white stone, particularly adapted for foundations of buildings, docks, breakwaters, and other constructions where great strength is required; but, owing to the numerous cavities it contains (produced by the empty casts of shells), it will not receive a close, even face, and is therefore not so well adapted for many other purposes of a more ornamental description. The rubbly bed is not much worked; but the white or best bed, when accessible is always quarried, and affords a white oolitic freestone, which takes a smooth, even face, and works freely in all directions.

The following analysis by Professor Daniell, gives the chemical composition of this stone:—

Silica	1·20
Carbonate of lime	95·16
Carbonate of magnesia	1·20
Iron and alumina	0·50
Water and loss	1·94
Bitumen	trace
	100·00

The other principal localities where the Portland stone is quarried are the Isle of Purbeck in Dorsetshire, where it is called Purbeck-Portland; and the Vale of Wardour, where (as at Chilmark and other places) it affords a freestone of a superior description. From 56,000 to 60,000 tons of stone are raised annually in the Isle of Portland.—H. W. B.

POST. A North of England term for any bed of firm rock.

POTASH, or POTASSA. (*Potasse*, Fr.; *Kali*, Ger.) This substance was so named from being prepared for commercial purposes by evaporating in iron pots the lixivium of the ashes of wood-fuel. In the crude state it consists, therefore, of such constituents of burned vegetables as are very soluble in water, and fixed in the fire. The potash-salts of plants which originally contained vegetable acids will be converted into carbonates; the sulphates will become sulphites, sulphides, or even carbonates, according to the manner of incineration; the nitrates will be changed into pure carbonates, while the muriates or chlorides will remain unaltered. Should quicklime be added to the solution of the ashes, a corresponding portion of caustic potassa will be introduced into the product, with more or less lime, according to the care taken in decanting off the clear lye for evaporation.

In America, where timber is in many places an incumbrance upon the soil, it is felled, piled up in pyramids, and burned, solely with a view to the manufacture of potash. The ashes are put into wooden cisterns, having a plug at the bottom of one of the sides under a false bottom; a moderate quantity of water is then poured on the mass, and some quicklime is stirred in. After standing for a few hours, so as to take up the soluble matter, the clear liquor is drawn off, evaporated to dryness in iron pots, and finally fused at a red heat into compact masses, which are grey on the outside and pink-coloured within.

Pearlash is prepared by calcining potashes upon a reverberatory hearth, till the whole carbonaceous matter, and the greater part of the sulphur, be dissipated: then lixiviating the mass in a cistern having a false bottom covered with straw, evaporating the clear lye to dryness in flat iron pans, and stirring it towards the end into white lumpy granulations.

The best pink Canadian potashes, as they are imported in casks containing about 5 cwts., contain pretty uniformly 60 per cent. of absolute potassa; and the best pearlashes contain 50 per cent.; the alkali in the former being nearly in a caustic state; in the latter carbonated.

All kinds of vegetables do not yield the same proportion of potash. The more succulent the plant, the more does it afford; for it is only in the juices that the vegetable salts reside, which are converted by incineration into alkaline matter. Herbaceous weeds are more productive of potash than the graminiferous species, or shrubs, and these than trees; and for a like reason twigs and leaves are more productive than timber. But plants in all cases are richest in alkaline salts when they have arrived at maturity. The soil in which they grow also influences the quantity of saline matter.

The following Table exhibits the average product in potash of several plants, according to the researches of Vauquelin, Pertuis, Kirwan, and De Saussure:—

In 1000 parts	Potassa	In 1000 parts	Potassa	In 1000 parts	Potassa
Pine or fir	0·45	Boxwood	2·26	Thistles	5·00
Poplar	0·75	Willow	2·85	Flax-stems	5·00
Trefoil	0·75	Elm and maple	3·90	Small rushes	5·08
Beechwood	1·45	Wheat-straw	3·90	Vine-shoots	5·50
Oak	1·53	Bark of oak-twigs	4·20	Barley-straw	5·80

In 1000 parts	Potassa	In 1000 parts	Potassa	In 1000 parts.	Potassa
Dry beech-bark .	6·00	Bastard chamomile		Thistles in full growth	35·37
Fern . . .	6·26	(*Anthemis cotula*, L.)	19·6	Dry straw of wheat	
Large rush . .	7·22	Sunflower-stalks .	20·00	before earing . .	47·0
Stalk of maize .	17·5	Common nettle .	25·03	Wormwood . . .	73·0
Bean-stalks . .	20·0	Vetch plant . .	27·50	Fumitory . . .	79·0

Stalks of tobacco, potatoes, chestnuts, chestnut-husks, broom, heath, furze, tansy, sorrel, vine-leaves, beet-leaves, orach, and many other plants, abound in potash salts. In Burgundy, the well-known *cendres gravitées* are made by incinerating the lees of wine pressed into cakes, and dried in the sun; the ashes contain fully 16 per cent. of potash. See Ashes of Plants.

The purification of pearlash is founded upon the fact of its being more soluble in water than the neutral salts which debase it. Upon any given quantity of that substance, in an iron pot, let one and a half times its weight of water be poured, and let a gentle heat be applied for a short time. When the whole has again cooled, the bottom will be encrusted with the salts, while a solution of nearly pure carbonate of potash will be found floating above, which may be drawn off clear by a syphon. The salts may be afterwards thrown upon a filter of gravel. If this lye be diluted with six times its bulk of water mixed with as much slaked lime as there was pearlash employed, and the mixture be boiled for an hour, the potash will become caustic, by giving up its carbonic acid to the lime. If the clear, settled lixivium be now syphoned off, and concentrated by boiling in a covered iron pan, till it assumes the appearance of oil, it will constitute the common 'caustic' of the surgeon, the *potassa fusa* of the shops. But to obtain potash chemically pure, recourse must be had to the bicarbonate, nitrate, or tartrate of potash, salts which, when carefully crystallised, are exempt from anything to render the potash derived from them impure. The bicarbonate having been gently ignited in a silver basin, is to be dissolved in six times its weight of water, and the solution is to be boiled for an hour, along with 1 lb. of slaked lime for every pound of the bicarbonate used. The whole must be left to settle without contact of air. The supernatant lye is to be drawn off by a syphon, and evaporated in an iron or silver vessel, provided with a small orifice in its close cover for the escape of the steam, till it assumes, as above, the appearance of oil, or till it be nearly red-hot. Let the fused potash be now poured out upon a bright plate of iron, cut into pieces as soon as it concretes, and put up immediately in a bottle furnished with a well-ground stopper. It is a hydrate of potash, being composed of 1 atom of potash 48, + 1 atom of water 9 = 57; or KO.HO (**KHO**).

A pure carbonate of potash may be also prepared by fusing pure nitre in an earthen crucible, and projecting charcoal into it by small bits at a time, till it ceases to cause deflagration. Or a mixture of 10 parts of nitre and 1 of charcoal may be deflagrated in small successive portions in a red-hot deep crucible. When a mixture of 2 parts of tartrate of potash, or crystals of tartar, and 1 of nitre is deflagrated, pure carbonate of potash remains mixed with charcoal, which by lixiviation, and the agency of quicklime will afford a pure hydrate. Crystals of tartar calcined alone yield also a pure carbonate.

In addition to the ashes of plants, other sources of potash are now utilized. The most important of these sources are the potash-minerals occurring in the upper part of the great salt-deposits of Stassfurt in Prussian Saxony and Kalucz in Galicia. These salts are *sylvine*, or chloride of potassium; *carnallite*, or chloride of potassium and magnesium; and *kainite*, a sulphate of potash and magnesia, with chloride of magnesium. See Abraum Salts.

Potash has also been extracted from certain felspars, from sea-water, from beet-root molasses, from the ash of sea-weeds, and from the suint of wool. But these sources are insignificant when compared with the great deposits of potash salts occurring naturally at Stassfurt, which have of late years been worked on a very extensive scale.

The Production of Potash Salts at Stassfurt.—A few details on these mines, which have produced so great a revolution in the manufacture of potash salts, will be useful. Stassfurt is situate about 20 kilos from Magdeburg, on the Anhalt frontier. The geological formation on which it lies is the Bunter Sandstone. The presence of a bed of rock-salt below this stratum was suspected in 1838. Borings were executed by order of the Prussian Government, and in 1851 the presence of a deposit of rock-salt, at least 330 meters in thickness, was ascertained. The formal working of the mines began in 1857. Before reaching the salt it was necessary to sink 260 meters through the sandstone, the gypsum, and the marl.

The saline deposit does not consist exclusively of common salt, and may be divided into four chief regions. The lowest bed is the largest, and consists entirely of rock-salt, traversed by slender veins of karstenite. It is about 240 meters in thickness.

We find next the region of *polyhalite*, still composed of rock-salt, but intersected by veins of 2 to 3 c.m. thick, formed of polyhalite, a mineral composed of the sulphates of lime, magnesia, and potash. This layer is about 64 meters in thickness, and is composed on an average of 91·2 per cent. chloride of sodium, 0·66 of karstenite, 6·63 of polyhalite, and 1·51 of hydrated chloride of magnesium.

To this stratum succeeds another of a different composition, and characterised by the presence of a saline mineral named *kieserite*. It consists of mono-hydrated sulphate of magnesia, in small microscopic needles. The layer contains 65 per cent. of chloride of sodium, 17 of kieserite, 13 of carnallite, 3 of chloride of magnesium, and 2 of karstenite. Its thickness is 56 meters. The upper region is formed of a group of salts chiefly magnesic and potassic, and formerly called *riddance salts* (*Abraumsalze*), because they were at first without industrial application, and were merely extracted to reach the rock-salt below. These salts are now the foundation of the trade of Stassfurt. The principal salt is *carnallite*, a chloride of potassium and magnesium. It has a red colour, due to the presence of oxide of iron in microscopic lamellæ. There are found also in this deposit *sylvine* and *Howellite*, a chloride of potassium containing often small quantities of sulphate of potash, and of sulphate and chloride of magnesium; *tachyhydrite*, a carnallite in which the chloride of potassium is replaced by chloride of calcium; and *boracite*, a combination of the borate and chloride of magnesium. Stassfurt, as we have stated, lies on the Prussian frontier, towards the borders of the Duchy of Anhalt. The Prussian workings, therefore, could not be extended to the south-west, where the geological conditions were most favourable. In 1855 the Government of Anhalt commenced operations within its own territory, with perfect success. The saline beds were reached at the depth of 145 meters, and soon a new salt was discovered in great quantity, giving a new impulse to the trade of the district. This is *kainite*, a compound of sulphate of magnesia and chloride of magnesium. Its discovery enabled the inhabitants to enter upon the manufacture of pure sulphate of potash, which is largely exported to England and the United States. Their applications are numerous. The chloride of potassium is used in the manufacture of saltpetre and carbonate of potash; the sulphate of potash is in great demand in the glass and alum works. Stassfurt exports also sulphate of magnesia and chloride of magnesium, which are extensively used in England for the discreditable purpose of adding to the weight of textile goods, and rendering them hygroscopic; bromine to an extent almost sufficient for the consumption of Europe, and boracic acid. Lastly, the impure salts obtained as waste in the various refining processes, consisting principally of salts of soda, magnesia, and potash, are skilfully combined, and sold as mineral manures, more or less rich in potash and magnesia. The demand for these manures has greatly increased of late years, especially in England and Germany. In 1869 the Prussian mine alone yielded 109,075,000 kilos of salts of potash, and 56,332,000 kilos of rock-salt, representing a total value of 916,960 francs. It is interesting to note that whereas the application of potassic salts in agriculture, some fifteen or twenty years ago, was found to produce little or no benefit, they are shown by more recent experiments to be highly valuable. Liebig has shown that the use of manures which contain only *some* of the ash-constituents of the crops merely enables the soil to be more rapidly exhausted of the other necessary constituents. See CARNALLITE; KAINITE; KIESERITE; SYLVINE.

Caustic potash, after being fused in a silver crucible at a red heat, retains 1 equivalent of water. Hence its composition in 100 parts is, potassium 70, oxygen 14, water 16. *Anhydrous potash*, or the oxide free from water, can be obtained only by the oxidation of potassium in air. It is composed of 83⅓ of metal and 16⅔ of oxygen.

Caustic potash may be crystallised; but in general it occurs as a white brittle substance of spec. grav. 1·708, which melts at a red heat, evaporates at a white heat, deliquesces into a liquid in the air, and attracts carbonic acid; is soluble in water and alcohol, forms soft soaps with fat oils, and soapy-looking compounds with resins and wax; dissolves sulphur, some metallic sulphurets, as those of antimony, arsenic, &c., as also silica, alumina, and certain other bases; and decomposes animal textures, as hair, wool, silk, horn, skin, &c. It should never be touched with the tongue or the fingers.

The only certain way of determining the quantity of free potash in any solid or liquid is from the quantity of a dilute acid of known strength which it can saturate.

The hydrate of potash or its lye often contains a notable quantity of carbonate, the presence of which may be detected by lime-water, and its amount be ascertained by the loss of weight which it suffers, when a weighed portion of the lye is poured into a weighed portion of dilute sulphuric acid poised in the scale of a balance.

The following Table exhibits the quantity of potash in 100 parts of *caustic lye*, at the respective densities:—

Sp. gr.	Pot. in 100	Sp. gr.	Pot. in 100	Sp. gr.	Pot. in 100	Sp. gr.	Pot. in 100	Sp. gr.	Pot. in 100
1·58	53·06	1·46	42·31	1·34	32·14	1·22	23·14	1·10	11·28
1·56	51·58	1·44	40·17	1·32	30·74	1·20	21·25	1·08	9·20
1·54	50·09	1·42	37·97	1·30	29·34	1·18	19·34	1·06	7·02
1·52	48·46	1·40	35·99	1·28	27·86	1·16	17·40	1·04	4·77

POTASH, BICARBONATE OF, is prepared by passing carbonic acid through a solution of the carbonate of potash. See BICARBONATES.

POTASH, BICHROMATE OF. See CHROMATES OF POTASH.

POTASH, BINOXALATE OF. *Salt of wood sorrel; Salt of sorrel; Sal acetosella.* (*Sel d'oseille*, Fr.)

The *Oxalis acetosella* is an odourless plant, but in taste it is agreeably acidulous. In some parts of Germany the binoxalate of potash is obtained in large quantities from this plant by evaporating the expressed juice. Five hundred parts of the plant yield four parts of the crystallised salt; its composition is, oxalic acid 2 parts, potash 1 part, water 2 parts.

It is sold under the name of *salt of lemons*, sometimes in a pure state, but more frequently mixed with *cream of tartar*, and is used for the removal of iron stains from linen.

POTASH, BITARTRATE OF. *Cream of tartar.* This salt is a constituent of many vegetable juices, especially of the juice of the grape. All the salt of commerce is obtained during the vinous fermentation; it deposits during the process of the formation of alcohol, and accordingly as it is obtained from white or red wine it is known by the name of *white or red argol.* The acid tartar is thus prepared in the wine-making districts of France.

Argol, which occurs in crystalline cakes, and is composed of the bitartrate of potash, tartrate of lime, and colouring-matter, is boiled in water; and the solution allowed to cool, by which a deposit of crystals is obtained. These are washed with cold water, and then dissolved in boiling water, in which are diffused clay and charcoal, which as they fall down receive the colouring-matter. The clear liquor is allowed to cool slowly, and crystals form.

This salt consists of potash 25·00, tartaric acid 70·21, water 4·79.

If cream of tartar is heated it is decomposed, swells up, evolves gaseous products, and is converted into *Black Flux.* See ASSAYING.

POTASH, CARBONATE OF. *Salt of tartar; Potashes; Pearlashes.* If land plants are burnt their ashes will be found to contain a considerable quantity of the carbonate of potash.

Carbonate of potash is composed of 48 parts of base and 22 of acid; or, in 100 parts, of 68·09 of potash and 31·91 of carbonic acid: that is, $KO.CO^2$ ($\mathbf{K^2CO^3}$).

Carbonate of potash, as it exists associated with carbon in calcined tartar, passes very readily into the *bicarbonate*, on being moistened with water, and having a current of carbonic acid gas passed through it. The absorption takes place so rapidly, that the mass becomes hot, and therefore ought to be surrounded with cold water. See POTASH.

POTASH, CAUSTIC. See POTASH.

POTASH, CHLORATE OF. See CHLORATE OF POTASH.

POTASH, CITRATE OF. This salt is formed by neutralising citric acid with carbonate of potash. Under the names of *lemon and kali, effervescing lemonade*, and the like, mixtures of dry citric acid in powder and dry carbonate of potash, with very dry sugar, are sold. These form very agreeable and healthful beverages.

POTASH, HYDRATE OF, or **CAUSTIC POTASH.** (*Potasse*, Fr.; *Kali*, Ger.) It may be obtained thus:—Mix a solution of 1 part of the dry carbonate of potash with 1 part of freshly-prepared dry hydrate of lime, and allow it to stand in a closed vessel for 24 hours at a temperature of 68° to 78° Fahr., frequently shaking it. The potash salt should be dissolved in 12 to 15 parts of water; the carbonate of lime separates in a granulated state, and the clear caustic lye may be decanted. A weaker lye may be obtained from the residue by fresh treatment with water. See POTASH.

POTASH, NITRATE OF. $KO.NO^5$ ($\mathbf{KNO^3}$.) Syns. *Nitre, Saltpetre, Prismatic nitre.* (*Nitrate de potasse*, Fr.; *Salpetersäures Kali*, Ger.) For the mode of purification, see GUNPOWDER. This well-known and useful salt is found native in various parts of the world, more especially in tropical climates. The formation of nitre in the earth appears to be much facilitated by warmth.

Preparation.—1. By lixiviation of earth impregnated with the salt. The earth is heated with water in tanks or tubs with false bottoms, and after sufficient digestion the solution is run off and evaporated to crystallisation. The nitre procured by the first operation is exceedingly impure, and contains large quantities of chloride of potassium, and some sulphate of potash. By repeated crystallisations the salt may be obtained pure. If the crude product of the lixiviation contains, as is often the case, the nitrates of lime or magnesia, they may be got rid of by the addition of carbonate of potash; the earths are precipitated as carbonates, and may be filtered off, while an equivalent quantity of nitrate of potash is formed, and remains in solution, thus:—

$$CaO.NO^5 + KO.CO^2 = CaO.CO^2 + KO.NO^5. \quad [\mathbf{Ca(NO^3)^2 + K^2CO^3 = CaCO^3 + 2KNO^3}.]$$

2. The second mode of preparing nitre which we shall consider, is from nitrate of soda and chloride of potassium. On dissolving equivalent quantities of these two salts in water, and salting down, double decomposition takes place. The chloride of sodium may be removed from the hot concentrated fluid by means of shovels, while the nitrate of potash, being much more soluble in hot than in cold water, remains in solution, but crystallises out on cooling. The decomposition takes place in accordance with the annexed equation:—

$$NaO.NO^5 + KCl = NaCl + KO.NO^5. \quad (\mathbf{NaNO^3 + KCl = NaCl + KNO^3}.)$$

The above reaction is one of great interest and importance, inasmuch as it enables us to convert Peruvian or 'cubic nitre,' as nitrate of soda is sometimes called, into the much more valuable salt, nitrate of potash. During the last war with Russia it was found that large quantities of chloride of potassium were exported, and found their way into that country. For some time no notice was taken, because the salt appeared too harmless to be declared contraband of war. Eventually it was found that it was entirely used in Russia for the purpose of affording nitrate of potash, by the process described. It need scarcely be said that the gunpowder made through the medium of our own chloride of potassium was employed against our troops in the Crimea.

3. Nitre may of course be prepared by neutralising nitric acid by means of carbonate of potash, or the caustic alkali. The process is evidently too expensive to be employed, except for the purpose of experimental illustration, or under other special circumstances.

The formation of nitre in the earth of hot climates is probably in most cases due to the decomposition of nitrogenised organic matters. The subject of nitrification is one upon which some controversy has taken place. It is supposed by some chemists that the chief source of the nitric acid is the ammonia produced during the decay of nitrogenous matters. The presence of bases appears to have a remarkable tendency to increase the production of the acid. It has been asserted that the ammonia which is produced suffers partial oxidation, the acid formed uniting with the undecomposed ammonia to form the nitrate of that alkali. On the other hand, it has been argued that the ammonia does not suffer oxidation, but that the nitrogen produced during the decay of organic matter combines, at the instant of its liberation with oxygen, to form nitric acid, which unites with the bases present. Nitrate of ammonia, no matter how formed, suffers double decomposition in presence of the carbonates of the alkaline earths, the result being the production of the nitrates of lime and magnesia. It is owing to the presence of the two latter salts in the crude liquor obtained by lixiviating nitrified earth, that the addition of carbonate of potash is so important, and causes so great an increase in the produce of nitre. It has been insisted by some observers that the presence of nitrogenous organic matters is not essential to the production of nitre. In support of this, it has been shown that large quantities of nitrates are often found where little or no organic matters are present. This has been explained by assuming that porous bodies have the power of absorbing water, oxygen, and nitrogen, and producing nitric acid from them. But it is evident that other forces exist capable of inducing the oxidation of atmospheric nitrogen. It has been experimentally demonstrated that nitric acid is produced during the discharge of atmospheric electricity. It is also probable that ozone plays an important part in the phenomena of nitrification. Perhaps most of the chemists who have investigated the subject, have been too anxious to assign the formation of nitre to one particular cause, whereas, the phenomena which have been noticed by different observers are in favour of the idea that several agencies are at work during the production of nitrates in the earth and in artificial nitre-beds.

During the time that France was fighting single-handed against the rest of Europe, great difficulty was found in obtaining sufficient nitre for the production of the vast amount of gunpowder necessary to enable her artillery to be effectively supplied with ammunition. This led the French chemists to establish artificial nitre-beds in various parts of the country. The success of the process may be judged of from the fact that they yielded 2,000 tons annually.

Nitre crystallises in colourless six-sided prisms. The crystals are anhydrous; large specimens when broken, however, generally show the presence of a little moisture mechanically adhering to the interstices. If wanted in fine powder, it must therefore be first coarsely bruised, and then dried, after which it may be finely pulverised and sifted.

By the careful application of heat, nitrate of potash may be melted without undergoing any decomposition or loss of weight. But if the heat be raised to redness, it begins to decompose, the degree to which the change takes place depending on the amount of heat and the time of exposure. By carefully heating, for some time, a large quantity of nitrite of potash is formed, oxygen gas being evolved. If the heat be raised, or the exposure to a high temperature be continued, a large quantity of nitrogen accompanies the oxygen, and the nitre becomes more and more changed, until finally, a mixture of potash with peroxide of potassium is attained. If copper filings, clipping, or shreds be mixed with the nitre, the decomposition proceeds much more readily, and Wöhler has proposed to prepare pure potash by this means. At high temperatures nitre is a potent agent of oxidation, so much so, that the diamond itself is attacked and converted into carbonic acid, which unites with the potash. Crystallised boron, which is said to equal if not exceed the diamond in hardness, is not attacked by fused nitre. The oxidising power of nitre is made use of in the arts in order to obtain bichromate of potash from chrome iron ore.

Nitrate of potash is sometimes used as a source of nitric acid, but nitrate of soda is in every way more economical. This will be evident when it is considered that it takes 101 parts of nitrate of potash to yield one equivalent of dry nitric acid (54 parts), whereas 85 parts of nitrate of soda yield the same amount of acid. See Nitric Acid.

Nitrate of potash is employed in blow-pipe experiments, in order to assist in the production of the green reaction characteristic of the presence of manganese. It often happens where the quantity of manganese is exceedingly small, as in rose quartz, that the green coloration with soda on platinum foil cannot be obtained; if, however, a little nitre be added, and the testing be repeated, the reaction generally appears without any trouble.

Nitrate of potash is greatly employed in the preparation of pyrotechnic mixtures. It ought always to be well dried and reduced to fine powder before being used.

Nitre is not unfrequently employed by the chemist for determining the percentage of sulphur in coal. For this purpose the coal, reduced to fine powder, is mixed with nitre and carbonate of soda, and projected by small portions into a silver crucible, maintained at a red heat. A platinum crucible must not be employed, as it is attacked by nitre in a state of fusion. The sulphur in the coal is converted, by the oxidising agency of the nitre, into sulphuric acid; the latter can then be converted into sulphate of baryta, and the percentage of sulphur ascertained from its weight.

Estimation of the Value of Nitre.—A great number of processes have been devised for the determination of the percentage of pure nitrate of potash in samples of the crude salt. All these processes are more or less incorrect, and a really accurate mode of determining the value of nitre has long been felt as a want by chemists. This want has been supplied by Messrs. Abel and Bloxam of the Woolwich Arsenal, who have devoted much labour and skill to the subject. Before detailing the successful process of the latter chemists, we will take a brief glance at the other methods commonly used for the purpose. The French process depends upon the principle that a solution, when saturated with one salt, is still capable of dissolving a considerable quantity of saline matter differing in its nature from the first. If, therefore, a saturated solution of nitre be poured upon pure nitre, no more is dissolved if the temperature remains the same as it was when the original solution was prepared. But if, on the other hand, the saturated solution of nitre be digested with an impure sample containing the chlorides of sodium, potassium, &c., the latter salts will be dissolved, and the pure nitre remaining can, after proper draining, &c., be dried and weighed. The loss of weight obviously represents the impurities removed. This process is subject to so many sources of error that the practical details need not be entered into.

Another mode of valuing nitre consists in fusing the salt, and, after cooling, breaking the cake: the fineness or coarseness and general characters of the fracture are the means whereby the greater or less value of the salt are ascertained. This process, which is known as the Swedish or Swartz's method, is far too dependent on the individual experience and dexterity of the operator to be of any value in the hands of the chemist whose attention is only now and then directed to the valuation of saltpetre. Moreover, although those who are in the habit of using it possess some confidence in its correctness, it is quite evident that it is impossible for such an operation to yield results of analytical accuracy.

The Austrian method has also been used by some, but it is quite inadmissible as a general working process. It consists in ascertaining the temperature at which the solution crystallises.

Gossart's method consists in determining the value of the nitre by measuring its power of oxidation. The latter is accomplished by finding the quantity of protoxide of iron which it can convert into peroxide. If to an acid solution of protosulphate of iron nitric acid or a nitrate be added, the proto is converted into a persalt at the expense of a portion of the oxygen of the nitric acid.

M. Pelouze endeavoured to improve the above process by using such an excess of the protosalt of iron that the nitre added should be able to convert only a portion of it into a persalt. The remaining protoxide was then converted into persalt by means of a solution of permanganate of potash of known strength. The data so obtained enabled the value of the nitre to be estimated. But even this process is liable to variations, so much so, indeed, that Messrs. Abel and Bloxam obtained in eleven experiments made with pure nitre as many different results.

The next process which we shall notice is that which the chemists generally have settled upon as yielding the best results. It is that of M. Gay-Lussac. It depends on the fact that if nitrate of potash be heated with charcoal, or, in fact, any carbonaceous matters in excess, the nitrate is converted into carbonate of potash, the amount of which may be accurately estimated by means of a standard solution of sulphuric acid. The chlorides which may be present are unacted upon by the charcoal, and do not, therefore, influence the result; but if sulphates be present, they are reduced by the carbon to sulphides, which, in consequence of being decomposed by the sulphuric acid, may cause serious errors. Fortunately the amount of sulphuric acid present in nitre is seldom sufficient to cause any great error. Any nitrate of soda present would come out in the final result as nitrate of potash, and thus become another source of error; in practice this is seldom likely to occur. The original process consists in weighing out 20 grammes (308·69 grains) of crude saltpetre, and mixing it with 5 grammes (77·17 grains) of charcoal, and 80 grammes (1234·7 grains) of chloride of sodium. The mixture is thrown little by little into a red-hot crucible, and, when the decomposition is over, allowed to cool. The residual mass is dissolved in water, filtered, and water passed through the filter until it amounts to 200 cubic centimeters (12·2 cubic inches). The amount of alkali is then ascertained with a burette and standard sulphuric acid. (See Alkalimeter.) Messrs. Abel and Bloxham have minutely and laboriously studied this operation, and detected its sources of difficulty and error. Their researches have led them to employ the following modification:—

Twenty grains of the sample are to be well mixed in a platinum crucible with 30 grains of finely-powdered resin and 80 grains of pure dry common salt. The heat of a wire-gauze flame is then applied, until no more vapour is given off. The crucible is then allowed to cool down a little, and 25 grains of chlorate of potash are added. A gentle heat is then applied until most of the chlorate is decomposed; the heat is then raised to bright redness for two or three minutes. The mass should be fluid, and free from floating charcoal. The mass, when cool, is removed to a funnel, and the crucible, &c., washed with boiling water. The mass is then dissolved in hot water, and the entire solution, coloured by litmus, is neutralised with the standard acid. In the annexed table 20 grains of pure nitre were taken for each experiment:—

Exp.	Nitre found	Nitre per cent.
1	20·00	100·00
2	20·00	100·00
3	19·97	99·85
4	19·97	99·85
5	20·08	100·40
6	20·08	100·40
7	20·08	100·40

These chemists, not yet satisfied, made 53 more experiments by this method. The mean result with pure nitre was 99·7 per cent. The mean of 25 of the above experiments was 98·7 per cent. The mean of the remainder was 100·7.

Subsequent experiments showed that greater accuracy might be obtained by substituting, for the resin, pure ignited finely-divided graphite, prepared by Professor Brodie's patented process. To perform the process, 20 grains of the nitre are to be mixed with 5 grains of ignited graphite and 80 grains of salt. The general process is conducted in the manner described in the operation with resin. The results are very exact, and apparently quite sufficient for all practical purposes.

POTASH, NITRITE OF. $KO.NO^3$ (**KNO^2**). When ordinary saltpetre, or nitrate of potash, is heated with sulphuric acid, in the cold, no special reaction becomes evident, as far as any evolution of gas is concerned; but if, previous to the addition of the acid, the nitre be strongly fused, it will be found, as soon as the admixture takes place, that red fumes are evolved. This arises from the fact, that nitrate of potash, when subjected to strong ignition, is decomposed with evolution of oxygen, the nitrate becoming gradually converted into the nitrite of potash, thus:—

$$KO.NO^5 = KO\,NO^3 + 2O. \quad (\mathbf{2KNO^3 = 2KNO^2 + O^2}).$$

This reaction acquires great interest from the circumstance, that to its correct explanation was owing the commencement of the fame of the illustrious Swedish chemist Scheele. A pharmaceutist, at Upsala, having heated some saltpetre to redness in a crucible, happened, when it became cold, to pour vinegar over it, when, to his surprise, red fumes were evolved. Gahn was applied to for an explanation; but, unable to comprehend the matter, he applied to Bergmann; but even he was as much in the dark as Gahn. The explanation which these eminent chemists were unable to give was supplied by the pharmaceutist's apprentice, the young Scheele. Bergmann, when informed by Gahn of Scheele's explanation, felt a strong desire to make his acquaintance, and ultimately they were introduced to each other.

Nitrite of potash has acquired some importance of late years, owing to the valuable properties, as a decomposing agent, which have been found by chemists to reside in nitrous acid.

Preparation.—Nitrate of potash is to be fused at a red heat for a considerable time. When cold, the contents of the crucible are to be dissolved out with boiling water, and the nitrate of potash remaining is to be removed as far as possible by crystallisation. The nitrite of potash may be obtained from the mother-liquor by evaporation and subsequent crystallisation. It is a neutral salt which deliquesces on exposure to the air. If a piece of strongly-fused nitre be put, when cold, into a solution of sulphate of copper, a very beautiful apple-green colour is produced, of a tint which is seldom observed, except in solutions containing the nitrite of that metal.

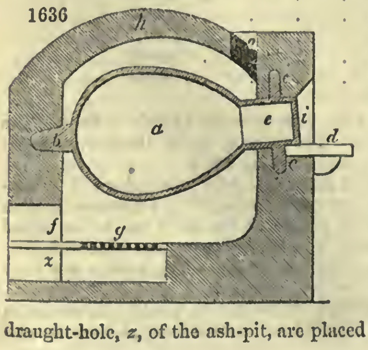
POTASH, PRUSSIATE OF. *Ferrocyanide of potassium or Yellow prussiate of potash.* $K^2FeCy^3 + 3HO$ ($\mathbf{K^4FeCy^6 + 3H^2O}$).

This salt occurs in a state of great purity in commerce, and is thus manufactured on the large scale:—

Among the animal substances used for the preparation of this lixivium, blood deserves the preference, where it can be had cheap enough. It must be evaporated to perfect dryness, reduced to powder, and sifted. Hoofs, parings of horns, hides, old woollen rags, and other animal offals, are, however, generally had recourse to, as condensing most azotised matter in the smallest bulk. Dried funguses have been also prescribed. These animal-matters may either be first carbonised in cast-iron cylinders, and the residual charcoal may then be taken for making the ferroprussiate; or the dry animal-matters may be directly employed. The latter process is apt to be exceedingly offensive to the workmen and neighbourhood, from the nauseous vapours that are exhaled in it. Eight pounds of horn (hoofs), or ten pounds of dry blood, afford upon an average one pound of charcoal. This must be mixed well with good pearlash, (freed previously from most of the sulphate of potash, with which it is always contaminated,) either in the dry way, or by soaking the bruised charcoal with a strong solution of the alkali: the proportion being one part of carbonate of potash to from 1½ to 2 parts of charcoal, or to about 8 parts of hard animal-matter.

The pot for calcining the mixture of animal and alkaline matter is egg-shaped, as represented at *a*, *fig.* 1636, and is considerably narrowed at the neck *e*, to facilitate the closing of the mouth with a lid *i*. It is made of cast iron, about two inches thick in the belly and bottom; this strength being requisite because the chemical action of the materials wears the metals away fast. It should be built into the furnace in a direction sloping downwards, (more than is shown in the figure,) and have a strong knob *b*, projecting from its bottom to support it upon the back wall, while its shoulder is embraced at the arms *c*, *c*, by the brickwork in front. The interior of the furnace is so formed as to leave but a space of a few inches round the pot, in order to make the flame play closely over its whole surface. The fire-door *f*, and the draught-hole, *z*, of the ash-pit, are placed in the posterior part of the furnace, in order

1636



that the workmen may not be incommoded by the heat. The smoke-vent *o*, issues through the arched top, *h*, of the furnace, towards the front, and is thence led backwards by a flue to the main chimney of the factory. *d* is an iron or stone shelf, inserted before the mouth of the pot, to prevent loss in shovelling out the semi-liquid paste. The pot may be half filled with the materials.

The calcining process is different, according as the animal substances are fresh or carbonised. In the first case, the pot must remain open, to allow of diligent stirring of its contents, with a slightly bent flat iron bar or scoop, and of introducing more of the mixture as the intumescence subsides, during a period of five or six hours, till the nauseous vapours cease to rise, till the flame becomes smaller and brighter, and till a smell of ammonia be perceived. At this time the heat should be increased, the mouth of the pot should be shut, and opened only once every half-hour, for the purpose of working the mass with the iron paddle. When on opening the mouth of the pot, and stirring the pasty mixture, no more flame rises, the process is finished.

If the animal ingredients are employed in a carbonised state, the pot must be shut as soon as its contents are brought to ignition by a briskly-urged fire, and opened for a few seconds only every quarter of an hour, during the action of stirring. At first, a body of flame bursts forth every time that the lid is removed; but by degrees this ceases, and the mixture soon agglomerates, and then softens into a paste. Though the fire be steadily kept up, the flame becomes less and less each time that the pot is opened; and when it ceases, the process is at an end. The operation, with a mass of 50 pounds of charcoal and 50 pounds of purified pearlash, lasts about 12 hours the first time that the furnace is kindled; but when the pot has been previously brought to a state of ignition, it takes only 7 or 8 hours. In a well-appointed factory the fire should be invariably maintained at the proper pitch, and the pots should be worked with relays of operatives.

The molten mass is now to be scooped out with an appropriate iron shovel, having a long shank, and caused to cool in small portions, as quickly as possible; but not by throwing it into water, as has sometimes been prescribed, for in this way a good deal of the cyanogen is converted into ammonia. If it be heaped up and kept hot in contact with air, some of the ferrocyanide is also decomposed, with diminution of the product. The crude mass is to be then put into a pan with cold water, dissolved by the application of a moderate heat, and filtered through cloths. The charcoal which remains upon the filter possesses the properties of decolouring syrups, vinegars, &c., and of destroying smells in a pre-eminent degree. It may also serve, when mixed with fresh animal-charcoal, for another calcining operation.

As the iron requisite for the formation of the ferrocyanide is in general derived from the sides of the pot, this is apt to wear out into holes, especially at its under side, where the heat is greatest. In this event it may be taken out of the furnace, patched up with iron-rust cement, and reinserted with the sound side undermost. The erosion of the pot may be obviated in some measure by mixing iron borings or cinder with the other materials, to the amount of one or two hundredths of the potash.

The above lixivium is not a solution of pure ferroprussiate; it contains not a little cyanide of potassium, which in the course of the process had not absorbed the proper dose of iron to form a ferrocyanide; it contains also more or less carbonate of potash, with phosphate, sulphate, hydrogenated sulphuret, muriate, and sulpho-cyanide of the same base, as well as phosphate of lime; substances derived partly from the impure potash, and partly from the incinerated animal-matters. Formerly that very complex impure solution was employed directly for the precipitation of prussian blue; but now, in all well-regulated works, it is converted by evaporation and cooling into crystallised ferroprussiate of potash. The mother-water is again evaporated and crystallised, whereby a somewhat inferior ferroprussiate is obtained. Before evaporating the lye, however, it is advisable to add as much solution of green sulphate of iron to it as will re-dissolve the white precipitate of cyanide of iron which first falls, and thereby convert the cyanide of potassium, which is present in the liquor, into ferrocyanide of potassium. The commercial prussiate of potash may be rendered chemically pure by making its crystals effloresce in a stove, fusing them with a gentle heat in a glass retort, dissolving the mass in water, neutralising any carbonate and cyanide of potassium that may be present, with acetic acid, then precipitating the ferroprussiate of potash by the addition of a sufficient quantity of alcohol, and finally crystallising the precipitated salt twice over in water. The sulphate of potash may be decomposed by acetate of baryta, and the resulting acetate of potash removed by alcohol.

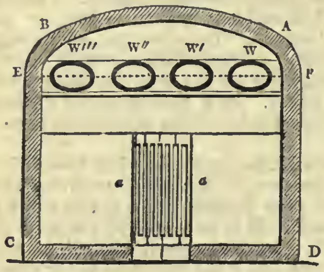
Berry's Patent Process.—Reduce charcoal into bits of the size of a walnut; soak them with a solution of carbonate of potash in urine, and then pour over them a solution of nitrate or acetate of iron; dry the whole by a moderate heat, and introduce them into the cast-iron tubes, presently to be described. The following proportions of constituents have been found to answer:—Ordinary potash, 30 parts; nitre, 10; acetate of iron, 15; charcoal or coke, 45 to 55; dried blood, 50. The materials, mixed and dried, are put into retorts similar to those for coal-gas. The animal-matter, however (the blood), is placed in separate compartments of pipes connected with the above retorts. The pipes containing the animal-matter should be brought to a red heat before any fire is placed under the retorts.

In *fig.* 1637, A B C D, is a horizontal section of a furnace constructed to receive four elliptical iron pipes. The furnace is arched in the part A B, in order to reverberate the heat, and drive it back on the pipes W, W′, W″, W‴. These pipes are placed on the plane E F, of the ellipsoid. *a a*, represents the grating or bars of the furnace to be heated with coal or coke; I I (*fig.* 1638), is the pot or retort.

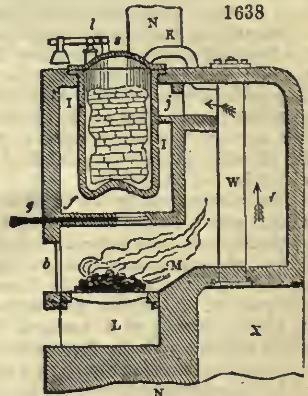
This pot or retort is placed in a separate compartment, as seen in *fig.* 1638, which is a vertical section, taken through *fig.* 1640 at the line G, H. K is a connecting tube from the retort and the elliptical pipes W.

In the section, *fig.* 1639, the shape of the tube K will be better seen; also its cocks *u*, and likewise its connection with the pipes W. *l*, (*fig.* 1638) is a safety-valve; *s*, the

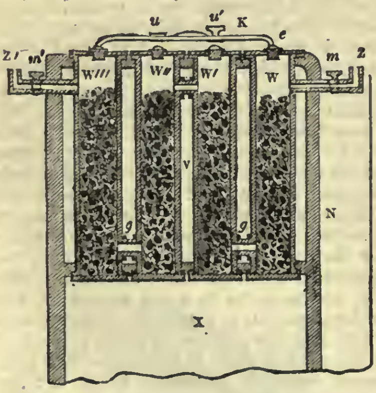
1637



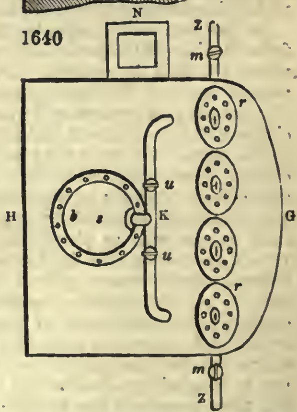
1638



1639



1640



cover of the pot or retort; L, is the ash-pit; and *b*, the door of the furnace; X, is an open space, roofed over, or a kind of shed, close to the furnace, and under it the pipes are emptied; M, an inclined plane behind the fire-bars.

The arrows indicate the direction of the current of heat. This current traverses the intervals left between the pipes, and ascends behind them, passing through the aperture *j*, in the brickwork, which is provided with a valve or damper, for closing it, as required. The heat passes through this aperture, and strikes against the sides of the pot when the valve is open. Another valve, *f*, *g*, must also be open to expose the pot or retort to the direct action of the fire. The smoke escapes by a lateral passage into a chimney, N.

It must be remarked that there is a direct communication between the chimney and that compartment of the furnace which contains the pipes, so that the heat, reflected from the part v, strikes on the pot or retort only when the pipes w, w, w″, w‴, are sufficiently heated.

In *fig.* 1639 are represented the junction-tubes, which connect the four pipes with their gas-burners, z, z, and the cocks *m m′*. *r*, *r*, *fig.* 1640, are covers, closing the pipes, and having holes formed in them; these holes are shut by the stoppers *e*.

Whether the pipes are placed in the vertical or horizontal position, it is always proper to be able to change the direction of the current of gas; this is easily done by closing, during one hour (if the operation is to last two hours), the cocks *u*, *m′* (*fig.* 1639), and opening those, *u′*, *m*; then the gas passes through *u′*, into the branch K, and entering w‴, passes through v into w′, through *g* into w′, and through 2nd *g* into w, and finally escapes by the burner z. During the following or other hour, the cocks *u′*, *m*, must be closed; the cocks *u*, *m′*, being opened, the current then goes from *u*, into K, w, w′, w″, w‴, and escapes by the burner z′, where it may be ignited.

The changing of the direction of the current dispenses, to a certain degree, with the labour required for stirring with a spatula the matters contained in the pipes; nevertheless, it is necessary, from time to time, to pass an iron rod or poker amongst the substances contained in the pipes. It is for this purpose that apertures are formed, so as to be easily opened and closed.

The patentee remarks, that although this operation is only described with reference to potash, for obtaining prussiate of potash, it is evident that the same process is applicable to soda; and when the above-mentioned ingredients are employed, soda being substituted for potash, the result will be prussiate of soda.

The process employed in the manufacture of ferrocyanide of potassium, by Hoffmayr and Prükner, is as follows:—The potash must be free from sulphate, for each atom of sulphur destroys an atom of the cyanide of potassium. A very strong heat is advantageous. The addition of from 1 to 3 per cent. of saltpetre is useful, when the mass is too long in fusing. A reverberatory furnace is recommended; but the flame must not beat too much upon the materials for fear of oxidising them. When the smoky red flame ceases, it is useful to throw in from time to time small portions of uncarbonised animal-matter, particularly where the flame first beats upon the mass, whereby the resulting gases prevent oxidation by the air. The animal-matters should not be too much carbonised, but left somewhat brown-coloured, provided they be readily pulverised. Of uncarbonised animal-matters, the proportions may be 100 parts dried blood, to from 28 to 30 of potash (carbonate), and from 2 to 4 of hammerslag (smithy scales), or iron filings. 2nd. 100 parts of horns or hoofs; from 33 to 35 potash; 2 to 4 iron. 3rd. 100 leather; 45 to 48 potash; and 2 to 4 iron. From blood, 8 to 9 per cent. of the prussiate are obtained; from horns, 9 to 10; and from leather, 5 to 6. The potash should be mixed in coarse particles, like peas, with the carbonised animal-matter, which may be best done in a revolving pot, containing cannon-balls. Of the animal-charcoal and potash equal parts may be taken, except with that from leather, which requires a few more parts of potash per cent. On the average, blood and horn-charcoal should afford never less than 20 per cent. of prussiate, nor the leather than 6; but by good treatment they may be made to yield, the first 25, and the last from 10 to 11.

POTASH, RED PRUSSIATE OF, or *Ferricyanide of potassium*, is prepared by passing chlorine gas through a solution of the ferrocyanide of potassium until it ceases to give a precipitate of Prussian blue, with a persalt of iron, and no longer. Its formula is $K^3Fe^2Cy^6$ ($\mathbf{K^3FeCy^6}$).

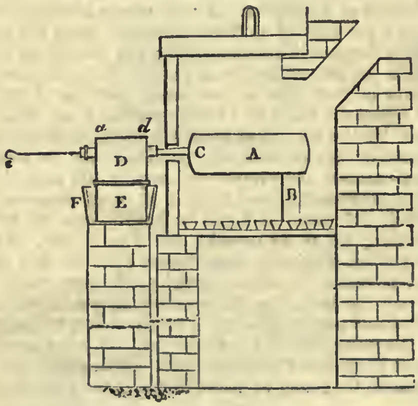
POTASSIUM (Eng. and Fr.; *Kalium*, Ger.) *Symb.* K; *At. wt.* 39. This is a metal deeply interesting, not only from its own properties, but from its having been the first link in the chain of discovery which conducted Sir H. Davy through many of the formerly mysterious and untrodden labyrinths of chemistry. It is the metallic base of potash.

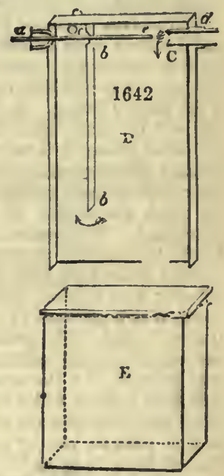
The easiest mode of obtaining this elementary substance is that contrived by Brünner. Into the orifice of one of the iron bottles, as A, *fig.* 1641, in which mercury is imported, adapt, by screwing, a piece of gun-barrel tube, 9 inches long; having brazed into its side, about three inches from its outer end, a similar piece of iron tube. Fill this retort two-thirds with a mixture of ten parts of cream of tartar, previously calcined in a covered crucible, and 1 of charcoal, both in powder; and lay it horizontally in an air furnace, so that while the screw orifice is at the inside wall, the extremity of the straight or nozzle-tube may project a few inches beyond the brickwork, and the tube brazed into it at right angles may descend pretty close to the outside wall, so as to dip its lower end a quarter of an inch beneath the surface of some rectified naphtha contained in a copper bottle surrounded by ice-cold water. By bringing the condenser vessel so near the furnace, the tubes along which the potassium-vapour requires to pass run less risk of getting obstructed. The horizontal straight end of the nozzle-tube should be shut by screwing a stopcock air-tight into it. By opening the cock momentarily, and thrusting in a hot wire, this tube may be readily kept free, without permitting any considerable waste of potassium. The heat should be slowly applied at first, but eventually urged to whiteness, and continued as long as potassuretted hydrogen continues to be disengaged. The retort and the part of the nozzle-tube exposed to the fire should be covered with a good refractory lute, as described under the article PHOSPHORUS. The joints must be perfectly air-tight; and the vessel freed from every trace of mercury, by ignition, before it is charged with the tartar-ash.

Tartar skilfully treated in this way will afford 3 per cent. of potassium; and when it is observed to send forth green fumes, it has commenced the production of the metal. Instead of the construction above described, the following form of apparatus may be employed:—

A, *fig.* 1641, represents the iron bottle, charged with the incinerated tartar; and B is a fire-brick support. A piece of fire-tile should also be placed between the bottom of the bottle and the back wall of the furnace, to keep the apparatus steady during the operation. Whenever the moisture is expelled, and the mass faintly ignited, the tube C should be screwed into the mouth of the bottle, through a small hole left for this purpose in the side of the furnace. That tube should be no longer, and the front wall of the furnace no thicker, than what is absolutely necessary. As soon as the reduction is indicated by the emission of green vapours, the receiver *d*, *a*, D, E, must be adapted; this is shown in a large scale in *fig.* 1642.

1641





This is a condenser, in two pieces, made of thin sheet copper: D, the upper part, is a rectangular box, open at bottom, about 10 inches high, by 5 or 6 long and 2 wide; near to the side *a*, it is divided inside into two equal compartments, up to two-thirds of its height; by a partition, *b*, *b*, in order to make the vapours that issue from C pursue a downward and circuitous path. In each of its narrow sides, near the top, a short tube is soldered, at *d* and *a*; the former being fitted air-tight into the end of the nozzle of the retort, while the latter is closed with a cork traversed by a stiff iron probe, *e*, which passes through a small hole in the partition *b*, *b*, under *c*, and is employed to keep the tube C clear by its drill-shaped steel point. In one of the broad sides of the box D, near the top, a bit of pipe is soldered on at *c*, for receiving the end of a bent glass tube of safety, which dips its other and lower end into a glass containing naphtha. E, is the bottom copper box, with naphtha, which receives pretty closely the upper case, D, and is to be immersed in a cistern of cold water, containing lumps of ice.

In this process, carbonate of potash is obtained by calcination of the tartar, and this carbonate is then decomposed by the carbon, with formation of carbonic oxide gas and elimination of metallic potassium. For details of the process, and for precautions to be observed, see Watts's 'Dictionary of Chemistry.'

Pure potassium, thus procured, or by Davy's original method, by acting upon fused potash under a film of naphtha, with the negative wire of a powerful voltaic battery, is a soft metal, which can be cut, like wax, with a knife, and its newly-cut surface possesses great brilliancy. It is fluid at 120° F. At 50° it is malleable, and has the lustre of polished silver; at 32° it is brittle, with a crystalline fracture; and at a heat approaching to redness, it begins to boil, is volatilised, and converted into a green-coloured gas, which condenses into globules upon the surface of a cold body. Its specific gravity in the purest state is 0·865 at 60°. When heated in the air, it takes fire, and burns very vividly. It has a stronger affinity for oxygen than any other known substance; and is hence very difficult to preserve in the metallic state. At a high temperature it reduces almost every oxygenised body. When thrown upon water, it kindles, and moves about violently upon the surface, burning with a violet flame, till it be consumed; that is to say, converted into potash. When thrown upon a cake of ice, it likewise kindles, and melts a hole in it. If a globule of it be laid upon wet turmeric-paper, it takes fire, and runs about, marking its desultory paths with red lines. The flame observed in these cases is owing chiefly to hydrogen, for it is at the expense of the water that the potassium burns, potassuretted hydrogen being formed.

POTASSIUM, BROMIDE OF. A compound resembling iodide of potassium, and prepared by similar processes.

POTASSIUM, CHLORIDE OF. This salt may be obtained from sea-water or from kelp, but it is now generally prepared by washing *carnallite*, a double chloride of potassium and magnesium, from which the latter chloride is readily removed by water. Chloride of potassium occurs among the Stassfurt salts as a distinct mineral known as *Sylvine*. See CARNALLITE; POTASH; SYLVINE.

POTASSIUM, CYANIDE OF. See CYANIDES.

POTASSIUM, HYDRATE OF. See POTASH.

POTASSIUM, IODIDE OF. Iodide of potassium is usually prepared by digesting 2 parts of iodine, and 1 part of pure iron filings, in 10 parts of water, till they have combined to form a solution of a pale green colour, which is a solution of the iodide of iron. This solution is decomposed with exactly the requisite quantity of carbonate of potash, and iodide of potassium is held in solution, the iron salt being precipitated. The iodide is then crystallised out.

A more recent process consists in digesting 1 part of amorphous phosphorus in 40 parts of warm water, and adding 20 of dry iodine. To the solution, carbonate of baryta is first added, and then baryta-water; the phosphate of baryta is filtered off, and the solution of iodide of barium treated with sulphate of potash, when iodide of potassium and sulphate of baryta are obtained.

Iodide of potassium is much used in photography to obtain the iodide of silver; and for this purpose its purity is of great importance. The iodide of potassium of commerce frequently contains carbonate of potash, caustic potash, and the bromide and chloride of potassium.

POTASSIUM, OXIDE OF. See POTASH.

POTATO. (*Pomme de terre*, Fr.; *Kartoffel*, Ger.) The well-known tuber (underground stem) of the *Solanum tuberosum*.

Many methods have at different times been tried for preserving potatoes in an unchangeable state and always ready to be dressed into a wholesome and nutritious dish, but none with such success as the plan of Mr. Downes Edwards, for which he obtained a patent in August 1840. The potatoes, being first clean-washed, are boiled in water or steamed, till their skins begin to crack, then peeled, freed from their specks and eyes, and placed in an iron cylinder, tinned inside, and perforated with many holes one-eighth of an inch in diameter. The potatoes are forced through these by the pressure of a piston. The pulp is finally dried on well-tinned plates of copper, moderately heated by steam, into a granular meal. When this is mixed into a pulp with hot water, and seasoned with milk, &c., it forms a very agreeable food, like fresh mashed potatoes. See STARCH.

POTATO-STARCH. *English Arrowroot.* See STARCH.

POTATO-SUGAR. See SUGAR.

POTSTONE, or *Lapis ollaris* (*Topfstein*, Ger.), is an impure variety of steatite used in Germany for ornamental purposes. See TALC.

POT METAL. A metal composed of lead and copper, used for making pots.

POTTER'S ORE. Picked lumps of the sulphide of lead (galena). See LEAD.

POTTERY and **PORCELAIN**; EARTHENWARE, STONEWARE. (Engl. and Fr.; *Steingut*, *Porcellan*, Ger.) The French call the potter's art *céramique*, from the Greek noun *κέραμος*, an earthen pot, or *burned clay*. In reference to chemical constitution, there are only two genera of ceramic ware. The first consists of a fusible earthy mixture, along with an infusible, which, when combined, are susceptible of becoming semi-vitrified and translucent in the kiln. This constitutes true *porcelain* or china-ware; which is also called *hard* and *genuine*, or *tender* and *spurious*, according to the quality and quantity of the fusible ingredients. The *tender* or *soft* porcelain is an earthy body, which is covered with and penetrated by a transparent glaze. The second kind consists of an infusible mixture of earths, which is refractory in the kiln and continues opaque. This is *pottery*, properly so called; but it comprehends several subspecies, which graduate into each other by imperceptible shades of difference. To this head belong earthenware, stoneware, *fayence*, delft-ware, iron-stone china, &c.

The glazed bricks from Babylon—the enamelled tiles from the ruined cities of the Desert—and the glazed coffins from those Assyrian cities of the dead discovered by Mr. Kennett Loftus, prove, contrary to the received ideas, that the earliest attempts to make a compact earthenware, with a painted glaze, did not originate with the Arabians in Spain about the ninth century; but it is certain that the art passed thence into Majorca, in which island they were carried on with no little success. In the 14th century, these articles, and the art of imitating them, were highly prized by the Italians, under the name of Majolica, and *porcellana*, from the Portuguese word for a cup. The first manufactory of this ware possessed by them was erected at Faenza, in the ecclesiastical States, whence the French term *fayence* is derived. The body of the ware was usually a red clay, and the glaze was opaque, being formed of the oxides of lead and tin, along with potash and sand, which glaze was in all probability the discovery of Luca della Robbia, which he had found 'after experiments innumerable.' Bernard Palissy, about the middle of the 16th century, manufactured the Palissy ware —which is remarkable for its beautiful glaze, and the imitation of plants and animals —at Saintes, in France; and not long afterwards the Dutch produced a similar article, of substantial make, under the name of Delft-ware, but destitute of those graceful forms and paintings for which the ware of Faenza was distinguished.

The English East India Company was formed in 1600, and in 1631 they imported China ware into England. The Dutch, however, in 1586, appear to have traded in this true porcelain. There was naturally a desire to imitate this beautiful manufacture. In this Böttcher made the first advance in 1709; although it is now known that a porcelain of *soft* paste was made at Florence as early as 1580. Böttcher was working in the laboratory of Tschirnhaus, an alchemist, at Dresden, and it is stated that some crucibles prepared by him assumed the character of Chinese porcelain. Böttcher made first a red ware, but eventually, by employing white clays (*Kaolin*) which were found near Schneeberg in the Erzgebirge, he made a true porcelain at Meissen. Eventually the manufacture spread to Dresden, Munich, and other places, and the celebrated Sèvres Pottery was established.

In England, porcelain appears to have been experimentally manufactured at Fulham, by Dwight, as far back as 1671; but it was not produced in quantity until about 1730, when works were established at Bow, and these were soon afterwards followed by the factories of Chelsea, Derby, and Worcester. Porcelain with *hard* paste, however, was not produced in this country until Cookworthy's celebrated discovery of the Cornish china-clay and china-stone—a discovery which led to the foundation of the porcelain works of Plymouth and Bristol.

Coarse ware was manufactured in Staffordshire as early as, if not earlier, than 1500. Dr. Shaw says, 'there exist documents which imply that during many centuries considerable quantities of common culinary articles were manufactured of red, brown, and mottled pottery.'—*History of Staffordshire Potteries.*

It was in 1670 that a work for making earthenware of a coarse description, coated with a common lead-glaze (butter pots), was formed at Burslem, which may be considered as the germ of the vast potteries now established in Staffordshire. The manufacture was improved about the year 1690, by two Germans, the brothers Elers, who were compelled to leave the Potteries in 1710, and it is said they settled in Chelsea. The introduction of the use of salt for glazing took place in 1690 at Palmer's pottery at Bagnall. It is to the late Josiah Wedgwood that this country and the world at large are mainly indebted for the great modern advancement of the *ceramic* art. It was he who first erected magnificent factories, where every resource of mechanical and chemical science was made to co-operate with the arts of painting, sculpture, and statuary, in perfecting this valuable department of the industry of nations. So sound were his principles, so judicious his plans of procedure, and so ably have they been prosecuted by his successors in Staffordshire, and especially by the late Herbert Minton, that a population of upwards of 100,000 operatives now derives a comfortable subsistence within a district formerly bleak and barren, of 8 miles long by 6 broad, which contains 250 kilns, and is significantly called 'The Potteries.'

Of the Materials of Pottery, and their Preparation.

Clay.—The best clay from which the Staffordshire ware is made comes from Poole in Dorsetshire, and a second quality from near Newton in Devonshire; but both are well adapted for working, being refractory in the fire, and becoming very white when burnt. The clay is cleaned as much as possible by hand and freed from loosely adhering stones at the pits where it is dug. For the manufacture of porcelain, and of the finer kinds of earthenware, the china-clay is used. (See Clay.) In the factory the clay is cut to pieces, and then kneaded into a pulp with water, by engines; instead of being broken down with pickaxes, and worked with water by hand-paddles, in a square pit or water-tank, an old process, called *blunging*. The clay is now thrown into a cast-iron cylinder, 20 inches wide and 4 feet high, or into a cone 2 feet wide at top and 6 feet deep, in whose axis an upright shaft revolves, bearing knives as radii to the shaft. The knives are so arranged, that their flat sides lie in the plane of a spiral line; so that by the revolution of the shaft, they not only cut through everything in their way, but constantly press the soft contents of the cylinder or cone obliquely downwards, on the principle of a screw. Another set of knives stands out motionless, at right angles from the inner surface of the cylinder, and projects nearly to the central shaft, having their edges looking opposite to the line of motion of the revolving blades. Thus the two sets of slicing implements, the one active, and the other passive, operate like shears in cutting the clay into small pieces, while the active blades, by their spiral form, force the clay in its comminuted state out at an aperture at the bottom of the cylinder or cone, whence it is conveyed into a cylindrical vat, to be worked into a pap with water. This cylinder is tub-shaped, being about four times wider than it is deep. A perpendicular shaft turns also in the axis of this vat, bearing cross spokes, one below another, of which the vertical set on each side is connected by upright staves, giving the moveable arms the appearance of two or four opposite square paddle-boards revolving with the shaft. This wooden framework, or large *blunger*, as it is called, turns round amidst the water and clay lumps, so as to beat them into a fine pap, from which the stony and coarse sandy particles separate, and subside to the bottom. Whenever the pap has acquired a cream-consistenced uniformity, it is run off through a series of wire, lawn, and silk sieves, of different degrees of fineness, which are kept in continual agitation backwards and forwards by a crank mechanism; and thus all the grosser parts are completely separated, and hindered from entering into the composition of the ware. This clay-liquor is set aside in proper cisterns, and diluted with water to a standard density.

Flints.—These are obtained in great quantities from the chalk formations. See FLINTS.

Chert, which is a flinty substance, found in the Mountain Limestone, is also employed. This is calcined and ground. See CHERT.

Felspar. Used both in the body and in glazing. See FELSPAR.

Bone.—Bone-ashes, (phosphate of lime), also enters into the composition of pottery.

Steatite, or *Soap-stone*, is occasionally employed. See STEATITE.

China-stone.—A decomposed granite. See CHINA-STONE.

These may be regarded as the substances which enter into the body of the ware.

Clay alone cannot form a proper material for pottery, on account of its great contractility by heat, and the consequent cracking and splitting in the kiln of the vessels made of it; for which reason a siliceous substance incapable of contraction must enter into the body of pottery. For this purpose, ground flint, called flint-powder by the potters, is universally preferred. The nodules of flint extracted from the chalk formation are washed, heated red-hot in a kiln, like that for burning lime, and thrown in this state into water, by which treatment they lose their translucency, and become exceedingly brittle. They are then reduced to a coarse powder in a stamping-mill or a crushing-mill. The pieces of flint are laid on a strong grating, and pass through its meshes whenever they are reduced by the stamps to a certain state of comminution. This granular matter is now transferred to the proper flint-mill, which consists of a strong cylindrical wooden tub, bottomed with flat pieces of massive *chert*, or horn-stone, over which are laid large flat blocks of similar chert, that are moved round over the others by strong iron or wooden arms projecting from an upright shaft made to revolve in the axis of the mill-tub. Sometimes the active blocks are fixed to these cross arms, and thus carried round over the passive blocks at the bottom. Into this cylindrical vessel a small stream of water constantly trickles, which facilitates the grinding motion and action of the stones, and works the flint-powder and water into a species of pap. Near the surface of the water there is a plug-hole in the side of the tub, by which the creamy-looking flint-liquor is run off from time to time, to be passed through lawn or silk sieves, similar to those used for the clay-liquor; while the particles that remain on the sieves are returned into the mill. This pap is also reduced to a standard density by dilution with water; whence the weight of dry siliceous earth present may be deduced from the measure of the liquor.

The standard clay- and flint-liquors are now mixed together, in such proportion by measure, that the flint-powder may bear to the dry clay the ratio of one to five, or occasionally one to six, according to the richness or plasticity of the clay; and the liquors are intimately incorporated in a revolving churn, similar to that employed for making the clay-pap. This mixture is next freed from its excess of water by evaporation in oblong stone troughs, called *slip-kilns*, bottomed with fire-tiles, under which a furnace-flue runs. The breadth of this evaporating trough varies from 2 to 6 feet; its length from 20 to 50; and its depth from 8 to 12 inches, or more.

By the dissipation of the water, and careful agitation of the pap, an uniform doughy mass is obtained; which, being taken out of the trough, is cut into cubical lumps. These are piled in heaps, and left in a damp cellar for a considerable time; that is, several months, in large manufactories. Here the dough suffers disintegration, promoted by a kind of fermentative action, due probably to some vegetable-matter in the water and the clay; for it becomes black, and exhales a fœtid odour. The argillaceous and siliceous particles get disintegrated also by the action of the water, in such a way that the ware made with old paste is found to be more homogeneous, finer grained, and not so apt to crack or to get disfigured in the baking, as the ware made with newer paste.

But this chemical comminution must be aided by mechanical operations; the first of which is called the potter's *slapping* or *wedging*. It consists in seizing a mass of clay in the hands, and, with a twist of both at once, tearing it into two pieces, or cutting it with a wire. These are again slapped together with force, but in a different direction from that in which they adhered before, and then dashed down on a board. The mass is once more torn or cut asunder at right angles, again slapped together, and so worked repeatedly for 20 or 30 times, which ensures so complete an incorporation of the different parts, that if the mass had been at first half black and half white clay, it would now be of a uniform grey colour. A similar effect is produced in some large establishments by a slicing machine, like that used for cutting down the clay lumps as they come from the pit.

In the axis of a cast-iron cylinder or cone, an upright shaft is made to revolve, from which the spiral-shaped blades extend, with their edges placed in the direction of rotation. The pieces of clay subjected to the action of these knives (with the reaction of fixed ones) are minced to small morsels, which are forced pell-mell by the screw-like pressure into an opening of the bottom of the cylinder or cone from which a horizontal pipe about 6 inches square proceeds. The dough is made to issue through this outlet, and is then cut into lengths of about 12 inches. These clay pillars or prisms are thrown back into the cylinder, and subjected to the same operation again and again, till the lumps have their particles perfectly blended together. This process may advantageously precede their being set aside to ripen in a damp cellar. In France the earthenware dough is not worked in such a machine; but after being beat with wooden mallets, a practice common also in England, it is laid down on a clean floor, and a workman is set to tread upon it with naked feet for a considerable time, walking in a spiral direction from the centre to the circumference, and from the circumference to the centre. In Sweden, and also in China (to judge from the Chinese paintings which represent their manner of making porcelain), the clay is trodden to a uniform mass by oxen. It is afterwards, in all cases, kneaded like baker's dough, by folding back the cake upon itself, and kneading it out alternately.

Although we have abundant evidence proving to us the importance of the so-called fermenting process, of the treading operation, and of the slapping, we are not in possession of any explanation, which is in the slightest degree reliable, as to any one of the changes which may be effected in the mass by these manipulations.

The basis of the English earthenware is a clay, brought from Dorsetshire and Devonshire, which lies at the depth of from 25 to 30 feet beneath the surface. It is composed of about 24 parts of alumina and 76 of silica, with other ingredients in very small proportions. This clay is very refractory in high heats, a property which joined to its whiteness when burned, renders it peculiarly valuable for pottery. It is also the basis of all the yellow biscuit-ware called *cream colour*, and in general of what is called the *printing body*; as also for the semi-vitrified ware of Wedgwood's invention, and of the tender (soft) porcelain.

The constituents of earthenware are, Dorsetshire clay, the powder of calcined flints, and of the decomposed granite called Cornish stone. The proportions are varied by the different manufacturers. The following are those generally adopted in one of the principal establishments of Staffordshire:—

For *cream colour* ware,	Silex or ground flints	20 parts.
	Clay	100 „
	Cornish stone	2 „

Composition of the Paste for receiving the Printing Body under the Glaze.

For this purpose the proportions of the flint and the felspar must be increased. The substances are mixed separately with water into the consistence of a thick cream, which weighs per pint, for the flints 32 ounces, and for the Cornish stone 28. The china-clay is added to the same mixture of flint and felspar, when a finer pottery or porcelain is required. That clay-cream weighs 24 ounces per pint. These 24 ounces in weight are reduced to one-third of their bulk by evaporation. The pint of dry porcelain-clay weighs 17 ounces, and in its first pasty state 24, as just stated. The dry flint-powder weighs 14½ ounces per pint; which when made into a cream weighs 32 ounces. To 40 measures of Teignmouth clay-cream there are added,

13 measures of flint-liquor.
12 „ „ porcelain clay ditto.
1 „ „ Cornish stone ditto.

The whole are well mixed by proper agitation, half dried in the *troughs* of the slip-kiln, and then subjected to the machine for cutting up the clay into junks. The above paste, when baked, is very white, hard, sonorous, and susceptible of receiving all sorts of impressions from the paper engravings. When the silica is mixed with the clay in the above proportions, it forms a compact ware, and the impression remains fixed between the biscuit and the glaze, without communicating to either any portion of the tint of the metallic colour employed in the engraver's press. The felspar gives strength to the biscuit, and renders it sonorous after being baked; while the china-clay has the double advantage of imparting an agreeable whiteness and great closeness of grain.

We must now proceed to a consideration of the manufacture. The clay being prepared, is submitted to the potter, who employs at the present day a wheel of the same description as that used in the days of Moses.

Throwing is performed upon a tool called the potter's lathe. This consists of an upright iron shaft, about the height of a common table, on the top of which is fixed, by its centre, a horizontal disc or circular piece of wood, of an area sufficiently great for the largest vessel to stand upon. The lower end of the shaft is pointed, and runs in a conical step, and its collar, a little below the top-board, being truly turned, is embraced in a socket attached to the wooden frame of the lathe. The shaft has a pulley fixed upon it, with grooves for 3 speeds, over which an endless band passes from a fly-wheel, by whose revolution any desired rapidity of rotation may be given to the shaft and its top-board. This wheel, when small, may be placed alongside, as in the turner's lathe, and then it is driven by a treadle and crank; or when of larger dimensions, it is turned by the arms of a labourer.

1643

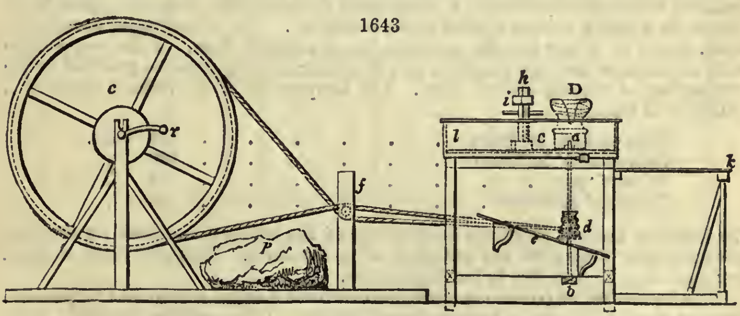


Fig. 1643 is the profile of the ordinary potter's lathe, for blocking-out round ware. c is the table or tray; *a* is the head of the lathe, with its horizontal disc; *a*, *b*, is the upright shaft of the head; *d*, pulleys with several grooves of different diameters, fixed upon the shaft, for receiving the driving-cord or band; *k* is a bench upon which the workman sits astride; *e*, the treadle foot-board; *l* is a ledge-board, for catching the shavings of clay which fly off from the lathe; *h* is an instrument, with a slide-nut *i*, for measuring the objects in the blocking-out; *c* is the fly-wheel, with its winch-handle, *r*, turned by an assistant; the sole-frame is secured in its place by the heavy stone *p*; *f* is the oblong guide-pulley, having also several grooves for converting the vertical movement of the fly-wheel into the horizontal movement of the head of the lathe.

D is one of the intermediate forms given by the potter to the ball of clay, as it revolves upon the head of the lathe.

In large potteries, the whole of the lathes, both for throwing and turning, are put in motion by a steam-engine. The vertical spindle of the lathe has a bevel wheel on it, which works in another bevel-toothed wheel fixed to a horizontal shaft. This shaft is provided with a long conical wooden drum, from which a strap ascends to a similar conical drum on the main lying shaft. The apex of the one cone corresponds to the base of the other, which allows the strap to retain the same degree of tension, while it is made to traverse horizontally, in order to vary the speed of the lathe at pleasure. When the belt is at the base of the driving-cone, it works near the vertex of the driven one, so as to give a maximum velocity to the lathe, and *vice versâ.*

During the throwing of any article, a separate mechanism is conducted by a boy, which makes the strap move parallel to itself along these conical drums, and nicely regulates the speed of the lathe. When the strap runs at the middle of the cones, the velocity of each shaft is equal. By this elegant contrivance of parallel cones reversed, the velocity rises gradually to its maximum, and returns to its minimum or slower motion when the workman is about to finish the article thrown. The strap is then transferred to a pair of loose pulleys, and the lathe stops. The vessel is now cut off at the base with a small wire; is dried, turned on a power-lathe, and polished as above described.

The same degree of dryness which admits of the clay being turned on the lathe, also suits for fixing on the handles and other appendages to the vessels. The parts to be attached being previously prepared, are joined to the circular work by means of a thin paste, which the workmen call *slip*, and the seams are then smoothed off with a wet sponge. They are now taken to a stove-room heated to 80° or 90° F., and fitted up with a great many shelves. When they are fully dried, they are smoothed over with a small bundle of hemp, if the articles be fine, and are then ready for the kiln, which is to convert the tender clay into the hard *biscuit.*

At a certain stage of the drying, called the *green state*, the ware possesses a greater tenacity than at any other, till it is baked. It is then taken to another lathe, called the *turning lathe*, where it is attached by a little moisture to the vertical face of a wooden chuck, and turned nicely into its proper shape with a very sharp tool, which also smooths it. After this it is slightly burnished with a smooth steel surface. A great variety of pottery wares, however, cannot be fashioned on the lathe, as they are not of a circular form. These are made by two different matters, the one called *press-work*, and the other *casting*. The press-work is done in moulds made of Paris plaster, the one half of the pattern being formed in the one side of the mould, and the other half in the other side: these moulding-pieces fit accurately together. All vessels of an oval form, and such as have flat sides, are made in this way. Handles of tea-pots, and fluted solid rods of various shapes, are formed by pressure also; viz. by squeezing the dough contained in a pump-barrel through different-shaped orifices at its bottom, by working a screw applied to the piston-rod. The worm-shaped dough, as it issues, is cut to proper lengths, and bent into the desired form. Tubes may be also made on the same pressure principle, only a tubular opening must be provided in the bottom-plate of the clay-forcing pump. The temperature of the various rooms in a pottery is as follows:—

Plate-makers' hothouse	108° Fahr.
Dish-makers' hothouse	106 ,,
Printers' shop	90 ,,
Throwers' hothouse	98 ,,

The branches against which the temperature of the hothouse is placed require that heat for drying their work and getting it off their moulds. The outer shops in which they work may be from five to ten degrees less.

The other method of fashioning earthenware articles is called *casting*, and is, perhaps, the most elegant for such as have an irregular shape. This operation consists in pouring the clay, in the state of pap or slip, into plaster-moulds, which are kept in a desiccated state. These moulds, as well as the pressure ones, are made in halves, which nicely correspond together. The slip is poured in till the cavity is quite full, and is left in the mould for a certain time, more or less, according to the intended thickness of the vessel. The absorbent power of the plaster soon abstracts the water, and makes the coat of clay in contact with it quite doughy and stiff, so that the part still liquid being poured out, a hollow shape remains, which when removed from the mould constitutes the half of the vessel, bearing externally the exact impress of the mould. The thickness of the clay varies with the time that the paste has stood upon the plaster. These *cast* articles are dried to the green state, like the preceding, and then joined accurately with *slip*. Imitations of flowers and foliage are elegantly executed in this way. This operation, which is called *furnishing*, requires very delicate and dexterous manipulation.

The saggers for the unglazed coloured ware should be covered inside with a glaze composed of 12 parts of common salt and 30 of potash, or 6 parts of potash and 14 of salt; which may be mixed with a little of the common enamel for the glazed pottery saggers. The bottom of each sagger has some bits of flints sprinkled upon it, which become so adherent after the first firing as to form a multitude of little prominences for setting the ware upon, when this does not consist of plates. It is the duty of the workmen belonging to the glaze-kiln to make the saggers during the intervals of their work; or if there be a relay of hands, the man who is not firing makes the saggers.

When the ware is sufficiently dry, and in sufficient quantity to fill a kiln, the next process is placing the various articles in the baked fire-clay vessels, which may be either of a cylindrical or oval shape; called *gazettes*, Fr.; *Kapseln*, Ger. These are from 6 to 8 inches deep, and from 12 to 18 inches in diameter. When packed full of the dry ware, they are piled over each other in the kiln. The bottom of the upper sagger forms the lid of its fellow below; and the junction of the two is luted with a ring of soft clay applied between them. These dishes protect the ware from being suddenly and unequally heated, and from being soiled by the smoke and vapours of the fuel. Each pile of saggers is called a *bung*.

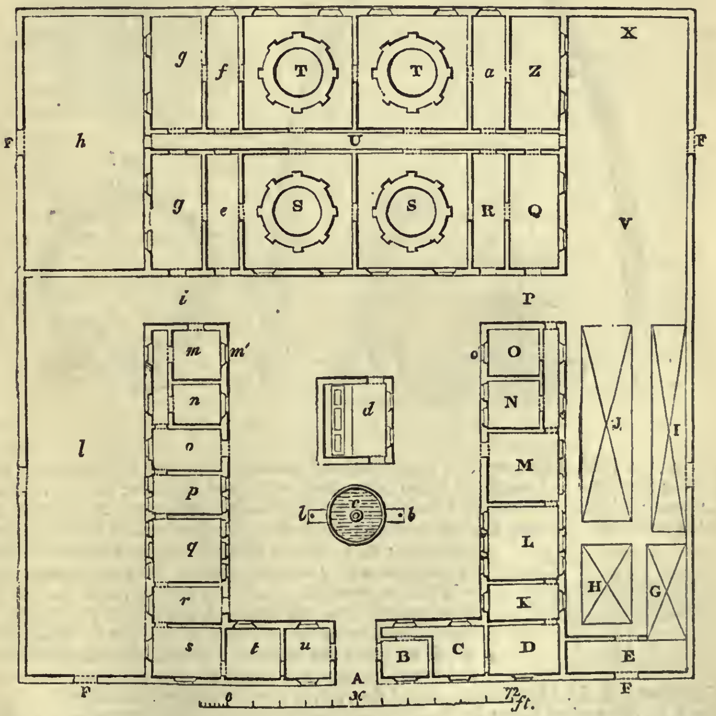
Plan of an English Pottery.

A pottery should be placed by the side of a canal or navigable river, because the articles manufactured do not well bear land-carriage.

A Staffordshire pottery is usually built as a quadrangle, each side being about 100 feet long, the walls 10 feet high, and the ridge of the roof 5 feet more. The base of the edifice consists of a bed of bricks, 18 inches high and 16 inches thick; upon which a mud wall in a wooden frame, called *pisé*, is raised. Cellars are formed in front of the buildings, as depôts for the pastes prepared in the establishment. The wall of the yard or court is 9 feet high and 18 inches thick.

A, *fig.* 1644, is the entrance door; B, the porter's lodge; C, a particular warehouse; D, workshop of the plaster-moulder; E, the clay depôt; F, F, large gates, 6 feet 8 inches high; G, the winter evaporation-stove; H, the shop for sifting the paste-liquors; I, sheds for the paste-liquor tubs; J, paste-liquor pits; K, workshop for the moulder of hollow ware; L, ditto of the dish or plate moulder; M, the plate drying-

1644



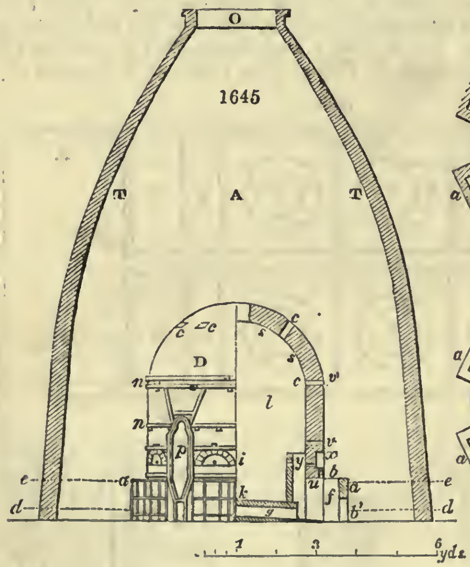
stove N, workshop of the biscuit-printers; O, ditto of the biscuit, with o', a long window; P, passage leading to the paste-liquor pits; Q, biscuit warehouse; R, place where the biscuit is cleaned as it comes out of the biscuit-kilns, S, S; T, T, enamel- or glaze-kilns; U, long passage; V, space left for supplementary workshops; X, space appointed as a depôt for the sagger fire-clay, as also for making the saggers; Z, the workshop for applying the glaze-liquor to the biscuits; *a*, apartment for cleaning the glazed ware; *b*, *b*, pumps; *c*, basin; *d*, muffles; *e*, warehouse for the finished stoneware; *f*, that of the glazed goods; *g*, *g*, another warehouse; *h*, a large space for the smith's forge, carpenter's shop, packing room, depôt of clays, saggers, &c. The packing and loading of the goods are performed in front of the warehouse, which has two outlets, in order to facilitate the work; *i*, a passage to the court or yard; *l*, a space for the wooden sheds for keeping hay, clay, and other miscellaneous articles; *m*, room for putting the biscuit into the saggers; *m'*, a long window; *n*, workshop with lathes and fly-wheels; *o*, drying-room; *p*, room for mounting or furnishing the pieces; *q*, repairing room; *r*, drying room of the goods roughly turned; *s*, rough turning or blocking-out room; *t*, room for beating the paste or dough; *u*, counting-house.

Pottery Kiln of Staffordshire.

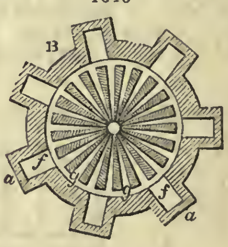
Figs. 1645, 1646, 1647, 1648, 1649, represent the kiln for baking the biscuit, and also for running the glaze, in the English potteries.

a, *a*, *figs.* 1645, 1646, 1647, are the furnaces which heat the kiln; of which *b*, in *fig.* 1645, are the upper mouths, and *b'* the lower; the former being closed more or less by the fire-tile *z*, shown in *fig.* 1649.

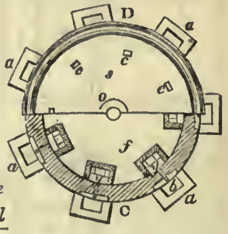
f is one fireplace; for the manner of distributing the fuel in it, see *fig.* 1649.



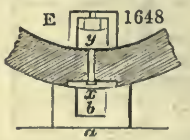
1646



1647



g, *y*, *figs.* 1645, 1649, are the horizontal and vertical flues and chimneys for conducting the flame and smoke. *l* is the laboratory, or body of the kiln; having its floor, *k*, sloping slightly downwards from the centre to the circumference. *x*, *y*, is the slit of the horizontal register leading to the chimney-flue, *y*, of the furnace, being the first regulator; *x*, *u*, is the vertical register-conduit, leading to the furnace or mouth *f*, being the second regulator; *v* is the register-slit above the furnace, and its vertical flue leading into the body of the kiln; *v'*, *c*, slit for regulating flue at the shoulder of the kiln; *i* is an arch which supports the walls of the kiln, when the furnace is under repair; *c*, *c*, are small flues in the vault *s* of the laboratory. *h*, *fig.* 1646, is the central flue, called *lunette*, of the laboratory.



T, T, is the conical tower or *howell*, strengthened with a series of iron hoops. O is the great chimney or *lunette* of the tower; *p* is the door of the laboratory, bound inside with an iron frame.

A, is the complete kiln and *howell*, with all its appurtenances.

B, *fig.* 1646, is the plan at the level *d, d*, of the floor, to show the arrangement and distribution of all the horizontal flues, both circular and radiating.

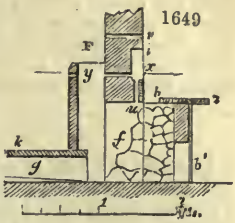
C, *fig.* 1647, is a plan at the level *e, e*, of the upper mouths *b*, of the furnaces, to show the disposition of the fireplaces of the vertical flues, and of the horizontal registers, or peep-holes.

D, *fig.* 1647, is a bird's-eye view of the top of the vault or dome *s*, to show the disposition of the vent-holes, *c, c*.

E, *fig.* 1648, is a detailed plan at the level *c, c*, of one furnace and its dependencies.

F, *fig.* 1649, is a transverse section, in detail, of one furnace and its dependencies.

1649



The same letters indicate the same objects in all the figures.

Charging of the kiln.—The saggers are piled up first in the space between each of the upright furnaces, till they rise to the top of the flues. These contain the smaller articles. Above this level large fire-tiles are laid, for supporting other saggers, filled with teacups, sugar-basins, &c. In the bottom part of the pile, within the preceding, the same sorts of articles are put; but in the upper part all such articles are placed as require a high heat. Four piles of small saggers, with a middle one 10 inches in height, complete the charge. As there are 6 piles between each furnace, and as the biscuit-kiln has 8 furnaces, a charge consequently amounts to 48 or 50 *bungs*, each composed of from 18 to 19 saggers. The inclination of the bungs ought always to follow the form of the kiln, and should therefore tend towards the centre, lest the strong draught of the furnaces should make the saggers fall against the walls of the kiln, an accident apt to happen were these piles perpendicular. The last sagger of each bung is covered with an unbaked one, three inches deep, in place of a round lid. The watches are small cups, of the same biscuit as the charge, placed in saggers, four in number, above the level of the flue-tops. They are taken hastily out of the saggers, lest they should get smoked, and are thrown into cold water.

When the charging is completed, the firing is commenced, with coal of the best quality. The management of the furnaces is a matter of great consequence to the success of the process. No greater heat should be employed for some time than may be necessary to agglutinate the particles which enter into the composition of the paste, by evaporating all the humidity; and the heat should never be raised so high as to endanger the fusion of the ware, which would make it very brittle.

Whenever the mouth or door of the kiln is built up, a child prepares several fires in the neighbourhood of the *howell*, while a labourer transports in a wheelbarrow a supply of coals, and introduces into each furnace a number of lumps. These lumps divide the furnace into two parts; those for the upper flues being placed above, and those for the ground flues below, which must be kept unobstructed.

The fire-mouths being charged, they are kindled to begin the baking, the regulator tile, *z*, *fig.* 1649, being now opened; an hour afterwards the bricks at the bottom of the furnace are stopped up. The fire is usually kindled at 6 o'clock in the evening, and progressively increased till 10, when it begins to gain force, and the flame rises half-way up the chimney. The second charge is put in at 8 o'clock, and the mouths of the furnaces are then covered with tiles; by which time the flame issues through the vent of the tower. An hour afterwards a fresh charge is made; the tiles *z*, which cover the furnaces, are slipped back; the cinders are drawn to the front, and replaced with small coal. About half-past 11 o'clock the kiln-man examines his furnaces, to see that their draught is properly regulated. An hour afterwards a new charge of coal is applied; a practice repeated hourly till 6 o'clock in the morning. At this moment he takes out his first *watch*, to see how the baking goes on. It should be at a very pale-red heat; but the watch of 7 o'clock should be a deeper red. He removes the tiles from those furnaces which appear to have been burning too strongly, or whose flame issues by the orifices made in the shoulder of the kiln; and puts tiles upon those which are not hot enough. The flames glide along briskly in a regular manner. At this period he draws out the watches every quarter of an hour, and compares them with those reserved from a previous standard kiln; and if he observes a similarity of appearance, he allows the furnaces to burn a little longer; then opens the mouths carefully and by slow degrees; so as to lower the heat and finish the round.

The baking usually lasts from 40 to 42 hours; in which time the biscuit-kiln may consume 14 tons of coals; of which four are put in the first day, seven the next day and following night, and the last four give the strong finishing heat.

Emptying the kiln.—The kiln is allowed to cool very slowly. On taking the ware out of the saggers, the biscuit is not subjected to friction, as in the foreign potteries, because it is smooth enough; but is immediately transported to the place where it is to be dipped in the glaze- or enamel-tub. A child makes the pieces ring, by striking with the handle of the brush, as he dusts them, and then immerses them into the glaze-cream; from which tub they are taken out by the enameller, and shaken in the air. The tub usually contains no more than 4 or 5 inches depth of the glaze, to enable the workman to pick out the articles more readily, and to lay them upon a board, whence they are taken by a child to the glaze-kiln.

Of Porcelain.

Porcelain is a kind of pottery ware whose paste is fine grained, compact, very hard, and faintly translucid; and whose biscuit softens slightly in the kiln. Its ordinary whiteness cannot form a definite character, since there are porcelain pastes variously coloured. There are two species of porcelain, very different in their nature, the essential properties of which it is of consequence to establish; the one is called *hard*, and the other *tender* or *soft*: important distinctions, the neglect of which has introduced great confusion into many treatises on this elegant manufacture.

Hard porcelain is essentially composed, first, of a natural clay containing some silica, infusible, and preserving its whiteness in a strong heat; this is almost always a true kaolin; secondly, of a flux, consisting of silica and alkali, composing a quartzose felspar rock, called *pe-tun-tse.* The glaze of this porcelain, likewise earthy, admits of no metallic substance.

The biscuit of the hard porcelain made at the French national manufactory of Sèvres is generally composed of a kaolin-clay, and of a decomposed felspar-rock; analogous to the china-clay of Cornwall and Cornish stone. Both of the above French materials come from Saint Yrieux-la-Perche, near Limoges.

After many experiments, the following composition has been adopted for the *service paste* of the Royal manufactory of Sèvres; that is, for all the ware which is to be glazed: silica, 59; alumina, 35·2; potash, 2·2; lime, 3·3. The conditions of such a compound are pretty nearly fulfilled by taking from 63 to 70 of the washed kaolin or china-clay, 22 to 15 of the felspar, nearly 10 of flint-powder, and about 5 of chalk. The glaze is composed solely of solid felspar, calcined, crushed, and then ground fine at the mill. This rock pretty uniformly consists of silica 73, alumina 16·2, potash 8·4, and water 0·6.

The kaolin is washed at the pit, and sent in this state to Sèvres, under the name of *decanted earth.* At the manufactory it is washed and elutriated with care; and its slip is passed through fine sieves. This forms the plastic, infusible, and opaque ingredient to which the substance must be added which gives it a certain degree of fusibility and semi-transparency. The felspar-rock used for this purpose should contain neither dark mica nor iron, either as an oxide or sulphide. It is calcined to make it crushable under stamp-pestles driven by machinery, and then ground fine in hornstone (chert) mills. This pulverulent matter being diffused through water, is mixed in certain proportions regulated by its quality, with the argillaceous slip. The mixture is deprived of the chief part of its water in shallow plaster pans without heat; and the resulting paste is set aside to ripen, in damp cellars, for many months.

When wanted for use, it is placed in hemispherical pans of plaster, which absorb the redundant moisture; after which it is divided into small lumps, and completely dried. It is next pulverised, moistened a little, laid on a floor, and trodden upon by a workman marching over it with bare feet in every direction; the parings and fragments of soft moulded articles being intermixed, which improve the plasticity of the whole. When sufficiently tramped, it is made up into masses of the size of a man's head, and kept damp till required.

The dough is now in a state fit for the potter's lathe; but it is much less plastic than earthenware paste, and is more difficult to fashion into the various articles; and hence one cause of the higher price of porcelain.

The round plates and dishes are shaped on plaster-moulds; but sometimes the paste is laid on as a crust, and at others it is turned into shape on the lathe. When a crust is to be made, a moistened sheep-skin is spread on a marble table; and over this the dough is extended with a rolling-pin, supported on two guide-rules. The crust is then transferred over the plaster-mould by lifting it upon the skin; for it wants tenacity to bear raising by itself. When the piece is to be fashioned on the lathe, a lump of the dough is thrown on the centre of the horizontal wooden disc, and turned into form as directed in treating of earthenware, only it must be left much thicker than in its finished state. After it dries to a certain degree on the plaster-mould, the workman replaces it on the lathe, by moistening it on its base with a wet sponge, and finishes its form with an iron tool. A good workman at Sèvres makes no more than from 15 to 20 porcelain plates in a day; whereas an English potter, with two boys, makes from 1,000 to 1,200 plates of earthenware in the same time. The pieces, which are not round, are shaped in plaster-moulds, and finished by hand. When the articles are very large, as wash-hand basins, salads, &c., a flat cake is spread above a skin on the marble slab, which is then applied to the mould with the sponge, as for plates; and they are finished by hand.

The projecting pieces, such as handles, beaks, spouts, and ornaments, are moulded and adjusted separately; and are cemented to the bodies of china-ware with slip, or porcelain dough thinned with water. In fact, the mechanical processes with porcelain and the finer stoneware are substantially the same; only they require more time and greater nicety. The least defect in the fabrication, the smallest bit added, an unequal pressure, the cracks of the moulds, although well repaired, and seemingly effaced in the clay shape, re-appear after it is baked. The articles should be allowed to dry very slowly; if hurried but a little, they are liable to be spoiled. When quite dry, they are taken to the kiln.

The kiln for hard porcelain at Sèvres is a kind of tower in two flats, constructed of fire-bricks; and resembles, in other respects, the earthenware kilns already figured and described. The fuel is young aspen wood, very dry, and cleft very small; it is put into the apertures of the four outside furnaces or fire-mouths, which discharge their flames into the inside of the kiln; each floor being closed in above, by a dome pierced with holes. The whole is covered in by a roof with an open passage, placed at a proper distance from the uppermost dome. There is, therefore, no chimney proper so called.

The raw pieces are put into the upper floor of the kiln; where they receive a heat of about the 60th degree of Wedgwood's pyrometer, and a commencement of baking, which, without altering the shape, or causing a perceptible shrinking of their bulk, makes them completely dry, and gives them sufficient solidity to bear handling. By this preliminary baking, the clay loses its property of forming a paste with water; and the pieces become fit for receiving the glazing coat, as they may be dipped in water without risk of breakage.

The glaze of hard porcelain is a felspar rock; this being ground to a very fine powder, is worked into a paste with water mingled with a little vinegar. All the articles are dipped into this milky liquid for an instant; and as they are very porous they absorb the water greedily, whereby a layer of the felspar-glaze is deposited on their surface, in a nearly dry state, as soon as they are lifted out. Glaze-pap is afterwards applied with a hair-brush to the projecting edges, or any points where it has not taken; and the powder is then removed from the part on which the article is to stand, lest it should get fixed to its support in the fire. After these operations, it is replaced in the kiln, to be completely baked.

The articles are put into saggers, like those of fine stoneware; and this operation is one of the most delicate and expensive in the manufacture of porcelain. The saggers are made of the plastic or potter's clay of Abondant, to which about a third part of cement of broken saggers has been added.

As the porcelain pieces soften somewhat in the fire, they cannot be set above each other, even were they free from glaze; for the same reason they cannot be baked on tripods, several of them being in one case, as is done with stoneware. Every piece of porcelain requires a sagger for itself. They must, moreover, be placed on a perfectly flat surface, because in softening they would be apt to conform to the irregularities of a rough one. When, therefore, any piece, a soup-plate for example, is to be *saggered*, there is laid on the bottom of the case a perfectly true disc or round cake of stoneware, made of the sagger material, and it is secured in its place on three small props of a clay-lute consisting of potter's clay mixed with a great deal of sand. When the cake is carefully levelled, it is moistened, and dusted over with sand, or coated with a film of fire-clay slip, and the porcelain is carefully set on it. The sand or fire-clay hinders it from sticking to the cake. Several small articles may be set on the same cake, provided they do not touch one another.

The saggers containing the pieces thus arranged are piled up in the kiln over each other, in the columnar form, till the whole space be occupied; leaving very moderate intervals between the columns to favour the draught of the fires. The whole being arranged with these precautions and several others too minute to be specified here, the door of the kiln is built up with three rows of bricks, leaving merely an opening 8 inches square, through which there is access to a sagger with the nearest side cut off. In this sagger are put fragments of porcelain intended to be withdrawn from time to time, in order to judge of the progress of the baking. These are called trial-pieces or watches (*montres*). This opening into the watches is closed by a stopper of stoneware.

The firing begins by throwing into the furnace-mouths some pretty large pieces of white wood; and the heat is maintained for about 15 hours, gradually raising it by the addition of a larger quantity of the wood, till at the end of that period the kiln has a cherry-red colour within. The heat is now greatly increased by the operation termed *covering the fire.* Instead of throwing billets vertically into the four furnaces, there is placed horizontally on the openings of these furnaces, aspen wood of a sound texture, cleft small, laid in a sloping position. The brisk and long flame which it yields dips into the tunnels, penetrates the kiln, and circulates round the sagger-piles. The heat augments rapidly, and at the end of 13 or 15 hours of this firing the interior of the kiln is so white that the watches can hardly be distinguished. The draught, indeed, is so rapid at this time, that one may place his hand on the slope of the wood without feeling incommoded by the heat. Everything is consumed, no small charcoal remains, smoke is no longer produced, and even the wood-ash is dissipated. It is obvious that the kiln and the saggers must be composed of a very refractory clay, in order to resist such a fire. The heat in the Sèvres kilns mounts as high as the 134th degree of Wedgwood.

At the end of 15 or 20 hours of the great fire, that is, after from 30 to 36 hours' firing, the porcelain is baked; as is ascertained by taking out and examining the watches. The kiln is suffered to cool during 3 or 4 days, and is then opened and discharged. The sand strewed on the cakes to prevent the adhesion of the articles to them, gets attached to their sole, and is removed by friction with a hard sandstone; an operation which one woman can perform for a whole kiln in less than 10 days; and is the last applied to hard porcelain, unless it needs to be returned into the hot kiln to have some defects repaired.

The materials of fine porcelain are very rare; and there would be no advantage in making a grey-white porcelain with coarser and somewhat cheaper materials, for the other sources of expense above detailed, and which are of most consequence, would still exist; while the porcelain, losing much of its brightness, would lose the main part of its value.

Its pap or dough, which requires tedious grinding and manipulation, is also more difficult to work into shapes, in the ratio of 80 to 1, compared to fine earthenware. Each porcelain plate requires a separate sagger; so that 12 occupy in the kiln a space sufficient for at least 38 earthenware plates. The temperature of a hard porcelain kiln being very high, involves a proportionate consumption of fuel and waste of saggers. With 40 cubic meters of wood, 12,000 earthenware plates may be completely fired, both in the biscuit- and glaze-kilns; while the same quantity of wood would bake at most only 1,000 plates of porcelain.

The process of bisque firing is as follows: the ware being finished from the hands of the potter is brought by him upon boards to the 'green-house,' so called from its being the receptacle for ware in the 'green' or unfired state. It is here gradually dried for the ovens; when ready it is carried to the 'sagger-house' in immediate connection with the oven in which it is to be fired, and here it is placed in the 'saggers:' these are boxes made of a peculiar kind of clay (a native marl) previously fired, and infusible at the heat required for the ware, and of form suited to the articles they are to contain. A little dry, pounded flint is scattered between pieces of china, and sand between earthenware, to prevent adhesion. The purpose of the sagger is to protect the ware from the flames and smoke, and also for its security from breakage, as in the clay state it is exceedingly brittle, and when dry, or what is called 'white,' requires great care in the handling. A plate sagger will hold twenty plates placed one on the other of earthenware, but china plates are fired separately in 'setters' made of their respective forms. The 'setters' for china plates and dishes answer the same purpose as the saggers, and are made of the same clay. They take in one dish or plate each, and are 'reared' in the oven in 'bungs' one on the other.

The hovels in which the ovens are built form a very peculiar and striking feature of the pottery towns, and forcibly arrest the attention and excite the surprise of the stranger, resembling as they closely do a succession of gigantic beehives. They are constructed of bricks about 40 feet in diameter, and about 35 feet high, with an aperture at the top for the escape of the smoke. The 'ovens' are of a similar form, about 22 feet diameter, and from 18 to 21 feet high, heated by fireplaces or 'mouths,' about nine in number, built externally around them. Flues in connection with these converge under the bottom of the oven to a central opening, drawing the flames to this point, where they enter the oven; other flues termed 'bags' pass up the internal sides to the height of about 4 feet, thus conveying the flames to the upper part.

When 'setting in' the oven, the firemen enter by an opening in the side, carrying the saggers with the ware placed as described; these are piled one upon another, from bottom to top of the oven, care being taken to arrange them so that they may receive the heat (which varies in different parts) most suited to the articles they contain. This being continued till the oven is filled, the aperture is then bricked up. The firing of earthenware bisque continues sixty hours, and of china forty-eight.

The quantity of coals necessary for a 'bisque' oven is from 16 to 20 tons; for a 'glost' oven from 4½ to 6 tons.

The ware is allowed to cool for two days, when it is drawn in the state technically called 'biscuit' or bisque, and is then ready for 'glazing,' except when required for printing or a common style of painting, both of which processes are done on the bisque prior to being 'glazed.'

Tender porcelain, or soft china-ware, is made with a vitreous frit, rendered less fusible and opaque by an addition of white marl or bone-ash. The frit is, therefore, first prepared. This, at Sèvres, is a composition, made with some nitre, a little sea salt, Alicant barilla, alum, gypsum, and much siliceous sand or ground flints. That mixture is subjected to an incipient pasty fusion in a furnace, where it is stirred about to blend the materials well; and thus a very white spongy frit is obtained. It is pulverised, and to every three parts of it, one of the white marl of Argenteuil is added; and when the whole are well ground, and intimately mixed, the paste of tender porcelain is formed.

As this paste has no tenacity, it cannot bear working till a mucilage of gum or black soap be added, which gives it a kind of plasticity, though even then it will not bear the lathe. Hence it must be fashioned in the press, between two moulds of plaster. The pieces are left thicker than they should be; and when dried, are finished on the lathe with iron tools.

In this state they are baked, without any glaze being applied; but as this porcelain softens far more during the baking than the hard porcelain, it needs to be supported on every side. This is done by baking on earthen moulds all such pieces as can be treated in this way, namely, plates, saucers, &c. The pieces are reversed on these moulds, and undergo their shrinkage without losing their form. Beneath other articles, supports of a like paste are laid, which suffer in baking the same contraction as the articles, and of course can serve only once. In this operation saggers are used, in which the pieces and their supports are fired.

The kiln for the tender porcelain at Sèvres is absolutely similar to that for the common earthenware; but it has two floors; and while the biscuit is baked in the lower story, the glaze is fused in the upper one; which causes considerable economy of fuel. The glaze of soft porcelain is a species of glass or crystal prepared on purpose. It is composed of flint, siliceous sand, a little potash or soda, and about two-fifth parts of lead oxide. This mixture is melted in crucibles or pots beneath the kiln. The resulting glass is ground fine, and diffused through water mixed with a little vinegar to the consistence of cream. All the pieces of biscuit are covered with this glazy matter, by pouring this slip over them, since their substance is not absorbent enough to take it on by immersion.

The pieces are encased once more each in a separate sagger, but without any supports; for the heat of the upper floor of the kiln, though adequate to melt the glaze, is not strong enough to soften the biscuit. But as this first vitreous coat is not very equal, a second one is applied, and the pieces are returned to the kiln for the third time. See Stone, Artificial, for a view of this kiln.

The manufacture of soft porcelain is longer and more difficult than that of hard; its biscuit is dearer, although the raw materials may be found everywhere; and it furnishes also more refuse. Many of the pieces split asunder, receive fissures, or become deformed in the biscuit-kiln, in spite of the supports; and this vitreous porcelain, moreover, is always yellower, more transparent, and incapable of bearing rapid transitions of temperature, so that even the heat of boiling water frequently cracks it. It possesses some advantages as to painting, and may be made so gaudy and brilliant in its decorations, as to captivate the vulgar eye.

The best English porcelain is made from a mixture of the Cornish and Devonshire kaolin (called china-clay), ground flints, ground Cornish stone, and calcined bones in powder, or bone-ash, besides some other materials, according to the fancy of the manufacturers. A liquid pap is made with these materials, compounded in certain proportions, and diluted with water. The fluid part is then withdrawn by the absorbent action of dry stucco basins or pans. The dough, brought to a proper stiffness, and perfectly worked and kneaded on the principles detailed above, is fashioned on the lathe, by the hands of modellers, or by pressure in moulds. The pieces are then baked to the state of biscuit in a kiln, being enclosed, of course, in saggers.

This biscuit has the aspect of white sugar, and being very porous, must receive a vitreous coating. The glaze consists of ground felspar or Cornish stone. Into this, diffused in water, along with a little fire-powder and potash, the biscuit ware is dipped, as already described. The pieces are then fired in the glaze-kiln, care being taken, before putting them into their saggers, to remove the glaze-powder from their bottom parts, to prevent their adhesion to the fire-clay vessel.

Mortar Body, is a paste composed of 6 parts of clay, 3 of felspar, 2 of silex, and 1 of china-clay.

Ironstone-China. Some of the English porcelain has been called ironstone-china. This is composed usually of 60 parts of Cornish stone, 40 of china-clay, and 2 of flint-glass; or 42 of felspar, the same quantity of clay, 10 parts of flints ground, and 8 of flint-glass. Slag from iron-smelting is sometimes introduced into the paste.

The glaze for the first composition is made with 20 parts of felspar, 15 of flints, 6 of red lead, and 5 of soda, which are fritted together; with 44 parts of the frit, 22 parts of flint-glass, and 15 parts of white lead, are ground.

The glaze for the second composition is formed of 8 parts of flint-glass, 36 of felspar, 40 of white lead, and 20 of silex (ground flints).

The English manufacturers employ three sorts of compositions for the porcelain biscuit: namely, two compositions not fritted; one of them for the ordinary table service; another for the dessert, service, and tea dishes; the third, which is fritted, corresponds to the paste used in France for sculpture; and with it all delicate kinds of ornaments are made.

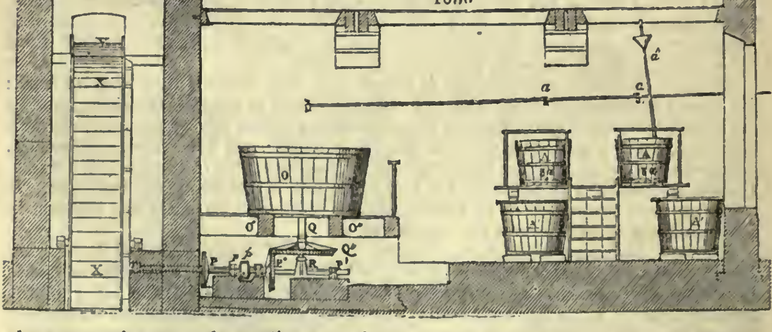
	First composition	Second composition		Third composition	
Ground flints . . .	75	. .	66	Lynn sand	150
Calcined bones . .	180	. .	100	. .	300
China-clay . . .	40	. .	96	. .	100
Clay	70	Granite	80	Potash	107

The glaze for the first two of the preceding compositions consists of, felspar 45, flints 9, borax 21, flint-glass 20, nickel 4. After fritting that mixture, add 12 parts of red lead. For the third composition, which is the most fusible, the glaze must receive 12 parts of ground flints, instead of 9; and there should be only 15 parts of borax, instead of 21.

Description of the Porcelain Mill.

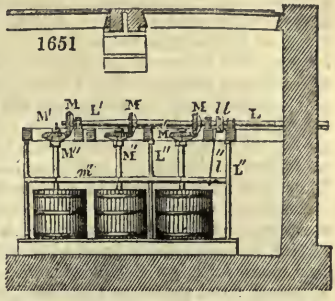
1. The following figures of a felspar and flint mill (*figs.* 1650, 1651) are taken from plans of apparatus constructed by Mr. Hall, of Dartford, and erected by him in the Royal Manufactory of Sèvres. There are two similar sets of apparatus, which may be employed together or in succession; composed each of an elevated tub A, and of

1650



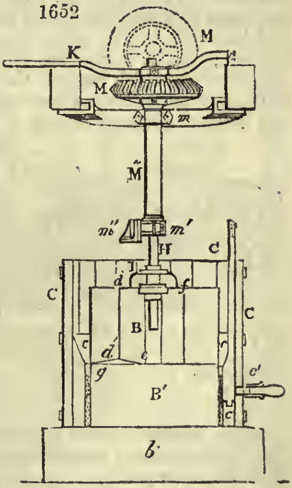
three successive vats of reception A', and two behind it, whose top edges are upon a lower level than the bottom of the casks A, A, to allow of the liquid running out of them with a sufficient slope. A proper charge of kaolin is first put into the cask A, then water is gradually run into it by the gutter adapted to the stopcock *a*, after which the mixture is agitated powerfully in every direction by hand with the stirring-bar, which is hung within a hole in the ceiling, and has at its upper end a small tin-plate funnel to prevent dirt or rust from dropping down into the clay. The stirrer may be raised or lowered so as to touch any part of the cask. The semi-fluid mass is left to settle for a few minutes, and then the finer argillaceous pap is run off by the stopcock *a'*, placed a little above the gritty deposit, into the zinc-pipe which conveys it into one of the tubs A′; but as this semi-liquid matter may still contain some granular substances, it must be passed through a sieve before it is admitted into the tub. There is, therefore, at the spot upon the tub where the zinc pipe terminates, a wire-cloth sieve, of an extremely close texture, to receive the liquid paste. This sieve is shaken upon its support, in order to make it discharge the washed kaolin. After the clay has subsided, the water is drawn off from its surface by a zinc syphon. The vats A′ have covers, to protect their contents from dust. In the pottery factories of England the agitation is produced by machinery instead of the hand. A vertical shaft, with horizontal or oblique paddles, is made to revolve in the vats for this purpose.

1651



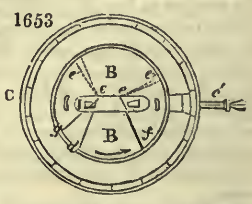
The *small triturating mill* is represented in *fig.* 1651. There are three similar grinding-tubs on the same line. The details of the construction are shown in *fig.* 1652, where it is seen to consist principally of a revolving millstone, B (*fig.* 1653), of a fast or sleeper millstone, B′, and of a vat, C, hooped with iron, with its top raised above the upper millstone. The lower block of hornstone rests upon a very firm basis, *b′*; it is surrounded immediately by the strong wooden circle *c*, which slopes out funnel-wise above, in order to throw back the earthy matters as they are pushed up by the attrition of the stones. That piece is hollowed out, partially to admit the key C, opposite to which is the faucet and spigot *c′*, for emptying the tub. When one operation is completed, the key C is lifted out by means of a peg put into the holes at its top; the spigot is then drawn, and the thin paste is run out into vats. The upper grindstone, B *d*, like the lower one, is about two feet in diameter, and must be cut in a peculiar manner. At first there is scooped out a hollowing in the form of a sector, denoted by *d e f*, *fig.* 1653; the arc *d f* is about one-sixth of the circumference, so that the vacuity of the turning grindstone is one-sixth of its surface; moreover, the stone must be channelled, in order to grind or crush the hard gritty substances. For this purpose, a wedge-shaped groove *d e g*, about an inch and a quarter deep, is made on its under face, whereby the stone, as it turns in the direction indicated by the arrow acts with this inclined plane upon all the particles in its course, crushing them and forcing them in between the stones, till they be triturated to an impalpable powder. When the grindstone wears unequally on its lower surface, it is useful to trace upon it little furrows, proceeding from the centre to the circumference, like those shown by the dotted lines *e′ e″*. It must, moreover, be indented with rough points by the hammer.

1652



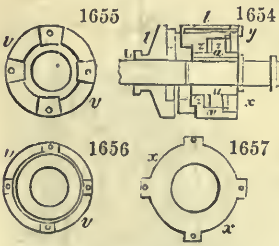
The turning hornstone-block is set in motion by the vertical shaft H, which is fixed by the clamp-iron cross, I, to the top of the stone. When the stone is new, its thickness is about 14 inches, and it is made to answer for grinding till it be reduced to about 8 inches, by lowering the clamp I upon the shaft, so that it may continue to keep its hold of the stone. The mannner in which the grindstones are turned is obvious from inspection of *fig.* 1651, where the horizontal axis L, which receives its impulsion from the great water-wheel, turns the prolonged shaft L′, or leaves it at rest, according as the clutch *l*, *l′*, is locked or open. The second shaft bears the three bevel wheels M, M, M. These work in three corresponding bevel wheels M′ M′ M′, made fast respectively to the three vertical shafts of the millstones, which pass through the cast-iron guide tubes M″M″. These are fixed in a truly vertical position by the collar-bar *m″*, *m′*, *fig.* 1652. In this figure we see at *m* how the strong cross-bar of

1653



cast iron is made fast to the wooden beams which support all the upper mechanism of the mill-work. The bearing *m'* is disposed in an analogous manner; but it is supported against two cast-iron columns, shown at L″ L″, in *fig.* 1651. The guide tubes M″ are bored smooth for a small distance from each of their extremities, and their interjacent calibre is wider, so that the vertical shafts touch only at two places. It is obvious, that whenever the shaft L′ is set agoing, it necessarily turns the wheels M and M′, and their guide tubes M″; but the vertical shaft may remain either at rest, or revolve, according to the position of the lever-click or catch K, at the top, which is made to slide upon the shaft, and can let fall a finger into a vertical groove cut in the surface of that shaft. The clamp-fork of the click is thus made to catch upon the horizontal bevel wheel M′, or to release it, according as the lever K is lowered or lifted up. Thus each millstone may be thrown out of or into gear at pleasure.

These stones make upon an average 11 or 12 turns in a minute, corresponding to 3 revolutions of the water-wheel, which moves through a space of 3 feet 4 inches in the second, its outer circumference being 66 feet. The weight of the upper stone, with its iron mountings, is about 6 cwts. when new. The charge of each mill in dry material is 2 cwts.; and the water may be estimated at from one-half to the whole of this weight; whence the total load may be reckoned to be at least 3 cwts.; the stone by displacement of the magma, loses fully 400 pounds of its weight, and weighs therefore in reality only 2 cwts. It is charged in successive portions, but it is discharged all at once. When the grinding of the siliceous or felspar matters is nearly complete, a remarkable phenomenon occurs: the substance precipitates to the bottom, and assumes in a few seconds so strong a degree of cohesion, that it is hardly possible to restore it again to the pasty or magma state; hence, if a millstone turns too slowly, or if it be accidentally stopped for a few minutes, the upper stone gets so firmly cemented to the under one, that it is difficult to separate them. It has been discovered, but without knowing why, that a little vinegar added to the water of the magma almost infallibly prevents that sudden stiffening of the deposit and stoppage of the stones. If the mills come to be set fast in this way, the shafts or gearing would be certainly broken, were not some safety provision to be made in the machinery against such accidents. Mr. Hall's contrivance to obviate the above danger is highly ingenious. The clutch *l*, *l′*, *fig.* 1651, is not a locking-crab, fixed in the common way, upon the shaft L; but it is composed, as shown in *figs.* 1654, 1655, 1656, 1657, of a hoop, *u*, fixed upon the shaft by means of a key, of a collar *v*, and of a flat ring or washer *x*, with four projections, which are fitted to the collar *v* by four bolts, *y*. *Fig.* 1655 represents the collar *v*, seen in front; that is, by the face which carries the clutch teeth; and *fig.* 1656 represents its other face, which receives the flat ring *x*, *fig.* 1657, in four notches corresponding to the four projections of the washer-ring. Since the ring *u* is fixed upon the shaft L, and necessarily turns with it, it has the two other pieces at its disposal, namely, the collar *v*, and the washer *x*, because they are always connected with it by the four bolts *y*, so as to turn with the ring *u*, when the resistance they encounter upon the shaft L′ is not too great, and to remain at rest, letting the ring *u* turn by itself, when that resistance increases to a certain pitch. To give this degree of friction, we need only interpose the leather washers *z*, *z′*, *fig.* 1654; and now, as the collar *coupling-box*, *v*, slides pretty freely upon the ring *u*, it is obvious that by tightening more or less the screw-bolts *y*, these washers will become as it were a lateral brake, to tighten more or less the bearing of the ring *u*, to which they are applied: by regulating this pressure, everything may be easily adjusted. When the resistance becomes too great, the leather washers, pressed upon one side by the collar *v*, of the washer *x*, and rubbed upon the other side by the prominence of the ring *u*, get heated to such a degree, that they are apt to become carbonised, and require replacement.



This safety clutch may be recommended to the notice of mechanicians, as susceptible of beneficial application in a variety of circumstances.

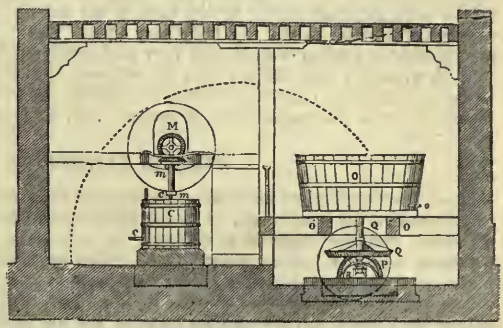
Great Porcelain Mill.—The large felspar and kaolin mill, made by Mr. Hall, for Sèvres, has a flat bed of hornstone, in one block, laid at the bottom of a great tub, hooped strongly with iron. In most of the English potteries, however, that bed consists of several flat pieces of chert or hornstone, laid level with each other. There is as usual a spigot and faucet at the side, for drawing off the liquid paste. The whole system of the mechanism is very substantial, and is supported by wooden beams.

The following is the manner of turning the upper blocks. In *fig.* 1650 the main horizontal shaft, P, bears at one of its extremities a toothed wheel, usually mounted upon the periphery of the great water-wheel (*fig.* 1658 shows this toothed wheel by a dotted line) at its other end: P carries the fixed portion *p* of a coupling-box, similar to the one just described as belonging to the little mill. On the prolongation of P, there is a second shaft, P′, which bears the moveable portion of that box, and an upright bevel wheel, P″. Lastly, in *figs.* 1650 and 1658, there is shown the vertical shaft Q, which carries at its upper end a large horizontal cast-iron wheel Q, not seen in this view, because it is sunk within the upper surface of the turning hornstone, like the clamp *d*, *f*, in *fig.* 1652. At the lower end of the shaft Q, there is the bevel wheel Q″, which receives motion from the wheel P″, *fig.* 1650.

The shaft, P, always revolves with the water-wheel; but transmits its motion to the shaft P′ only when the latter is thrown into gear with the coupling-box *p*′, by means of its forked lever. Then the bevel wheel P′ turns round with the shaft P′, and communicates its rotation to the bevel wheel Q″, which transmits it to the shaft Q, and to the large cast-iron wheel, which is sunk into the upper surface of the revolving hornstone.

The shaft Q is supported and centred by a simple and solid adjustment; at its lower part, it rests in a step R, which is supported upon a cast-iron arch, Q′, seen in profile in *fig.* 1650; its base is solidly fixed by four strong bolts. Four set-screws above R, *fig.* 1650, serve to set the shaft Q truly perpendicular: thus supported, and held securely at its lower end, in the step at R, *figs.* 1650 and 1658, it is embraced near the upper end by a brass bush or collar, composed of two pieces, which may be drawn closer together by means of a screw. This collar is set into the summit of a great truncated cone of cast-iron, which rises within the tub through two-thirds of the thickness of the hornstone bed; having its base firmly fixed by bolts to the bottom of the tub, and having a brass collet to secure its top. The iron cone is cased in wood. When all these pieces are well adjusted and properly screwed up, the shaft Q revolves without the least vacillation, and carries round with it the large iron wheel Q′, cast in one piece, and which consists of an outer rim, three arms or radii, and a strong central nave, made fast by a key to the top of the shaft Q, and resting upon a shoulder nicely turned to receive it.

1658



Upon each of the three arms, there are adjusted, with bolts, three upright substantial bars of oak, which descend vertically through the body of the revolving mill to within a small distance of the bed-stone; and upon each of the three arcs of that wheel-ring, comprised between its three strong arms, there are adjusted, in like manner, five similar uprights, which fit into hollows cut in the periphery of the moving stone. They ought to be cut to a level at their lower part, to suit the slope of the bottom of the tub O, *figs.* 1650 and 1658, so as to glide past it pretty closely, without touching.

The speed of this large mill is eight revolutions in the minute. The turning hornstone describes a mean circumference of 141⅓ inches (its diameter being 45 inches), and of course moves through about 100 feet per second. The tub, O, is 52 inches wide at bottom, 56 at the surface of the sleeper block (which is 16 inches thick), and 64 at top, inside measure. It sometimes happens that the millstone throws the pasty mixture out of the vessel, though its top is 6 inches under the lip of the tub O; an inconvenience which can be obviated only by making the pap a little thicker; that is, by allowing only from 25 to 30 per cent. of water; then its density becomes nearly equal to 2·00, while that of the millstones themselves is only 2·7; whence, supposing them to weigh only 2 cwts., there would remain an effective weight of less than ½ cwt. for pressing upon the bottom and grinding the granular particles. This weight appears to be somewhat too small to do much work in a short time; and therefore it would be better to increase the quantity of water, and put covers of some convenient form over the tubs. It is estimated that this mill will grind nearly 5 cwts. of hard kaolin or felspar gravel, in 24 hours, into a proper pap.

Stoneware.

It is with great difficulty that any satisfactory distinction can be made between the different kinds of ware; they slide by nice degrees into one another. Stoneware of the ordinary kind, such as we see in jars, dram-pipes, and the variety of chemical utensils which are made in the Lambeth potteries, is constituted of the plastic clay, united in various proportions with some felspathic mineral, sands of different kinds, and in some cases with cement—stone or chalk; these mixtures being subjected to a heat which is sufficient to produce a partial fusion of the mass—this condition of semi-fusion being the distinguishing character of stoneware. The finer varieties of stoneware are made from well-selected clays, which, when burnt, will not have much colour. These are united with some fluxing material, by which that condition of semi-fusion is obtained which is necessary to the production of stoneware. The glaze of stoneware was always a salt glaze; it has, however, recently been the practice to glaze with a mixture of Cornish stone, flint, &c., as for earthenware.

Earthenware.

This ware is exemplified in the Majolica ware, the Fayence of the French, the Dutch or Delft ware, and by the common varieties of pottery which are at present in general use in this country. All the varieties of earthenware—and they are many—consist of clay bodies, coated with an easily-fusible glaze, containing lead or borax. In Delft and Majolica ware the surface is coated with an opaque white glaze or enamel containing binoxide of tin.

Poole clay, Devonshire clay, Cornish clay, and many of the clays from the Coal-measures, and other geological formations, enter into the composition of earthenware. These are combined with certain proportions of ground flint. Porous vessels for cooling water and wine, now made extensively in many parts of this country, are similar to the ancient Spanish cooling vessels.

The Spanish *alcarazzas*, or cooling vessels, are made porous, to favour the exudation of water through them, and maintain a constantly moist evaporating surface. Lasteyrie says, that granular sea salt is an ingredient of the paste of the Spanish alcarazzas; which being expelled partly by the heat of the baking, and partly by the subsequent watery percolation, leaves the body very open. The biscuit should be charged with a considerable portion of sand, and very moderately fired.

With what has been already said in reference to the modes of manufacture, added to the remarks on printing, glazing, &c., which are to follow, the general principles which obtain in the manufacture of pottery, will, we think, be sufficiently understood.

Printing, Painting, &c.

There are two distinct methods of printing in use for china and earthenware; one is transferred on the bisque, and is the method by which the ordinary printed ware is produced, and the other is transferred on the glaze. The first is called 'press-printing,' and the latter 'bat-printing.' The engraving is executed upon copper plates, and for press-printing is cut very deep to enable it to hold a sufficiency of colour to give a firm and full transfer to the ware. The printer's shop is furnished with a brisk stove, having an iron plate on the top immediately over the fire, for the convenience of warming the colour while being worked, also a roller-press and tubs. The printer has two female assistants, called 'transferers,' and also a girl called a 'cutter.' The copper-plate is charged with colour mixed with thick boiled oil by means of a knife and 'dabber,' while held on the hot stove-plate for the purpose of keeping the colour fluid; and the engraved portion being filled, the superfluous colour is scraped off the surface of the copper by the knife, which is further cleaned by being rubbed with a boss made of leather. A thick firm oil is required to keep the different parts of the design from flowing into a mass or becoming confused while under the pressure of the rubber, in the process of transferring. A sheet of paper of the necessary size and of a peculiarly thin texture, called 'pottery tissue,' after being saturated with a thin solution of soap-and-water, is placed upon the copper-plate, and being put under the action of the press, the paper is carefully drawn off again (the engraving being placed on the stove), bringing with it the colour by which the plate was charged, constituting the pattern. This impression is given to the 'cutter,' who cuts away the superfluous paper about it; and if the pattern consists of a border and a centre the border is separated from the centre, as being more convenient to fit to the ware when divided. It is then laid by a transferer upon the ware and rubbed first with a small piece of soaped flannel to fix it, and afterwards with a rubber formed of rolled flannel. This rubber is applied to the impression very forcibly, the friction causing the colour to adhere firmly to the bisque surface, by which it is partially imbibed; it is then immersed in a tub of water, and the paper washed entirely away with a sponge, the colour, from its adhesion to the ware, and being mixed with oil, remaining unaffected. It is now necessary, prior to 'glazing,' to get rid of this oil, which is done by submitting the ware to heat in what are called 'hardening kilns,' sufficient to destroy it and leave the colour pure. This is a necessary process, as the glaze, being mixed with water, would be rejected by the print, while the oil remained in the colour.

The printing under the earthenware-glaze is generally performed by means of cobalt, and has different shades of blue according to the quantity of colouring-matter employed. After having subjected this oxide to the processes requisite for its purification, it is mixed with a certain quantity of ground flints and sulphate of baryta, proportioned to the dilution of the shade. These materials are fritted and ground; but before they are used, they must be mixed with a flux consisting of equal parts by weight of flint-glass and ground flints, which serves to fix the colour upon the biscuit, so that the immersion in the glaze-liquor may not displace the lines printed on, as also to aid in fluxing the cobalt.

The 'bat-printing' is done upon the glaze, and the engravings are for this style exceedingly fine, and no greater depth is required than for ordinary book engravings. The impression is not submitted to the heat necessary for that in the bisque, and the medium of conveying it to the ware is also much purer. The copper-plate is first charged with linseed oil, and cleaned off by hand, so that the engraved portion only retains it. A preparation of glue being run upon flat dishes about a quarter of an inch thick, is cut to the size required for the subject, and then pressed upon it, and being immediately removed, draws on its surface the oil with which the engraving was filled. The glue is then pressed upon the ware, with the oiled part next the glaze, and being again removed, the design remains; though, being in a pure oil, scarcely perceptible. Colour finely-ground is then dusted upon it with cotton wool, and a sufficiency adhering to the oil leaves the impression perfect, and ready to be fired in the enamel-kilns.

The following are the processes usually practised in Staffordshire for printing under the glaze:—

The cobalt, or whatever colour is employed, should be ground upon a porphyry slab, with a varnish prepared as follows:—A pint of linseed oil is to be boiled to the consistence of thick honey, along with 4 ounces of rosin, half a pound of tar, and half a pint of oil of amber. This is very tenacious, and can be used only when liquefied by heat; which the printer effects by spreading it upon a hot cast-iron plate.

The printing plates are made of copper, engraved with pretty deep lines in the common way. The printer, with a leathern muller, spreads upon the engraved plate, previously heated, his colour, mixed up with the above oil varnish, and removes what is superfluous with a pallet knife; then cleans the plate with a dossil filled with bran tapping, and wiping as if he were removing dust from it. This operation being finished, he takes the paper intended to receive the impression, soaks it with soap-water, and lays it moist upon the copper-plate. The soap makes the paper part more readily from the copper, and the thick ink part more readily from the biscuit. The copper-plate is now passed through the engraver's cylinder press, the proof-leaf is lifted off and handed to the women, who cut it into detached pieces, which they apply to the surface of the biscuit. The paper best fitted for this purpose is made entirely of linen rags; it is very thin, of a yellow colour, and unsized, like tissue blotting-paper.

The earthenware biscuit never receives any preparation before being imprinted, the oil of the colour being of such a nature as to fix the figures firmly. The printed paper is pressed and rubbed on with a roll of flannel, about an inch and a half in diameter, and 12 or 15 inches long, bound round with twine, like a roll of tobacco. This is used as a burnisher, one end of it being rested against the shoulder, and the other end being rubbed upon the paper; by which means it transfers all the engraved traces to the biscuit. The piece of biscuit is laid aside for a little, in order that the colour may take fast hold; it is then plunged into water, and the paper is washed away with a sponge.

When the paper is detached, the piece of ware is dipped into a caustic alkaline lye to saponify the oil, after which it is immersed in the glaze-liquor, with which the printed figures readily adhere. This process, which is easy to execute, and very economical, is much preferable to the old plan of passing the biscuit into the muffle after it had been printed, for the purpose of fixing and volatilising the oils. When the paper impression is applied to pieces of porcelain, they are heated before being dipped in the water, because, being already semi-vitrified, the paper sticks more closely to them than to the biscuit, and can be removed only by a hard brush.

The impression above the glaze is done by quite a different process, which dispenses with the use of the press. A quantity of fine clean glue is melted and poured hot upon a large flat dish, so as to form a layer about a quarter of an inch thick, and of the consistence of jelly. When cold it is divided into cakes of the size of the copper-plates it is intended to cover.

The operative (a woman) rubs the engraved copper-plate gently over with linseed oil boiled thick, immediately after which she applies the cake of glue, which she presses down with a silk dossil filled with bran. The cake licks up all the oil out of the engraved lines; it is then cautiously lifted off, and transferred to the surface of the glazed ware which it is intended to print. The glue-cake being removed, the enamel surface must be rubbed with a little cotton, whereby the metallic colours are attached only on the lines charged with oil: the piece is then heated under the muffle. The same cake of glue may serve for several impressions.

Ornaments and Colouring.—Common earthenware is coloured by means of two kinds of apparatus: the one called the blowing-pot, the other the warming-pot. The ornaments made in relief in France are made hollow (intaglio) in England, by means of a mould engraved in relief, which is passed over the article. The impression which it produces is filled with a thick clay-paste, which the workman throws on with the blowing-pot. This is a vessel like a tea-pot, having a spout, but it is hermetically sealed at top with a clay plug, after being filled with the pasty liquor. The workman by blowing in at the spout, causes the liquor to fly out through a quill pipe which goes down through the clay pipe into the liquor. The jet is made to play upon the piece while it is being turned upon the lathe; so that the hollows previously made in it by the mould or stamp are filled with a paste of a colour different from that of the body. When the piece has acquired sufficient firmness to bear working, the excess of the paste is removed by an instrument called a *tournason*, till the ornamental figure produced by the stamp be laid bare; in which case merely the colour appears at the bottom of the impression. By passing in this manner several layers of clay-liquor of different colours over each other with the blowing-pot, net-work and decorations of different colours and shades are very rapidly produced.

The serpentine or snake pots, established on the same principle, are made of tin plate in three compartments, each containing a different colour. These open at the top of the vessel in a common orifice, terminated by small quill tubes. On inclining the vessel, the three colours flow out at once in the same proportion at the one orifice, and are let fall upon the piece while it is being slowly turned upon the lathe, whereby curious serpent-like ornaments may be readily obtained. The clay-liquor ought to be in keeping with the stoneware-paste. The blues succeed best when the ornaments are made with the finer pottery mixtures given above.

White and yellow figures upon dark-coloured grounds are a good deal employed. To produce yellow impressions upon brown stoneware, ochre is ground up with a small quantity of antimony. The flux consists of flint glass and flints in equal weights. The composition for white designs is made by grinding silex up with that flux, and printing it on as for blue colours, upon brown or other coloured stoneware, which shows off the light hues.

Metallic Lustres applied to Stoneware.—The metallic lustre being applied only to the outer surface of vessels, can have no bad effect on health, whatever substances be employed for the purpose; and as the glaze intended to receive it is sufficiently fusible, from the quantity of lead it contains, there is no need of adding a flux to the metallic coating. The glaze is in this case composed of 60 parts of litharge, 36 of felspar, and 15 of flints.

The silver and platina lustres are usually laid upon a white ground, while those of gold and copper, on account of their transparency, succeed only upon a coloured ground. The dark-coloured earthenware is, however, preferable, as it shows off the colours to most advantage; and thus the shades may be varied by varying the colours of the ornamental figures applied by the blowing-pot.

The gold and platina lustre is almost always applied to a paste body made on purpose, and coated with the above-described lead-glaze. This paste is brown, and consists of 4 parts of clay, 4 parts of flints, an equal quantity of kaolin (china-clay), and 6 parts of felspar. To make brown figures in relief upon a body of white paste, a liquor is mixed up with this paste, which ought to weigh 26 ounces per pint, in order to unite well with the other paste, and not to exfoliate after it is baked.

Preparation of Gold Lustre.—Dissolve first in the cold, and then with heat, 48 grains of fine gold in 288 grains of aqua regia, composed of 1 ounce of nitric acid and 3 ounces of muriatic acid; add to that solution 4½ grains of grain tin, bit by bit; and then pour some of that compound solution into 20 grains of balsam of sulphur diluted with 10 grains of oil of turpentine. The balsam of sulphur is prepared by heating a pint of linseed oil and 2 ounces of flowers of sulphur, stirring them continually till the mixture begins to boil; it is then cooled, by setting the vessel in cold water; after which it is stirred afresh, and strained through linen. The above ingredients, after being well mixed, are to be allowed to settle for a few minutes; then the remainder of the solution of gold is to be poured in, and the whole is to be triturated till the mass has assumed such a consistence that the pestle will stand upright in it; lastly, there must be added to the mixture 30 grains of oil of turpentine, which being ground in, the gold lustre is ready to be applied. If the lustre is too light or pale, more gold must be added, and if it have not a sufficiently violet or purple tint, more tin must be used.

Platina lustre.—Of this there are two kinds: one similar to polished steel, another lighter and of a silver-white hue. To give earthenware the steel colour with platina, this metal must be dissolved in aqua regia composed of 2 parts of muriatic acid and 1 part of nitric. The solution being cooled, and poured into a capsule, there must be added to it, drop by drop, with continual stirring with a glass rod, a *spirit of tar*, composed of equal parts of tar and sulphur boiled in linseed oil and filtered. If the platina-solution be too strong, more spirit of tar must be added to it; but if too weak, it must be concentrated by boiling. Thus being brought to the proper pitch, the mixture may be spread over the piece, which being put into the muffle, will take the aspect of steel.

The preparation of platinum, by means of which the silver lustre is given to earthenware, is prepared as follows:—After having dissolved to saturation the metal in aqua regia, composed of equal parts of nitric and muriatic acid, the solution is to be poured into a quantity of boiling water. At the same time, a capsule, containing solution of sal-ammoniac, is placed upon a sand-bath, and the platinum-solution being poured into it, the metal will fall down in the form of a yellow precipitate, which is to be washed with cold water till it is perfectly edulcorated, then dried, and put up for use.

This metallic lustre is applied very smoothly by means of a flat camel's-hair brush. It is then to be passed through the muffle-kiln; but it requires a second application of the platinum to have a sufficient body of lustre. The articles sometimes come black out of the kiln, but they get their lustre by being rubbed with cotton.

Dead silver on porcelain is much more easily affected by fuliginous vapours than burnished. It may, however, by the following process, be completely protected. The silver must be dissolved in very dilute acid, and slowly precipitated; and the metallic precipitate well washed. The silver is then laid (in wavy lines?) upon the porcelain before being coloured (or if coloured, the colour must not be any preparation of gold) in a pasty state and left for 24 hours, at the expiration of which time the gold is to be laid on and the article placed in a moderate heat. The layer of gold must be very thin, and laid on with a brush over the silver before firing it; when, by the aid of a flux and a cherry-red heat, the two metals are fixed on the porcelain.

An iron lustre is obtained by dissolving a bit of steel or iron in muriatic acid, mixing the solution with the spirit of tar, and applying it to the surface of the ware.

Aventurine glaze.—Mix a certain quantity of silver-leaf with the above-described soft glaze, and grind the mixture along with some honey and boiling water, till the metal assume the appearance of fine particles of sand. The glaze being naturally of a yellowish hue, gives a golden tint to the small fragments of silver disseminated through it. Molybdena may also be applied to produce the aventurine aspect.

The granite-like gold lustre is produced by throwing lightly with a brush a few drops of oil of turpentine upon the goods already covered with the preparation for gold lustre. These cause it to separate and appear in particles resembling the surface of granite. When marbling is to be given to earthenware, the lustres of gold, platinum, and iron are used at once, which, blending in the fusion, form veins like those of marble.

Of late years a beautiful lustre has been given to porcelain by a process patented in 1857 by Messrs. Gillet and Brianchon, of Paris, and largely used at the works of Worcester and Belleek. The effect is obtained by using nitrate of bismuth as a flux to the metallic oxides which give colour, and by employing oil of lavender as a vehicle. (Spec. Patent, No. 1896, July 8, 1857.)

Pottery and ware of the Wedgwood type.—This is a kind of semi-vitrified ware, called *dry bodies*, which is not susceptible of receiving a superficial glaze. This pottery is composed in two ways: the first is with barytic earths, which act as fluxes upon the clays, and form enamels: thus the Wedgwood *jasper-ware* is made.

The white vitrifying pastes, fit for receiving all sorts of metallic colours, are composed of 47 parts of sulphate of baryta, 15 of felspar, 26 of Devonshire clay, 6 of sulphate of lime, 15 of flints, and 10 of sulphate of strontia. This composition is capable of receiving the tints of the metallic oxides and of the ochreous metallic earths: Manganese produces the dark purple colour; gold, precipitated by tin, a rose colour; antimony, orange; cobalt, different shades of blue; copper is employed for the browns and the dead-leaf greens; nickel gives, with potash, greenish colours.

One per cent. of oxide of cobalt is added; but one half, or even one quarter, of a per cent. would be sufficient to produce the fine Wedgwood blue, when the nickel and manganese constitute 3 per cent., as well as the carbonate of iron. For the blacks of this kind, some English manufacturers mix black oxide of manganese with the black oxide of iron, or with ochre. Nickel and umber afford a fine brown. Carbonate of iron, mixed with bole or *terra di Sienna*, gives a beautiful tint to the paste; as also manganese with cobalt, or cobalt with nickel. Antimony produces a very fine colour when combined with the carbonate of iron in the proportion of 2 per cent., along with the ingredients necessary to form the above-described vitrifying paste.

The following is another vitrifying paste, of a much softer nature than the preceding:—Felspar, 30 parts; sulphate of lime, 23; silex, 17; potter's clay, 15; kaolin of Cornwall (china-clay), 15; sulphate of baryta, 10.

These vitrifying pastes are very plastic, and may be worked with as much facility as English pipe-clay. The round ware is usually turned upon the lathe. It may, however, be moulded, as the oval pieces always are. The more delicate ornaments are cast in hollow moulds of baked clay, by women and children, and applied with remarkable dexterity upon the turned and moulded articles. The coloured pastes have such an affinity for each other, that the detached ornaments may be applied not only with a little gum-water upon the convex and concave forms, but they may be made to adhere without experiencing the least cracking or chinks. The coloured pastes receive only one fire, unless the inner surface is to be glazed; but a gloss is given to the outer surface. The enamel for the interior of the black Wedgwood ware is composed of 6 parts of red lead, 1 of silex, and 2 ounces of manganese, when the mixture is made in pounds' weight.

The operation called *smearing* consists in giving an external lustre to the unglazed semi-vitrified ware. The articles do not in this way receive any immersion, nor even the aid of the brush or pencil of the artist; but they require a second fire. The saggers are coated with the salt-glaze already described. These cases, or saggers, communicate by reverberation the lustre so remarkable on the surface of the English stoneware, which one might suppose to be the result of the glaze-tub, or of the brush. Occasionally also a very fusible composition is thrown upon the inner surface of the muffle, and 5 or 6 pieces called *refractories* are set in the middle of it, coated with the same composition. The intensity of the heat converts the flux into vapour; a part of this is condensed upon the surfaces of the contiguous articles, so as to give them the desired brilliancy.

Enamel-colours for painting on porcelain are metallic oxides incorporated with a fusible flux. Gold, precipitated by tin, furnishes the crimson, rose, and purple; oxides of iron and chrome produce reds; the same oxides yield black and brown, also obtained from manganese and cobalt; orange is from oxides of uranium, chromium, antimony, and iron; greens from oxides of chromium and copper; blue from oxides of cobalt and zinc. The fluxes are borax, flint, oxides of lead, &c. They are worked in essential oils and turpentine, and a very great disadvantage under which the artist labours, is that the tints upon the palette are in most cases different from those they assume when they have undergone the necessary heat, which not only brings out the true colour, but also, by partially softening the glaze and the flux, causes the colour to become fixed to the ware. This disadvantage will be immediately apparent in the case where a peculiar delicacy of tint is required, as in flesh-tones, for instance. But the difficulty does not end here, for as a definite heat can alone give to a colour a perfect hue, and as the colour is continually varying with the different stages of graduated heat, another risk is incurred; that resulting from the liability of its receiving the heat in a greater or less degree than is actually required, termed 'over-fired' and 'short-fired.' As an instance of its consequence, we cite rose-colour or crimson, which when used by the painter is a dirty violet or drab; during the process of firing it gradually varies with the increase of heat from a brown to a dull reddish hue, and from that progressively to its proper tint. But if by want of judgment or inattention of the fireman the heat is allowed to exceed that point, the beauty and brilliancy of the colour are destroyed beyond remedy, and it becomes a dull purple. On the other hand, should the fire be too slack, the colour is presented in one of its intermediate stages, as already described, but in this case extra heat will restore it. Nor must we forget to allude to casualties of cracking and breaking in the kilns by the heat being increased or withdrawn too suddenly, a risk to which the larger articles are peculiarly liable. These vicissitudes render enamel-painting in its higher branches a most unsatisfactory and disheartening study, and enhance the value of those productions which are really successful and meritorious.

In enamelling, ground-laying is the first process, in operating on all designs to which it is applied; it is extremely simple, requiring principally lightness and delicacy of hand. A coat of boiled oil adapted to the purpose being laid upon the ware with a pencil, and afterwards levelled, or as it is technically termed 'bossed,' until the surface is perfectly uniform; as the deposit of more oil on one part than another would cause a proportionate increase of colour to adhere, and consequently produce a variation of tint. This being done, the colour, which is in a state of fine powder, is dusted on the oiled surface with cotton-wool; a sufficient quantity readily attaches itself, and the superfluity is cleared off by the same medium. If it be requisite to preserve a panel ornament or any object white upon the ground, an additional process is necessary, called 'stencilling.' The stencil (generally a mixture of rose-pink, sugar, and water) is laid on in the form desired with a pencil, so as entirely to protect the surface of the ware from the oil, and the process of 'grounding,' as previously described, ensues. It is then dried in an oven to harden the oil and colour, and immersed in water, which penetrates to the stencil, and, softening the sugar, is then easily washed off, carrying with it any portion of colour or oil that may be upon it, and leaving the ware perfectly clean. It is sometimes necessary, where great depth of colour is required, to repeat these colours several times. The 'ground-layers' do generally, and should always, work with a bandage over the mouth to avoid inhaling the colour-dust, much of which is highly deleterious. 'Bossing' is the term given to the process by which the level surfaces of various colours so extensively introduced upon decorated porcelain are effected. The 'boss' is made of soft leather.

The process of gilding is as follows:—The gold (which is prepared with quicksilver and flux) when ready for use appears a black dust; it is used with turpentine and oils similar to the enamel-colours, and like them worked with the ordinary camels'-hair pencil. It flows very freely, and is equally adapted for producing broad massive bands and grounds, or the finest details of the most elaborate design.

To obviate the difficulty and expense of drawing the pattern on every piece of a service, when it is at all intricate, a 'pounce' is used, and the outline dusted through with charcoal,—a method which also secures uniformity of size and shape. Women are precluded from working at this branch of the business, though from its simplicity and lightness it would appear so well adapted for them. Firing restores the gold to its proper tint, which first assumes the character of 'dead gold:' its after brilliancy being the result of another process, termed 'burnishing.'

Glazing.—A good enamel is an essential element of fine pottery and porcelain; it should experience the same dilatation and contraction by heat and cold as the biscuit which it covers. The English enamels contain nothing prejudicial to health, as many of the foreign glazes do; no more lead being added to the former than is absolutely necessary to convert the siliceous and aluminous matters with which it is mixed into a perfectly neutral glass.

Three kinds of glazes are used in Staffordshire: one for the common pipe-clay or cream-coloured ware; another for the finer pipe-clay ware to receive impressions, called *printing body;* a third for the ware which is to be ornamented by painting with the pencil.

The glaze of the first or common ware is composed of 53 parts of white lead, 16 of Cornish stone, 36 of ground flints, and 4 of flint-glass; or of 40 of white lead, 36 of Cornish stone, 12 of flints, and 4 of flint- or crystal-glass. These compositions are not fritted; but are employed after being simply triturated with water into a thin paste.

The following is the composition of a glaze intended to cover all kinds of figures printed in metallic colours: 26 parts of white felspar are fritted with 6 parts of soda, 2 of nitre, and 1 of borax; to 20 pounds of this frit, 26 parts of felspar, 20 of white lead, 6 of ground flints, 4 of chalk, 1 of oxide of tin, and a small quantity of oxide of cobalt, to take off the brown cast, and give a faint azure tint, are added.

The following recipe may also be used:—Frit together 20 parts of flint-glass, 6 of flints, 2 of nitre, and 1 of borax; add to 12 parts of that frit, 40 parts of white lead, 36 of felspar, 8 of flints, and 6 of flint-glass; then grind the whole together into an uniform cream-consistenced paste.

As to the ware which is to be painted, it is covered with a glaze composed of 13 parts of the printing-colour frit, to which are added 50 parts of red lead, 40 of white lead, and 12 of flint; the whole having been ground together.

The above compositions produce a very hard glaze, which cannot be scratched by the knife, is not acted upon by vegetable acids, and does no injury to potable or edible articles kept in the vessels covered with it. It preserves for an indefinite time the glassy lustre, and is not subject to crack and exfoliate, like most of the Continental stoneware made from common pipe-clay.

In order that the saggers in which the articles are baked, after receiving the glaze, may not absorb some of the vitrifying matter, they are themselves coated, as above mentioned, with a glaze composed of 13 parts of common salt and 30 parts of potash, simply dissolved in water, and brushed over them.

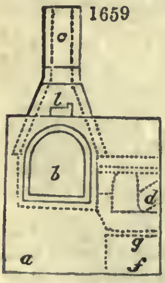
Glaze-kiln.—This is usually smaller than the biscuit-kiln, and contains no more than 40 or 45 bungs or columns, each composed of 16 or 17 saggers. Those of the first bung rest upon round tiles, and are well luted together with a finely-ground fire-clay of only moderate cohesion; those of the second bung are supported by an additional tile. The lower saggers contain the cream-coloured articles, in which the glaze is softer than that which covers the blue-printed ware; this being always placed in the intervals between the furnaces, and in the uppermost saggers of the columns. The bottom of the kiln, where the glazed ware is not baked, is occupied by printed biscuit-ware.

Pyrometric balls of red clay, coated with a very fusible lead-enamel, are employed in the English potteries to ascertain the temperature of the glaze-kilns. This enamel is so rich, and the clay upon which it is spread is so fine-grained and compact, that even when exposed for three hours to the briskest flame, it does not lose its lustre. The colour of the clay alone changes, whereby the workman is enabled to judge of the degree of heat within the kiln. At first the balls have a pale red appearance; but they become browner with the increase of the temperature. The balls, when of a slightly dark-red colour, indicate the degree of baking for the hard glaze of pipe-clay ware; but if they become dark brown, the glaze will be much too hard, being that suited for *ironstone*-ware; lastly, when they acquire an almost black hue, they show a degree of heat suited to the formation of a glaze upon porcelain.

The *glazer* provides himself at each round with a stock of these ball *watches*, reserved from the preceding baking, to serve as objects of comparison; and he never slackens the firing till he has obtained the same depth of shade, or even somewhat more; for it may be remarked, that the more rounds a glaze-kiln has made, the browner the balls are apt to become. A new kiln bakes a round of enamel-ware sooner than an old one; as also with less fuel, and at a lower temperature. The watch-balls of these first rounds have generally not so deep a colour as if they were tried in a furnace three or four months old. After this period, cracks begin to appear in the furnaces; the horizontal flues get partially obstructed, the joinings of the brickwork become loose; in consequence of which there is a loss of heat and waste of fuel; the baking of the glaze takes a longer time, and the pyrometric balls assume a different shade from what they had on being taken out of the new kiln, so that the first watches are of no comparable use after two months. The baking of enamel is commenced at a low temperature, and the heat is progressively increased; when it reaches the melting-point of the glaze, it must be maintained steadily, and the furnace-mouths be carefully looked after, lest the heat should be suffered to fall. The firing is continued 14 hours, and then gradually lowered by slight additions of fuel; after which the kiln is allowed from 5 to 6 hours to cool.

Muffles.—The paintings and the printed figures applied to the glaze of earthenware and porcelain are baked in muffles of a peculiar form. *Fig.* 1659 is a lateral elevation of one of these muffles; *fig.* 1660 is a front view. The same letters denote the same parts in the two figures.

1659



1660

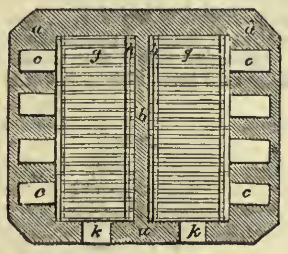
a is the furnace; *b*, the oblong muffle, made of fire-clay, surmounted with a dome pierced with three apertures, *k*, *k*, *k*, for the escape of the vaporous matters of the colours and volatile oils with which they are ground up; *c* is the chimney; *d*, *d*, feedholes, by which the fuel is introduced; *e*, the fire-grate; *f*, the ash-pit; channels are left in the bottom of the furnace to facilitate the passage of the flame beneath the muffle; *g* is a lateral hole, which makes a communication across the furnace in the muffle, enabling the kiln-man to ascertain what is passing within; *k*, *k*, are the lateral chinks for observing the progress of the firing or flame; *l* is an opening scooped out in the front of the chimney to modify its draught.

The articles which are printed or painted upon the glaze are placed in the muffle without saggers, upon tripods, or moveable supports furnished with feet. The muffle being charged, its mouth is closed with a fire-tile well luted round its edges. The fuel is then kindled in the fireplaces *d*, *d*, and the door of the furnace is closed with bricks, in which a small opening is left for taking out samples, and for examining the interior of the muffle. These sample or trial-pieces, attached to a strong iron wire, show the progress of the baking operation. The front of the fireplaces is covered with a sheet-iron plate, which slides to one side, and may be shut whenever the kiln is charged.

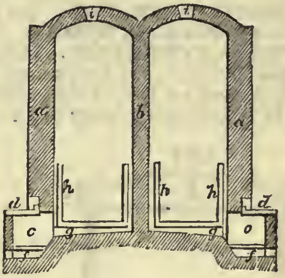
Soon after the fire is lighted, the flame, which communicates laterally from one furnace to another, envelopes the muffle on all sides, and thence rises up the chimney.

A patent was obtained by Mr. W. Ridgway for the following construction of oven, in which the flames from the fireplaces are conveyed by parallel flues, both horizontal and vertical, so as to reverberate the whole of the flame and heat upon the goods after its ascension from the flues. His oven is built square instead of round, a fire-proof partition-wall being built across the middle of it, dividing it into two chambers, which are covered in by two parallel arches. The fireplaces are built in the two sides of the oven opposite to the partition-wall: from which fireplaces narrow flues rise in the inner face of the wall, and distribute the flame in a sheet equally over the whole of its surface. The other portion of the heat is conveyed by many parallel or diverging horizontal flues, under and across the floor or hearth of the oven, to the middle or partition-wall; over the surface of which the flame which ascends from the numerous flues in immediate contact with the wall is equally distributed. This sheet of ascending flame strikes the shoulder of the arch, and is reverberated from the saggers beneath, till it meets the flame reverberated from the opposite side of the arch, and both escape at the top of the oven. The same construction is also applied to the opposite chamber. In *figs.* 1661 and 1662, *a* represents the square walls or body of the oven; *b*, the partition-wall; *c*, the fireplaces or furnaces, with their iron boilers; *d*, the mouths of the furnaces for introducing the fuel; *f*, the ash-pits; *g*, the horizontal flues under the hearth of the oven; *h*, the vertical flues; *i*, the vents in the top of the arches; and *k*, the entrances to the chambers of the ovens.

1661



1662



Before this article is concluded it is necessary that we should notice the attempts which have been made, with various degrees of success, to employ porcelain as a means for multiplying the productions of high art in a cheap form. Under the various terms of Statuary Porcelain, Parian, Carrara, &c., are produced numerous works of art, many of which are distinguished by their beauty. As the most direct method of illustrating the process of making these figures, let us suppose the object under view to be a figure or group, and this we will assume to be 2 feet high in the model. The clay, which is of the most perfect character, is mixed with flint, as in the case of manufacturing the finest stoneware china, and it is used in a semi-liquid state about the consistency of cream: this is poured into the moulds forming the various parts of the subject (sometimes as many as fifty): the shrinking that occurs before these casts can be taken out of the mould, which is caused by the absorbent nature of the plaster of which the mould is composed, is equal to a reduction of one inch and a half in the height. The moulds are made of plaster of Paris, which, when properly prepared, has the property of absorbing water so effectually that the moisture is extracted from the clay, and the ware is enabled to leave the mould, or 'deliver' with care and rapidity. Prior to use, the plaster (gypsum) is put into long troughs, having a fire running underneath them, by which means the water is drawn off, and it remains in a state of soft powder: and if its own proportion of water be again added to it, it will immediately set into a firm compact body, which is the case when it is mixed to form the mould. These casts are then put together by the 'figure-maker,' the seams (consequent upon the marks caused by the subdivisions of the moulds) are then carefully removed, and the whole worked upon to restore the cast to the same degree of finish as the original model. The work is then thoroughly dried to be in a fit state for firing, as if put in the oven while damp the sudden contraction consequent upon the great degree of heat instantaneously applied, would be very liable to cause it to crack; in the process it again suffers a further loss of one inch and a half by evaporation, and it is now but 1 foot 9 inches. Again in the 'firing' of the bisque-oven, its most severe ordeal, it is diminished 3 inches, and is then but 18 inches high, being 6 inches or one-fourth less than the original. Now, as the contraction should equally affect every portion of the details of the work, in order to realise a faithful copy, and as added to this contingency are the risks in the oven of being 'over-fired' by which it would be melted into a mass, and of being 'short-fired,' by which its surface would be imperfect, it is readily evident that a series of difficulties present themselves which require considerable practical experience successfully to meet. Indeed, the difficulties which surround the manufacture of Parian prevent its being rendered to the public at such a price as those would desire who wish to secure the introduction, amongst the people, of all examples which are calculated to refine their tastes. A biscuit-china is, by a somewhat similar process, employed in several of the porcelain-manufactories on the Continent for the production of statuettes, busks, &c., but in colour and character they are all inferior to the English Parian. See Bricks; Clay; Tiles.

Our *Exportations* of earthenware and chinaware have been as follow:—

1866	1867	1868	1869	1870
£1,685,864	£1,666,054	£1,682,721	£1,827,798	£1,746,153

1871	1872	1873	1874
£1,731,483	£1,936,187	£2,048,872	£1,742,653

POUDRE BARYTIQUE. See Explosive Agents.

POWDER, COLONIA. See Explosive Agents.

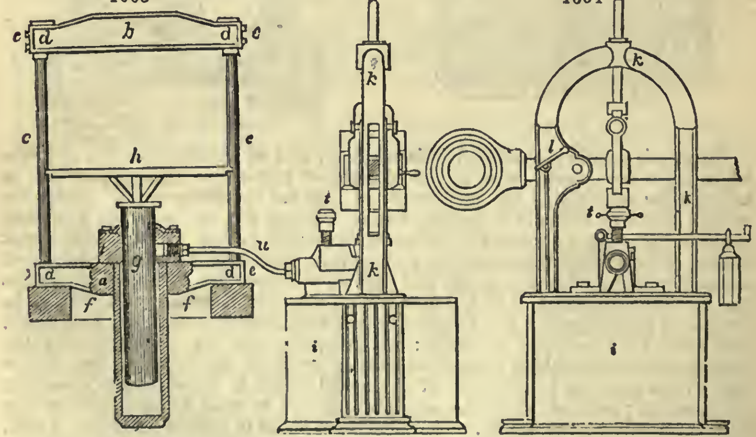
PRECIPITATE is any matter separated in minute particles from a fluid holding matter in solution, which subsides to the bottom of the vessel in a pulverulent form.

PRECIPITATE, RED. Red oxide of mercury.

PRECIPITATE, WHITE. An ammoniacal chloride of mercury.

PRESS, HYDRAULIC. Though the explanation of the principles of this powerful machine belongs to a work upon mechanical engineering rather than to one upon manufactures, yet as it is often referred to in this work, a brief description of it cannot be unacceptable to many of our readers.

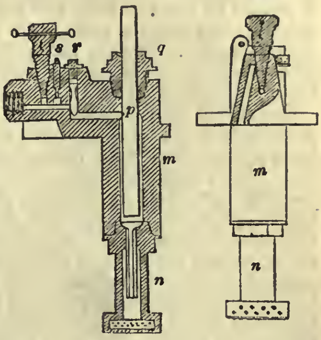
1663 1664



The framing consists of two stout cast-iron plates, *a*, *b*, which are strengthened by projecting ribs, not seen in the section, *fig.* 1663.. The top or crown-plate *b*, and the base-plate *a*, *a*, are bound most firmly together by 4 cylinders of the best wrought iron, *c*, *c*, which pass up through holes near the ends of the said plates, and are fast wedged in them. The flat pieces *e*, *e*, are screwed to the ends of the crown and base-plates, so as to bind the columns laterally. *f*, is the hollow cylinder of the press, which, as well as the ram *g*, is made of cast iron. The upper part of the cavity of the cylinder is cast narrow, but is truly and smoothly rounded at the boring-mill, so as to fit pretty closely round a well-turned ram or piston; the under part of it is left somewhat wider in the casting. A stout cup of leather, perforated in the middle, is put upon the ram, and serves as a valve to render the neck of the cylinder perfectly water-tight by filling up the space between it and the ram; and since the mouth of the cup is turned downwards, the greater the pressure of water upwards, the more forcibly are the edges of the leather valve pressed against the insides of the cylinder, and the tighter does the joint become. This was Bramah's beautiful invention.

Upon the top of the ram, the press-plate, or table, strengthened with projecting ridges, rests, which is commonly called the 'follower,' because it follows the ram closely in its descent. This plate has a half-round hole at each of its four corners, corresponding to the shape of the four iron columns along which it glides in its up-and-down motions of compression and relaxation.

1665 1666



k, *k*, *figs.* 1663 and 1664, is the framing of a force-pump with a narrow barrel; *i* is the well for containing water to supply the pump. To spare room in the engraving, the pump is set close to the press, but it may be removed to any convenient distance, by lengthening the water-pipe *u*, which connects the discharge of the force-pump with the inside of the cylinder of the press. *Fig.* 1665 is a section of the pump and its valves. The pump *m*, is of bronze; the suction-pipe *n*, has a conical valve with a long tail; the solid piston or plunger *p*, is smaller than the barrel in which it plays, and passes at its top through a stuffing-box *q*; *r* is the pressure-valve, *s* is the safety-valve, which in *fig.* 1664 is seen to be loaded with a weighted lever; *t* is the discharge-valve, for letting the water escape from the cylinder, beneath the ram, back into the well. See the winding passages in *fig.* 1666. *u* is the tube which conveys the water from the pump into the press-cylinder. In *fig.* 1664, two centres of motion for the pump-lever are shown. By shifting the bolt into the centre nearest the pump-rod, the mechanical advantage of the workman may be doubled. Two pumps are generally mounted in one frame for one hydraulic press: the larger to give a rapid motion to the ram at the beginning, when the resistance is small; the smaller to give a slower but more powerful impulsion, when the resistance is much increased. A pressure of 500 tons may be obtained from a well-made hydraulic press with a ten-inch ram, and a two and a one inch set of pumps. See Water Pressure Machine.

PRINCE'S METAL, or Prince Rupert's metal, is a brass containing about 25 per cent. of zinc.

PRINTING. (*Imprimerie, typographie*, Fr.; *Buchdruckerkunst*, Ger.) The art of taking impressions from types and engravings in relief.

History.—The art itself is of comparatively modern origin, only 400 years having elapsed since the first book, properly so called, issued from the press; but we cannot doubt that its principle was known to the ancients. It has certainly been practised in the East from a very early period, and in a manner similar to our own first attempts. That a rude kind of printing was known to the Babylonians is evident from the undecayed bricks of that city which have been found stamped with various cuneiform and hieroglyphic characters; but as the stamp itself was in one piece or block, it was inapplicable to the propagation of knowledge, from its cost and tediousness of production.

The Chinese are the only people who have continued this primitive mode of printing to the present time. Their earliest attempts are stated in their chronicles to have been made about 50 years before the Christian era; but it was not till the reign of the Emperor Ming-tsong (927–934 A.D.) that any great advance was made in printing large numbers of comparatively cheap books. The name of the Chinese Caxton was Tong-tao. He obtained permission of the Emperor in 932 to print and circulate copies of the 'Classical Works,' as they are called, by taking impressions from stone plates, the letters cut into them, so that the impression on the paper was black and the letters themselves left white. This is still the case in all Chinese lithographic printing. Tong-tao, however, subsequently obtained the Emperor's sanction to cut in wood and print an edition of the nine 'King,' or classical books, for the use of the Imperial College in Peking. This was completed in 952; and, although intended only for the pupils of the college, it was made purchasable by any person in the empire. The process pursued in the printing of this work is precisely the same as at the present day, the following being the *modus operandi*:—

The work intended to be printed is handed to a caligraphist, who writes the separate pages on fine tracing-paper; these are given to the engraver, who glues them face downwards upon a thin plate of hard wood, called *li*, resembling that of the pear-tree, and he cuts away with a sharp instrument all those parts of the wood on which nothing is traced, leaving the transcribed characters in relief and ready for printing. The Chinese printer then, having no notion of the printing press, makes use of two fine brushes, both held in the right hand, one of which contains ink, the other dry. With the former he blackens the letters; the latter he passes gently over the paper which has been laid on them. By this means an expert workman can take a large number of impressions in one day. As the Chinese paper is thin and transparent, it is printed on one side only, two pages side by side, and the sheet has a black line down the middle, as a guide to the binder, who folds it double, and fastens the open leaves together. Various attempts have been made in the Celestial Empire to substitute moveable types for the wooden blocks, but they have always terminated in a return to the old method.

The ancient Romans made use of metal-stamps, with characters engraved in relief, to mark their articles of trade and commerce; and Cicero, in his 'De Naturâ Deorum,' has a passage from which Toland imagines the moderns have taken the hint of printing. Cicero orders the types to be made of metal, and calls them *formæ literarum*, the very words used by the first printers to express them. In Virgil's time, too, brands, with letters, were used for marking cattle, &c., with the owner's name. Landseer (*Lectures on the Art of Engraving*, 8vo. 1807) observes, 'Had the modern art of making paper been known to the ancients, we had probably never heard the names of Faust and Finiguerra; for with the same kind of stamps which the Romans used for their pottery and packages, books might also have been printed; and the same engraving which adorned the shields and pateras of the more remote ages, with the addition of paper, might have spread the rays of Greek and Etrurian intelligence over the world of antiquity. Of the truth of this assertion I have the satisfaction to lay before you the most decided proofs, by exhibiting engraved Latin inscriptions, both in cameo and intaglio, from the collection of Mr. Douce, with impressions taken from them at Mr. Savage's letter-press but yesterday [1805]. One of them is an intaglio stamp, with which a Roman oculist was used to mark his medicines; the other, which is of metal, and in cameo, is simply the proper name of the tradesman by whom it has probably been used. 'T[itus] Valagini Mauri.' *Fig.* 1667 is a facsimile of the latter stamp.

1667

Books before the Invention of Printing.—The value of books and the esteem in which they were held before the invention of printing, were such, that notaries were employed to make the conveyance with as much care and attention as if estates were to be transferred. It was then thought the worthy occupation of a life either to copy or collect an amount of reading which modern improvements now present to us for a few shillings. Galen tells us that Ptolemy Philadelphus gave the Athenians 15 talents, with exemption from all tribute, and a great convoy of provisions, for the autographs and originals of the tragedies of Æschylus, Sophocles, and Euripides. 'Pisistratus is said to have been the first among the earliest of the Greeks who projected an immense collection of the works of the learned, and is supposed to have been the collector of the scattered works which passed under the name of Homer.'—*D'Israeli, Curiosities of Literature.*

Among the Romans the bulk or goodness of a man's library was the distinguishing mark of his excellence or wisdom. Middleton (*Life of Cicero*), speaking of Cicero himself, says: 'Nor was he less eager in making a collection of Greek books, and forming a library, by the same opportunity of Atticus's help. This was Atticus's own passion; who, having free access to all the Athenian libraries, was employing his slaves in copying the works of their best writers, not only for his own use, but for sale also, and the common profit both of the slave and the master.'

The passion for the enjoyment of books has in all ages led their lovers to cover them with the most costly and ornamental bindings. The ancients commonly adorned them with pendent ornaments of variously-coloured cloth, and the covers were stained with scarlet or purple colour: 'Hirsutus sparsis ut videare comis' (*Ovid*), and 'Purpureo fulgens habitu, radiantibus uncis' (*Martial*). The *unci* were rollers of wood or ivory, round which the books were rolled to prevent injury to their fronts. Ovid and Tibullus call them *cornua*, from the similarity of their ends to horns. Epistles differed from books in this: the leaves were folded together, and tied round with linen tape, and sealed with *creta Asiatica*, while books were 'bound' as above. If, however, there were more epistles than one, 'or if one epistle was to be preserved in the library, it was enclosed and turned round, and not folded: hence the word *volumen*' (*Arts of the Greeks and Romans*). 'Video quod agas: tuas quoque epistolas vis referam in volumina' (*Cicero*).

The orders respecting books in the 'Close Rolls' of the Middle Ages are interesting, not only as illustrating the literary taste of the age, but principally because they generally contain some circumstance which shows the scarcity and value of the article. It was not until a period considerably subsequent to the invention of printing that the cost and rarity of books ceased to obstruct the advancement of learning and the diffusion of knowledge.

Block Books.—Incredible difficulties were encountered by those who undertook first to lay open the stores of ancient learning, from the scarcity of MSS.; for the literary treasures of antiquity had suffered from the malice of men as well as from the hand of time. The time had now come, however, when the world's inheritance of the knowledge of Greece and Rome was to be secured from any further destruction. The art of printing books from engraved blocks of wood was no doubt invented in Holland; and, apart from the great interest created by the object for which the block books were designed, namely, the propagation of the Scriptures (being, as it were, the forerunner of the Reformation), they are extremely valuable as exhibiting the first attempts at engraving on wood in the form of books, many of them having preceded the art of printing by moveable types.—*Sotheby's 'Block Books.'*

But that prints without text, or letter-press as it is termed, were in common use at a period considerably anterior to that of the block books there is abundant evidence. It is related by Papillon, (*Traité Historique et Pratique de la Gravure en Bois*,) that the heroic actions of Alexander the Great were engraved on wood by the two Cunio, Alexander Alberic and his sister Isabella, and impressions printed from the blocks as early as 1285; and his statement has been supported by Ottley, ('Early Hist. of Engraving upon Copper and Wood, &c.,' 2 vols. 4to. 1816,) and Singer, ('Hist. of Playing Cards, &c.,' London, 4to. 1816). But Jackson, ('Hist. of Wood Engraving,') takes some trouble to prove that Papillon was excessively credulous, if not deranged. Towards the end of the fourteenth century, too, playing cards were engraved and printed for the amusement of Charles VI. King of France, who reigned from 1380 to 1421. The print of St. Christopher carrying the infant Saviour on his back across the sea, in the collection of Earl Spencer, bears an inscription and the date 1423 at the bottom of the same block; but one in the possession of Mr. J. A. G. Weigel of Leipsic is supposed to be the work of even an earlier artist.[1] These circumstances, together with the fact that the Government of Venice published a decree, dated October 11, 1441, wherein the art and mystery of making 'playing cards and coloured figures printed' are stated to have fallen into decay in consequence of the great quantity which had been made out of that state, and which were now prohibited under pain of forfeiture and fine,[2] all prove that the knowledge and practice of printing, although not applied to the spread of knowledge and the multiplication of books, had yet an existence in Europe long before the time to which it is usually attributed.

When the substructure had been completed, the work was pursued with the utmost eagerness. Great numbers of books were produced, evidently in the Chinese manner above described; for the diversity of the characters found in block books has been a never-ending puzzle to those who have endeavoured to ascertain the printer by comparison of the formation of the letters used. The workmanship of many of these picture-books was of a coarse description, without shadowing or 'cross-hatching,' tastelessly daubed over with broad colours, especially those printed for circulation amongst the poorer classes. Those best known of this class were called *Biblia Pauperum*, poor men's books, or rather books for poor preachers, and consisted of a series of rude engravings, each occupying a page, but divided into compartments containing pictorial illustrations of the most remarkable incidents mentioned in the Books of Moses, the Gospels, and the Apocalypse.

Invention of Moveable Types.—Gutenberg.—About the year 1438, while the learned Italians were eagerly deciphering their recently-discovered MSS., and slowly circulating them from hand to hand, it fell to the lot of a few obscure Germans to perfect the greatest discovery recorded in the annals of mankind. The notion of printing by moveable types, and thereby saving the endless labour of cutting new blocks of letters for every page, was reserved for John Gutenberg of Mayence. Born in that city about the beginning of the century, he settled at Strasburg about 1424, and commenced printing in the house of one Dritzehen. But having been engaged in a lawsuit connected with Dritzehen's family, and exhausted his means, he returned to Mayence, where he resumed his typographic employment in partnership with a wealthy goldsmith, named John Fust or Faust. After many experiments with

[1] A copy of Mr. Weigel's print may be seen in Sotheby's 'Block Books,' vol. ii. p. 161.
[2] This must be regarded as the earliest authentic document respecting Printing.

his presses and moveable types, Gutenberg succeeded in printing an edition of the Vulgate, the Mayence or Mazarin Bible, so called from a copy having been discovered in the library of Cardinal Mazarin in Paris. The work was done between the years 1450 and 1455, and was printed on vellum; but there are several paper copies in England, France, and Germany. The partnership between Gutenberg and Fust having been dissolved, and the former being unable to repay part of the capital advanced by the wealthy goldsmith, the whole of the printing apparatus fell into the hands of Fust, who 'printed off a considerable number of copies of the Bible, to imitate those which were commonly sold as MSS.; and he undertook the sale of them at Paris. It was his interest to conceal this discovery, and to pass off his printed copies for MSS. But, enabled to sell his Bibles at sixty crowns, while the other scribes demanded five hundred, this raised universal astonishment; and still more when he produced copies as fast as they were wanted, and even lowered his price. The uniformity of the copies increased the wonder. Informations were given in to the magistrates against him as a magician; and in searching his lodgings a great number of copies were found. The red ink,—and Fust's red ink is peculiarly brilliant,—which embellished his copies, was said to be his blood; and it was solemnly adjudged that he was in league with the infernals. Fust at length was obliged, to save himself from a bonfire, to reveal his art to the Parliament of Paris, who discharged him from all prosecution in consideration of the wonderful invention.'—*D'Israeli, Curiosities of Literature.*

This Bible was printed with large *cut* metal types; but in 1457 a magnificent edition of the 'Psalter' appeared, printed by Fust and his assistant and son-in-law, Peter Schœffer, who had been taken into partnership. In this book the new invention was announced to the world in 'a boasting colophon,' though certainly not unreasonably bold. Another edition of the 'Psalter,' one of an ecclesiastical book, Durand's account of Liturgical Offices,[1] one of the Constitutions of Pope Clement V., and one of a popular treatise on general science, called the Catholicon,[2] filled up the interval till 1462, when the second Mayence Bible proceeded from the same printers. This, in the opinion of some, is the earliest book in which *cast* metal types were employed; those of the Mazarin Bible having been cut by the hand. But this is a controverted point. In 1465 Fust and Schœffer published an edition of Cicero's 'Offices,' the first tribute of the new art to polite literature.—*Hallam, Europe during the Middle Ages*, vol. iii. p. 470.

After the lapse of a few years the pupils and workmen of Fust and Schœffer, dispersed into various countries by the sacking of Mayence, under the Archbishop Adolphus, the invention was thereby publicly made known, and the art spread over all parts of Europe. Before the year 1500, printing presses had been set up in 220 places, and a multitude of editions of the classical writers given to the world. Santander (*Dictionnaire Bibliographique choisi du quinzième Siècle*, &c., Bruxelles, 1805, 3 vols.), in his interesting and masterly work, gives at the end of his first volume a chronological table of 200 places where the art was practised during the 15th century, with the names of the printers and of the first productions of their presses. We cannot afford room for this list; but must be content to state that from Mayence the art was transplanted to Haarlem and Strasburg; from Haarlem to Rome, in 1466, by Sweynheym and Pannartz, who were the first to make use of Roman types; to Paris in 1469; to England in 1474; and to Spain in 1475; and spread so rapidly that, between the years 1469 and 1475, most towns in Germany, Italy, and the Netherlands had made successful attempts in the production of printed copies of the most valued authors of the time.

Printing in England.—Until about the period of the Restoration, William Caxton was universally acknowledged to have introduced the art of printing into this country. in or about the year 1471. But, in 1664, a Mr. Richard Atkyns, in a work called 'The Original and Growth of Printing,' &c., brought before the notice of the curious a little book, printed at Oxford, bearing the date 1468, three years before the period usually assigned to the labours of Caxton. This work took literary men by surprise, and gave rise to the most violent discussions. It is related by Atkyns that a Dutchman of the name of Frederic Corsellis was induced to desert his employers in the Low Countries, and that one Richard Turnour, an agent of King Henry VI., assisted by William Caxton, who was well known in Holland as a merchant, and therefore likely to throw the jealous possessors of the new art off their guard, brought him to England, where at Oxford he was set to work by Archbishop Bourchier, ten years before the date of Caxton's first book.[3] But the silence of Caxton

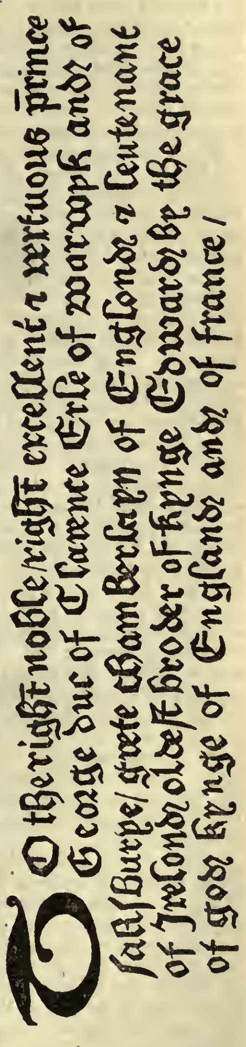
[1] 'Rational Divinorum Officiorum' of William Durand, 1459.

[2] 'Catholicon Jannensis,' 1460, in the King's Library.

[3] The title of this volume of Corsellis is, 'Exposicio Sancti Jeronimi in Simbolum Apostolorum ad Papam Laurentiam,' and at the end, 'Explicit Exposicio, &c. Impressa Oxonis, et finita Anno Domini MCCCCLXVIII., XVII die Decembris."

on a subject in which he took the utmost interest, and in which it is stated on this occasion he was an important actor, is a strong argument against the authenticity of the story. Indeed, M. Santander (vol. i. p. 328) does not for a moment entertain the pretensions of Corsellis, and agrees with Dr. Conyers Middleton in considering that the date MCCCCLXVIII. ought to have been MCCCCLXXVIII., an X having been by accident omitted by the compositor:—'Voilà ce que Richard Atkyns imagina, et les moyens dont il se servit, en 1664, pour soutenir contre le corps des libraires de Londres, que l'imprimerie était un droit de la couronne en Angleterre. Mais le docteur Middleton, dans sa "Dissertation sur l'Origine de l'Imprimerie en Angleterre," imprimée à Cambridge, en 1734, in 4°, a prové démonstrativement, que l'impression d'Oxford, de "l'Expositio S. Jeronimi in Simbolum Apostolorum," est de l'an 1478, le compositeur ayant omis un X dans la date de la souscription (faute typographique dont nous avons plusieurs exemples dans les impressions du XV^e^ siècle).' Amongst other examples of blunders of this description, the learned Doctor observes:—'But whilst I am now writing, an unexpected instance has fallen into my hands, to the support of my opinion; an "Inauguration Speech of the Woodwardian Professor, Mr. Mason," just fresh from the press, with its date given ten years earlier than it should have been, by the omission of an X, viz. MDCCXXIV.; and the very blunder exemplified in the last piece printed at Cambridge, which I suppose to have happened in the first from Oxford.'

1668



Whether, however, Caxton was or not the first English printer, it is quite certain that he was the first who made use of cast metal types, the works of Corsellis having been executed with merely wooden ones. During a long residence abroad he had acquired a practical knowledge of the art; and on his return to England in 1471, set up a press at Westminster Abbey, in an old chapel[1] adjoining that edifice; and was for many years engaged in translating and printing books on a variety of subjects. His first work is 'Le Recueil des Histoires de Troyes' of Raoul le Fevre, chaplain to the Duchess of Burgundy; but 'The Dictes and Sayinges of the Philosophers' is the earliest book known to have issued from his press with the date and place of printing; and we have no proof at all that his six earlier works[2] were printed in this country. Indeed, it is stated in the Life of Caxton, in Ames's 'Typ. Antiquities,' p. xcv, that the French and English editions of the 'Histories of Troy' are justly 'admitted to have been printed abroad.'

The types used in Caxton's works, as well as in those of most of the early printers, were the Gothic or *black-letter* characters, said to have been invented by Ulphilas, first bishop of the Mœso-Goths. A facsimile of Caxton's types is here annexed, *fig.* 1668, showing the formation of his letters; and proving to our mind that, as compared with the specimens we have seen of the characters used by the Oxford printer Corsellis, they have an undoubted claim to the greater antiquity.

Caxton is said to have printed 64 books; and was followed by his pupils or assistants, Theodore Rood, John Lettou, William Machilinia, and Wynkyn de Worde, all foreigners, and Thomas Hunt, an Englishman. All these pioneers of the art worthily maintained the honour of their master's name; and Wynkyn de Worde is especially remarkable for his improvements and typographical excellence, and as having been the first printer in England who introduced the Roman letter. He printed 410 works.

[1] From which circumstance an assemblage of printers is to this day called a 'chapel.'

[2] Viz. 1. 'Le Recueil des Histoires de Troyes;' 2. 'Propositio clarissimi oratoris Magistri Johannis Russell,' &c.; 3. 'Recuyell of the Histories of Troye'; 4. 'The Game and Playof the Chesse;' 5. The same; and 6. 'A Boke of the hoole Lyf of Jason.'

The spirit and taste of the patrons of the first printers are shown in the character of their earliest works, religious books and romances constituting the greater part of the productions of the father of English printing. But the art, although at first countenanced by the clergy, was soon looked upon with extreme jealousy by the Church. Efforts were made towards the publication of the Word of God; but for the first 60 or 70 years all copies of the Scriptures were printed in the Latin or some other language, not understood by the generality of the people. A new era had, however, arrived. The doctrines of the Reformation had proclaimed the Bible as man's best guide and teacher, and the people yearned to possess Bibles. Wickliffe's translation was never printed. The part of the Sacred Writings in the English language first produced by the printing press was the New Testament, translated by William Tindal, assisted by Miles Coverdale, afterwards Bishop of Exeter: it was printed at Antwerp, in 1526; but as it gave offence to Wolsey and the Church, the whole impression was bought up and burnt. The first complete English Bible printed by authority was Tindal's version, revised and compared with the original by Coverdale, and afterwards examined by Cranmer, who wrote a preface for it. Of this edition, hence called 'Cranmer's Bible,' 500 copies were printed by Grafton and Whitchurch, to whom Henry VIII., in letters patent, dated November 13, 1539, granted the sole right of printing the Bible for five years. It was ordered by royal proclamation to be set up in all churches throughout the kingdom, under a penalty of 40*s.* a month in every case of neglect. So great was the demand for copies of the Scriptures in the 16th century, that we have in existence 326 editions of the English Bible, or parts of the Bible, printed between 1526 and 1600.

The progress of the art in the first century of its existence was remarkable; but the earliest English printers did not attempt what the Continental ones were doing for the ancient classics. 'Down to 1540, no Greek book had appeared from an English press; Oxford had only printed a part of Cicero's Epistles; Cambridge no ancient writer whatever. Only three or four old Roman writers had been reprinted, at that period, throughout England. But a great deal was done for public instruction by the course which our early printers took; for, as one of them says: "Divers famous clerks and learned men translated and made many noble works into our English tongue, whereby there was much more plenty and abundance of English used than there was in times past." The English nobility were, probably, for more than the first half-century of English printing, the great encouragers of our press:—they required translations and abridgments of the classics, versions of French and Italian romances, old chronicles, and helps to devout exercises. Caxton and his successors abundantly supplied these wants, and the impulse to most of their exertions was given by the growing demand for literary amusement on the part of the great. Caxton, speaking of his "Boke Eneydos," says: "This present book is not for a rude uplandish man to labour therein, nor read it; but only for a clerk and a noble gentleman, that feeleth and understandeth in feats of arms, in love, and in noble chivalry." But a great change was working in Europe; the "rude uplandish man," if he gave promise of talent, was sent to school. The priests strove with the laity for the education of the people; and not only in Protestant but in Catholic countries were schools and universities everywhere founded. Here, again, was a new source of employment for the press—A, B, C's, or Absics, Primers, Catechisms, Grammars, Dictionaries, were multiplied in every direction. Books became, also, during this period, the tools of professional men. There were not many works of medicine, but a great many of law. The people, too, required instruction in the ordinances they were called upon to obey; and thus the Statutes, mostly written in French, were translated and abridged by Rastell, our first law-printer.

'After all this rush of the press of England towards the diffusion of existing knowledge, it began to assist in the production of new works, but in very different directions. Much of the poetry of the sixteenth century, which our press spread around, will last for ever: its controversial divinity has, in great part, perished. Each, however, was a natural supply, arising out of the demand of the people; as much as the chronicles, and romances, and grammars were a natural supply; and as the almanacks, and mysteries, and ballads, which the people then had, were a natural supply. Taken altogether, the activity of the press of England, during the first period of our enquiry, was very remarkable. Ames and Herbert have recorded the names of 350 printers in England and Scotland, or of foreign printers engaged in producing books for England, that flourished between 1471 and 1600. The same authors have recorded the titles of nearly 10,000 distinct works printed amongst us during the same period. Many of these works, however, were only single sheets, but on the other hand, there are, doubtless, many not here registered.' Dividing the total number of books printed during these 130 years, we find that the average number of distinct works produced each year was 75.'—*Penny Magazine.*

The first book in which Greek types occur is Cicero's 'Offices,' printed in the year 1465, in which the characters are so imperfect that the words are with difficulty deciphered; but the first work printed wholly with Greek types is a Greek Grammar, written by the learned Constantine Lascaris, printed in Milan by Dionysius Paravisinus, in 1476, in 4to. It went through several editions in Italy, France, and Switzerland. One of them, that of Aldus, printed in Venice in 1495, is the first Aldine book printed with a date. One of the most elegant specimens of ancient Greek typography, valued not only for its beauty, but also for its rarity and the accuracy of its text, is the 'Argonautica, Flor. ap Junta, 1500,' 4to. *editio princeps.*

It was not unusual for the early printers of Greek, as well as of other works, to endeavour to imitate the characters of the MSS. of the age. In this they were more or less successful. An exceedingly beautiful specimen of this kind of printing is the *editio princeps* of Isocrates: 'Orat. à Demetrio Chalcondyla, Gr. Mediol. ap. Henr. Germanus et Sebastianus ex Pontremula,' 1493, folio. The text of this edition is said to be remarkably accurate. Fabricius considers it more so than that of the Aldine edition of 1513.

The first Greek book printed in Rome was the works of Pindar: 'Pindari Opera Gr. cum Scholiis Callieggi.' Rome, 1515, 4to. This is also remarkable as the first edition with the Scholia. The first Greek work printed at Cambridge was Plato's 'Menexenus, sive Funebris Oratio, Exhortatio ad Patriam amandam atque defendam. Cantab.' Greek types were not introduced into Scotland till after the middle of the 16th century. In a 4to. volume printed in Edinburgh in 1563, entitled, 'The Confutation of the Abbote of Crosraguel's Masse,' there is an Epistle by the Printer to the Reader, apologising for his want of Greek characters, which he was obliged to supply by manuscript.

The first work printed with Roman types was Cicero's 'Epistolæ Familiares,' by Sweynheym and Pannartz, at Rome, in 1467. Italic type was invented by Aldus Manutius, about 1500.

Italy has the honour also of having printed the first Hebrew Bible, at Soncino, a small city in the Duchy of Milan, in 1488, under the superintendence of two Jewish rabbins, named Joshua and Moses. The edition of Brescia, of 1494, was used by Luther in making his German translation. But Hebrew types were not introduced into England for many years after this period; for we find that in 1524, Dr. Robert Wakefield, chaplain to Henry VIII., complains, in his 'Oratio de Laudibus,' &c., that he was obliged to omit his whole third part, as the printer (Wynkyn de Worde) had no Hebrew types. Towards the end of the 16th century, various works were printed in Syriac, Arabic, Persian, Armenian, and Coptic or modern Egyptian types; some to gratify the curiosity of the learned, and others for the liturgic uses of the Christians in the Levant.

In the 16th century the broils consequent on the Reformation, although that event stimulated religious enquiry, did much to impede the progress of the art in England. But the civil wars and the gloomy religious spirit which succeeded till the pedantry and verbal criticism of the reign of James I., and which prevailed to the Restoration, interrupted still more the production of works calculated to cultivate the understanding. Indeed, we cannot but regard this period as the least favourable to the diffusion of knowledge of any period in the history of our literature. In the British Museum is a collection of controversial and quibbling tracts amounting to the enormous number of 30,000,[1] while the impressions of new books printed during these stormy times were very few. Dr. Johnson has well remarked that the nation, from 1623 to 1664, was satisfied with two editions of Shakspeare's Plays, which, probably, together did not amount to a thousand copies. But during this period we must not forget the present Authorised Version of the Bible, translated by the forty-seven distinguished scholars appointed by James I., and printed in 1611, which is allowed by competent judges to be one of singular merit, and indeed the most perfect ever produced. An unfavourable effect was also produced on our national literature, and on the progress of the press, by the licentiousness introduced by the literary parasites and courtezans of the Restoration. Under such a state of mental depression, Milton could obtain only 15*l.* for the MS. of his immortal 'Paradise Lost,' and an Act of Parliament was actually in force enacting that only twenty printers should practise their art in the whole kingdom! Burton, who lived near this time, has drawn a miserable picture of the abject condition of literary men when they had such patrons to rely upon:—'Rhetoric only serves them to curse their bad fortunes; and many of them, for want of means, are driven to hard shifts. From grasshoppers they turn humble-bees and wasps, plain parasites, and make the Muses mules, to satisfy their hunger-starved paunches and get a meal's meat.'

[1] Tomlinson's Collection.

In addition to these impediments, the Crown endeavoured, in the reign of Charles II., to destroy the activity of the press; 'and in this it had the example not only of all former reigns (in which nothing had been legally published without a license), but of the Long Parliament itself, which had laid severe restrictions upon the printing of "scandalous and unlicensed papers." At one time, indeed, it was ordered that no printing should be carried on anywhere but in the City of London and the two Universities; and all London printers were to enter into a bond of 300*l.* not to print anything against the Government, or without the name of the author (or at least of the licenser) on the title-page, in addition to their own.'—*Eccleston's Eng. Antiquities*, p. 325.

It has been ascertained, by counting, that the whole number of books printed during the fourteen years from 1666 to 1680, was 3,550; of which 247 were divinity, 420 law, and 153 physic, so that two-fifths of the whole were professional books; 397 were school-books, and 253 on subjects of geography and navigation, including maps. Taking the average of these fourteen years, the total number of works produced yearly was 253; but deducting the reprints, pamphlets, single sermons, and maps, we may fairly assume that the yearly average of new books was much under 100. Of the number of copies constituting an edition we have no record; we apprehend it must have been small, for the price of a book, so far as we can ascertain it, was considerable.

The period from the accession of George III. to the close of the 18th century is marked by the rapid increase of the demand for popular literature, rather than by any prominent features of originality in literary production. Periodical literature spread on every side; newspapers, magazines, reviews, were multiplied; and the old system of selling books by hawkers was extended to the rural districts and small provincial towns. Of the number-books thus produced, the quality was indifferent, with a few exceptions; and the cost of these works was considerable. The principle, however, was then first developed, of extending the market, by coming into it at regular intervals with fractions of a book, so that the humblest customer might lay by each week in a savings'-bank of knowledge. This was an important step, which has produced great effects, but which is even now capable of a much more universal application than it has ever yet received. Smollett's 'History of England' was one of the most successful number-books; it sold to the extent of 20,000 copies.

We may exhibit the rapid growth of the publication of new books, by examining the catalogues of the latter part of the eighteenth century, passing over the earlier years of the reign of George III. In the 'Modern Catalogue of Books,' from 1792 to the end of 1802, eleven years, we find that 4,096 new works were published, exclusive of reprints not altered in price, and also exclusive of pamphlets: deducting one-fifth for reprints, we have an average of 372 new books per year. This is a prodigious stride beyond the average of 93 per year of the previous period. But we are not sure that our literature was in a more healthy condition. From some cause or other, the selling price of books had increased, in most cases 50 per cent., in others, 100 per cent. The 2*s.* 6*d.* duodecimo had become 4*s.*; the 6*s.* octavo, 10*s.* 6*d.*; and the 12*s.* quarto, 1*l.* 1*s.* It would appear from this that the exclusive market was principally sought for new books; that the publishers of novelties did not rely upon the increasing number of readers; and that the periodical works constituted the principal supply of the many. The aggregate increase of the commerce in books must, however, have become enormous, when compared with the previous fifty years; and the effect was highly beneficial to the literary character. The age of patronage was gone.

According to the Census of 1861, upwards of 26,000 persons are employed in printing and 11,000 in bookbinding.

Printing in Scotland.—Printing was introduced into Scotland, and begun in Edinburgh, about 30 years after Caxton had brought it into England. Mr. Watson, in his 'History of Printing,' says that the art was introduced into Scotland from the Low Countries by the priests who fled thither from the persecutions at home. Be this as it may, we find James IV. granting a patent in 1507 to Walter Chapman, a merchant of Edinburgh, and Andrew Mollar, a workman, to establish a press in that city. According to bibliographers, the most ancient specimen of printing in Scotland extant is a collection, entitled the 'Porteus of Nobleness,' Edinburgh. In 1509, a 'Breviary of the Church of Aberdeen' was printed at Edinburgh; and a second part in the following year. Very few works, however, appear to have issued from the Scottish press for the next 30 years; but from 1541, the date from which we find James V. granting licenses to print, the art has been pursued with success in the metropolis. At present, and from the beginning of the present century, it is perhaps the most distinguished craft in the city, being conducted in all its departments of type-founding, printing, publishing, and, we may add, paper-making at the mills in the vicinity.

Ireland.—Printing was not known in Ireland till about the year 1551, when a book in black letter was issued from a press in Dublin; but till the year 1700 very little printing was executed in Ireland, and even since that period the country has acquired little celebrity in this department of the arts, although possessing some respectable printing establishments.

America.—The art of printing has readily taken root and flourished among the civilised inhabitants of North America. The first printing press established in the American colonies was one set up at Cambridge, in Massachusetts, in the year 1638, the era of the foundation of Harvard College of that place. It was only established by the exertions and joint contributions of different individuals in Europe and America; and there is no doubt that the mechanism and types were imported from England. The first work which issued from this press was the 'Freeman's Call,' and the second the 'Almanac for New England,' both in 1639; the first book printed was the New England version of the Psalms, an octavo volume of 300 pages. In 1676 books began to be printed at Boston; in 1686 printing became known in Philadelphia; and in 1693 in New York. In the year 1700 there were only four printing presses in the Colonies. Since that period, and especially since the revolution, which removed everything like a censorship of the press, the practice of the art has undergone enormous expansion. Among the occupations enumerated in the Census of 1850 were 14,740 printers and 3,414 bookbinders. In their style of typography and bookmaking the Americans are still inferior to the English, sacrificing beauty and durability to economy and despatch.—*Chambers's Information.*

France.—The activity of the French press has very greatly increased since the time of the first Napoleon. Count Daru, in 1827 (*Notions Statistiques sur la Libraire*), estimated the number of printed sheets (exclusive of newspapers) produced by the French press in 1816, at 66,852,883; and it appears that in 1836 the number of printed sheets (exclusive of newspapers) had increased to 118,857,000; so that it may now be fairly estimated at from 130,000,000 to 140,000,000 of sheets. The quality of many of the works which have issued from the French press is also very superior, such as the 'Biographie Universelle,' the 'Art de vérifier les Dates,' and 'Bayle's Dictionary;' and it is doubted whether such books could have been published in any other country.

Germany.—The German printing press is always in a state of the greatest activity; and the trade in books is very much facilitated by the book-fairs of Leipzic, the Easter fair especially being frequented by all the booksellers of Germany, besides those of France, Switzerland, Denmark, Livonia, &c., in order to settle their mutual concerns and form new connections. In 1814 began a literary deluge, which still continues to increase. For the 5,000 works which then sufficed for the annual demand, we have now from 6,000 to 8,000. Private libraries are diminishing, and the public ones are daily increasing.

In Austria the printing press has made rapid strides of late years. The Imperial Printing-office in Vienna, under the able management of M. Auer, has become an establishment of the highest interest. At the Exhibition of 1851, he presented to the notice of the public a collection of the Lord's Prayer, printed with Roman type in 608 languages and dialects, the second section of which contained 206 languages and dialects, printed in the characters proper to the language of the respective nation. He has collected together the following founts, many of which are, however, to be found in the British type-foundries:—

Russia.—The art was not introduced into Russia till the year 1560, when it was made known by a Russian merchant, who conveyed thither the materials of a printing-office, with which many neat editions were printed. But as the Russians are a very superstitious nation, and apt to raise scruples without any foundation, some of them, apprehending that printing might make some confusion or change in their religion, hired men to destroy the types and presses. No attempt was made to repair this injury or to discover the perpetrators of this fact. However, since that time they have admitted the press into Moscow and St. Petersburg, where until recently it made but slow progress.

Turkey.—The total number of books printed in Constantinople during the years 1871 and 1872 were 169, of which 39 were on theology and legislation, 38 on moral literature and poetry, 28 on history and biography, 26 on various sciences, and 38 on linguistic subjects. The Turkish Imperial Printing-office showed the greatest activity in its publications, having turned out from its presses in the year 1871 alone 46,000 volumes for commercial and general purposes, and 74,000 volumes destined for the use of schools, and in 1871 50,880 of the former description and 45,000 of the latter. —*Levant Herald.*

Peculiarities of Early Printed Books.—The following are the points peculiar to the productions of the first printers:—

1. Their forms were generally either large or small folio, or at least quarto; the lesser sizes were not in use.

2. The leaves were without running title, direction word, number of pages, or divisions into paragraphs.

3. The character itself was a rude old gothic, mixed with secretary, designed on purpose to imitate the handwriting of those times; the words were printed so close to one another that it was difficult and tedious to be read, even by those who were used to manuscripts and to this method, and often led the inattentive reader into mistakes.

4. Their orthography was various and often arbitrary, disregarding method.

5. They had very frequent abbreviations, which in time grew so numerous and difficult to be understood, that it became necessary to write a book to teach the mode of reading them.

6. Their periods were distinguished by no other points than double or single ones, that is, the colon and full point; but a little after they introduced an oblique stroke, thus /, which answered the purpose of our comma.

7. They used no capital letters to begin a sentence, or for proper names of men or places.

8. They left blank spaces for titles and initial letters or other ornaments, in order to have them supplied by the illuminators, whose art, though in vogue before and after that time, did not long survive the improvements made by the printers in this branch of their art. These ornaments were exquisitely fine, and curiously variegated with the most beautiful colours, and even with gold and silver; the margins likewise were frequently charged with every variety of figures of saints, birds, beasts, monsters, flowers, &c., which had sometimes a relation to the contents of the page, though often none at all. These embellishments were costly, but for those who could not afford a great price, there were inferior ornaments, which could be done at a much cheaper rate.

9. The name of the printer, his place of residence, &c. &c., were wholly omitted, or put at the end of the book, not without some pious ejaculation or doxology.

10. The date was likewise omitted or involved in some circumstantial period, or else printed either at full length, or by numerical letters, and sometimes partly one way and partly the other, thus, one thousand CCCC and lxxiii., &c., but always at the end of the book.

11. There was no variety of characters, no intermixture of Roman and Italic, these being of later invention, but their pages were continued in a Gothic letter of the same size throughout.

12. They printed but a few copies at once, for 200 or 300 was then esteemed a large impression, but upon encouragement from the learned, they increased their numbers in proportion.

Newspapers, &c.—The period of the English Revolution will be ever memorable in the literary history of this country for the establishment in great part of periodical literature. But English newspapers, properly so called, date from the first year of the Long Parliament, the oldest that has been discovered being a quarto pamphlet of a few leaves, entitled 'The Diurnal Occurences, or Daily Proceedings of both houses in this great and happy Parliament, from the 3rd November, 1640, to the 3rd of November, 1641. London: printed for William Cooke, and are to be sold at his shop at Furnival's Inn Gate, in Holborn, 1641.' (*Fig.* 1669.) More than 100 papers with different titles appear to have been published from this time to the death of the king, and upwards of 80 from that date to the Restoration. These were at first published weekly; but, as the interest increased, twice or thrice a week; and even, it would seem, daily, at least for a time. Such were the 'French Intelligences,' the 'Dutch Spy,' the 'Scots Dove,' &c.; but 'Mercuries' of all sorts were the favourite title. Thus they had 'Mercurius Acheronticus,' 'Mercurius Democritus,' 'Aulicus,' 'Britannicus,' 'Laughing Mercury,' and 'Mercurius Mastix,' which last faithfully lashed all the rest. The great newspaper editors of the day were Marchmont Needham on the Presbyterian, and Sir John Birkenhead on the Royalist side. These were followed by Sir Roger l'Estrange, who has also been ranked amongst the patriarchs of the newspaper press. Pamphlets were also issued in prodigious numbers during those troubled times; the average being calculated at four or five new ones every day.—*Eccleston's English Antiquities.*

1669

In 1709, one daily paper, fifteen papers, three times a week, and one twice a week, were published in the metropolis. In 1724 there were three daily, six weekly, and ten three-times-a-week papers, in London; and provincial newspapers had been established in various places. The reign of Queen Anne also witnessed a new and most successful species of literature—the issue of the 'Guardian,' 'Spectator,' and other such literary sheets, published at short intervals. The strong good sense of Cave, the printer, originated the 'Gentleman's Magazine,' which completely established the principle that the patronage of men of letters is best confided to the people, and not to the great and fashionable. This publication soon had rivals to contend with in the 'Monthly,' 'European,' 'London,' and 'Critical;' but it has survived them all; and a complete set of 'The Gentleman' is highly prized at the present day, and is extremely amusing and valuable.

The first newspaper published in Scotland was the 'Caledonian Mercury,' in 1660, under the title of 'Mercurius Caledonius;' but its publication was soon after interrupted. In 1750 a newspaper was, for the first time, attempted in Glasgow.

The increase of newspapers in America has been much more rapid than in this country; in consequence partly, no doubt, of the greater increase of population in the Union, but more probably of their freedom from taxation, and of the violence of party contests. According to a return published some few years back, the aggregate circulation of papers and other publications was about 5,000,000; and the entire number of copies printed annually in the United States amounted to about 422,600,000 annually.

The first newspaper published in the West Indies is said to have been the 'Barbadoes Mercury.' It was established in 1733, and died in 1852.

Practice of Printing.—The workmen principally employed in printing are of two kinds: *compositors*, who *set up* the types into lines and pages according to the MS. or *copy* furnished by the author; and *pressmen*, who apply ink to the surface of the *form* of types, and take off the impressions upon paper.

Composition.—The mode of proceeding described hereafter is that which is pursued in most of the extensive establishments in London:—The first thing to be done, when the sizes of page, type, and paper, are determined on, is to look over the MS., and see that it is correctly paged. It is then handed to a *clicker*, or foreman of a *companionship*, or certain number of compositors, each of whom has a *taking of copy*, or convenient portion of MS., given to him, to be set up in type.

Types.—Although most of the early printers were type-founders themselves, it does not appear in any prologue or colophon to the books printed by Caxton that he lays claim to the title of type-founder. It would appear that he obtained his type, which is precisely of the same character as that of John Brito of Bruges, from that city, or from the same founders who supplied or manufactured it for John Valdener of Utrecht. But as the art extended the workmanship became inferior; 'so that while the productions of the first printers were executed in a very superior style, and the embellishments showed a great proficiency both in design and engraving, the productions of their competitors had all the crudeness and imperfection of a new invention; and in the 17th century it had retrograded to a very low state. At the commencement of the 18th century, Caslon made great improvements in types; as also, Baskerville of Birmingham, in 1750, both in types and printing: which were subsequently carried on by Besley, Bulmer, Clowes, Corrall, Davison, McCreery, Spottiswoode, Whittingham, and a few others in London; by the Foulis, in Glasgow; the Ballantynes, in Edinburgh; by Bodoni at Parma; by Didot in Paris;' and by Brockhaus in Leipzic.

Printers' types (from τύπος, *tupos*, literally *a blow*, hence the mark left by a blow,) are of great variety in size, amounting to forty or fifty: the smallest is called *Brilliant*, but is seldom used; *Diamond* is a size larger, and *Pearl* larger still, which latter type is used for printing the smallest Bibles and Prayer-books.

The following is a view of the comparative sizes used in printing books:—

Diamond . . .	To the art of printing it is acknowledged we owe the Reformation. It has been justly remarked that

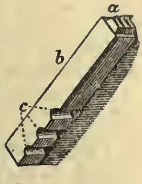
Small Pica . .	To the art of printing it is acknowledged we owe
Pica	To the art of printing it is acknowledged we
English . . .	To the art of printing it is acknowled
Great Primer .	To the art of printing it is ack

The larger sizes, used for printing bills posted in the streets, or broadsides, are usually called *Double Pica*, *Two-line Pica*, *Two-line English*, *Five-line Pica*, *Ten-line Pica*, and so on. A complete assortment of printing types of one size is called a *fount*, and the fount may be regulated to any weight. Type-founders have a scale, or *bill*, as it is called, of the proportional quantity of each letter required for a fount. The letter *e*, as will be seen from the *bill* on the following page, is used more, and the letter *z* less, frequently than others.

In setting up indexes and similar matter, the capitals mentioned would be considerably deficient. This would also be the case with French and Italian works, where accented letters are used in great numbers.

The type itself is a thin metallic bar, an inch in length (see *fig.* 1670), which represents the letter *m*: *a* is the face, *b* the *body*, and *c* the *nicks* or notches. Whatever size of type is used, each letter must be perfectly true in its angles, otherwise the form could never be *locked up*. Besides letters, there are types for commas, periods, quotation-marks, semicolons, and all other characters used in printing.

1670



Type-metal is an alloy of lead and antimony, the usual proportions being one part of antimony to three of lead; but a superior and harder kind is sometimes made by alloying two parts of lead with one of antimony and one of tin. Both of these alloys take a sharp impression from the mould or matrix, owing to their expansion on solidification, and they are hard enough to stand the work of the press, without being brittle or liable to fracture. Roman and Italic types are the letters most commonly used in printing books in Europe and America, and these have undergone every change in form that fancy or taste could suggest: *fat-faced*, or those which print black; *skeleton*, or those which print with a fine, uniform line; *antique*, or those with an almost uniform thickness, but strong and heavy; *clarendon*, a modification of antique; *expanded*, or letters widened horizontally; *Elzevir* and *compressed*, or tall thin letters; *Baskerville*, a good, round, bold face; *Italic*, inclining to the left, as well as to the right; and all the varieties of *church-text*, *German-text*, *Gothic*, and *Elizabethan*; *old cut* and *old style*; *script*, &c. The scale of sizes given on p. 642, from Savage, shows the variations in the depth of the type cast by the different founders.

Bill of Pica.—Weight 800 Pounds.—Italic $\frac{1}{10}$th.

In Moxon's time, in 1683, it will be seen that there were only ten types with specific names, whereas, we have now twenty-one.

The materials from which types and stereotype-plates are cast are technically called *metal*, and consist of certain proportions of lead, tin, and antimony, melted together. Until recently, types were always cast in little moulds held in the hands, the melted metal being poured in from a small ladle; but now they are thrown off with great rapidity by machinery. The type-casting machine consists of a mould, constructed so as, by means of a crank, to open for the purpose of letting the type drop out, and then to shut together again very closely and exactly; the opening and shutting being performed every time the crank is turned once round. Each time the crank revolves, and is brought up to the furnace-mouth (a small orifice not much larger than a pin-hole), and takes a supply of metal. This metal is driven by a force-pump in a reservoir, worked by the crank, into the mould, and the type is formed. The types are then rubbed smooth upon stones; *set up*, or arranged in rows, for inspection by the *dresser*, who carefully examines them, and rejects those which are bad, giving the perfect ones the finishing touch. The most complete process is, perhaps, that of Messrs. Johnson and Atkinson. A double line of grooves is placed side by side. At one end is a reservoir of molten lead, to which the mould is brought; a jet of metal is thrown into the mould, which then opens, and deposits the type on a travelling apparatus in the groove. As the groove fills, it is impelled along, and in its progress, the shanks are taken off. At the end, the position of the type is reversed by the machinery into the returning groove, in which it is rubbed, dressed, has the bottoms planed, and the nicks cut. On arriving at the exit end of the groove, it is received into a type-founder's stick, which has to be removed as it is filled, and the type is then ready for packing. The great advantage in type-machines consists in the increased facility of production. One machine and one man in ten hours will produce 30,000 brevier types (or 60 lbs.), the size used for this work, while by hand-labour only 5,000 (or 10 lbs.,) could be cast in the same time.

Messrs. Miller and Richards, of Edinburgh and London, employ not less than eighty steam type-casting machines, equalling in production the labour of 480 men.

Number of Lines of the different-sized Types contained in One Foot.

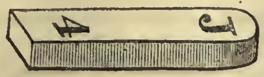
The beauty of type depends upon the delicacy with which the *matrix*, or mother-type, is formed. This mould is a short thick bar of copper, with the form of the letter intended to be produced stamped on one side of it (*fig.* 1671). The letter of the matrix is stamped in by means of a punch, a small piece of steel, a letter cut upon one end, and the other end a flat head to receive the blow of a hammer (*fig.* 1672).

The length of the body of a type is called its *height to paper*; and this, unfortunately, is not uniform, there being a London and a Scotch height, the former not so high as the latter.

In the last century, a fount of type weighing 500 lbs. was considered a good weight; but now, so much has printing increased, it is not an uncommon thing in the principal

1671



1672

houses in London to keep a fount of 20,000 or 30,000 lbs. in common use. The following are the names of the types in English, Dutch, French, German, and Italian; but some of the German names vary in different parts of Germany:—

1. Diamond, the smallest.
2. Pearl. (*Fr.* La Parisienne or Sédanoise; *Ger.* Perle; *Ital.* Occhio di Mosca.)
3. Ruby.
4. Nonpareil. (*Dutch,* Nonpareil; *Fr.* La Nonpareille; *Ger.* Nonpareille; *Ital.* Nompariglia.)
5. Emerald.
6. Minion. (*Fr.* La Mignonne; *Ger.* Colonel; *Ital.* Mignona.)
7. Brevier. (*Dutch,* Brevier; *Fr.* Le Petit Texte; *Ger.* Petit, or Jungfer; *Ital.* Piccolo Testo.)
8. Bourgeois. (*Dutch,* Bourgeois; *Fr.* La Gaillarde; *Ger.* Bourgeois; *Ital.* Gagliarda.)
9. Long Primer. (*Dutch,* Garmond; *Fr.* Le Petit Romain; *Ger.* Corpus, or Garmond; *Ital.* Garamone.)
10. Small Pica. (*Dutch,* Dessendiaan; *Fr.* La Philosophie; *Ger.* Brevier, or Rheinländer; *Ital.* Filosofia.)
11. Pica. (*Dutch,* Mediaan; *Fr.* Le Cicéro; *Ger.* Cicero; *Ital.* Lettura.)
12. English. (*Dutch,* Augustyn; *Fr.* Le Saint-Augustin; *Ger.* Mittel; *Ital.* Silvio.)
13. Great Primer. (*Dutch,* Text; *Fr.* Le Gros Romain; *Ger.* Tertia; *Ital.* Testo.)
14. Paragon. (*Dutch,* Paragon; *Fr.* Le Petit Parangon; *Ger.* Paragon; *Ital.* Paragone.)
15. Double Pica. (*Dutch,* Dubbelde Dessendiaan; *Fr.* Le Gros Parangon; *Ger.* Text, or Secunda; *Ital.* Due Linee Filosofia.)
16. Two-line Pica. (*Dutch,* Dubbelde Mediaan; *Fr.* Les Deux Points de Cicéro, La Palestine; *Ger.* Doppelcicero.)
17. Two-line English. (*Dutch,* Dubbelde Augustyn; *Fr.* Le Petit Canon; *Ger.* Doppelmittel; *Ital.* Canoncino.)
18. Two-line Great Primer. (*Dutch,* Kanon; *Fr.* Les Deux Points de Gros Romain; *Ger.* Kleine Canon; *Ital.* Grosso Testo.)
19. Two-line Double Pica. (*Dutch,* Groote Kanon; *Fr.* Le Trismégiste; *Ger.* Grobe Canon.)
20. Trafalgar.
21. Canon. (*Dutch,* Parys Romeyn; *Fr.* Le Gros Canon; *Ger.* Kleine Missal; *Ital.* Canone.)

In 1457 cast types were invented by Peter Schoeffer; in 1800, the lever, or American mould, was introduced; in 1823, Henri Didot's polymatype, still successfully used in France, was worked in London by Pouchée, but failed through the opposition of the associated type-founders; in 1853, Mr. Johnson patented his machine for casting type mechanically without variation of body; and in the year following, he perfected his process for making hard metal type by substituting tin for lead, entirely or partially, in the ordinary compounds.

The types are arranged, each sort by itself, in two *cases,*—an upper and a lower,—in little cells or *boxes.* The upper case, having ninety-eight boxes, contains the capital and small capital letters, figures, accents, and other types not used so frequently as the smaller letters; and in the lower case, having fifty-four boxes, are disposed the small letters, together with the points, spaces, quadrats, &c. The boxes in the cases are arranged in the best possible manner for facilitating the work of the compositor, and enabling him to pick up the types rapidly,—the letters most frequently used being placed nearest to his hand.

In *setting up,* or *composing,* the compositor stands opposite to his cases; and, having received directions respecting the size of the type, the width of the page, the author's wishes as to punctuation, capitals, italics, &c., places his copy or MS. before him, on a spare part of the upper case, and holds in his left hand a small instrument called a *composing stick,* usually made of iron, with a moveable slide, capable, by means of a screw, of being adjusted to the different widths required in miscellaneous printing, as

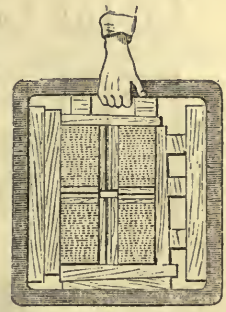
seen in the illustration (*fig.* 1673). With the right hand he picks up the types, and arranges them one by one in his composing stick. He does not look at the face, but only glances at the nick (*fig.* 1670, *c*), and takes it for granted that if it come from the

1673

right box it must be the right letter. He secures each letter with the thumb of the left hand, as the types are placed side by side in line from left to right; and, when he comes to the end of his line, and finds that he has a syllable or word which will not fill out the measure, he has to perform a task which requires considerable care and taste. This is called *justification*. The first and last letters must be at the extremities of the line; and there must not be wide spaces between some words and crowding in others, but the distances between them must be made as nearly as possible uniform by changing the *spaces* (or short blank types, not so high as the letters, and therefore giving no impression), and thus *getting in* or *driving out* part or the whole of a word. The first line being thus justified, the compositor proceeds with the setting-up of the next, and so on with a sufficient number of lines to fill his stick, and then lifts the *handful*, or mass of types, out of the stick, and places them upon a *galley*, or oblong tray of wood or metal, having an edge to the left side and top half an inch in height. This operation of filling and emptying the stick is repeated till the galley is sufficiently full, or the taking of copy is finished; when the *matter*, as it is then called, is taken away by the clicker, who divides it into the required lengths of pages, placing head-lines, signatures, &c., and binding them round tightly with cord. The clicker then *lays down* the pages in their proper positions on the *imposing stone*,—a flat, smooth slab of stone, or, better, of iron. The *chase*, a frame of iron, divided into compartments like the sashes of a window, is put round the pages, and the form *dressed* thus: a set of *furniture*, consisting of slips of wood or metal, about half an inch in height, and of various thicknesses, is placed, some at the head, called *head-sticks*, some between the pages, called *gutters*, and others at the sides and feet, called *side-* and *foot-sticks*. The side- and foot-sticks are larger at one end than at the other, so that small wedges of wood, or *quoins*, may be driven tightly between them and the sides of the chase, locking up the types so firmly, that the *form*, as the mass is called (*fig.* 1674), may be carried from place to place with perfect safety. A form of eight pages of this Dictionary contains between 40,000 and 50,000 separate letters and spaces.

1674



The sizes of books are reckoned by the number of leaves into which a sheet of paper is folded. Thus the largest size is *broadside*, or the whole size of the sheet; *folio*, or half the sheet; *quarto*, or a sheet folded into four leaves; *octavo*, or the sheet folded into eight leaves; *duodecimo*, or the sheet folded into twelve leaves; and so on. In imposing, the pages are of course laid down in positions the reverse of those they will take when printed. The following Tables show the mode of imposing some of the most common sizes.

When the process of imposing is completed, the form is carried to a press, and an impression is taken, called the *first proof*. This proof, with the MS., is handed to the corrector of the press, or *reader*, and a *reading boy* reads the copy to him while he examines the proof and marks the necessary corrections and errors of the compositor. In correcting a proof-sheet a set of symbols are used for the purpose of calling the attention of the compositor to the several kinds of errors, and to direct him how they

(The Inner Form is the reverse of this.)

are to be amended. These marks are best shown by the following specimen of a corrected proof from Brande's 'Dictionary,' the explanation of each mark being given in the left-hand column :—

1. Where a word is to be changed from small letters to capitals, draw three lines under it, and write *caps.* in the margin.

2. Where there is a wrong letter, draw the pen through that letter, and make the right one opposite in the margin.

3. A letter turned upside down.

4. The substitution of a comma for another point, or for a letter put in by mistake.

5. The insertion of a hyphen.

6. To draw the letters of a word close together.

7. To take away a superfluous letter or word the pen is struck through it, and a round top *d* made opposite, being the contraction of *deleatur*, to expunge.

8. Where a word has to be changed to Italic draw a line under it, and write *Ital.* in the margin; and where a word has to be changed from Italic to Roman, write *Rom.* opposite.

9. When words are to be transposed three ways of marking them are shown; but they are not usually numbered except more than three words have their order changed.

10. The transposition of letters in a word.

11. To change one word for another.

12. The substitution of a period or a colon for any other point. It is customary to encircle these two points with a line.

13. The substitution of a capital for a small letter.

14. The insertion of a word, or a letter.

15. When a paragraph commences where it is not intended, connect the matter by a line, and write in the margin opposite *run on.*

16. Where a space or a quadrat stands up and appears, draw a line under it, and make a strong perpendicular line in the margin.

17. When a letter of a different size from that used, or of a different face, appears in a word, draw a line either through it or under it, and write opposite *wf.*, for 'wrong fount.'

18. The marks for a paragraph, when its commencement has been omitted.

19. When one or more words have been struck out, and it is subsequently decided that they shall remain, make dots under them, and write the word *stet* in the margin.

20. The mark for a space where it has been omitted between two words.

21. To change a word from small letters to small capitals make two lines under the word, and write *sm. caps.* opposite. To change a word from small capitals to small letters make one line under the word, and write in the margin *lo. ca.* for 'lower case.'

22. The mark for the apostrophe; and also the marks for turned commas, which designate extracts.

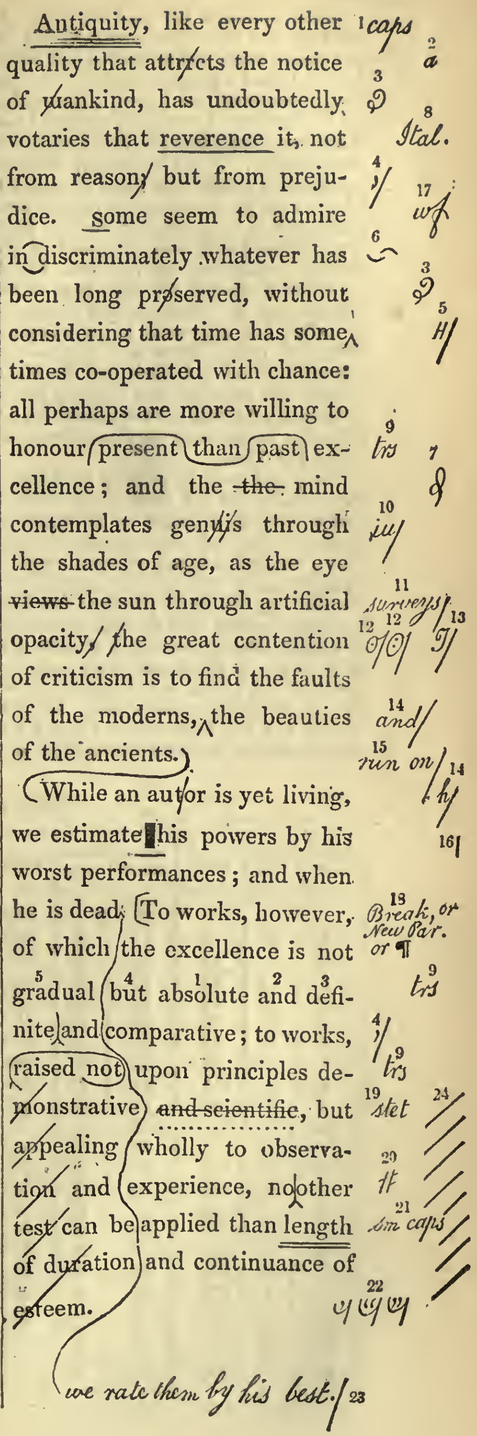
23. The manner of marking an omission, or an insertion, when it is too long to be written in the side margin. When this occurs it may be written either at the top or the bottom of the page.

24. Marks when lines or words are not straight.

The subjoined specimen, when corrected, would be as follows:—

ANTIQUITY, like every other quality that attracts the notice of mankind, has undoubtedly votaries that *reverence* it, not from reason, but from prejudice. Some seem to admire indiscriminately whatever has been long preserved, without considering that time has sometimes co-operated with chance: all perhaps are more willing to honour past than present excellence; and the mind contemplates genius through the shades of age, as the eye surveys the sun through artificial opacity. The great contention of criticism is to find the faults of the moderns, and the beauties of the ancients. While an author is yet living, we estimate his powers by his worst performances; and when he is dead, we rate them by his best.

To works, however, of which the excellence is not absolute and definite, but gradual and comparative; to works, not raised upon principles demonstrative and scientific, but appealing wholly to observation and experience, no other test can be applied than LENGTH of duration and continuance of esteem.



When the reader has read his proof, it is handed to the compositor, who unlocks the form, and makes the corrections in the types, by lifting out the wrong letters by means of a sharp awl or *bodkin*, and putting in right ones in their places. The form is then locked up again, taken to the press, and another proof is *pulled*. This is termed *the revise*, and is sent to the reader, with his first proof, that he may see that all the corrections have been properly made, put queries against doubtful matters for the author's consideration, and send it, thenceforth called a *clean proof*, with the MS., to the author. When the author returns his proof and revise, and is satisfied that the sheet is correct, the form, after having been finally read with care for press, is taken to the press or machine to have the requisite number of impressions struck off. Before this is done, however, care is taken that the matter at the beginning of the sheet connects with that at the end of the preceding, that the pages are correct, and that the 'signatures' are in order. The signatures are generally small capital letters, placed at the foot of the first page of each sheet, commencing with B, and omitting the J, V, and W. They are said to have been first used by John Koelhof, at Cologne, in 1472; but they exist in an edition of 'Terence,' printed by Antonio Zorac, at Milan, in 1470. There is a Venetian edition of 'Baldi Lectura super Codic,' &c., printed by John de Colonia and Jo. Manthen de Gherretzem, in 1474, in which it is evident that these printers had only just become acquainted with the use of signatures, as these marks were not introduced till one-half of the work had been printed. The following Tables show the signatures and folios of any given number of sheets in 8vo, 12mo, and 18mo.

The paper used in printing is always damped before being sent to the press, wet paper taking the ink considerably better than dry. The warehouseman delivers the proper quantity of paper to the wetter, which is wetted thus:—The quire of paper is opened, its back broken, and divided into three, four, or five portions, or *dips*, drawn through a trough of clean water and laid on a board, dip after dip, till a convenient heap is made. This is put into a screw press, a little pressure applied, and the next day the whole is *turned* and slightly pressed again, so that fresh surfaces of the paper coming into contact, the moisture is equally diffused throughout the heap. The paper used in printing is of three kinds: *imperfect paper*, consisting of 20 quires of 24 sheets, or 480 sheets to the ream; *perfect paper* (that most generally used) consisting of 21½ quires, or 516 sheets; and *news paper*, consisting of 20 quires of 25 sheets each to the ream, or 500 sheets. The *stamped sheets* of newspaper (generally called *stamps*, and the plain paper *blanks*) are always received and delivered by the nett number without allowing for spoilage in the press-work; but in book-work it is the

practice to allow 16 sheets in each ream for 'tympan-sheet' and spoiled sheets. The following Table shows the quantity of perfect and imperfect paper required for one sheet of 16 pages of a work like 'Ure's Dictionary,' from 12 to 10,000 copies:—

Quantity required of *perfect* paper			Quantity required of *imperfect* paper			For printing 1 sheet of 16 pages	Total number of copies the paper will make

Press-work.—The pressman first lays the inner form on the press, and prints one copy, which is called a *press revise*; this he takes to the person appointed to revise it, and while that is being done proceeds to secure the form on the table of the press by means of quoins; to place his tympan-sheet; to fix the points which make small holes in the paper that enable him to cause the pages to fall precisely on the back of each other when the second side of the paper is printed, and to produce an even and uniform impression in all the pages. He then cuts his frisket, which preserves the margin of the paper clean, and, when the revise is corrected, proceeds to ink the surface of the types by means of rollers. When the whole impression of one side of the paper is printed, he lifts the form off the press, washes the ink off the face of the type with lye, and rinses it with water. He then proceeds in a similar manner with the outer form, which completes the sheet. This process is continued sheet after sheet till the work is complete.

When the sheet is printed the compositor lays it up, distributes the type, and proceeds, sheet after sheet, till the body of the work is finished; then the title, dedication, preface, introduction, contents, index, and any other prefatory matter is proceeded with, these being always printed the last. This distribution of the types, or putting back the letters into the several compartments of the case where they belong, is performed with the greatest rapidity. The compositor wets the whole page or form, and takes up a number of lines on his composing rule. This wetting causes the types to adhere slightly together, and renders the manipulation easy. He then takes up a few words between his right-hand finger and thumb, and by a dexterous motion he throws off the several letters into their various boxes. Distribution is performed four times faster than composition.

After the sheets have been printed on both sides, the warehouseman takes them away, and hangs them up on poles to dry, varying the number of sheets hung up together from five or six to ten or eleven, according to the heat of the room, or the pressure of business. When dry the sheets are taken down from the poles, carefully knocked up and put away in the warehouse in piles; and when the book is nearly finished from ten to fourteen consecutive sheets are laid upon the gathering-board in order, and collected sheet by sheet by boys, who deposit each *gathering* in a heap at the end of the table, so constructed that when a boy has deposited his gathering he has only to turn himself and begin again. These gatherings are then carefully *collated*, to ascertain that the different sheets are correct and in order, and folded up the middle. When the work is finished the gatherings are put together, or *in books*, one of each, which forms a copy of the work, and pressed. The work is now completed, and awaits the order of the bookseller, &c., to deliver the copies to the bookbinder.

Printing in Colours.—In many of the old printed books, the initial letters, and occasionally other parts, were printed in red. This was done by two workings at press, and was an imitation of the earlier fashion of illuminating MSS. The practice is still followed in some almanacs, the saints' days and holidays being 'red-letter days.' Some ingenious contrivances have been devised for working in various colours; and a few years since a curious book was written and published on the subject by Mr. Savage. Still more recently, printing in gold and other metals has been practised. This is done by printing with a sort of size, and afterwards applying the metal-leaf. But the specimens of printing in colours produced by Mr. Kronheim are really beautiful as works of art. The copy picture is made in colours, and the blocks for printing each colour and shade are cut in relief on 'surface metal' plates, consisting of perfectly smooth plates of type-metal. These plates are then printed by the ordinary method, great care, however, being taken that each colour falls in its right place.

The following is the mode of printing two or more 'rainbow tints' at the same time:—Take the cut, ink it well and rather full, with black ink, and get a perfect impression on paper not very damp; then lay the face of the printed paper carefully on the surface of the block prepared for engraving the whites on the tinted ground, and give it a good soft pull. This will transfer to the tint block a facsimile of the wood-engraving itself. This block is then handed over to the engraver, who cuts out the whites for the clouds, shadows, water, &c., according to his taste, and with a view to effect. The tint-block is printed first, and then the black block is put to press, and the pressman must be careful in distributing his different inks to make them fade away and blend at the given points. This is an easy matter after a little practice.

Laws affecting the Press.—As to the laws relating to the press, see 39 Geo. III. c. 79, amended by 51 Geo. III. c. 65, and 2 & 3 Vict. c. 12. There is no censorship over the press; which is, however, amenable to the remedy of an injured party, or to the correction of criminal justice (*Wharton's Law Lex.* 2nd ed. 1860).—R. J. C.

PRINTING BLOCKS—ELECTRO. Two patents taken out by Mr. H. G. Collins are likely to prove of essential service to the publishing world. By the one he is enabled to take on vulcanised caoutchouc, prepared with an equally elastic surface, an impression in transfer from any steel- or copper-plate, wood-block, stereotype, lithographic-stone, or, in fact, from an original drawing, if done in transfer-ink or transfer-paper, and increase or reduce the same to any required size. This is effected by expanding the india-rubber in one case, after it has received the impression; and in the other, before the impression is made. In the first instance, the impression is enlarged as the elastic material expands; in the other it is reduced by allowing the already expanded india-rubber to contract in its frame: then laying the expanded or contracted copy down upon stone, and treating it after the usual manner of lithography. This presents a vast field for adapting the plates of any work of acknowledged merit which may have cost some hundreds or thousands of pounds, and years to produce, to the wants of the public in these days of cheap and well-illustrated literature, by bringing out the same works in a reduced size, which, but for this plan, no publisher would think of attempting. Many plates also, such as portraits, public buildings, or landscapes, may be enlarged and issued separately. This last applicatiou is particularly suitable for maps, as any one, from the size of a school atlas, may be taken and made to serve for large wall-maps without the cost of engraving the same. The rapidity with which this alteration of size can be accomplished is not among the least of its recommendations; for an engraving that would take several months in the ordinary mode may be completed in from two to three days. Two remarkable instances of the excellent reductions obtainable by this process are given in the square 16mo. editions of Moore's 'Melodies' and Macaulay's 'Lays of Ancient Rome,' published by Messrs. Longman & Co.

This patent offers the same facilities to a vast number of the manufactures of the country, such as the lace trade, cotton printers, damask and moreen houses, potteries, paper-hangings; in fact, to all or every one who employ *art* or *design* in their calling. It will be well to observe that the size can not only be enlarged or diminished, as the case may be, but the pattern can be altered in form; thus a circular design can be made into an oval, if required. Mr. Collins, by his second patent, is enabled, after these impressions are once upon the stone, to make them into electro-blocks, thus reducing also the cost of printing engraved plates, which is effected in the following manner:—The impression being placed on the lithographic-stone or the zinc-plate—either one or the other can be employed—acid is applied to abrase to a certain extent the stone or metal over the unprotected portions; when this is sufficiently deep a mould is taken in wax, the surface of which being prepared is subjected to the electrotype process, and thus a copper-block is obtained. See PHOTOZINCOGRAPHY.

PRINTING INK. (*Encre d'imprimerie*, Fr.; *Buchdruckerfarbe*, Ger.) After reviewing the different prescriptions given by Moxon, Breton, Papillon, Lewis, those in Nicholson's and the Messrs. Aikins' Dictionaries, in Rees's Cyclopædia, and in the French Printer's Manual, Mr. Savage[1] says, that the *Encyclopædia Britannica* is the only work, to his knowledge, which has given a recipe by which a printing ink might be made that could be used, though it would be of inferior quality, as acknowledged by the editor: for it specifies neither the qualities of the materials, nor their due proportions. The fine black ink made by Mr. Savage has, he informs us, been pronounced by some of our first printers to be unrivalled, and has procured for him the large medal from the Society for the Encouragement of Arts.

1. *Linseed-oil.*—Mr. Savage says that the linseed-oil, however long boiled, unless set fire to, cannot be brought into a proper state for forming printing ink; and that the flame may be most readily extinguished by the application of a pretty tight tin cover to the top of the boiler, which should never be more than half full. The French prefer nut-oil to linseed; but if the latter be old, it is fully as good, and much cheaper, in this country at least.

2. *Black rosin* is an important article in the composition of good ink; as by melting it in the oil, when that ingredient is sufficiently boiled and burnt, the two combine, and form a compound approximating to a natural balsam, like that of Canada.

3. *Soap.*—This is a most important ingredient in printer's ink, which is not even mentioned in any of the recipes prior to that in the *Encyclopædia Britannica.* For want of soap, ink accumulates upon the face of the types, so as completely to clog them up after comparatively few impressions have been taken; it will not wash off without alkaline lyes, and it skins over very soon in the pot. Yellow rosin-soap is the best for black inks; for those of light and delicate shades, white curd-soap is preferable. Too much soap is apt to render the impression irregular, and to prevent the ink from drying quickly. The proper proportion has been hit when the ink works clean, without clogging the surface of the types.

4. *Lamp-black.*—The vegetable lamp-black sold in firkins takes by far the most varnish, and answers for making the best ink. See BLACK.

5. *Ivory-black* is too heavy to be used alone as a pigment for printing ink; but it may be added with advantage by grinding a little of it upon a muller with the lamp-black, for certain purposes; for instance, if an engraving on wood is required to be printed so as to produce the best possible effect. See IVORY-BLACK.

6. *Indigo* alone, or with an equal weight of Prussian blue, added in small proportion, takes off the brown tone of certain lamp-black inks. Mr. Savage recommends a little Indian red to be ground in with the indigo and Prussian blue, to give a rich tone to the black ink.

7. *Balsam of copaiba*, mixed, by a stone and a muller with a due proportion of soap and pigment, forms an extemporaneous ink, which the printer may employ very advantageously when he wishes to execute a job in a peculiarly neat manner.

After the smoke begins to rise from the boiling oil, a bit of burning paper stuck in the cleft end of a long stick should be applied to the surface, to set it on fire, as soon as the vapour will burn; and the flame should be allowed to continue (the pot being meanwhile removed from over the fire, or the fire taken from under the pot) till a sample of the varnish, cooled upon a pallet-knife, draws out the strings of about half an inch long between the fingers. To 6 quarts of linseed-oil thus treated, 6 pounds of rosin should be gradually added, as soon as the froth of the ebullition has subsided. Whenever the rosin is dissolved, one pound and three quarters of dry

[1] In his work on the Preparation of Printing Ink; 8vo., London, 1832.

brown soap, of the best quality, cut into slices, is to be introduced cautiously, for its water of combination causes a violent intumescence. Both the rosin and soap should be well stirred with a spatula. The pot is to be now set upon the fire again, in order to complete the combinations of all the constituents.

Put next of well-ground indigo and Prussian blue, each 2½ ounces, into an earthen pan, sufficiently large to hold all the ink, along with 4 pounds of the best mineral lamp-black, and 3½ pounds of good vegetable lamp-black; then add the warm varnish by slow degrees, carefully stirring, to produce the perfect incorporation of all the ingredients. This mixture is next to be subjected to a mill, or slab and muller, till it be levigated into a smooth, uniform paste.

One pound of a superfine printing ink may be made by the following recipe of Mr. Savage:—Balsam of copaiba, 9 oz.; lamp-black, 3 oz.; indigo and Prussian blue together, p. æq. $1\frac{1}{4}$ oz.; Indian red, $\frac{3}{4}$ oz.; turpentine (yellow) soap, dry, 3 oz. This mixture is to be ground upon a slab, with a muller, to an impalpable smoothness. The pigments used for colouring printing inks are: carmine, lakes, vermilion, red lead, Indian red, Venetian red, chrome yellow, chrome red or orange, burnt *terra di Sienna*, gall-stone, Roman ochre, yellow ochre, verdigris, blues and yellows mixed for greens, indigo, Prussian blue, Antwerp blue, umber, sepia, &c.

PRINTING MACHINE. (*Typographie mécanique*, Fr.; *Druckmaschine*, Ger.) No improvement had been introduced in these important machines, from the invention of the art of printing, till the year 1798, a period of nearly 350 years. In Dr. Dibdin's interesting account of printing, in the *Bibliographical Decameron*, may be seen representations of the early printing presses, which exactly resemble the wooden presses in use a few years back.

For the first essential modification of the old press, the world is indebted to the late Earl Stanhope. His press is formed of iron, without any wood; the table upon which the form of types is laid, as well as the *platen* or surface which immediately gives the impression, is of cast iron, made perfectly level; the platen being large enough to print a whole sheet at one pull. The compression is applied by a beautiful combination of levers, which give motion to the screw, cause the platen to descend with progressively increasing force till it reaches the type, when the power approaches the maximum; upon the infinite lever principle, the power being applied to straighten an obtuse-angle jointed lever. This press, however, like all its flat-faced predecessors, does not act by a continuous, but a reciprocating motion; nor does it much exceed the old presses in productiveness, since it can turn off only 250 impressions per hour; but it is capable of producing much finer press-work than any steam- or hand-machine yet invented, for this reason: the best work requires the best ink, which is stiff, and requires a longer time in distributing over and beating into the form of types than the thin, oily, and consequently browner ink required by the rapidly moving machine. It is a remarkable fact that the *Penny Magazine* was printed at the hand-press, although the editor assured his readers that the cylindrical form of machine was capable of printing the finest impressions from woodcuts. The machine, however, has the advantage of uniformity of colour in inking throughout a whole impression. The iron platen of the Stanhope press was supposed at one time to wear out types much sooner than the old wooden one, but experience does not warrant us in supporting this statement.

The first person who publicly projected a self-acting printing press was Mr. William Nicholson, the able editor of the *Philosophical Journal*, who obtained a patent in 1790: 1, for imposing types upon a cylindrical surface (see *fig.* 1675); 2. for applying the ink upon the surface of the types, &c., by causing the surface of a cylinder smeared with the colouring-matter to roll over them; or else causing the types to apply themselves to the cylinder. For the purpose of spreading the ink evenly over this cylinder, he proposed to apply three or more distributing rollers longitudinally against the inking-cylinder, so that they might be turned by the motion of the latter. 3. 'I perform,' he says, '*all my impressions by the action* of a cylinder or cylindrical surface; that is, I cause the paper to pass between two cylinders, one of which has the form of types attached to it, and forming part of its surface; and the other is faced with cloth, and serves to press the paper so as to take off an impression of the colour previously applied; or otherwise I cause the form of types, previously coloured, to pass in close and successive contact with the paper wrapped round a cylinder with woollen.' See *figs.* 1675 and 1676.[1]

The first operative printing machine was undoubtedly contrived by, and constructed under the direction of, M. König, a clock-maker from Saxony, who, so early as the year 1804, was occupied in improving printing presses. Having failed to interest the

[1] The black parts in these little diagrams, 1675, 1676, indicate the inking apparatus; the diagonal lines, the cylinders upon which the paper to be printed is applied; the perpendicular lines, the plates or types; and the arrows show the track pursued by the sheet of paper.

Continental printers in his views, he came to London soon after that period, and submitted his plans to Mr. T. Bensley and Mr. G. Woodfall, well-known printers, and to Mr. R. Taylor, late one of the editors of the 'Philosophical Magazine.'

1675

Nicholson's, for arched type.

1676

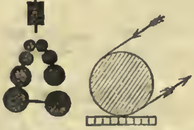
Nicholson's, for common type.

These gentlemen afforded Mr. König, and his assistant Bauer, a German mechanic, liberal pecuniary support. In 1811, he obtained a patent for a method of working a common hand-press by steam-power, and 3,000 copies of signature H of the 'New Annual Register' were printed by it; but, after much expense and labour, he was glad to renounce the scheme. He then turned his mind to the use of a cylinder for communicating the pressure, instead of a flat plate; and he finally succeeded, sometime before November 28, 1814, in completing his printing automaton; for on that day the editors of the 'Times' informed their readers that they were perusing for the first time a newspaper printed by steam-impelled machinery; it is a day, therefore, which will be ever memorable in the annals of typography.

In that machine the form of type was made to traverse horizontally under the pressure-cylinder, with which the sheet of paper was held in close embrace by means of a series of endless tapes. The ink was placed in a cylindrical box, from which it was extruded by means of a powerful screw, depressing a well-fitted piston; it then fell between two iron rollers, and was by their rotation transferred to several other subjacent rollers, which had not only a motion round their axes, but an alternating traverse motion (endwise). This system of equalising rollers terminated in two, which applied the ink to the types. (See *fig.* 1677.) This plan of inking evidently involved a rather complex mechanism, was hence difficult to manage, and sometimes required two hours to get into good working trim.

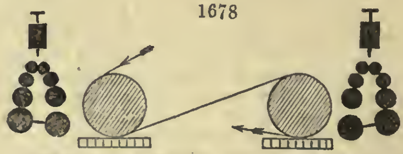
In order to obtain a great many impressions rapidly from the same form, a paper-conducting cylinder (one embraced by the paper) was mounted upon each side of the inking apparatus, the form being made to traverse under both of them. This double-action machine threw off 1,100 impressions per hour when first finished; and by a subsequent improvement, no less than 1,800

1677



König's single, for one side of the sheet.

1678



König's double, for both sides of the sheet.

Mr. König's next feat was the construction of a machine for printing both sides of the newspaper at each complete traverse of the forms. This resembled two single machines, placed with their cylinders towards each other, at a distance of two or three feet; the sheet was conveyed from one paper-cylinder to another, as before, by means of tapes; the track of the sheet exactly resembled the letter S laid horizontally, thus, ∽; and the sheet was turned over or reversed in the course of its passage. At the first paper-cylinder it received the impression from the first form, and at the second received it from the second form; whereby the machine could print 750 sheets of book letter-press on both sides in an hour. This new register apparatus was erected for Mr. T. Bensley, in the year 1815, being the only machine made by Mr. König for printing upon both sides. See *fig.* 1678.

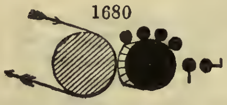
1679

Donkin and Bacon's, for type.

Messrs. Donkin and Bacon had for some years previous to this date been busily engaged with printing machines, and had indeed, in 1813, obtained a patent for an apparatus, in which the types were placed upon the sides of a revolving prism; the ink was applied by a roller, which rose and fell with the eccentricities of the prismatic surface, and the sheet was wrapped upon another prism fashioned so as to coincide with the eccentricities of the type-prism. One such machine was erected for the University of Cambridge. (See *fig.* 1679.) It was a beautiful specimen of ingenious contrivance and good workmanship. Though it was found to be too complicated for common operatives, and defective in the mechanism of the inking process, yet it exhibited for the first time the elastic inking-rollers, composed of glue combined with treacle, which alone constitute one of the finest inventions of modern typography.

In the year 1815, Mr. Cowper turned his mind to the subject of printing machines, and in co-operation with his partner, Mr. Applegath, carried them to an unlooked-for degree of perfection. In 1816, Mr. Cowper obtained a patent for curving stereotype-plates, for the purpose of fixing them on a cylinder. Several machines so mounted, capable of printing 1,000 sheets per hour upon both sides, are at work at the present day. (See *figs.* 1680 and 1681.) In these machines, Mr. Cowper places two paper-cylinders side by side, and against each of them a cylinder for holding the plates; each of these four cylinders is about two feet in diameter. Upon the surface of the stereotype-plate cylinder, four or five inking-rollers of about three inches in diameter are placed; they are kept in their position by a frame at each end of the said cylinder, and the axles of the rollers rest in vertical slots of the frame, whereby having perfect freedom of motion, they act by their gravity alone, and require no adjustment.

1680



Cowper's single, for curved stereotype.

1681

Cowper's double, for both sides of the sheet.

The frame which supports the inking-rollers, called the waving-frame, is attached by hinges to the general framework of the machine; the edge of the stereotype-plate cylinder is indented, and rubs against the waving-frame, causing it to vibrate to and fro, and consequently to carry the inking-rollers with it, so as to give them an unceasing traverse movement. These rollers distribute the ink over three-fourths of the surface of the cylinder, the other quarter being occupied by the curved stereotype-plates. The ink is contained in a trough, which stands parallel to the said cylinder, and is formed by a metal roller revolving against the edge of a plate of iron; in its revolution it gets covered with a thin film of ink, which is conveyed to the plate-cylinder by a distributing roller vibrating between both. The ink is diffused upon the plate-cylinder, as before described; the plates in passing under the inking rollers become charged with the coloured varnish; and as the cylinder continues to revolve, the plates come into contact with a sheet of paper on the first paper-cylinder, which is then carried by means of tapes to the second paper-cylinder, where it receives an impression upon its opposite side from the plates upon the second cylinder. Thus the printing of the sheet is completed.

In order to adapt this method of inking to a flat type-form machine, it was merely requisite to do the same thing upon an extended flat surface or table, which had been performed upon an extended cylindrical surface. Accordingly, Messrs. Cowper and Applegath constructed a machine for printing both sides of the sheet from type, including the inking apparatus, and the mode of conveying the sheet from the one paper-cylinder to the other, by means of drums and tapes. It is highly creditable to the scientific judgment of these patentees, that in new-modelling the printing machine, they dispensed with forty wheels, which existed in Mr. König's apparatus when Mr. Bensley requested them to apply their improvements to it.

The distinctive advantages of these machines, and which have not hitherto been equalled, are the uniform distribution of the ink, the equality as well as delicacy with which it is laid upon the types, the diminution in its expenditure, amounting to one half upon a given quantity of letter-press, and the facility with which the whole mechanism is managed. The hand inking-roller and distributing-table, now so common in every printing-office in Europe and America, is the invention of Mr. Cowper, and was specified in his patent. The vast superiority of the inking apparatus in his machines over the balls used of old, induced him to apply it forthwith to the common press, and most successfully. See *fig.* 1682.

1682

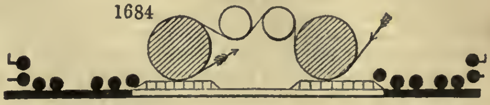
Cowper's inking-table and roller.

To construct a printing machine which shall throw off two sides at a time with exact register, that is, with the second side placed precisely upon the back of the first, is a very difficult problem, which was practically solved by Messrs. Applegath and Cowper. It is comparatively easy to make a machine which shall print the one side of a sheet of paper first, and then the other side, by the removal of one form, and the introduction of another; and thus far did Mr. König advance. A correct register requires the sheet, after it has received its first impression from one cylinder, to travel round the peripheries of the cylinders and drums, at such a rate as to meet the types of the second side at the exact point which will ensure this side falling with geometrical nicety upon the back of the first. For this purpose, the cylinders and drums must revolve at the very same speed as the carriage underneath; hence the least incorrectness in the workmanship will produce such defective typography as will not be endured in book-printing at the present day, though it may be tolerated in newspapers. An equable distribution of the ink is of no less importance to beautiful letter-press. See *figs.* 1683, 1684.

1683

Applegath and Cowper's single.

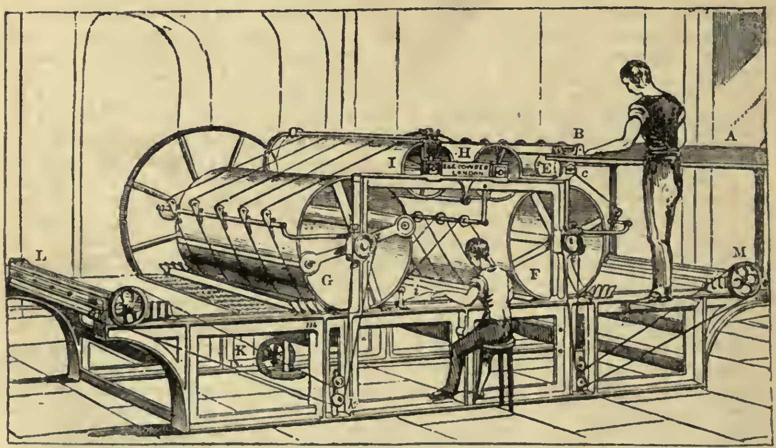
1684



Applegath and Cowper's double.

The machines represented in *figs.* 1685, 1686, 1687, are different forms of those which have been patented by Messrs. Applegath and Cowper. That shown in *figs.* 1685, 1687, prints both sides of the sheet during its passage, and is capable of throwing off nearly 1,000 finished sheets per hour. The moistened quires of blank paper being piled upon a table, A, the boy, who stands on the adjoining platform, takes up one sheet after another, and lays them upon a feeder B, which has several linen girths passing across its surface, and round a pulley at each end of the feeder; so that whenever the pulleys begin to revolve, the motion of the girths carries forward the sheet, and delivers it over the entering roller E, where it is embraced between two

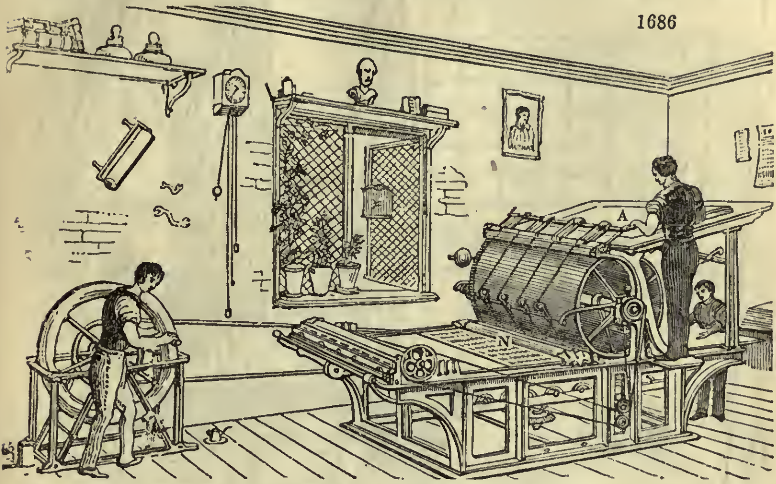
1685



series of endless tapes, that pass round a series of tension rollers. These tapes are so placed as to fall partly between, and partly exterior to, the pages of the printing; whereby they remain in close contact with the sheet of paper on both of its sides during its progress through the machine. The paper is thus conducted from the first printing-cylinder F, to the second cylinder G, without having the truth of its register impaired, so that the coincidence of the two pages is perfect. These two great cylinders, or drums, are made of cast iron, turned perfectly true upon a self-acting lathe; they are clothed in these parts, corresponding to the typographic impression, with fine woollen cloth, called *blankets* by the pressmen, and revolve upon powerful shafts, which rest in brass bearings of the strong framing of the machine. These bearings, or plummer blocks, are susceptible of any degree of adjustment, by set screws. The drums, H and I, are made of wood; they serve to conduct the sheet evenly from the one printing-cylinder to the other.

One series of tapes commences at the upper part of the entering drum E, proceeds in contact with the right-hand side and under surface of the printing-cylinder F, passes next over the carrier-drum H, and under the carrier-drum I; then encompassing the left-hand side and under portion of the printing-drum G, it passes in contact with the small tension rollers *a*, *b*, *c*, *d*, *fig.* 1687, and finally arrives at the roller E, which may be called the commencement of the one series of endless tapes. The other series may be supposed to commence at the roller *h*; it has an equal number of tapes, and corresponds with the former in being placed upon the cylinders so that the sheets of paper may be held securely between them. This second series descends from the roller *h*, *fig.* 1687, to the entering drum E, where it meets and coincides with the first series in such a way that both sets of tapes proceed together *under* the printing cylinder F, *over* H, *under* I, and *round* G, until they arrive at the roller *i*, *fig.* 1685, where they separate, after having continued in contact, except at the

1686

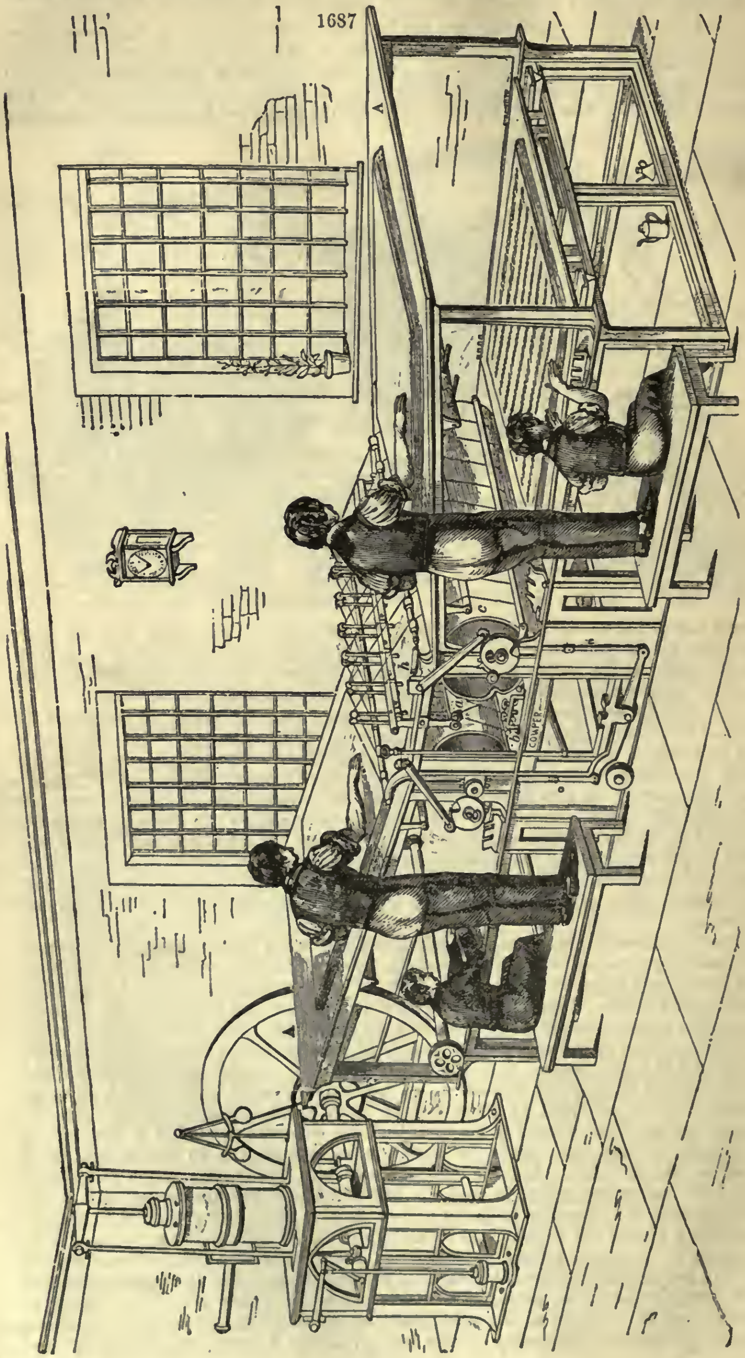


places where the sheets of paper are held between them. The tapes descend from the roller *i*, to a roller at *k*, and, after passing in contact with rollers at *l*, *m*, *n*, they finally arrive at the roller *h*, where they were supposed to commence. Hence two series of tapes act invariably in contact, without the least mutual interference.

The various cylinders and drums revolve very truly by means of a system of toothed wheels and pinions mounted at their ends. Two horizontal forms of types are laid at a certain distance apart upon the long carriage M, adjoining to each of which there is a flat metallic plate, or inking-table, in the same plane. The common carriage, bearing its two forms of type and two inking-tables, is moved backwards and forwards, from one end of the printing machine to the other, upon rollers attached to the frame-work, and in its traverse brings the types into contact with the sheet of paper clasped by the tapes round the surfaces of the printing cylinders. This alternate movement of the carriage is produced by a pinion working alternately into the opposite sides of a rack under the table. The pinion is driven by the bevel wheels K.

The mechanism for supplying the ink, and distributing it over the forms, is one of the most ingenious and valuable inventions belonging to this incomparable machine, and is so nicely adjusted that a single grain of the pigment may suffice for printing one side of a sheet. Two similar sets of inking apparatus are provided; one at each end of the machine, adapted to ink its own form of type. The metal roller L, called the *ductor* roller, as it draws out the supply of ink, has a slow rotatory motion communicated to it by a catgut cord, which passes round a small pulley upon the end of the shaft of the printing cylinder G. A horizontal plate of metal, with a straight-ground edge, is adjusted by set screws, so as to stand nearly in contact with the ductor roller. This plate has an upright ledge behind, converting it into a sort of trough or magazine, ready to impart a coating of ink to the roller, as it revolves over the table. Another roller, covered with elastic composition (see *supra*), called the vibrating roller, is made to travel between the ductor roller and the inking-table; the vibrating roller, as it rises, touches the ductor roller for an instant, abstracts a film of ink from it, and then descends to transfer it to the table. There are three or four small rollers of distribution, placed somewhat diagonally across the table at M (included only two inches from a parallel to the end of the frame), furnished with long slender axles, resting in vertical slots, whereby they are left at liberty to revolve and to traverse at the same time; by which compound movement they are enabled to efface all inequality in the surface of the varnish, or to effect a perfect distribution of the ink along the table. The table thus evenly smeared, being made to pass under the three or four proper inking-rollers, N, *fig.* 1687, imparts to them an

1687



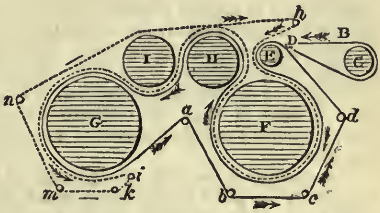
uniform film of ink, to be immediately transferred by them to the types. Hence each time that the forms make a complete traverse to and fro, which is requisite for the printing of every sheet, they are touched no less than eight times by the inking-rollers. Both the distributing- and inking-rollers turn in slots, which permit them to rise and fall so as to bear with their whole weight upon the inking-table and the form, whereby they never stand in need of any adjustment by screws, but are always ready for work when dropped into their respective places.

Motion is given to the whole system of apparatus by a strap from a steam-engine going round a pulley placed at the end of the axle at the back of the frame.

The operation of printing is performed as follows (see *fig.* 1688):—

The sheets being carefully laid, one by one, upon the linen girths, at the feeder B, the rollers C and D are made to move, by means of a segment wheel, through a portion of a revolution. This movement carries on the sheet of paper sufficiently to introduce it between the two series of endless tapes at the point where they meet each other upon the entering drum E. As soon as the sheet is fairly embraced between the tapes, the rollers C and D are drawn back, by the operation of a weight, to their original position, so as to be ready to introduce another sheet into the machine. The sheet, advancing between the endless tapes, applies itself to the blanket upon the printing cylinder F, and as it revolves meets the first form of types, and receives their impression; after being thus printed on one side, it is carried over H and under I, to the blanket upon the printing cylinder G, where it is placed in an inverted position; the printed side being now in contact with the blanket, and the white side being outwards, meets the second form of types at the proper instant, so as to receive the second impression, and get completely printed. The perfect sheet, on arriving at the point *i*, where the two series of tapes separate, is tossed out by centrifugal force into the hands of a boy.

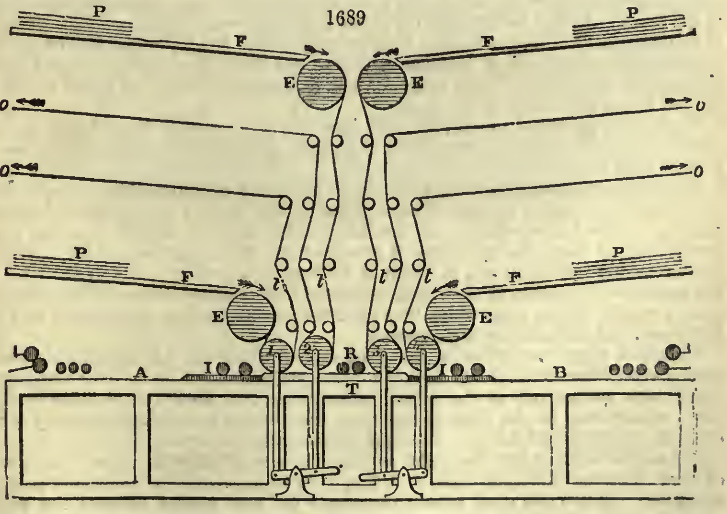
1688



The diagram, *fig.* 1688, shows the arrangement of the tapes, agreeably to the preceding description; the feeder B, with the rollers C and D, is seen to have an independent endless girth.

The diagram, *fig.* 1689, explains the structure of a machine contrived by Messrs. Applegath and Cowper for printing 'The Times' newspaper; but which is now superseded by Mr. Applegath's Vertical Printing Machine. Here there are four places to lay on the sheets, and four to take them off; consequently, the assistance of eight lads is required. P, P, P, P, are the four piles of paper; F, F, F, F, are the four feeding-boards;

1689



E, E, E, E, are the four entering drums, upon which the sheets are introduced between the tapes *t*, *t*, *t*, *t*, whence they are conducted to the four printing cylinders, 1, 2, 3, 4;

T is the form of type; I, I, are two inking-tables; of which one is placed at each end of the form. The inking apparatus is similar to that above described, with the addition of two central inking-rollers R, which likewise receive their ink from the inking-tables. The printing cylinders 1, 2, 3, 4, are made to rise and fall about half an inch; the first and third simultaneously, as also the second and fourth. The form of type, in passing from A to B, prints sheets at 1 and 3; in returning from B to A, it prints sheets at 4 and 2; while the cylinder alternately falls to give the impression, and rises to permit the form to pass untouched.

Each of the lines marked *t*, consists of two endless tapes, which run in contact in the parts shown, but separate at the entering drums E, and at the taking-off parts *o*, *o*, *o*, *o*. The return of the tapes to the entering drum is omitted in the diagram, to avoid confusion of the lines.

The sheets of paper being laid upon their respective feeding-boards, with the fore edges just in contact with the entering drum, a small roller, called the drop-down roller, falls down at proper intervals, upon the edges of the sheets; the drum and the roller being then removed, instantly carry on the sheet, between the tapes *t*, downwards to the printing cylinder, and thence upwards to *o*, *o*, *o*, *o*, where the tapes are parted, and the sheet falls into the hands of the attendant boy.

This invention fully answered the purpose of 'The Times' until the immense demand upon its powers rendered it necessary to provide a machine which could *work off from* 12,000 to 15,000 *copies of the paper per hour.*

Mr. Applegath, to whom the world is indebted for the invention of the printing machine capable of doing this large duty, decided on abandoning the reciprocating motion of the type-form, and arranging the apparatus so as to render the motion continuous. This necessarily involved circular motion, and accordingly he resolved upon attaching the columns of type to the sides of a large drum or cylinder, placed with its axis vertical, instead of the horizontal frame which had been hitherto used. A large central drum is erected, capable of being turned round its axis. Upon the sides of this drum are placed vertically the columns of type. These columns, strictly speaking, form the sides of a polygon, the centre of which coincides with the axis of the drum, but the breadth of the columns is so small compared with the diameter of the drum, that their surfaces depart very little from the regular cylindrical form. On another part of this drum is fixed the inking-table. The circumference of this drum in 'The Times' printing machine measures 200 inches, and it is consequently 64 inches in diameter.

The general form and arrangement of the machine are represented in *fig.* 1690, where D is the great central drum which carries the types and inking-tables.

This drum is surrounded by eight cylinders, R, R, &c., also placed with their axes vertical, upon which the paper is carried by tapes in the usual manner. Each of these cylinders is connected with the drum by toothed wheels, in such a manner that their surfaces respectively must necessarily move at exactly the same velocity as the surface of the drum. And if we imagine the drum thus in contact with these eight cylinders to be put in motion, and to make a complete revolution, the type-form will be pressed successively against each of the eight cylinders, and if the type were previously inked, and each of the eight cylinders supplied with paper, eight sheets of paper would be printed in one revolution of the drum.

It remains, therefore, to explain, first, how the type is eight times inked in each revolution; and secondly, how each of the eight cylinders is supplied with paper to receive their impression.

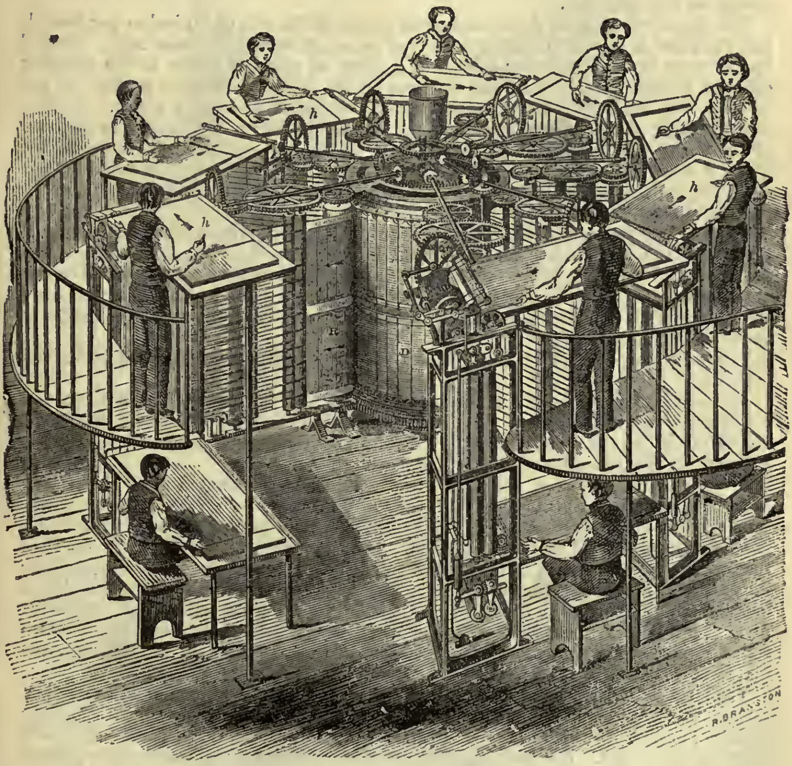
Beside the eight paper-cylinders are placed eight sets of inking-rollers; near these are placed two ductor rollers. These ductor rollers receive a coating of ink from reservoirs placed above them. As the inking-table attached to the revolving drum passes each of these ductor rollers, it receives from them a coating of ink. It next encounters the inking-rollers, to which it delivers this coating. The types next, by the continued revolution of the drum, encounter these inking-rollers, and receive from them a coating of ink, after which they meet the paper-cylinders, upon which they are impressed, and the printing is completed.

Thus in a single revolution of the great central drum the inking-table receives a supply eight times successively from the ductor rollers, and delivers over that supply eight times successively to the inking-rollers, which, in their turn, deliver it eight times successively to the faces of the type, from which it is conveyed finally to the eight sheets of paper held upon the eight cylinders by the tapes.

Let us now explain how the eight cylinders are supplied with paper. Over each of them is erected a sloping desk, *h*, *h*, &c., upon which a stock of unprinted paper is deposited. Beside this desk stands the 'layer on,' who pushes forward the paper, sheet by sheet, towards the fingers of the machine.

These fingers, seizing upon it, first draw it down in a vertical direction between tapes in the eight vertical frames until its vertical edges correspond with the position of the form of type on the printing cylinder. Arrived at this position its vertical motion is stopped by a self-acting apparatus provided in the machine, and it begins to move horizontally, and it is thus carried towards the printing cylinder by the tapes. As it passes round this cylinder it is impressed upon the type, and printed. It is then carried back horizontally by similar tapes on the other side of the frame, until it arrives at another desk, where the 'taker off' awaits it. The fingers of the machine are there disengaged from it, and the 'taker off' receives it, and disposes it upon the desk. This movement goes on without interruption; the moment that one sheet descends from the hands of the 'layer on,' and being carried vertically downwards begins to move horizontally, space is left for another, which he immediately supplies, and in this manner he delivers to the machine at the average rate of two

1690



sheets every five seconds; and the same delivery taking place at each of the eight cylinders, there are 16 sheets delivered and printed every five seconds.

It is found that by this machine in ordinary work between 10,000 and 11,000 per hour can be printed; but with very expert men to deliver the sheets, a still greater speed can be attained. Indeed, the velocity is limited, not by any conditions affecting the machine, but by the power of the men to deliver the sheets to it.

In case of any misdelivery, a sheet is spoiled, and, consequently, the effective performance of the machine is impaired. If, however, a still greater speed of printing were required, the same description of machine, without changing its principle, would be sufficient for the exigency; it would be necessary that the types should be surrounded with a greater number of printing cylinders.

It may be right to observe that these surrounding cylinders and rollers, in the case of 'The Times' machine, are not uniformly distributed round the great central drum; they are so arranged as to leave on one side of that drum an open space equal to the width of the type-form. This is necessary in order to give access to the type-form so as to adjust it.

One of the practical difficulties which Mr. Applegath had to encounter in the solution of the problem, which he has so successfully effected, arose from the shock produced to the machinery by reversing the motion of the horizontal frame, which in the old machine carried the type-form and inking-table, a moving mass which weighed a ton! This frame had a motion of 88 inches in each direction, and it was found that such a weight could not be driven through such a space with safety at a greater rate than about 45 strokes per minute, which limited its *maximum* producing power to 5,000 sheets per hour.

Another difficulty in the construction of this vast piece of machinery was, so to regulate the self-acting mechanism that the impression of the type-form should always be made in the centre of the page, and so that the space upon the paper occupied by the printed matter on one side may coincide exactly with that occupied by the printed matter on the other side.

The type-form fixed on the central drum moves at the rate of 70 inches per second, and the paper is moved in contact with it of course at exactly the same rate. Now, if by any error in the delivery or motion of a sheet of paper, it arrive at the printing cylinder 1–70th part of a second too soon or too late, the relative position of the columns will vary by 1–70th part of 70 inches—that is to say, by 1 inch. In that case the edge of the printed matter on one side would be an inch nearer to the edge of the paper than on the other side. This is an incident which rarely happens, but when it does, a sheet, of course, is spoiled. The waste, however, from that cause is considerably less in the present vertical machine than in the former less powerful horizontal one.

The vertical position of the inking-rollers is more conducive to the goodness of the work—for the type and engraving are only touched on their extreme surface—than the horizontal machine, where the inking-rollers act by gravity; also any dust shaken out of the paper, which formerly was deposited upon the inking-rollers, now falls upon the floor. With this machine 50,000 impressions have been taken without stopping to brush the form or table.

The principle of this vertical-cylinder machine is capable of almost unlimited extension.

An American machine, the invention of R. Hoe and Company, of New York, was a few years ago introduced to this country. Machines of this description were made for 'The Times,' and other newspaper offices, by Mr. Whitworth of Manchester. The following is Mr. Hoe's description of this machine:—

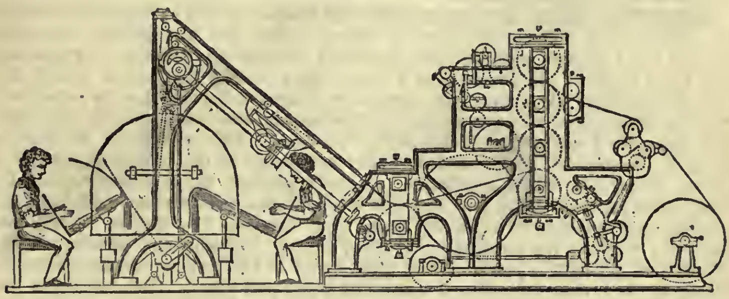
A horizontal cylinder of about 4½ feet in diameter is mounted on a shaft, with appropriate bearings; about one-fourth of the circumference of this cylinder constitutes the bed of the press, which is adapted to receive the form of types—the remainder is used as a cylindrical distributing-table. The diameter of the cylinder is less than that of the form of types, in order that the distributing portion of it may pass the impression-cylinders without touching. The ink is contained in a fountain placed beneath the large cylinder, from which it is taken by a ductor roller, and transferred by a vibrating distributing-roller to the cylindrical distribution-table; the fountain roller receives a slow and continuous rotatory motion, to carry up the ink from the fountain.

The large cylinder being put in motion, the form of types thereon is, in succession, carried to eight corresponding horizontal impression-cylinders, arranged at proper distances around it, which give the impression of eight sheets, introducing one at each impression-cylinder. For each impression-cylinder there are two inked rollers, which vibrate on the distributing surface while taking a supply of ink, and at the proper time pass over the form, when they again fall to the distributing surface. Each page is locked up upon a detached segment of the large cylinder, called by the compositors a 'turtle,' and this constitutes the bed and chase. The column-rules run parallel with the shafts of the cylinder, so as to bind to types near the top. These wedge-shaped column-rules are held down to the bed or 'turtle' by tongues, projecting at intervals along their length, and sliding in rebated grooves cut cross-wise in the face of the bed; the space in the grooves between the column-rules being filled with sliding blocks of metal, accurately fitted, the outer surface level with the surface of the bed, the ends next the column-rules being cut away underneath to receive a projection on the sides of the tongues and screws at the end and side of each page to lock them together, the types are as secure on this cylinder as they can be on the old flat bed.

In 'The Times' office there are two of those machines, one of them being a ten-cylinder machine, which is regularly employed to print 16,000 sheets an hour, and it appears capable of printing 18,000. It is only by means of these two American machines, and two of Applegath's, all working on the different sides of the paper, that the enormous supply required every morning can be produced.

The Walter Press (*fig.* 1691).—In 1862, the circulation of 'The Times' having considerably increased, together with the necessity of issuing quadruple and sextuple sheets, caused the proprietors to increase the power of the machines then in use, and the whole has since been completely superseded by various new productions. The first of these is the Walter Press, brought to maturity in 'The Times' Printing-office, and manufactured on the premises in Printing-House Square. It is almost an original invention; its principal merits being its simplicity, compactness, speed, and economy. It is what is called a 'perfecting machine,' as it prints both sides of the sheet at one revolution. The paper passing through the machine in a direct line, and with mechanical precision, the register will always be perfect; that is to say, the pages on one

1691



side are printed exactly on the back of the pages on the other side. The Walter machine occupies a space of only 14 feet by 5 feet, or less than any other machine yet introduced. The speed being altogether independent of manual dexterity, and regulated solely by mechanical appliances, is capable of increase in a way that no other printing machine on any other principle can possibly be. The exclusive use of stereotype-plates releases the type from all wear and tear, so that a fount of type, instead of being renewed every two years, will last at least twenty. The type at present employed in printing 'The Times' has been in use about 15 years. The plates, after being employed for one day's impression, are melted down for the next. The paper mounted on a huge reel, 3 miles 120 yards in length, as it comes from the paper-mill, appears to fly through among the cylinders at the rate of nearly 1,000 feet a minute, and is printed in less than 25 minutes; each reel, when printed, produces 4,350 newspapers. It is led from the reel into a series of small cylinders, where it passes through a trough of cold water, and is then brought between the first and second of four cylinders raised perpendicularly above each other. The top cylinder is encircled by stereotype-casts from four pages of type, and the lowest of the four cylinders is similarly surrounded by stereotype-plates of the remaining four pages of the newspaper. In passing through the first pair of impression-cylinders it is printed on one side. It is next reversed, and passes through the second pair of cylinders, where it is printed on the other side. It then continues its course onwards, passing between two cutting-cylinders, placed in the centre of the machine, which divide the web of the now printed paper into its proper length, forming a complete newspaper. The sheets are then rapidly conducted by tapes into a swing frame, which, as it vibrates, delivers them alternately on either side, and deposits them on tables at which two lads sit to receive them. The sole attendants necessary are those two lads and an overlooker, who places the stereotype-plates on the machine, starts it, and attends to the rolls of paper as they are unwound. The delay in changing from one reel to another scarcely exceeds one minute. The sheets are printed at the rate of 12,000 copies per hour. The machine is almost self-acting, the ink being pumped up into an ink-box from a cistern in the room below. An index is fixed to each machine, which counts each sheet as it is cut. Four, and sometimes five, of these machines are necessary for the printing of 'The Times,' according to the time required for its publication; the whole number being printed in from one hour to one hour and a half. If four machines are required, four stereotype-plates are required from each page. If five machines, five plates of each page, which would be forty plates in the whole. Each page is cast in about twenty minutes.

The following table shows the number of letters in each of the morning newspapers, taken during the month of April 1873:—

Morning Post	632,886	Standard	708,428
Morning Advertiser	684,715	Daily Telegraph	1,053,200
Daily News	704,619	The Times	2,195,963

Platen Machine, or the Spottiswoode Press.—The first successful application of steam, as a motive power, to printing presses with a platen and vertical pressure was made in the office where this book is being printed. Convinced of the superiority of the impression made by flat as compared with that of cylindrical pressure, Mr. Andrew Spottiswoode, assisted by his chief engineer, Mr. Brown, succeeded, after many experiments, in perfecting a machine which combines the excellence of the hand-press with more than four times its speed, and a uniformity in colour which can never be attained by inking by hand. The main point of the invention is the endless screw or drum which takes the carriage and type under the platen, and, after the impression is taken, returns it to its original position.

PRINTING AND NUMBERING CARDS. It will be remembered that in the early days of railway travelling, the ticket system then in vogue at the various stations was a positive nuisance; as every ticket before it was delivered to a passenger had to be stamped and torn out of a book,—thus causing the loss of considerable time to travellers when many passengers were congregated. The first to remedy this was Mr. Edmondson, who constructed an ingenious apparatus for printing the tickets with consecutive numbers, and also dating the same. This gave great facilities for checking the accounts of the station clerks; but owing to the imperfect manner of inking, consequent on the construction of the apparatus, the friction to which the tickets were exposed, before they were delivered up, in a great manner obliterated the printing, and occasionally rendered them quite illegible. By Messrs. Church and Goddard's machine for printing, numbering, cutting, counting, and packing railway tickets, this difficulty is removed, and great speed is attained in manufacturing the tickets, as the several operations are simultaneously performed. Pasteboard cut into strips by means of rollers is fed into the machine, by being laid in a trough, and brought under the prongs of a fork (working with an intermittent movement), which pushes the strips successively forward between the first pair of a series of guide or carrying rollers. There are four pairs of rollers, placed so as to conduct the strip through the machine in a horizontal line; and an intermittent movement is given them for the purpose of carrying the strips forward a short distance at intervals. The standards of the machine carry, at the top, a block termed 'the platen,' as it acts the part of the press-head in the common printing machine,—portions of it projecting downwards between the upper rollers of the first and second, and second and third pairs of carrying rollers, nearly to the horizontal plane, in which the pasteboard lies, so as to sustain it at those points while it receives the pressure of the printing types and numbering discs, hereafter referred to. The types to designate the nature of the ticket, as 'Birmingham, First Class,' are secured in a 'chase,' upon a metal plate or table, which also carries the numbering discs for imprinting the figures upon the cards; and the table by a cam action is alternately raised, to bring the types and numbering discs in contact with the pasteboard, and then lowered into a suitable position, to admit of an inking-roller moving over the types and numbering discs, and applying ink thereto. The table likewise carries at one end a knife, which acts in conjunction with a knife-edge, projecting downwards from the fixed head of the machine, and thereby gives the cross-cut to the strips between the third and fourth pairs of carrying rollers,—thus severing each into a given number of tickets. The strip of pasteboard which is fed into the machine stops on arriving at the second pair of carrying rollers; and, on the ascent of the printing-table, the types print on that portion which is between the first and second pairs of rollers. The strip then passes on to the third pair of rollers, where it stops; and, on the table again ascending, the numbering discs imprint the proper number upon the pasteboard between the second and third pairs; the type, in the meanwhile, printing what is to be the next following ticket. On the next ascent of the table, the strip has advanced to the fourth pair of rollers; and the knives being now brought into contact, the printed and numbered portion of the strip is severed. The now completed ticket is lastly delivered by the fourth pair of rollers into a hollow guide piece, and conducted to a box below, provided with a piston, which, to facilitate the packing of the tickets in the box, can be adjusted to any height to receive the tickets as they fall. To avoid the necessity of having to count the tickets after they are taken from the receiving box, a counting apparatus, connected with the working parts of the machine, is made to strike a bell on the completion of every hundred or more tickets, so as to warn the attendant to remove them from the box. The inking apparatus is assimilated in character to self-acting inkers in ordinary printing presses; and the numbering discs are worked in a manner very similar to those for paging books.

A simple arrangement of apparatus for printing and numbering cards has been introduced by Messrs. Harrild and Sons. The types are fixed in a metal frame, which also carries the numbering discs. This frame is mounted on a rocking shaft, and is furnished with a handle, whereby it is rocked to bring down the types and discs upon the card, to produce the impression. When the frame is raised again, the units disc is moved forward one figure, and the types are inked by a small roller, which takes its supply of ink from an inking-table, that forms the top of the frame.

M. Baranowski, of Paris, invented a machine for printing and numbering tickets, and also indicating the number printed. The types and numbering discs are carried by a horizontal rotating shaft, upon which, near each end thereof, is a metal disc; and upon the periphery of these discs a metal frame is affixed, which carries the types and numbering discs, and corresponds in curvature with the edge of the discs. The types for printing the inscription upon the ticket are arranged at right angles to the length of the shaft, which position admits of some lines of the inscription being printed in one colour, and the remainder in another colour. In the type-frame a slot or opening is formed lengthwise of the shaft; and behind this opening are three numbering discs, and three discs for indicating the quantity of tickets numbered,—all standing in the same row. The numbering discs are made with raised figures, which project through the slot, in order to print the number upon the ticket; and on the peripheries of the registering discs (which move simultaneously with their corresponding numbering discs), the figures are engraved. The tickets to be printed and numbered are placed in a rectangular box or receiver, having at the bottom a flat sliding piece, which has a reciprocating motion for the purpose of pushing the lowest ticket out of the box, through an opening in the front side thereof, beneath an elastic pressing-roller of india-rubber; the type-frame (with the types and figures properly inked), is at the same time brought, by the rotation of its shaft, into contact with the ticket beneath the pressing roller, and as it continues its motion, it causes the ticket to move forward beneath the pressing roller, and to be properly printed and numbered. The ticket then falls from the machine; and the type-frame, carried on by the revolution of the shaft, brings that number on the registering discs which corresponds with the number printed on the ticket, under a small opening in the case, covered with glass; whereby the number of tickets printed will be indicated.

PRINTING, NATURE. See Nature Printing.

PRINTING ROLLERS. Elastic inking-rollers were introduced by Messrs. Donkin and Bacon. They are made of a mixture of glue and treacle, or of glue and honey; the American honey, it is said, being preferred. 1 pound of good glue is softened by soaking in cold water for twelve hours, and then it is united, by means of heat, with about two pounds of ordinary treacle. See Printing.

Messrs. Hoe & Co. give the following directions for making and preserving composition-rollers: For *cylinder-press rollers*, Cooper's No. 1. x glue is sufficient for ordinary purposes, and will be found to make as durable rollers as higher-priced glues:—

Place the glue in a bucket or pan, and cover it with water; let it stand half an hour, or until about half penetrated with water (care should be used not to let it soak too long), then pour it off, and let it remain until it is soft. Put it in the kettle and cook it until it is thoroughly melted. If too thick, add a little water until it becomes of proper consistency. The molasses may then be added, and well mixed with the glue by frequent stirring. When properly prepared, the composition does not require boiling more than an hour. Too much boiling candies the molasses, and the roller consequently will be found to lose its suction much sooner. In proportioning the material, much depends upon the weather and temperature of the place in which the rollers are to be used. 8 pounds of glue to 1 gallon of sugar-house molasses, or syrup, is a very good proportion for summer, and 4 pounds of glue to 1 gallon of molasses for winter use.

Hand-press rollers may be made of Cooper's No. 1¼ (one and a quarter) glue, using more molasses, as they are not subject to so much hard usage as *cylinder-press rollers*, and do not require to be as strong; for the more molasses that can be used the better is the roller. Before pouring a roller, the mould should be perfectly clean, and well oiled with a swab, but not to excess.

Rollers should not be washed immediately after use, but should be put away with the ink on them, as it protects the surface from the action of the air. When washed and exposed to the atmosphere for any length of time, they become dry and skinny. They should be washed about half an hour before using them. In cleaning a *new* roller, a little oil rubbed over it will loosen the ink, and it should be scraped clean with the back of a case-knife. It should be cleaned in this way for about one week, when *lye* may be used. New rollers are often spoiled by washing them too soon with lye. Camphene may be substituted for oil; but owing to its combustible nature it is objectionable, as accidents may arise from its use.

PRINTING, STEREOTYPE. See STEREOTYPE.

PROOF SPIRIT. See ALCOHOL.

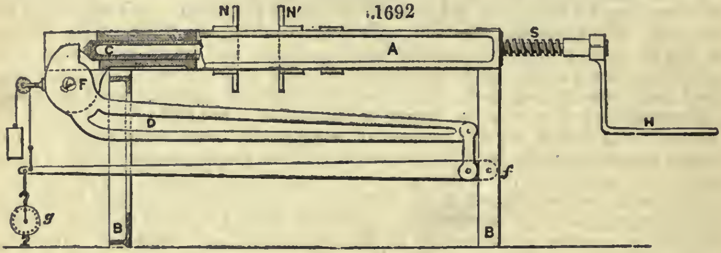
PROPYLENE. A gas obtained among the products of the decomposition of amylic alcohol. See GAS-COAL.

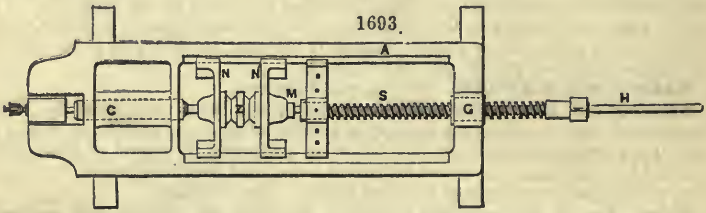
PROTEINE. The name given to the substance obtained by digesting albuminous matters in weak caustic potash, and precipitating by acetic acid.

PROTOGINE (πρῶτος, first; γίγνομαι, to form). A granite composed of felspar, quartz, and talc. This term is nearly restricted to the French geologists.

PROUSTITE, or *Light Red Silver Ore.* An arsenio-sulphide of silver, resembling pyrargyrite, but distinguished by its paler cochineal-red colour. It is a valuable ore, found in Saxony, Mexico, Chili, Nevada, &c. See SILVER.

PROVING MACHINE. The figures show a useful machine for testing the quality and power of india-rubber springs, designed by Mr. George Spencer, of the





firm of Geo. Spencer and Co., and used by them for that purpose. *Fig.* 1692 shows an elevation, partly in section, of the machine: *fig.* 1693 a plan of the same. A is a strong cast-iron frame, supported by two cast-iron standards, B, B; C is a sliding piston, working in a hole cast in the end of frame, A, one end of which impinges against the short arm of a strong cast-iron lever, D, forming one of a system of compound levers as shown, having fulcrums at F and *f*, and provided with a Salter's balance, *g*, to register the power exerted by the spring.

At the other end of frame, A, a brass nut, G, is placed in a hole in the frame, through which a square-threaded screw, S, works by means of the handle, H, or by a long lever of wrought iron, according to the power of spring to be tested.

The spring to be tested is placed between the two sliding guide-plates, N, N′, and a wrought-iron bolt passed through the plates, N, N′, and spring, Z, and passing into the hollow piston, C, for the purpose of keeping the spring in correct position, and receiving in its hollow head, M, the end of the screw, S. The action may be thus described:—The handle, H, being turned, the screw, S, advances and pushes on the plate N′, by means of the bolt-head, M. The other plate, N, rests against the piston, C, and is pressed against it by the intervening spring, Z. The leverage, D, is so arranged that 1 lb. on the dial is equal to 2 cwts. on the spring, or, in other words, is 1 in 224. Springs of a force of 20 tons can be tested by this machine safely. See CAOUTCHOUC.

PROVISIONS, CURING OF. See MEATS, PRESERVED; PUTREFACTION.

PRUNELLA. A thin woollen or mixed stuff now chiefly used for covering shoes, especially such as are worn by old women.

PRUNUS. A genus of the *Rosaceæ*, containing several species which yield edible fruits. The varieties of *P. domestica* are known as plums, greengages, and damsons. *P. cerasus* is the cherry; *P. Armeniaca* the apricot; and *P. spinosa* the sloe or blackthorn.

PRUSSIAN BLUE. (*Berliner Blau*, Ger.) This is, in its pure state, a ferrocyanide of iron (ferric-ferrocyanide). When organic matters abounding in nitrogen, such as dried blood, horns, hair, skins, or hoofs of animals, are triturated along with potash in a strongly-ignited iron pot, a dark grey mass is obtained, that affords to water the liquor originally called *lixivium sanguinis*, or blood-lye. This solution yields crystals, known in commerce as the yellow prussiate of potash. If to this salt solutions of any per-salt of iron be added, Prussian blue is formed. If the iron in the salt employed be present as protoxide, it will afford a precipitate, at first pale blue, which turns dark blue in the air. If, however, the salt employed contains peroxide of iron (ferric salts) the precipitate is at once a dark blue. The white cyanide of iron (the prussiate of the pure protoxide) when exposed to the air in a moist condition, becomes, as above stated, dark blue; yet the new combination formed in this case through absorption of oxygen, is essentially different from that resulting from the precipitation by the peroxide of iron, since it contains an excess of the peroxide in addition to the usual two cyanides of iron. It has been therefore called *basic* Prussian blue, and, from its dissolving in pure water, *soluble* Prussian blue.

Both kinds of Prussian blue agree in being void of taste and smell, in attracting humidity from the air when they are artificially dried, and being decomposed at a heat above 348° Fahr. The neutral or insoluble Prussian blue is not affected by alcohol; the basic, when dissolved in water, is not precipitated by that liquid. Neither is it acted upon by dilute acids; but they form with concentrated sulphuric acid a white pasty mass, from which they are again reproduced by the action of cold water. They are decomposed by strong sulphuric acid at a boiling-heat, and by strong nitric acid at common temperatures; but they are hardly affected by the muriatic. They become green with chlorine, but resume their blue colour when treated with deoxidising reagents. When Prussian blue is digested in warm water along with potash, soda, or lime, peroxide of iron is separated, and a ferroprussiate of potash, soda, or lime remains in solution.

The precipitation of Prussian blue.—Green sulphate of iron is commonly employed by the manufacturer, on account of its cheapness, for mixing with solution of the ferroprussiate, in forming Prussian blue, though the persulphate, nitrate, or muriate of iron would afford a much richer blue pigment. Whatever salt of iron be preferred, it should be carefully freed from any cupreous impregnation, as this would give the pure blue a dirty brownish cast. The green sulphate of iron is the most advantageous precipitant, on account of its affording protoxide, to convert into ferrocyanide any cyanide of potassium that may happen to be present in the uncrystallised lixivium. The carbonate of potash in that lixivium might be saturated with sulphuric acid before adding the solution of sulphate of iron; but it is more commonly done by adding a certain portion of alum, in which case alumina falls along with the Prussian blue; and though it renders it somewhat paler, yet it proportionally increases its weight; whilst the acid of the alum saturates the carbonate of potash, and prevents its throwing down iron-oxide, to degrade by its brown-red tint the tone of the blue. For every pound of pearlash used in the calcination, from two to three pounds of alum are employed in the precipitation. When a rich blue is wished for, the free alkali in the Prussian lye may be partly saturated with sulphuric acid, before adding the mingled solutions of copperas and alum. One part of the sulphate of iron is generally allowed for 15 or 20 parts of dried blood, and 2 or 3 of horn-shavings or hoofs. But the proportion will depend very much upon the manipulations; which, if skilfully conducted, will produce more of the cyanides of iron, and require more copperas to neutralise them. The mixed solutions of alum and copperas should be progressively added to the lye as long as they produce any precipitate. This is not at first a fine blue, but a greenish grey, in consequence of the admixture of some white cyanide of iron; it becomes gradually blue by the absorption of oxygen from the air, which is favoured by agitation of the liquor. Whenever the colour seems to be as beautiful as it is likely to become, the liquor is to be run off by a spigot or cock from the bottom of the precipitation vats, into flat cisterns, to settle. The clear supernatant fluid, which is chiefly a solution of sulphate of potash, is then drawn off by a syphon; more water is run on with agitation to wash it, which after settling is again drawn off; and whenever the washings become tasteless, the sediment is thrown upon filter sieves, and exposed to dry, first in the air of a stove, but finally upon slabs of chalk or Paris-plaster. But for several purposes, Prussian blue may be best employed in the fresh pasty state, as it then spreads more evenly over paper and other surfaces.

A good article is known by the following tests:—It feels light in the hand, adheres to the tongue, has a dark lively blue colour, and gives a smooth deep trace; it should not effervesce with acids, as when adulterated with chalk; nor become pasty with boiling water, as when adulterated with starch. The Paris blue, prepared without alum, with a peroxide salt of iron, displays, when rubbed, a copper-red lustre, like indigo. Prussian blue, degraded in its colour by an admixture of free oxide of iron, may be improved by digestion in dilute sulphuric or muriatic acid, washing, and drying.

Its relative richness in the real ferroprussiate of iron may be estimated by the quantity of potash or soda which a given quantity of it requires to destroy its blue colour.

Sulphuretted hydrogen passed through Prussian blue diffused in water whitens it; while prussic acid is eliminated, sulphur is thrown down, and the sesquicyanide of iron is converted into the single cyanide. Iron and tin operate in the same way. When Prussian blue is made with two atoms of ferrocyanide of potassium instead of one, it becomes soluble in water. Soluble Prussian blue is generally prepared by adding perchloride of iron to excess of ferrocyanide of potassium.

For the mode of applying this pigment in dyeing, see Calico-Printing.

A process for Prussian blue, which deserves notice, as the first in which that interesting compound was made to any extent independently of animal-matter, was introduced by Mr. Lewis Thompson, who received a medal from the Society of Arts, in 1837, for this invention. He observed that in the common way of manufacturing prussiate of potash, the quantity of nitrogen furnished by a given weight of animal-matter is not large, and seldom exceeds 8 per cent.; and of this small quantity, at least one half appears to be dissipated during the ignition. It occurred to him that the atmosphere might be economically made to supply the requisite nitrogen, if caused to act in favourable circumstances upon a mixture of carbon and potash. He found the following to answer:—Take of pearlash and coke, each 2 parts; iron turnings, 1 part; grind them together into a coarse powder; place this in an open crucible, and expose the whole for half an hour to a full red heat in an open fire, with occasional stirring of the mixture. During this process, little jets of purple flame will be observed to rise from the surface of the materials. When these cease, the crucible must be removed and allowed to cool. The mass is to be lixiviated; the lixivium, which is a solution of ferrocyanide of potassium, with excess of potash, is to be treated in the usual way, and the black matter set aside for a fresh operation, with a fresh dose of pearlash. Mr. Thompson stated that one pound of pearlash, containing 45 per cent. of alkali, yielded 1,355 grains of pure Prussian blue, or ferrocyanide of iron, or about 3 ounces avoirdupois.

Of late years several improvements have been introduced into the manufacture of Prussian blue, relating chiefly to oxidation of the white precipitate thrown down from a solution of green sulphate of iron and alum by means of yellow prussiate of potash. Instead of oxidising this precipitate by exposure to the atmosphere, recourse may be had to the oxidising power of chlorine; thus nitro-muriatic acid (aqua regia) may be added to the precipitate. Perchloride of iron or perchloride of manganese may be used with similar effect.

Prussian blue may also be prepared from the ammoniacal liquor of gas-works, or from the spent lime of gas-purifiers.

PRUSSIAN BROWN. A fine deep brown colour obtained by adding the yellow prussiate of potash (ferrocyanide of potassium) to a solution of sulphate of copper.

PRUSSIATE OF POTASH. See Potash, Prussiate of.

PRUSSIC ACID. See Hydrocyanic Acid.

PSILOMELANE. An ore of Manganese, which see.

PUDDLING OF IRON. See Iron.

PUFF PASTE. A preparation of flour and butter, which is in great demand, not only at the pastry-cooks', but in almost every private family. Take a certain quantity of flour, say half a pound, put it upon a wooden board, make a hole or depression in the centre, and mix it with somewhat less than half a pint of cold water, so as to make a softish paste; dry it off from the board by shaking a little flour over and under, as is well known, but do not 'work it' more than you can help. Take now a quarter of a pound of fresh butter, which should be *as hard as possible* (and therefore it should be kept in as *cold* a place as practicable, the ice closet, if procurable, being the best place), and squeeze out all the water, or butter-milk which it contains, by kneading it with one hand on the board. This operation is called in French '*manier le beurre.*' Roll now the paste prepared as above into a flat, thick, square slab, extending about 6 or 7 inches; lay the pat of butter, treated as above, in the middle of the slab of paste, and so wrap the butter up into it by folding the sides of the paste all round over it; roll the whole mass gently with the rolling-pin, so as to form a thick sheet, put it upon a tin plate, or tray, cover it with a linen cloth wetted with water as cold as possible, and leave the whole at rest for about a quarter of an hour in a cold place. At the end of that time, roll the mass with the rolling-pin into a sheet about 15 or 16 inches long, and fold it into three, one over the other; roll it out again into a sheet as before, and again fold it into three, one over the other, as before, and repeat this operation once more, making three times in all. Put the square mass, with a wet cloth upon it, in a cold place for another quarter of an hour, as before, and at the end of that time roll it out with the rolling-pin, and fold it into three, one over the other, as above; and do this once more, making five times in all, after which the paste is ready for use. Care must be taken, during the rolling, continually to dust the board and the paste with a little flour, to prevent sticking. The paste may now be placed in the dish, or tin, in which it is to be baked, taking care to cut the protruding edges with a pointed and sharp knife, so as to leave the paste all round with a clean cut edge, for otherwise *it will not puff up or swell.* The thick edges of pies and tarts are made by cutting strips of the paste with the knife, and carefully laying them on all round, taking *care to leave the edges quite sharp.* The prepared articles are then put in an oven, previously brought to a good heat, and the elastic vapour disengaged from the butter and water will at once cause the paste to swell into parallel layers of great tenacity, and *apparently* light, but really very heavy, since each of these thin laminæ is compact and distinct. It is essential to the success of the operation that the floor of the oven should be hot.

PUMICE-STONE (*Pierre-ponce*, Fr.; *Bimstein*, Ger.) is a spongy, vitreous-looking mineral, consisting of fibres of a silky lustre, interlaced with each other in all directions. It floats upon water, is harsh to the touch, having in mass a mean sp. gr. of 0·914; though brittle, it is hard enough to scratch glass and most metals. Its colour is usually greyish white; but it is sometimes bluish, greenish, reddish, or brownish. It fuses without addition at the blowpipe into a white enamel. According to Klaproth, it is composed of silica, 77·5; alumina, 17·5; oxide of iron, 2; potassa and soda, 3; in 100 parts. The acids have hardly any action upon pumice-stone. The chief localities of pumice are, the Islands of Lipari, Ponza, Ischia, Vulcano, Andernach, upon the banks of the Rhine; in Teneriffe, Iceland, and Auvergne, &c.

PUMP. See Hydraulic Machinery.

PURBECK MARBLE. A hard bluish-grey limestone, so called from its being found in the Isle of Purbeck, where it occurs in the upper beds of the formation of that name. Like the Sussex marble, it is susceptible of a fine polish, and is crowded with the remains of a species of freshwater snail (*Paludina carinifera*), and the beauty of the marble is the result of the pattern produced by the sections of the included shells. These latter are of a much smaller species than those which occur in the Sussex marble, and the difference in the size of the shells affords an easy means of distinguishing between the two marbles.

Many old sepulchral monuments are partly composed of Purbeck marble; as are also the slender shafts and columns of many of the Gothic churches of this country, of which there are examples in the Temple Church in London, Westminster Abbey, Winchester and Salisbury Cathedrals, &c.

Fine blocks of this marble are still quarried in the Isle of Purbeck, but, except for ecclesiastical purposes, it is little used, in consequence probably of its inferiority to other marbles with regard to colour.—H. W. B.

PURPLE OF CASSIUS, *Gold purple* (*Pourpre de Cassius*, Fr.; *Goldpurpur*, Ger.). See Cassius, Purple of.

PURPLE OF MOLLUSCA. A viscid fluid, secreted by the *Buccinum lapillus*, and some other shell-fish. The Tyrian dye of the Greeks, and Imperial Purple of the Romans, was in all probability obtained from the same source,—the mollusca of the Mediterranean Sea. See Murexide.

PURPLE DYES. The purple dyes now obtained by more or less complex processes from coal-tar are so incomparably superior to any others, both in brilliancy and permanence, that their production has opened up a new era in dyeing and calico-printing. See Aniline, &c.

PURPURIC ACID is an acid obtained by treating uric or lithic acid with dilute nitric acid. It has a fine purple colour. See Murexide.

PURPURIN is the name of a colouring principle, supposed by Robiquet and Colin to exist in madder. See Madder.

PURREE. A yellow colouring-matter, imported into Europe from India and China. It is said to be formed from the urine of camels, elephants, and buffaloes, after the animals have eaten the fruit of the mangosteen. Stenhouse, however, believes it to be a vegetable extract mixed with magnesia. It is much used in the manufacture of Indian yellow, which is employed in oil and water-colour painting.

PUTREFACTION, *and its Prevention.* (*Fäulniss*, Ger.) Putrefaction is the spontaneous decomposition of albuminoid or protein and gelatine compounds, when exposed to a limited amount of air. It is the decomposition of bodies containing nitrogen, called by some persons azotised bodies, although they are produced only by life, are the principal means of producing life, and more fitly called *zoogens.*

Conditions of the Prevention of Putrefaction. The circumstances by which putrefaction is counteracted, are: 1, the chemical change of the azotised juices; 2, the abstraction of water; 3, the lowering of the temperature; and 4, the exclusion of oxygen. The methods actually in use may be called salting, smoking, drying, exclusion of air, and parboiling.

1. *The chemical changes of the azotised juices.*—The substance which in dead animal-matter is first attacked with putridity, and which serves to communicate it to the solid fibrous parts, is albumen, as it exists combined with more or less water in all the animal fluids and soft parts. In those vegetables also which putrefy, it is the albumen probably which first suffers decomposition; and hence those plants which contain most of that proximate principle are most apt to become putrid, and most resemble in this respect animal substances. The albumen when dissolved in water, very readily putrefies in a moderately warm air; but when coagulated, it seems as little liable to putridity as fibrin itself. By this change it throws off the superfluous water, becomes solid, and may then be easily dried. Hence those means which by coagulation make the albumen insoluble, or form with it a new compound, which does not dissolve in water, but which resists putrefaction, are powerful antiseptics. Whenever the albumen is coagulated, the uncombined water may be easily evaporated, and the residuary solid matter may be readily dried in the air, so as to be rendered unsusceptible of decomposition.

Some acids combine with the albumen, without separating its solution; such is the effect of vinegar, citric acid, tartaric acid, &c.

Tannin combines with the albuminous and gelatinous parts of animals, and forms insoluble compounds, which resist putrefaction; on which fact the art of tanning is founded.

Alcohol, oil of turpentine, and some other volatile oils, likewise coagulate albumen, and thereby protect it from putrescence. The most remarkable operation of this kind is exhibited by wood-vinegar, chiefly in consequence of the *creasote* contained in it, according to the discovery of Reichenbach. This peculiar substance has so decided a power of coagulating albumen, that even the minute portion of it present in pyroligneous vinegar assists in preserving animal parts from putrefaction, when they are simply soaked in it. Thus, also, flesh is cured by wood-smoke. Distilled wood-tar likewise protects animal-matter from change, by the creasote it contains. The pyroligneous acid was said to contain five per cent. of creasote; it does not do so now.

The metallic salts operate yet more effectually as antiseptics, because they form with albumen still more intimate combinations. Under this head we class the green and red sulphates of iron, chloride of zinc, the acetate of lead, and corrosive sublimate; the latter, however, from its poisonous qualities, can be employed only on special occasions. Nitrate of silver, though equally noxious to life, is so antiseptic that a solution containing only $\frac{1}{500}$th of the salt is capable of preserving animal-matter from corruption.

2. *Abstraction of water.*—Even in those cases where no separation of the albumen takes place in a coagulated form, or as a solid precipitate, by the operation of a substance foreign to the animal juices, putrefaction cannot go on, any more than other kinds of fermentation, in bodies wholly or in a great measure deprived of their water, as the albumen itself runs much more slowly into putrefaction, when less water is contained in it; and in the desiccated state it is as little susceptible of alteration as any other dry vegetable- or animal-matter. Hence, the proper drying of an animal substance becomes a universal preventive of putrescence. In this way fruits, herbs, cabbages, fish, and flesh may be preserved from corruption. If the air be not cold and dry enough to cause the evaporation of the fluids before putrescence begins, the organic substance must be dried by artificial means, such as by being exposed in thin slices in properly-constructed air-stoves. At a temperature under 140° F., the albumen dries up without coagulation, and may then be redissolved in cold water, with its valuable properties unaltered. Mere desiccation, indeed, can hardly ever be employed upon flesh. Culinary salt is generally had recourse to, either alone or with the addition of saltpetre or sugar. These alkaline salts abstract water in their solution, and, consequently, concentrate the aqueous solution of the albumen; whence, by converting the simple watery fluid into salt water, which is in general less favourable to the fermentation of animal-matter than pure water, and by expelling the air, and probably by chemical combinations, they counteract putridity. On this account salted meat may be dried in the air much more speedily and safely than fresh meat. The drying is promoted by heating the meat merely to such a degree as to consolidate the albumen, and eliminate the superfluous water.

3. *Defect of warmth.*—As a certain degree of heat is requisite for the vinous fermentation, so is it for the putrefactive. If in a damp atmosphere, or in one saturated with moisture, if the temperature stand at from 70° to 80° F., the putrefaction goes on most rapidly; but it proceeds languidly at a few degrees above freezing, and is suspended altogether at that point. The mammoths found in the Siberian ice are proofs of the preservative influence of low temperature. In temperate climates, ice-houses serve the purpose of keeping meat fresh and sweet for any length of time.

4. *Abstraction of oxygen gas.*—As the putrefactive decomposition of a body first commences with the absorption of oxygen from the atmosphere, so it may be retarded by the exclusion of this gas. It is not, however, enough to remove the aerial oxygen from the surface of the body, but we must expel all the oxygen that may be diffused among the vessels and other solids, as this portion suffices in general to excite putrefaction, if other circumstances be favourable. The expulsion is most readily accomplished by a boiling or lower heat, which, by expanding the air, evolves it in a great measure. Milk, soup, solution of gelatine, &c., may be kept long in a fresh state, if they be subjected in an air-tight vessel every other day to a boiling heat. Oxygenation may be prevented in several ways: by burning sulphur or phosphorus in the air of the meat receiver; by filling this with compressed carbonic acid; or with oils, fats, syrups, &c., and then sealing it hermetically. Charcoal-powder recently calcined is efficacious in preserving meat, as it not only excludes air from the bodies surrounded by it, but intercepts the oxygen by condensing it, and causing it to combine with putrefying substances. When butchers' meat is enclosed in a vessel filled with sulphurous acid, it absorbs the gas, and remains for a considerable time proof against corruption. The same result is obtained if the vessel be filled with ammoniacal gas. At the end of 76 days such meat has still a fresh look, and may be safely dried in the atmosphere.

Peculiar Antiseptic Processes.—Upon the preceding principles and experiments depend the several processes employed for protecting substances from putrescence and corruption. Here we must distinguish between those bodies which may be preserved by any media suitable to the purpose, as anatomical preparations or objects of natural history, and those bodies which, being intended for food, can be cured only by wholesome and agreeable means.

Preservation of specimens of animals, &c.—Many methods have been planned to preserve animals: all of them dependent on substances mentioned under DISINFECTANTS. Charles Waterton used corrosive sublimate dissolved in alcohol. The skin of the animal being separated, is dipped into the solution and dried. The inside of the animal is always removed, the bones scraped clean and dipped, the feathers or hairs touched by the solution, or the whole immersed in it. Sometimes alcohol of 60 to 70 per cent. is used, or alcohol of 30 per cent. with creasote dissolved in it. Sulphurous acid will not suit when there are colours, but sulphites of the alkalis have been injected into the veins and arteries with good result; as also sulphurous acid and creasote. Peron preserved fishes for specimens on shipboard by floating them in an alcoholic liquor by corks, thus preventing them from being pressed. He first washed them in sea-water, vinegar, and camphor spirits: he corked the vessels with tallowed corks. Dufresne wrapped each in a cloth with tow between the specimens, and all in alcoholic liquids. Louis Vernet used arsenic, 1 lb. in 40 gallons of water. Sulphate of zinc was proposed for embalming by Comte de Fontainemoreau, sometimes adding alcohol. Wood is preserved by Kyan's process, corrosive sublimate being used; also by Bethel's process, the use of heavy oil of tar; and manures are preserved by carbolates by MacDougall. Injection of the arteries and veins by chloride of zinc, chloride of arsenic, and chloride of aluminium, sulphate of zinc, and sulphates, corrosive sublimate, &c., have all been tried, and are more or less satisfactory. Peppers and spices of all kinds have been used in stuffing and embalming, and may all be made to act when care is employed and abundance used. Girolamo Segato dried bodies so hard that he made a table of 214 pieces of human flesh from different parts of the body. He is said also to have made members preserve their elasticity for an indefinite time. Some remarkable specimens of this kind are said to exist, and have received the honour of sanctity. Waterton made skins preserve their flexibility for some days by the use of corrosive sublimate and slow drying. Dr. Ure says, 'for preserving animal bodies in an embalmed form, mummy-like, a solution of chloride of mercury and wood-vinegar is most efficacious. As there is danger in manipulating with that mercurial salt, and as in the present state of our knowledge of creasote, we have it in our power to make a suitable strong solution of this substance in vinegar or spirit of wine, I am led to suppose that it will become the basis of most antiseptic preparations for the future.'

CURING OF PROVISIONS.

Flesh, &c.—The ordinary means employed for preserving butchers' meat are, drying, smoking, salting, and pickling or souring.

Drying.—The best mode of operating is as follows:—The flesh must be cut into slices from 2 to 6 ounces in weight, immersed in boiling water for five or six minutes, and then laid on open trellis-work in a drying-stove, at a temperature kept steadily about 122° F., with a constant stream of warm dry air. That the boiling water may not dissipate the soluble animal-matters, very little of it should be used, just enough for the meat to be immersed by portions in succession, whereby it will speedily become a rich soup, fresh water being added only as evaporation takes place. It is advantageous to add a little salt, and some spices, especially coriander-seed, to the water. After the parboiling of the flesh has been completed, the soup should be evaporated to a gelatinous consistence, in order to fit it for forming a varnish to the meat after it is dried, which may be completely effected within two days in the oven. By this process two-thirds of the weight is lost. The perfectly dry flesh must be plunged, piece by piece, in the fatty gelatinous matter liquefied by a gentle heat; then placed once more in the stove, to dry the layer of varnish. This operation may be repeated two or three times, in order to render the coat sufficiently uniform and thick. Butchers' meat dried in this way keeps for a year, affords, when cooked, a dish similar to that of fresh meat, and is therefore much preferable to salted provisions. The drying may be facilitated, so that larger lumps of flesh may be used, if they be imbued with some common salt immediately after the parboiling process, by stratifying them with salt, and leaving them in a proper pickling tub for 12 hours before they are transferred to the stove. The first method, however, affords the more agreeable article.

Baron Cha. Wetterstedt enclosed meat in corn- or potato-flour, then dried it on shelves at 120° F. Graefer, in 1780, parboiled and then dried. Some have proposed to hang the substances up and to allow no air to approach without passing it first through chloride of calcium to dry it. Milk was formerly preserved by drying to a powder.

Smoking.—This process consists in exposing meat previously salted, or merely rubbed over with salt, to wood-smoke in an apartment so distant from the fire as not to be unduly heated by it, and into which the smoke is admitted by flues at the bottom of the side walls. Here the meat combines with the empyreumatic acid of the smoke, and gets dried at the same time. The quality of the wood has an influence upon the smell and taste of the smoke-dried meat; smoke from beech wood and oak being preferable to that from fir and larch. Smoke from the twigs and berries of juniper, from rosemary, peppermint, &c., imparts somewhat of the aromatic flavour of these plants. A slow smoking with a slender fire is preferable to a rapid and powerful one, as it allows the empyreumatic principles time to penetrate into the interior substance, without drying the outside too much. To prevent soot from attaching itself to the provisions, they may be wrapped in cloth, or rubbed over with bran, which may be easily removed at the end of the operation.

The process of smoking depends upon the action of the wood-acid, or the creasote volatilised with it, which operates upon the flesh. The same change may be produced in a much shorter time by immersing the meat for a few hours in pyroligneous acid, then hanging it out in a dry air, which, though moderately warm, makes it fit for keeping, without any taint of putrescence. After a few days' exposure, it loses the empyreumatic smell, and then resembles thoroughly-smoked provisions. The meat dried in this way is in general somewhat harder than by the application of smoke, and therefore softens less when cooked, a difference to be ascribed to the more sudden and concentrated operation of the wood vinegar, which effects in a few hours what would require smoking for several weeks.

Salting.—The meat should be rubbed well with common salt, containing about one-sixteenth of saltpetre, and one thirty-secondth of sugar, till every crevice has been impregnated with it; then sprinkled over with salt, laid down for 24 or 48 hours, and, lastly, subjected to pressure. It must next be sprinkled anew with salt, packed into proper vessels, and covered with the brine obtained in the act of pressing, rendered stronger by boiling down. For household purposes it is sufficient to rub the meat well with good salt, to put it into vessels, and load it with heavy weights, in order to squeeze out as much pickle as will cover its surface. If this cannot be had, a pickle must be poured on it, composed of 4 pounds of salt, 1 pound of sugar, and 2 ozs. of saltpetre dissolved in 2 gallons of water.

Mr. Fitch patented the use of a liquid containing 2 cwts. of common salt to the product of distillation of 2 cwts. of wood, adding sugar, treacle, and saltpetre. Some people drive the salt in by force of pressure, some by centrifugal motion.

Milk has been preserved by the use of carbonate of soda, preventing acidity. Alum has been patented, for shellfish especially. See Milk, Condensed.

E. Masson injects the veins and arteries of carcases with a solution containing 10½ oz. of common salt and 3½ of nitre in 2½ pints of water. D. R. Long injects antiputrescent and flavouring substances, such as salt, saltpetre, spices, and vinegar. J. Murdoch injected chloride of aluminium, a very powerful agent, common salt, and nitre. Brooman communicated a proposal to use, first, sulphurous gas, and then coat thick with a substance keeping out the air. Chloride of lime has also been used in chambers holding meat, and sulphur has been burnt and nitrous gas has been evolved in similar places.

Preserving with vinegar, sugar, &c.—Vinegar dissolves or coagulates the albumen of flesh, and thereby counteracts its putrescence. The meat should be washed, dried, and then laid in strong vinegar. Or it may be boiled in the vinegar, allowed to cool in it, and then set aside in a cold cellar, where it will keep sound for several months.

Fresh meat may be kept for some months in water deprived of its air. If we strew on the bottom of a vessel a mixture of iron-filings and flowers of sulphur, and pour over them some water which has been boiled, so as to expel its air, meat immersed in it will keep a long time, if the water be covered with a layer of oil, from half an inch to an inch thick. Meat will also keep fresh for a considerable period when surrounded with oil, or fat of any kind, so purified as not to turn rancid of itself especially if the meat be previously boiled. This process is called 'potting.'

Eggs.—These ought to be taken new laid. The essential point towards their preservation is the exclusion of the atmospheric oxygen, as their shells are porous, and permit the external air to pass inwards, and to excite putrefaction in the albumen. There is also some oxygen always in the air-cell of the eggs, which ought to be expelled or rendered inoperative, which may be done by plunging them for 5 minutes in water heated to 140° F. The eggs must then be taken out, wiped dry, besmeared with some oil (not apt to turn rancid) or other unctuous matter, packed into a vessel with their narrow ends uppermost, and covered with sawdust, fine sand, or powdered charcoal. Eggs coated with gum arabic and packed in charcoal will keep fresh for a year. Lime-water, or rather milk of lime, is an excellent vehicle for keeping eggs in. Some persons coagulate the albumen partially, and also expel the air by boiling the eggs for two minutes, and find the method successful. When eggs are intended for hatching, they should be kept in a cool cellar. Eggs exposed, in the holes of perforated shelves, to a constant current of air lose about $\frac{3}{4}$ of a grain of their weight daily, and become concentrated in the albuminous part, so as to be little liable to putrefy. Each egg requires a hole in the shelf for itself. For long sea voyages, the surest means of preserving eggs is to dry up the albumen and yolk by first triturating them into a homogeneous paste, then evaporating this in an air-stove or a water-bath heated to 125°, and putting up the dried mass in vessels which may be made air-tight. When used, it should be dissolved in 3 parts of cold or tepid water.

The excellent process for preserving all kinds of butchers' meat, fish, and poultry, first contrived by M. Appert is described in the article MEATS, PRESERVED. That article also contains a description of the methods now practised for the preservation of Australian meat, which at the present time is largely imported into this country.

PUTTY POWDER. Binoxide of tin, obtained by treating metallic tin with nitric acid, when the metal is converted into hydrated metastannic acid, and this when heated becomes anhydrous. In this state it is known as *putty powder*, and is employed as a polishing agent; it is also used to impart an opaque white colour to enamels and dial-plates.

PYRARGYRITE, or *Dark-red Silver-ore.* An antimonio-sulphide of silver, forming a valuable ore at Andreasberg in the Hartz, in Mexico, and in Chile. See SILVER.

PYRETHRUM. A genus of plants belonging to the natural order *Compositæ.* It contains the feverfew and the pellitory of Spain.

PYRIDINE, $C^{10}H^5N$ (**C^5H^5N**). A volatile base homologous with picoline, lutidine, collidine, and parvoline. It was discovered by Anderson in bone-oil. It is also contained in Dorset shale, naphtha, coal-naphtha, and in crude chinoline.

PYRITES. A term originally applied to yellow sulphide of iron, because it struck fire with steel. It is in strictness still confined to this mineral; but where sulphur exists in combination with copper, cobalt, or nickel, these minerals also are called pyrites.

1. *Iron Pyrites, Mundic; Schwefelkies, Eisenkies.*—This important mineral is dimorphous, crystallising both in the cubic and rhombic systems, the latter variety being known by the special name of *Marcasite*, or *white iron pyrites.* Its composition is a bisulphide of iron, FeS^2, containing 46·7 per cent. of iron and 53·3 per cent. of sulphur; but on the large scale it almost invariably contains gold, from mere traces up to a workable quantity (several ounces per ton), and by intimate association with copper pyrites, copper; such varieties are known as *copper mundic*, to distinguish them from ordinary pyrites, or *sulphur mundic*, whose chief value is as a source of sulphuric acid.

Cubical pyrites occurs in variously-modified crystals, the usual forms being cubes or pentagonal dodecahedra, or combinations of both. The finest specimens are obtained in the iron mines of Elba and Traversella: the colour is of a brassy-yellow, with a nearly black streak, and the hardness (6 to 7) about that of soft steel; sp. gr. 4·9 to 5·1. When heated alone, a portion of the sulphur is volatilised, leaving a magnetic sulphide; but with the access of air the sulphur is burnt to sulphurous acid, and may be completely expelled, the iron passing into the state of peroxide, which, if sufficiently free from other substances may be utilised as an iron ore. This is a recent application, the material so obtained being known as *purple ore*, or *blue billy*. When exposed to moist air, pyrites becomes rapidly changed into sulphate of protoxide of iron, which, by a further absorption of oxygen, gives rise to numerous complicated minerals, containing peroxide of iron and sulphuric acid, known as basic persulphates. Marcasite is much more susceptible to such changes than the cubical form. When the oxidising action takes place very slowly, so that the sulphates may be removed as they are produced, pyrites may become completely changed into hydrated peroxide of iron without change of form. This is commonly observed in pseudomorphous crystals of pyrites, the resulting minerals containing about the same percentage of iron as the original: the change takes place without any great alteration of volume.

2. *Magnetic Iron Pyrites, Pyrrhotine.*—This mineral crystallises in the hexagonal system, and occurs chiefly in the crystalline rocks, in veins with various ores. Its colour is between bronze-yellow and copper-red, with a pinchbeck-brown tarnish; streak greyish-black; it is more or less magnetic. When heated in an open tube it yields sulphurous acid fumes, but no sublimate; before the blowpipe on charcoal in the reducing flame it fuses to a black strongly-magnetic globule; it is soluble in hydrochloric acid, evolving sulphuretted hydrogen and depositing sulphur. According to G. Rose, this mineral always contains a larger proportion of sulphur than corresponds with the simple sulphide FeS; and he adopts for it the formula $5FeS + Fe^2S^3$; corresponding with 60·44 iron and 39·56 sulphur, which agrees very closely with the analyses that have been made by Stromeyer, H. Rose, and others.

3. *Mispickel; Arsenical Iron; Arsenikkies.*—This mineral crystallises in the rhombic system, and is also found massive, granular, or columnar, and disseminated. It is brittle, with an uneven fracture; colour, silver-white, or almost steel-grey, with a greyish or yellowish tarnish; specific gravity 6 to 6·2. When heated in a closed tube it yields first a red, then a brown sublimate of sulphide of arsenic, and then metallic arsenic. Some varieties contain silver or gold, in others part of the iron is replaced by cobalt or nickel. Viewing it as a double sulphide and arsenide of iron, its formula would be $FeS^2 + FeAs$, which requires iron, 33·5; sulphur, 19·9; arsenic, 46·6. A specimen analysed by Plattner gave iron, 34·46; sulphur, 20·07; arsenic, 45·46. Mispickel is common in the mines of Freiberg in Saxony, and in the tin mines of Bohemia, Silesia, and in Cornwall. It is of no use as an ore of iron, but it is occasionally worked for the silver it contains, and as an ore of arsenic.

4. *Lölingite*, or *Leucopyrite; Glanzarsenikkies; Arseneisen, Mohsine;* contains iron, sulphur, and arsenic. It occurs at Reichenstein in Silesia, in serpentine, and is principally of interest from having been the first mineral from which gold was extracted by Plattner's process of acting on the burnt residues after the removal of arsenic with chlorine gas. (See CHLORINATION.) Dana gives the following analyses of Lölingite:—

	Arsenic	Sulphur	Iron	Nickel	Cobalt	
Reichenstein	65·99	1·94	28·06	...	...	*Hoffmann*
Fossinn	70·09	1·33	27·39	...	...	*Scheerer*
Schladming	60·41	5·20	13·49	13·37	5·10	*Hoffmann*

The name *leucopyrite* is derived from λευκός, *leukos*, white, and pyrites; it was given to the species by Shepard in 1835, antedating Haidinger's *Lölingite* and Chapman's *Mohsine*.

5. *Copper Pyrites, Chalcopyrite, Yellow Copper Ore.*—The common copper ore of Cornwall. It appears to be a double sulphide of copper and iron; its composition being, sulphur, 34·9; copper, 34·6; iron, 30·5. See COPPER.

6. *Tin Pyrites, Sulphide of Tin; Bell-metal Ore.*—This mineral is found in many of the Cornish mines. Its composition is—sulphur, 30·0; tin, 27·2; copper, 29·7; iron, 13·1.

The production of iron pyrites in the United Kingdom in 1872 and 1873 is shown at top of next page.

Imports of Pyrites of Iron, Copper, or Sulphur, in 1874.

500,831 tons; value 1,259,985*l.*

Iron pyrites, or mundic, is a mineral which is largely employed in the manufacture of copperas and of sulphuric acid. The pyrites ('brasses') of the Coal-measures are used in the preparation of copperas. Mr. Kirwan, in his 'Mineralogy,' gives us the following passage, which shows that the changes which take place in the sulphur ores (*Martial Pyrites*) had been well studied by him:—

'Vitriol is formed in these stones by exposing them a long time to the action of the air and moisture, or by torrefaction in open air, and subsequent exposure to its action, which operation in some cases must be often repeated, according to the proportion of

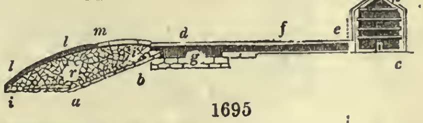
sulphur, and the nature of the earth; the calcareous pyrites are those in which it is most easily formed, and they effloresce the soonest. Good pyrites, properly treated, yield about two-thirds of their weight of vitriol.' See SULPHURIC ACID.

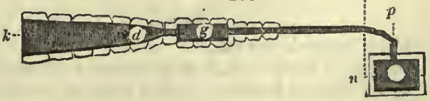
In the chemical works of Yorkshire the '*coal brasses*' are exposed in thin beds, which are often turned over to the action of the air. The sulphur is converted by the oxygen of the air into sulphuric acid, which combines with the iron, forming sulphate of protoxide of iron or *copperas*, which is dissolved out and crystallised. The same result may be obtained more quickly by roasting the sulphur ores.

Roasting of Pyrites.—Figs. 1694, 1695 represent a furnace which has been long employed at Fahlun in Sweden, and several other parts of that kingdom, for roasting iron pyrites in order to obtain sulphur. This apparatus was constructed by the celebrated Gahn. *Fig.* 1694 is a vertical section, in the line *k d n o* of *fig.* 1695, which is a plan of the furnace; the top being supposed to be taken off. In both figures the conduit may be imagined to be broken off at *e*; its entire length in a straight line is 43 feet beyond the dotted line *e n*, before the bend, which is an extension of this conduit. Upon the slope *a b* of a hillock *a b c*, lumps, *r*, of iron pyrites are piled upon the pieces of wood *i*, for roasting. A conduit, *d f e*, forms the continuation of the space denoted by *r*, which is covered by stone slabs so far as *f*, and from this point to the chamber, *h*, it is constructed in boards. At the beginning of this conduit there is a recipient, *g*. The chamber *h* is divided into five chambers by horizontal partitions, which permit the circulation of the vapours from one compartment to another. The ores *r*, being distributed upon the billets of wood *i i*, whenever these are fairly kindled, they are covered with small ore, and then with rammed earth, *l l*. Towards the point *m*, for the space of a foot square, the ores are covered with moveable stone slabs, by means of which the fire may be regulated, by the displacement of one or more, as may be deemed necessary. The liquid sulphur runs into the recipient *g*, whence it is laded out from time to time. The sublimed sulphur passes into the conduit *f e*, and the chamber *h*, from which it is taken out, and washed with water, to free it from sulphuric acid, with which it is somewhat impregnated; it is afterwards distilled in cast-iron retorts. The residuum of the pyrites is turned to account in Sweden for the preparation of a common red colour, much used as a pigment for wooden buildings.

1694



1695



Enormous quantities of iron pyrites exist in Spain, and are now being brought to this country. The sulphur ores contain a small quantity of copper, which increases their value.

In the year 1838 the King of Naples granted a monopoly of Sicilian sulphur to Messrs. Faix & Co. of Marseilles; this had the effect of greatly increasing the price of that substance, and the immediate result was the employment of iron pyrites as a source of sulphur in the manufacture of sulphuric acid. The consumption of this mineral materially increased from that date, and for many years the supply was principally derived from the mines of Cornwall and from those of Wicklow in Ireland.

About the year 1853 pyrites containing a small percentage of copper began to be imported from Spain and Portugal, and considerable quantities of ordinary pyrites are derived from Norway. The increased importance, however, of this branch of industry will be appreciated when it is stated that the annual importation into the United Kingdom of pyrites for the manufacture of sulphuric acid is about 450,000 tons, of which at least 321,500 tons contain a sufficient amount of copper to render its treatment, for that metal, commercially advantageous.

The principal mines from which the chemical trade is now supplied with cupreous pyrites are those of Mr. James Mason at San Domingos in Portugal, and those of the Tharsis Sulphur and Copper Company in the south of Spain. The ores from these localities do not differ very materially from each other; and the following analysis, made by Mr. Claudet, of a specimen from Mr. Mason's mines, may be taken as representing an average sample:—

Analysis of Mason's Pyrites.

In the manufacture of sulphuric acid this pyrites is burnt in kilns supplied with a limited amount of air; the products of combustion being thence conducted into leaden chambers, as in the case of vitriol manufactured from ordinary brimstone. The residue or 'burnt ore' was formerly, to a great extent, smelted for copper, and from the large amount of oxide of iron present acted as a valuable flux for more siliceous ores.

Burnt ore, resulting from the treatment of San Domingos pyrites, may be taken as having the following average composition:—

Silver 18 dwts. per ton.

Soluble in water; sulphate of copper, 4·12 per cent. = 1·65 of copper.

The cinder, or burnt ore, which remains in the pyrites-kilns of the sulphuric-acid makers, although sometimes still smelted as a flux for other ores, is now generally treated by a process of wet extraction, conducted in the following way:—

The ore from which the principal portion of sulphur has been removed by burning, but which still retains from 3 to 5 per cent. of that body, and a nearly equal amount of copper, together with a little silver, is first mixed with 15 per cent. of rock-salt, and then reduced to a state of fine division, by being passed between powerful crushing rollers to which proper sieving apparatus is attached.

The ore thus ground, and ultimately mixed with salt, is next calcined in a reverberatory furnace at a low-red heat. By this calcination sulphur is oxidised, and the resulting sulphuric acid, combining with the sodium of the common salt, forms sodium sulphate; the copper, on the other hand, becomes converted into chloride by the action of liberated hydrochloric acid, and a highly soluble salt of that metal is the result.

This roasting with salt is sometimes conducted in revolving mechanical furnaces, somewhat similar to those employed for the calcination of tin ores in Cornwall; in other cases muffle-furnaces are employed, whilst in many establishments open reverberatory furnaces, heated by gas, are made use of; the flame being first taken beneath the tile-bottom forming the hearth, and afterwards through the body of the furnace. Whatever may be the form of furnace adopted, the flues in connection therewith are in communication with a condensing tower, packed with crenulated brickwork, through which a spray of water is constantly descending, which thus acquires a sufficient degree of acidity to render it of value during the succeeding operation of washing.

The acid waters from the condenser are also found to contain traces of copper, which is thus retained, and a certain amount of loss of that metal thereby prevented. When open furnaces are made use of, the amount of copper recovered is exceedingly small, and of little or no commercial value; it is however stated that when muffle-furnaces are employed, the quantity of that metal caught in the condensers is much more considerable. It must, however, be remembered that close furnaces consume a much larger amount of fuel than open ones, and that the time required for the operation is when they are employed much longer. It is therefore believed that any advantage to be derived from the recovery of a somewhat larger amount of volatilised copper is, in the case of the muffle-furnace, more than counterbalanced by the loss of time experienced and the increased expenditure of fuel.

In the close furnace the calcination of each charge of the mixture of ground burnt ore and common salt occupies twelve hours. In the open furnace heated by gas a charge of three tons is drawn every six hours. On being withdrawn from the furnace the calcined ore, whilst still warm, is taken in iron waggons to lixiviating vats.

These vary considerably in their dimensions, but a very convenient size is 11 feet square and 3 feet 6 inches deep. Each tank is provided with a false bottom of perforated tiles, supported on bricks placed on-edge, these are covered, to a depth of five inches, with sifted cinders, which form a filter, and on this is placed the ore to be lixiviated. The charge of a tank of the dimensions above given is about 15 tons. Each charge of the lixiviating vats generally receives some eight or ten successive washings, either with hot water, with weak copper-liquors, or with water acidulated by hydrochloric acid; the necessary amount of the latter is usually obtained from the condensing towers attached to the establishment, but in the case of very refractory ores this is not always found to be sufficient.

The washing-tanks require to be placed at a sufficient height above the floor to allow of the copper-liquors being tapped directly into wooden spouts, by which they are conveyed into a series of tanks of similar dimensions, where the copper is precipitated in the metallic state, by means of scrap-iron. This operation is facilitated by heating the solutions by a jet of steam conveyed into them through a leaden pipe.

In order to separate the cement-copper produced from the fragments of undissolved iron with which it is mixed, it is placed on a platform composed of plates of perforated cast iron, which forms the head of a box or tank filled with hot water to a depth of about four inches over the surface of the plates. It is here stirred briskly with an iron rake, by which the copper is made to pass through the holes in the 'grid,' whilst the fragments of iron, remaining on its surface, are raked off into shallow baskets, in which they are again taken to the precipitating vats.

The precipitated copper, which thus collects in the washing-box, is subsequently allowed to drain, and, after being dried in a properly-constructed stove, is either sold to the smelters, or is fused and refined in the establishment in which it is produced. The precipitate thus obtained from Spanish and Portuguese pyrites usually contains from 75 to 80 per cent. of copper, and a little over 20 oz. of silver per ton.

The spent ore, remaining in the lixiviating tanks, is washed until it retains only 0·20 per cent. of copper, when it is removed for the reception of a fresh charge of calcined ore. This substance, which is known as 'purple ore,' or 'blue billy,' meets with a ready sale to the various iron works, where it is chiefly employed for the fettling of puddling furnaces, although it is also extensively employed in the blast-furnace. It has the following average composition:—

Analysis of Purple Ore from Portuguese Pyrites.

Ferric oxide	96·00
Lead, as sulphate	0·75
Copper	0·20
Sulphur	0·36
Lime	0·40
Cobalt, Arsenic, and Chlorine	trace
Phosphorus	trace
Soda	0·10
Insoluble residue	2·11
Total	99·92

Although it has been long known to those engaged in copper-extraction that Spanish pyrites contains a notable quantity of silver, together with distinct traces of gold, no successful attempt to render it available had been made up to the year 1870, when Mr. F. Claudet patented a process for the separation of this metal from ordinary copper-liquors by the addition of a soluble iodide.

The amount of silver contained in burnt ore seldom exceeds 18 dwts. per ton, but as the whole of this is never obtained in solution, it follows, that in order to obtain satisfactory commercial results, the process adopted should be both economical and expeditious.

The tanks in which burnt ore, roasted with common salt, is lixiviated. usually receive from eight to ten successive washings, and the liquors from the first three of these contain nearly 95 per cent. of the total amount dissolved; the first three washings are therefore alone treated for the precious metals. For the purpose of removing the soluble salts from the roasted ore, hot water is first employed, and, as a large proportion of the sodium chloride used remains undecomposed, it acts as a solvent for the silver chloride produced during the operation of furnacing. The analysis of a first washing from a lixiviating tank gave Mr. Claudet the following results:—

Analysis of Strong Liquors.

Sp. Gr. = 1·240	Contents per gallon
Sodium sulphate	10·092
„ chloride	4·474
Chlorine, combined with metals	4·630
Copper	3·700
Zinc	480
Lead	40
Iron	32
Calcium	52
Silver	3·06
Arsenic, antimony, bismuth, &c., not estimated	trace

Proportion of copper to silver, 10,000 : 8·2.

The several operations for the recovery of the silver are conducted in the following manner, and, as the first three washings contain nearly the whole of that metal, these are alone operated on:—

These liquors are first run into suitable wooden cisterns, each of a capacity of about 2,700 gallons, where they are allowed to settle.

The yield of silver per gallon of the solution is now ascertained by taking a measured quantity, to which are added hydrochloric acid, potassium iodide, and a solution of acetate of lead. The precipitate thus formed is thrown upon a filter, and, after being dried, is fused with a suitable flux. Argentiferous lead is thus obtained in the form of a button of convenient size, which is passed to the cupel, and from the weight of the resulting silver the amount of that metal, in a gallon of the copper-liquors, is readily calculated.

After thus determining the amount of silver contained in a gallon of the liquor to be operated on, it is drawn off into another vat, of slightly larger capacity than the settler, and, at the same time, the exact amount of some soluble iodide necessary to precipitate the silver present (a solution of kelp being employed by preference) is run into it from a graduated tank, together with a quantity of water equal to about one-tenth the volume of the copper-liquor. During the filling of the second tank its contents are constantly stirred, and, when filled, they are allowed to settle during 48 hours. The liquors are then run off, and the tank is again filled; the precipitate which is deposited in the bottom of these tanks is, about once a fortnight, washed into a vessel prepared for its reception.

This precipitate is chiefly composed of a mixture of lead sulphate, lead chloride, silver iodide, and subsalts of copper, from which the latter are removed by washing with water acidulated by hydrochloric acid. Thus freed from copper, the precipitate is decomposed by metallic zinc, which reduces the silver iodide completely, and also the lead chloride. The results of this decomposition are: 1st. A precipitate, rich in silver, containing a valuable amount of gold. 2nd. Zinc iodide, which, after being standardised, is employed in subsequent operations for the precipitation of silver.

The argentiferous precipitate finally obtained, after the decomposition of the iodides by metallic zinc, contains nearly 60 per cent. of lead, a trace of copper, and a little zinc; the amount of silver present varies from 1,500 to 2,000 oz. per ton; the yield of gold remains nearly constant at 20 oz. per ton. This process is employed at the Copper Extraction Works of Messrs. Muspratt Brothers and Bentley, Flint; at those of Messrs. Morris & Co., Stockwith-on-Trent; and at those of the Widnes Metal Co., Widnes. At the latter establishment the results of two years' regular working showed that 0·65 oz. of silver and 3 grs. of gold had been extracted from each ton of ore worked; leaving a profit of nearly 3*s.* per ton on the operation, after paying all expenses, including loss of iodide, &c.—J. A. P.

PYRITES, COBALT. See COBALT.

PYRITES, COPPER. See COPPER.

PYRITES, MAGNETIC. See PYRITES.

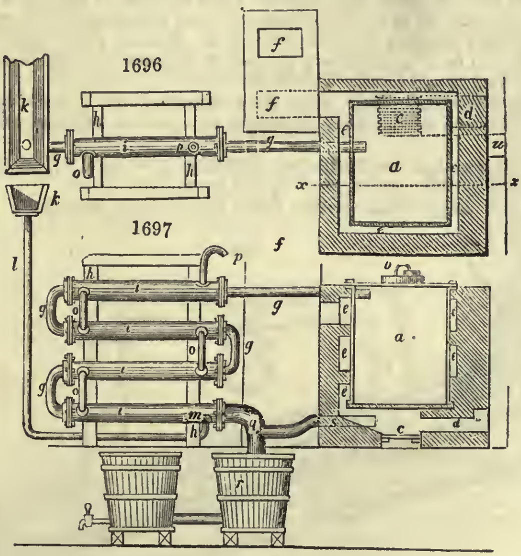
PYROACETIC SPIRIT. See ACETIC ACID.

PYROGALLIC ACID. If gallic acid is carefully heated to about 400°, it is totally decomposed into carbonic acid and pyrogallic acid, which sublimes in brilliant white plates; it is easily soluble in ether, alcohol, and water; it reacts feebly acid, it fuses at 240°, and sublimes at 400°. If a solution containing peroxide of iron be added to a solution of pyrogallic acid, a black colour is struck, but the iron is rapidly reduced to a state of protoxide, and the liquor assumes a rich red tint.—*Kane.*

Dr. Stenhouse has fully investigated the formation of gallic and of pyrogallic acid; to his papers on this subject those interested are referred. Pyrogallic acid has of late years been largely employed in PHOTOGRAPHY, which see. It has also been used to dye the hair a light brown. See GALL NUTS.

PYROLIGNEOUS ACID. See ACETIC ACID.

The apparatus represented in *figs.* 1696 and 1697 is a convenient modification of that exhibited under acetic acid, for producing pyroligneous acid. *Fig.* 1696 shows



the furnace in a horizontal section drawn through the middle of the flue which leads to the chimney. *Fig.* 1697 is a vertical section taken in the dotted line *x*, *x*, of *fig.* 1696. The chest *a* is constructed with cast-iron plates bolted together, and has a capacity of 100 cubic feet. The wood is introduced into it through the opening *b*, in the cover, for which purpose it is cleft into billets of moderate length. The chest is heated from the subjacent grate *c*, upon which the fuel is laid, through the fire-door, *d*. The flame ascends spirally through the flues *e e*, round the chest, which terminate in the chimney, *f*. An iron pipe, *g*, conveys the vapours and gaseous products from the iron chest to the condenser. This consists of a series of pipes laid zigzag over each other, which rests upon a framework of wood. The condensing tubes are enclosed in larger pipes, *i i*; a stream of cold water being caused to circulate in the interstitial spaces between them. The water passes down from a trough *k*, through a conducting tube *l*, enters the lowest cylindrical case at *m*, flows thence along the series of jackets *i*, *i*, *i*, being transmitted from the one row to the next above it, by the junction-tubes *o*, *o*, *o*, till at *p* it runs off in a boiling-hot state. The vapours proceeding downwards in an opposite direction to the cooling stream of water, get condensed into the liquid state, and pass off at *q*, through a discharge-pipe, into the first close receiver *r*, while the combustible gases flow off through the tube *s*, which is provided with a stopcock to regulate the magnitude of their flame under the chest. As soon as the distillation is fully set agoing, the stopcock upon the gas-pipe is opened; and after it is finished, it must be shut. The fire should be supplied with fuel at first, but after some time the gas generated keeps up the distilling heat. The charcoal is allowed to cool during 5 or 6 hours, and is then taken out through an aperture in the back of the chest, which corresponds to the opening *u*, *fig.* 1696, in the brickwork of the furnace. About 60 per cent. of charcoal may be obtained from 1,000 feet of fir-wood, with a consumption of as much brush-wood for fuel.

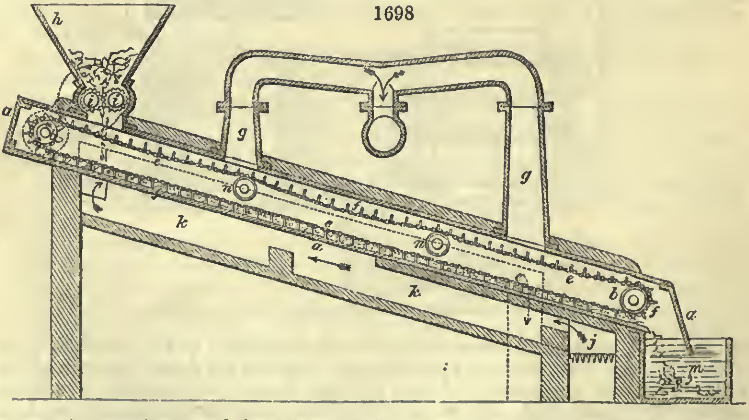
A new mode of distilling wood and producing this acid has been introduced by Mr. W. H. Bowers, of Manchester. In the rectangular retort which is used there are two revolving drums, one at each end. On these drums are endless chains; on these chains there is formed a flat surface by means of bars laid across. A hopper supplies this surface with the sawdust or other material to be heated. The surface is somewhat inclined. A very small engine is used to set the endless chain in motion. The sawdust is carried from the upper end of the retort to the lower, during which time it is exposed to heat and becomes distilled. At its lower end, as it is turning over the drum, it falls in a carbonised state into water. The vapours are carried away by pipes, as in the usual method, and the water-joint at the lower part of the retort prevents any escape in that direction, whilst the thickness of the mass of sawdust passing into the retort readily prevents any from passing out there. It is said that one retort can do the work of five of those made on Halliday's plan with the screw. Two of them produce with slow motion 2,500 gallons of acid in six days. The motion may be increased at will, and heat regulated accordingly. There are scrapers to prevent charcoal clogging the bars forming the inclined plane, and the apparatus does not require to be stopped for any purpose of cleansing. It feeds and discharges continuously, from month to month.

Sawdust, wood-turnings, small chips, spent dye-wood, and tanners' bark, peat, and such like ligneous and carbonaceous substances, are distilled, and the carbon discharged as shown.

It is believed also that the distillation is effected more rapidly, and the gases more directly removed by this method, than by any other.

Fig. 1698 is a longitudinal section taken through the middle of the retort or

1698



rectangular vessel *a*, *a*, *a*; *b*, *b* are the revolving drums on which the endless chain *c*, *e*, *c*, revolves; *f*, *f* are cross-bars or scrapers; *g*, *g*, are tubes to convey the gases, one from the lower and one from the higher point of the moving plane; *h* is a hopper filled with sawdust and other material to be distilled; the supply is regulated by two small cog-wheels *i*, *i*; *j*, the fire-place; *k*, *k*, the flues; *m* is a cistern showing the level of the water and the carbon falling into it, the lower part of the retort dipping into it. See Acetic Acid; Creosote.

PYROLITHE. See Explosive Agents.

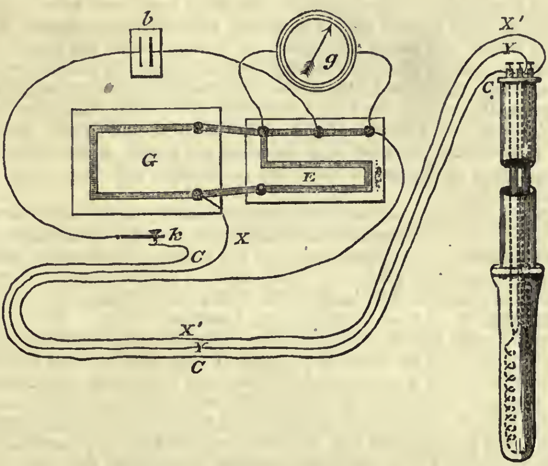
PYROLUSITE. Native peroxide of manganese. See Manganese.

PYROMETER. An instrument employed to measure temperatures which are too high to be determined by any thermometer. Some pyrometers have been constructed of bars of metal; the rates of expansion of which are known, and by which, therefore, any high degree of heat could be, with some precision, determined. The pyrometer of Wedgwood was formerly much employed; but it is a very defective instrument. It consists of two slightly convergent pieces of copper, between which a small cylinder of clay is set; the latter contracts by the heat, and the convergence is therefore increased. Its amount being measured, the heat to which the cylinder has been exposed can be calculated.

A good pyrometer is an instrument much wanted. Messrs. Siemens Brothers have devised a pyrometer which essentially consists of a length of fine platinum wire doubled back upon itself, and coiled upon a cylinder of refractory clay. The ends of the coil are fastened to stout platinum wires of such a length that their farther extremities never reach a very high temperature, and these in their turn are connected by copper wires with binding-screws on the outside case of the pyrometer. The copper wires are inclosed in a stout tube of wrought iron, about 3·5 centimeters in diameters and 120 centimeters long, which projects from the furnace or other space whose temperature is required, and forms a handle and support for the whole instrument. The part to be inserted in the furnace, namely, the coil of platinum wire, is protected by a case or sheath, which is fastened by screws to one end of the iron tube.

The indications depend on the changes which the electrical resistance of the platinum coil undergoes when its temperature is altered. *Fig.* 1699 will fully explain the

1699



whole arrangement. In order to avoid the errors which might otherwise arise from the heating of the leading wires connecting the pyrometer with the measuring apparatus, the undivided current of the testing battery is conveyed by a wire, which passes down the stem of the instrument, and is denoted by C in the figure, to the beginning of the pyrometer-coil, where it divides into two parts; one of which, after traversing the coil, is conveyed up the stem and back to the battery by the wire marked X, while the other part is conveyed by a precisely similar wire, X′, to the standard against which the coil is to be measured. Thus, in the comparison, the resistance-wire X acts as an addition to that of the pyrometer-coil, and that of the wire X′ as an equal addition to the resistance of the standard. In the figure, G represents the resistance coils; E the platinum-silver resistance coils; *b* the testing battery; *g* the galvanometer; and *k* the key.

A committee of the British Association was appointed to report on the action of this electrical pyrometer. Some of their results will be found in the 'Reports of the British Association for 1872 and 1873.'

An Acoustical Pyrometer.—At the American National Academy of Science, at Cambridge, U.S.A., an interesting paper has been read by Dr. A. M. Mayer, of Hoboken, on an acoustical pyrometer. He commenced by giving a description of his method of measuring the surfaces of sound-waves. An open organ-pipe, provided with a König's nodal capsule, is connected with a small gas-jet placed in front of a revolving cubical mirror. Alongside of this jet is placed another of König's capsules, also furnished with a gas-jet, and attached to a heavy rubber tubing, some meters in length; to the other end of this tube one of Helmholtz's resonators is attached by means of its beak. The resonator and organ-pipe must both be of the same note. On sounding the organ-pipe the gas-jet attached to its capsule is alternately increased and diminished, and this flame, when viewed in the revolving mirror, appears to consist of a series of serrations; while, if viewed when the pipe is not sounding, it appears as a continuous band. If now the resonator be brought close to the mouth of the pipe, the flame attached to it is also agitated, and it is very easy to make the serrations of one flame correspond with those of the other by slight changes in the adjustment. If the resonator be removed gradually from before the mouth of the pipe, it will be seen that the serrations no longer coincide, but, at a certain point, the elevations of one flame coincide with the depressions of the other. On removing the resonator still farther, the crests again combine, and on removing it still farther they again separate. On measurement it is found that when the flames are in opposition, the distance of the resonator from its first position near the organ-pipe is just half a wave-length; and when they again coincide, the distance is a whole wave-length. This same object may be accomplished in another way, namely, by increasing the length of the tube connecting the resonator with its capsule. The resonators remaining stationary at the mouth of the pipe, the increased length of tube which it is necessary to add to make a trough correspond with a crest is equal to half a wave-length. He increases the length of the tube by means of two glass tubes, one of which slides air-tight into the other. If, instead of increasing the length of the tube, the air is rarefied by heating in the tube, the same object is accomplished—the same number of waves pass in a given time through the tube; but if the air is heated, each wave is increased in length, and consequently part of the waves are driven, as it were, out of the tube. Therefore, if the tube is made of iron, platinum, or other suitable material, and placed in a furnace, we shall see, as the tube is gradually heated, the crest of the flame corresponding to the resonator gradually passing away from the crest of the other flame, and finally corresponding with the second crest, and then with the third, and so on. By counting the number of waves thus driven out, and knowing the length of the tube, it is easy to calculate the length of the waves remaining in the tube, and from these lengths the increased temperature.

PYROPE, or *Bohemian Garnet.* From the mountains on the south side of Bohemia, imbedded in trap tufa. It occurs also at Zöblitz, in Saxony, in serpentine.

PYROPHORUS. The generic name of any chemical preparation which inflames spontaneously on exposure to the air. The sulphide of potassium is a good example of this when it is prepared with lamp-black, in the place of charcoal.

PYROTECHNY. (*Feux d'artifice*, Fr.; *Feuerwerke*, Ger.) The composition of luminous devices with explosive combustibles is a modern art resulting from the discovery of gunpowder. The finest inventions of this kind are due to the celebrated Ruggieri, father and son, who executed in Rome and Paris, and the principal capitals of Europe, the most beautiful and brilliant fire-works that were ever seen. The following description of some of their processes will probably prove interesting:—

The three prime materials of this art are, nitre, sulphur, and charcoal, with filings of iron, steel, copper, and zinc, and resin, camphor, lycopodium, &c. Gunpowder is used either in grain, half-crushed, or finely ground, for different purposes. The longer the iron-filings, the brighter red and white sparks they give; those being preferred which are made with a very coarse file, and quite free from rust. Steel-filings and cast-iron borings contain carbon, and afford a more brilliant fire, with wavy radiations. Copper-filings give a greenish tint to flame; those of zinc a fine blue colour; the sulphuret of antimony gives a less greenish blue than zinc, but with much smoke; amber affords a yellow fire, as well as colophony, and common salt; but the last must be very dry. Lamp-black produces a very red colour with gunpowder, and a pink with nitre in excess.

Golden showers are formed with lamp-black and nitre; yellow micaceous sand is also employed for the same purpose. All the copper salts tinge the flame green; those of strontia a red colour; and baryta and its salts also impart a peculiar green. Lycopodium burns with a rose colour and a magnificent flame; but it is principally employed in theatres to represent lightning, or to charge the torch of a Fury.

Fire-works are divided into three classes: 1, those to be set off upon the ground; 2, those which are shot up into the air; and 3, those which act upon or under water.

Composition for *jets of fire:* gunpowder, 16 parts; charcoal, 3 parts.

Brilliant revolving-wheel; for a tube less than $\frac{3}{4}$ of an inch: gunpowder, 16; steel-filings, 3. When more than $\frac{3}{4}$: gunpowder, 16; filings, 4.

Chinese or jasmine fire; when less than $\frac{3}{4}$ of an inch: gunpowder, 16; nitre, 8; charcoal (fine), 3; sulphur, 3; pounded cast-iron borings (small), 10. When wider than $\frac{3}{4}$: gunpowder, 16; nitre, 12; charcoal, 3; sulphur, 3; coarse borings, 12.

A fixed brilliant; less than $\frac{3}{4}$ in diameter: gunpowder, 16; steel-filings, 4; or gunpowder, 16, and finely-pounded borings, 6.

Fixed suns are composed of a certain number of jets of fire distributed circularly, like the spokes of a wheel. All the fusees take fire at once through channels charged with quick matches. *Glories* are large suns with several rows of fusees. *Fans* are portions of a sun, being sectors of a circle. *Patte d'oie* is a fan with only three jets.

The *Mosaic* represents a surface covered with diamond-shaped compartments, formed by two series of parallel lines crossing each other. This effect is produced by placing at each point of intersection, four jets of fire, which run into the adjoining ones. The intervals between the jets must be associated with the discharge of others, so as to keep up a succession of fire in the spaces.

Cascades imitate sheets or jets of water. The Chinese fire is best adapted to such decorations.

Fixed stars. The bottom of a rocket is to be stuffed with clay, the vacant space is to be filled with the following composition, and the mouth covered with pasteboard, which must be pierced into the preparation, with five holes, for the escape of the luminous rays, which represent a star:—

	Ordinary	Brighter	Coloured
Nitre	16	12	0
Sulphur	4	6	6
Gunpowder-meal . .	4	12	16
Antimony . . .	2	1	2

Lances are long rockets of small diameter, made with cartridge-paper. Those which burn quickest should be the longest. They are composed as follows:—

White lances: nitre, 16; sulphur, 8; gunpowder, 4 parts.

Blueish-white lances: nitre, 16; sulphur, 8; antimony, 4 parts.

Blue lances: nitre, 16; antimony, 8 parts.

Yellow lances: nitre, 16; sulphur, 8; gunpowder, 16; amber, 8 parts.

Yellower lances: nitre, 16; sulphur, 4; gunpowder, 16; colophony, 3; amber, 4 parts.

Greenish lances: nitre, 16; sulphur, 6; antimony, 6; verdigris, 6 parts.

Pink lances: nitre, 16; gunpowder, 3; lamp-black, 1.

Cordage is represented by imbuing soft ropes with a mixture of nitre, 2; sulphur, 16; antimony, 1; resin of juniper, 1 part.

The Bengal flames consist of nitre, 7; sulphur, 2; antimony, 1. This mixture is pressed strongly into earthen porringers, with some bits of quick-match strewed over the surface.

Revolving suns are wheels upon whose circumference rockets of different styles are fixed, and which communicate by *conduits*, so that one is lighted up in succession after another. The composition of their common fire is, for sizes below $\frac{3}{4}$ of an inch: gunpowder-meal, 6; charcoal, not too fine, 3. For larges sizes: gunpowder, 20; charcoal, not too fine, 4. For *fiery radiations:* gunpowder, 16; yellow micaceous sand, 2 or 3. For *mixed radiations:* gunpowder, 16; pitcoal, 1; yellow sand, 1 or 2.

The *waving or double Catherine wheels*, are two suns turning upon the same axis in opposite directions. The fusees are fixed obliquely and not tangentially to their peripheries. The wheel-spokes are charged with a great number of fusees; two of the four wings revolve in one direction, and the other two in the opposite; but always in a vertical plane.

The *girandoles, caprices, spirals*, and some others have on the contrary a horizontal rotation. The fire-worker may diversify their effects greatly by the arrangement and colour of the jets of flame. Let us take for an example the *globe of light.* Imagine a large sphere turning freely upon its axis, along with a hollow hemisphere, which revolves also upon a vertical axis passing through its under pole. If the two pieces be covered with coloured lances or cordage, a fixed luminous globe will be formed, but if horizontal fusees be added upon the hemisphere, and vertical fusees upon the sphere, the first will have a relative horizontal movement, the second a vertical movement, which, being combined with the first, will cause it to describe a species of curve, whose effect will be an agreeable contrast with the regular movement of the hemisphere. Upon the surface of a revolving sun, smaller suns might be placed, to revolve like statellites round their primaries.

Ruggieri exhibited a luminous serpent pursuing with a rapid winding pace a butterfly which flew continually before it. This extraordinary effect was produced in the following way:—Upon the summits of an octagon he fixed eight equal wheels turning freely upon their axles, in the vertical plane of the octagon. An endless chain passed round their circumference, going from the interior to the exterior, covering the outside semi-circumference of the first, the inside of the second, and so in succession; whence arose the appearance of a great festooned circular line. The chain, like that of a watch, carried upon a portion of its length, a sort of scales pierced with holes for receiving coloured lances, in order to represent a fiery serpent. At a little distance there was a butterfly constructed with white lances. The piece was kindled commonly by other fire-works, which seemed to end in their play, by projecting the serpent from the bosom of the flames. The motion was communicated to the chain by one of the wheels, which received it like a clock from the action of a weight. This remarkably curious mechanism was called by the artists a *salamander.*

The rockets which rise into the air with a prodigious velocity are among the most common, but not least interesting, fire-works. When employed profusely they form those rich volleys of fire which are the crowning ornaments of a public fête. The cartridge is similar to that of other jets, except in regard to its length, and the necessity of pasting it strongly, and planing it well; but it is charged in a different manner. As the sky-rockets must fly off with rapidity, their composition should be such as to kindle instantly throughout their length, and extricate a vast volume of elastic fluids. To effect this purpose, a small cylindric space is left vacant round the axis; that is, the central line is tubular. The fire-workers call this space 'the soul of the rocket' (*l'âme de la fusée*). On account of its somewhat conical form, hollow rods, adjustable to different sizes of broaches or skewers, are required in packing the charge; which must be done while the cartridge is sustained by its outside mould, or copper cylinder. The composition of sky-rockets is as follows:—

When the bore is . . .	$\frac{3}{4}$ of an inch;	$\frac{3}{4}$ to 1;	$1\frac{2}{3}$.
Nitre	16	16	16
Charcoal . . .	7	8	2
Sulphur . . .	4	4	4
Brilliant Fire.			
Nitre	16	16	16
Charcoal . . .	6	7	8
Sulphur . . .	4	4	4
Fine steel-filings . .	3	4	5
Chinese Fire.			
Nitre	16	16	16
Charcoal . . .	4	5	6
Sulphur . . .	3	3	4
Fine borings of cast iron	3 coarser	4	5

The cartridge being charged as above described, the *pot* must be adjusted to it, with the *garniture;* that is, the serpents, the crackers, the stars, the showers of fire, &c. The pot is a tube of pasteboard wider than the body of the rocket, and about one-third of its length. After being strangled at the bottom like the mouth of a phial, it is attached to the end of the fusee by means of twine and paste. These are afterwards covered with paper. The garniture is introduced by the neck, and a paper plug is laid over it. The whole is enclosed within a tube of pasteboard terminating in a cone, which is firmly pasted to the pot. The quick-match is now finally inserted into the *soul* of the rocket. The rod attached to the end of the sky-rockets, to direct their flight, is made of willow or any other light wood. M. Ruggieri replaced the rod by conical wings, containing explosive materials, and thereby made them fly farther and straighter.

The *garnitures* of the sky-rocket pots are the following:—

Stars are small, round, or cubic solids, made with one of the following compositions, and soaked in spirits. *White stars:* nitre, 16; sulphur, 8; gunpowder, 3. Others more vivid consist of nitre, 16; sulphur, 7; gunpowder, 4.

Stars for golden showers: nitre, 16; sulphur, 10; charcoal, 4; gunpowder, 16; lamp-black, 2. Others yellower are made with nitre, 16; sulphur, 8; charcoal, 2; lamp-black, 2; gunpowder, 8.

The *serpents* are small fusees made with one or two cards; their bore being less than half an inch. The *lardons* are a little larger, and have three cards. The *retilles* are smaller. Their composition is, nitre, 16; charcoal, not too fine, 2; gunpowder, 4; sulphur, 4; fine steel-filings, 6.

The *petards* are cartridges filled with gunpowder and strangled.

The *saxons* are cartridges clayed at each end, charged with the brilliant burning fire, and perforated with one or two holes at the extremity of the same diameter.

The *cracker* is a round or square box of pasteboard, filled with granulated gunpowder, and hooped all round with twine.

Roman candles are fusees which throw out very bright stars in succession. With the composition (as under) imbued with spirits and gum-water, small cylindric masses are made, pierced with a hole in their centre. These bodies, when kindled and projected into the air, form the stars. There is first put into the cartridge a charge of fine gunpowder of the size of the star; above this charge a star is placed; then a charge of composition for the Roman candles.

The *stars*, when less than ¾ of an inch, consist of nitre, 16; sulphur, 7; gunpowder, 5. When larger, of nitre, 16; sulphur, 8; gunpowder, 8.

Roman candles, nitre, 16; charcoal, 6; sulphur, 3. When above ¾ of an inch, nitre, 16; charcoal, 8; sulphur, 6.

The *girandes*, or bouquets, are those beautiful pieces which usually conclude a firework exhibition; when a multitude of jets seem to enblazon the sky in every direction, and then fall in golden showers. This effect is produced by distributing a number of cases open at top, each containing 140 sky-rockets, communicating with one another by quick-match strings planted among them. The several cases communicate with each other by *conduits*, whereby they take fire simultaneously, and produce a volcanic display.

The *water fire-works* are prepared like the rest; but they must be floated either by wooden bowls, or by discs and hollow cartridges fitted to them.

Blue fire for lances may be made with nitre, 16; antimony, 8; very fine zinc-filings, 4. Chinese paste for the stars of Roman candles, bombs, &c.:—Sulphur, 16; nitre, 4; gunpowder-meal, 12; camphor, 1; linseed oil, 1; the mixture being moistened with spirits.

The *feu Grégeois* of Ruggieri, the son:—Nitre, 4; sulphur, 2; naphtha, 1

The *red-fire* composition is made by mixing 40 parts of nitrate of strontia, 13 of flowers of sulphur, 5 of chlorate of potash, and 4 of sulphuret of antimony.

Green fire may be made by using nitrate of baryta, instead of nitrate of strontia. Chloride of thallium also imparts a fine green colour to pyrotechnic mixtures.

White fire is produced by igniting a mixture of 48 parts of nitre, 13¼ sulphur, 7¼ sulphuret of antimony; or, 24 nitre, 7 sulphur, 2 realgar; or, 75 nitre, 24 sulphur, 1 charcoal; or, finally, 100 of gunpowder-meal, and 25 of cast-iron fine borings.

The *blue-fire* composition is, 4 parts of gunpowder-meal, 2 of nitre, sulphur and zinc, each 3 parts,

Picrate of ammonia is now used for the production of very brilliant coloured flames.

Prof. Church has published the following very interesting process for the production of coloured flames:—Bibulous paper is soaked for ten minutes in a mixture of 4 parts, by measure, of oil of vitriol with 5 parts of strong fuming nitric acid, and when washed out thoroughly with warm distilled water, is dried at a gentle heat. The gun-paper thus prepared is then saturated with chlorate of strontium, with chlorate of barium, or with nitrate of potassium, by immersion in a warm solution of these salts; a solution of chlorate of copper also may be used. If, after complete drying, a small pellet of any of these papers be made, lighted at one point at a flame, and then thrown into the air, a flash of intensely-coloured light is produced, while the combustion is so perfect that there is no perceptible ash. The barium salt gives a beautiful green light, the strontium salt a crimson, the potassium salt a violet, and the copper salt a fine blue. The chlorate may be prepared sufficiently pure for these experiments by mixing warm solutions of the chlorides of barium, strontium, or copper, with an equivalent quantity of a warm solution of chlorate of potassium. The clear liquid is to be poured off the precipitated chloride of potassium, and employed for the saturation of different portions of the gun-paper. The foregoing makes an admirable lecture-experiment, for illustrating the colours imparted to flame by barium, strontium, and other salts.

PYROXANTHINE. A substance detected in pyroxylic spirit by Mr. Scanlan. He thus describes this compound:—

If potash-water be added to raw wood-spirit (*pyroligneous*), as long as it throws down anything, a precipitate is produced, which is *pyroxanthine*, mixed with tarry matter. The precipitate is to be collected on a filter-cloth, and submitted to a strong pressure between folds of blotting-paper; it is next to be washed with cold alcohol, spec. grav. 0·840, in order to free it from any adhering tarry matter; when the pyroxyline is left nearly pure. If it be dissolved in boiling alcohol, or hot oil of turpentine, it crystallises regularly on cooling, in bright square prisms, of a fine yellow colour, that look opaque to the naked eye, but when examined under the microscope, have the transparency and colour of ferroprussiate of potash. Its turpentine-solution affords crystals of a splendid orange-red colour, having the appearance of minute plates, whose form is not discernible by the naked eye, but when examined by the microscope, they are seen to be thin right rectangular prisms. The orange-red colour is only the effect of aggregation; for when ground to powder, these crystals become yellow; and under the microscope, the difference in colour between the two is very slight. Its melting-point is 318° Fahr. It sublimes at 300° in free air; heated in a close tube in a bath of mercury, it emits vapour at 400°; it then begins to decompose, and is totally decomposed at 500°. Sulphuric acid decomposes it, producing a beautiful blue colour, which passes into crimson, as the acid attracts water from the atmosphere, and it totally disappears on plentiful dilution with water, leaving carbon of a dirty brown colour. Its alcoholic or turpentine-solution imparts a permanent yellow dye to vegetable- or animal- matter.

Pyroxanthine consists, according to the analysis of Drs. Apjohn and Gregory, of carbon, 75·275; hydrogen, 5·609; oxygen, 19·116, in 100 parts.

PYROXYLIC SPIRIT. Syns. *Pyroligneous spirit*, *Pyroligneous ether*, *Wood-spirit*, *Wood-naphtha*, *Methylic alcohol*, *Hydrate of methyle*, *Hydrated oxide of methyle*. $C^2H^4O^2 = C^2H^3O,HO$ (**CH^4O**). Density of strongest wood-spirit at 32°, 0·8179. Density at 68°, 0·798. Density of vapour, 1·12 = 4 volumes. Boiling-point, 150° Fahr.

Wood-spirit was first recognised as a distinct substance by Taylor, in 1812. Its true nature, however, was unknown until the appearance of the important research of MM. Dumas and Peligot, in 1835.

Pyroxylic spirit is obtained from the liquid products of the distillation of wood by taking advantage of its superior volatility. The crude wood-vinegar, if distilled *per se*, yields up to a certain point highly impure and weak spirit. It is, however, free from ammonia and alkaloïds. If, on the other hand, the vinegar is first neutralised by lime or soda previous to the distillation of the spirit, it is rendered more free from acetate of methyle and some other impurities, but it then contains alkaloïds and ammonia. At times the quantity of the latter substance present is so large that the spirit smokes strongly on the approach of a rod dipped in hydrochloric or acetic acid. In order to apply this test, it is obvious that the hydrochloric acid must be diluted until it does not fume by itself. By repeated rectifications over lime or chalk, rejecting the latter portions, the wood-spirit may be obtained colourless, and of a strength varying from 80 to 90 per cent. of pure spirit, the specific gravity being from 0·870 to 0·830.

Inasmuch as wood-spirit boils at a temperature far less than the point of ebullition of the impurities ordinarily found in it, it may always be greatly improved in solvent power, appearance, and odour, by mere rectification on the water-bath or in a rectifying-still. But, nevertheless, a certain quantity of the more volatile impurities always accompany the methylic alcohol, being carried over with its vapour. Among the foreign bodies may be mentioned the hydrocarbons of the benzole series. These may be entirely removed by mixing the crude spirit with three or four times its volume of water; the hydrocarbons are thus rendered insoluble and rise to the surface of the fluid. By means of a separator the lower layer may be removed, and after two or three rectifications, at as low a temperature as possible, the spirit may be procured quite clean.

To obtain wood-spirit quite pure it is generally recommended to mix it with chloride of calcium, and again rectify on a steam- or water-bath. By operating in this manner, the methylic alcohol combines with the chloride of calcium, forming a compound not decomposable at the temperature of the water-bath. The impurities present therefore distil away, leaving in the still a compound of pure methylic alcohol with chloride of calcium. But this latter compound possesses little stability, and may be decomposed by the mere addition of water, which liberates the spirit. It is then to be distilled away from the salt, and after one or two rectifications over quicklime will be quite pure.

It is highly important that wood-spirit should be of considerable purity if required for the purpose of dissolving the gums. It is true, that so far as its use for dissolving shellac is concerned, there is no need for extreme purity, as shellac will dissolve in most specimens of wood-spirit. But it is not in this case the mere solvent power that is required; for if a solution of shellac in impure wood-spirit be employed by hatters, the vapour evolved is so irritating to the eyes that the workmen are unable to proceed. If the spirit has the property of fuming on the approach of a rod dipped in acetic or hydrochloric acids, it may be taken for granted that it will be incapable of dissolving gum-sandarach. This arises from the fact that such spirit has been distilled from an alkaline base, such as lime or soda, and contains alkaloïds, ammonia, and various other impurities which destroy its solvent power. The alkaline reaction may be destroyed and the spirit rendered fit for use by adding 2 or 3 per cent. of sulphuric acid and then distilling. The alkaloïds and many other impurities will then be retained, and the spirit may either be used at once or still further purified by dilution with water and subsequent rectification. It is possible to combine the two processes at one operation, by diluting the spirit with four times its bulk of water, and adding just enough oil of vitriol to the diluted liquid to give it a faint acid reaction to litmus-paper. It is absolutely essential to the success of this process that the mixture of spirit, water, and acid be perfectly well mixed.

A wood-spirit which refuses to dissolve sandarach may often be rendered a good solvent by adding from 5 to 7 per cent. of acetone. See ACETONE.

When wood-spirit is required in a state of extreme purity for the purpose of research, it may be obtained by distilling oxalate of methyle with water. Oxalate of methyle, or methyle oxalic ether may be prepared by distilling equal parts of sulphuric acid, oxalic acid, and wood-spirit. The distillate when evaporated very gently yields crystals of the compound in question. As it does not volatilise below 322° F., the retort containing the materials for its preparation requires to be pretty strongly heated to bring the ether over. It may be purified by sublimation from oxide of lead.

Pure methylic alcohol is a colourless transparent liquid, neutral, very inflammable, burning with a blue flame like common alcohol. It has a very nauseous flavour, and is fiery in the mouth. It dissolves in any proportion in water, alcohol, or ether, and is a good solvent for fatty bodies and certain resins. It is miscible with essential oils.

Wood-spirit may be detected even when greatly diluted with alcohol, by the brown colour which it assumes in presence of solid caustic potash. Even when alcohol contains only 2 per cent. of wood-spirit, it acquires a yellow tint in ten minutes on addition of powdered caustic potash. In half an hour the colour becomes brown.

According to Mr. Maurice Scanlan, wood-spirit may be distinguished from acetone (with which it appears to have sometimes been confounded in medicine), by the action of a saturated solution of chloride of calcium, which readily mixes with the former, but separates immediately from the latter.

Wood-spirit is but seldom employed now in the arts, as it is generally cheaper and more convenient to use the mixture of 90 parts of spirit of wine with 10 parts of purified wood-spirit, which is now permitted by Government to be employed free of duty under the title of 'methylated spirit.'

The following table contains the percentages of pure wood-spirit of the specific gravity 0·8136 in various mixtures; the temperature at which the experiments must be made to correspond with the above table being 60° F.—

Specific gravity	Real spirit per cent.	Over Excise proof	Specific gravity	Real spirit per cent.	Over or under proof
·8136	100·00		·9032	68·50	13·10
·8216	98·00	64·10	·9060	67·56	11·40
·8256	96·11	61·10	·9070	66·66	9·30

·8984	70·42	16·30	·9620	35·71	40·60
·9908	69·44	15·30			

According to M. Deville, the above table is not absolutely correct, the spirit used by Dr. Ure not having been entirely free from water. M. Deville's numbers are as follow:

Specific gravity	Percentage of wood-spirit
0·8070	100
0·8371	90
0·8619	80
0·8873	70

Specific gravity	Percentage of wood-spirit
0·9072	60
0·9232	50
0·9429	40
0·9576	30
0·9709	20
0·9751	10
0·9857	5

Wood-spirit unites with chloride of calcium with such energy that the liquid enters into ebullition. The product of the union is sufficiently stable to endure a heat considerably above the boiling-point of water, without giving off the alcohol. Water, however, destroys the compound, and enables the spirit to be distilled away on the water-bath.

Methylic alcohol, treated with solution of bleaching powder, yields chloroform, but the resulting product is not so fine as that prepared from the vinic alcohol. In fact, methylic alcohol is seldom or never found in commerce of such purity as to enable good chloroform to be prepared by the action of chloride of lime. Moreover, it should be mentioned that so acrid and pungent are the products of the action of chlorine on the bodies accompanying crude wood-spirit, that great danger would be incurred in using a chloroform containing even minute traces of them. The following equation represents the action of the chlorine of the bleaching powder on wood-spirit:—

$$\underbrace{C^2H^4O^2}_{\text{Wood-spirit.}} + 4Cl = \underbrace{C^2HCl^3}_{\text{Chloroform.}} + 2HO + HCl. \quad (\mathbf{CH^4O + 4Cl = CHCl^3 + H^2O + HCl.})$$

C. G. W.

PYROXYLINE is one of the names given to gun-cotton. See GUN-COTTON.

PYRRHOTINE. Magnetic pyrites. See PYRITES.

PYRROL. C^8H^5N ($\mathbf{C^4H^5N}$). A volatile organic base, discovered in coal-naphtha by Rungé. It has been chiefly studied by Dr. Anderson. Its vapour possesses the singular property of dyeing fir-wood, moistened with hydrochloric acid, a deep red.

Q

QUANNET, THE. A kind of file. It is especially used for scraping zinc-plates for the process denominated anastatic printing.

QUARTATION is the alloying of one part of gold, that is to be refined, with three parts of silver, so that the gold shall constitute one *quarter* of the whole, and thereby have its particles so far separated as to be able to protect the other metals originally associated with it, such as silver, copper, lead, tin, palladium, &c., from the action of the nitric or sulphuric acid employed in the parting process. See REFINING.

QUARTZ. Silex; pure silica in the insoluble state. Quartz includes, as sub-species: *Rock-crystal, Rose-quartz, Amethyst, Prase* or *Chrysoprase,* and several varieties of chalcedony, as *Cat's-eye, Plasma, Chrysoprase, Onyx, Sardonyx, &c.* Lustre of quartz, vitreous, inclining sometimes to resinous; colours, very various; fracture conchoïdal; hardness, 7; specific gravity, 2·69. See SILICA.

QUASSIA is the wood of the root of the *Quassia excelsa*, a tree which grows in Surinam, the East Indies, &c. It affords to water an intensely bitter decoction, which is occasionally used in medicine, and was formerly substituted by some brewers for hops, but is now prohibited under severe penalties. It affords a safe and efficacious fly-water, or poison for flies.

QUEEN'S METAL. An alloy formed of 2 parts of tin and 1 part each of lead, antimony, and bismuth.

QUEEN'S WARE. See POTTERY.

QUEEN'S WOOD. See BRAZIL WOOD.

QUEEN'S YELLOW. Turbith's mineral; the yellow subsulpnate of mercury.

QUERCITRON is the bark of the *Quercus nigra*, or yellow oak, a tree which grows in North America. The colouring principle of this yellow dye-stuff has been called *Quercitron*, by its discoverer, Chevreul. If forms small pale yellow spangles, like those of *Aurum musivum*; has a faint acid reaction, is pretty soluble in alcohol, hardly in ether, and little in water. Solution of alum developes from it, by degrees, a beautiful yellow dye. See CALICO-PRINTING.

QUICKLIME. Caustic lime. See LIME.

QUICKSILVER. *Imported* in 1874, 2,988,447 lbs.; value £841,208. See MERCURY.

QUILL. See FEATHERS.

QUINIDINE is one of the alkaloïds obtained from the cinchona barks, and is found in most of them. The quantity, however, varies with the quality of the bark; *Cinchona Calisaya*, or *yellow bark*, which is the most prized, containing *quinine*, with but little, if any, *quinidine*, while some of the Loxa barks contain *quinidine*, and some *cinchonine*, and little or no *quinine*; such are the H.O. Crown barks.

Quinidine was discovered in 1833 by MM. Henry and Delandre. It has the same composition as quinine, $C^{40}H^{24}N^2O^4$ ($\mathbf{C^{20}H^{24}N^2O^2}$), but is nevertheless a distinct alkaloïd.

It is obtained from the barks containing it in the same manner as quinine from the quinine-yielding barks; and owing to the employment of the inferior barks in the manufacture of this latter alkaloïd or its sulphate, some quinidine is always present in it, but from the greater solubility of the salts of quinidine, they principally remain in the mother-liquors, from which the sulphate of quinine has crystallised.

QUININE. This alkaloïd is found, together with four other alkaloïds, in the cinchona barks, of which there are numerous varieties, some containing principally *quinine*, as the *Calisaya* or yellow bark, which is the most valuable of all the barks on that account; others containing principally *quinidine* and *cinchonine*, with but little *quinine*.

Quinine is the principal of these alkaloïds, and is now manufactured on a very large scale for medicinal purposes, it being a valuable tonic and febrifuge.

It was usually prepared from the *C. Calisaya*, but, owing to the scarcity and high price of this bark, several of the inferior barks have been employed in its manufacture, and on that account the quinine of commerce frequently contains some of the other alkaloïds. The sulphate is the only salt of quinine which is manufactured for commercial purposes, and is generally known, though improperly, as 'Disulphate of quinine.'

The following is the process most generally followed in the manufacture of this salt:—The coarsely-powdered bark is digested with hot dilute sulphuric or hydrochloric acid for one or two hours; the liquor is strained off, and the bark treated with a fresh portion of still more dilute acid for the same time. This process may be repeated a third time, but the liquor then obtained, containing so little quinine, is used for a fresh portion of bark. The liquors from the first and second digestions are strained and mixed, and are then mixed with lime, magnesia, or carbonate of soda, until the liquid acquires a slight alkaline reaction, which may be known by its turning red litmus-paper blue. Owing to the solubility of quinine, to a certain extent, in milk of lime and chloride of calcium, carbonate of soda is the best to be used for this purpose. A precipitate is formed, which is separated from the supernatant liquid by straining through a cloth. This dark-coloured mass, which contains the alkaloïds, colouring-matter, some lime, and some sulphate of lime,—these latter, of course, only when both lime and sulphuric acid have been used in the process,—is treated with boiling ordinary alcohol, which dissolves the alkaloïds and colouring-matter. This solution is filtered, and the greater part of the alcohol removed by distillation, when a brown viscid mass remains; this is treated with dilute sulphuric acid, till the solution remains slightly acid; this solution is then digested with animal-charcoal, filtered, evaporated, and allowed to cool, when the sulphate of quinine crystallises out, together with some sulphate of quinidine or cinchonine, according to the barks which have been employed; but, owing to the greater solubility of these latter salts than the sulphate of quinine, they principally remain in the mother-liquors. When *pure* animal-charcoal has not been used, the sulphate of quinine is likely to be contaminated with some sulphate of lime, formed by the action of the sulphuric acid on the lime in the animal-charcoal; and in this process also some quinine is likely to be precipitated by the lime and lost in the animal-charcoal.

In order to separate the sulphate of quinine thus obtained from the sulphates of quinidine and cinchonine, advantage is taken of the greater solubility of the two latter salts, as above mentioned, and by several crystallisations the sulphate of quinine may be obtained nearly free from these salts. The quantity of sulphate of quinine obtained from each pound of bark of course varies with the bark used. Some of the best *Calisaya* bark will yield half an ounce of the sulphate from every pound of bark, while many other barks which are used in the manufacture of sulphate of quinine do not yield a quarter of an ounce.

A process has been patented by Mr. Edward Herring for the manufacture of sulphate of quinine without the use of alcohol, and it yields the article known as 'hospital sulphate of quinine' at the first crystallisation and without the use of animal-charcoal. The following is the outline of the process:—

The powdered bark is boiled in solution of caustic alkali (soda preferred), which removes the useless extractive, gummy matters, and colouring-matter. After being well boiled, the bark is washed and pressed. This process of boiling with alkali, &c., may be repeated, if necessary, and the bark, after being well washed and pressed, having become decolourised, is boiled with dilute sulphuric acid, being kept constantly stirred whilst boiling. After the separation of the liquid, the bark is boiled with a second portion of dilute acid, and sometimes with a third; but the liquid from the last boiling is kept to be used for a fresh portion of bark. The first and second portions are mixed, strained, and treated with soda, which precipitates the alkaloïds; the precipitate is washed and pressed, and then digested with dilute sulphuric acid, which dissolves the alkaloïds; this solution is evaporated and allowed to cool, when the sulphate of quinine crystallises out, accompanied with some sulphates of quinidine and cinchonine, if the bark employed contained these latter alkaloïds in any quantity. The sulphate of quinine thus obtained is dried, and forms the unbleached or hospital quinine. When the sulphate of quinine is required quite pure, this is treated with *pure* animal-charcoal, and subjected to two or three further crystallisations.

It will be seen that the principal points in this process are the extraction of the colouring-matter by the caustic alkali and the use of *pure* animal-charcoal in producing the perfectly white sulphate, which prevents completely the admixture of sulphate of lime with the sulphate of quinine.

This process yields from 80 to 90 per cent. of the quinine contained in the bark employed; and to obtain the remaining 10 or 20 per cent. the blood-red solutions formed by boiling the bark with the caustic alkali are treated with dilute hydrochloric acid in excess, which retains in solution any alkaloïds that are present. This solution is strained and mixed with lime. The precipitate thus formed is collected, pressed, dried, and powdered.

It is then digested with *benzol*, or any solvent which is not a solvent of lime. These various tinctures or preparations are well agitated with dilute sulphuric acid, which extracts the quinine, &c.; when allowed to settle, the *benzol*, *oil of turpentine*, or *lard*, whichever has been used, rises to the surface. The acid liquid is then syphoned off and evaporated, and the sulphate of quinine obtained from it is purified by two or three crystallisations, when it yields a salt equal to that obtained by the first process, viz. the unbleached or hospital sulphate of quinine.

The sulphate of quinine of commerce is the neutral sulphate, and has the following composition:—$2C^{40}H^{24}N^2O^4,2HSO^4 + 14$ aq. (**$2C^{20}H^{24}N^2O^2,H^2SO^4 + 7H^2O$**).

When pure it occurs as white spangles, or slender needles, which are slightly flexible, and possess a pearly lustre and an intensely bitter taste. It effloresces in the air, and loses about 12 atoms of water (*Baup*). It requires for solution, 740 parts of cold water and 30 parts of boiling water, 60 parts of alcohol at ordinary temperatures, and much less of boiling alcohol.

Its solution in acidulated water turns the plane of polarisation strongly to the left, and presents a blue tint, which is due to a peculiar refraction of the rays of light on the first surface of the solution, and is termed *fluorescence* by Professor Stokes, who, as well as Sir John Herschel, has examined the cause of it, the latter referring it to epipolic dispersion.

Heated to 212° F., sulphate of quinine becomes luminous, which is augmented by friction, and the rubbed body is found to be charged with a vitreous electricity, sensible to the electroscope. It fuses easily, and in that state resembles fused wax; at a higher temperature it assumes a red colour, and at length becomes charred. When a solution of quinine is treated with chlorine and ammonia, it yields a bright green solution, very characteristic of quinine.

Besides the neutral sulphate, there exists an acid sulphate, or *bisulphate*, of the following composition:—$C^{40}H^{24}N^2O^4,2HSO^4 + 16HO$. (**$C^{20}H^{24}N^2O^2,H^2SO^4 + 8H^2O$**).

It is formed by dissolving the neutral sulphate in dilute sulphuric acid, evaporating and crystallising. It crystallises in rectangular prisms, or silky needles. It is much more soluble in water than the neutral sulphate, requiring only 11 parts of water at ordinary temperatures to dissolve it. The solution reddens blue litmus-paper.

It fuses in its water of crystallisation, and at 212° F. loses 24·6 per cent. of water (*Liebig* and *Baup*). With sulphate of sesquioxide of iron, it forms a double salt, which crystallises in octahedra resembling those of alum.

Adulteration of sulphate of quinine.—Owing to the high price of sulphate of quinine, it is often adulterated with various substances, as alkaline and earthy salts, boracic acid, sugar, starch, manite, margaric acid, salicine, sulphates of cinchonine and quinidine; the two latter substances will be found in most of the commercial sulphate of quinine, and are not looked upon as fraudulent mixtures when present only in small quantities, arising then from the imperfect purification of the sulphate of quinine. Sometimes, however, sulphate of cinchonine is present in large quantities, and this is effected by briskly stirring the solution from which the sulphate of quinine is crystallising, when, although under other circumstances the sulphate of cinchonine would remain in solution, it will by this agitation be deposited in a pulverulent form, together with the sulphate of quinine. No doubt this fraud had been practised to a considerable extent. See CINCHONA BARK.

R

RABBET. That part of the keel, and stern stern-post of a ship which is cut for the plank of the bottom to fit into.

RABBIT (*Lepus cuniculus*). This well-known little animal is not only employed largely as food, but it furnishes to manufactures useful articles in its skin. The quantity used in this country and on the Continent is enormous.

RABBLE. *A metallurgical tool.* The stirring-tool used in the process of puddling iron. See IRON.

RABBLING. The working of iron in a puddling-furnace with the rabble.

RACK. An inclined plane on which the ore and slime are washed and separated. *Racking* is the process of separating the heavy metallic ores from the earthy matter with which they are mixed.

RADICAL or **RADICLE, CHEMICAL.** In modern chemistry, a group of elements which is common to a series of allied compounds. See Watts's 'Dictionary of Chemistry.'

RADICALS, ALCOHOL. Hydrocarbons, such as methyl and ethyl, which may be supposed to exist in the alcohols. Thus ordinary ethyl-alcohol, $C^4H^6O^2$ (**C^2H^6O**), may be regarded as a compound of the radical ethyl, C^4H^5 (**C^2H^5**), with the group of elements HO^2 (hydroxyl **HO**).

RAFFAELLE WARE. A name sometimes applied to Majolica ware. This pottery was made in the city of Urbino, and it has been said that the designs for many of the pieces were 'furnished by the scholars of Raffaelle from the original drawings of their great master,' and hence the name. See MAJOLICA.

RAG. Any hard coarse-grained rock, whether sedimentary or eruptive, is provincially called 'rag'; hence such stones as Kentish rag, Rowley rag, &c.

RAGS. The fragments and shreds of linen, cotton, or woollen fabrics. Linen and cotton rags are collected from all quarters for the purpose of making paper-pulp. The quantity imported annually is seldom less than 11,000 tons. Woollen rags of every kind are worked up into *mungo* and *shoddy*. (See these terms.) Coarse cloths and druggets are made of them; and the fine dust of woollen rags is used in preparing the beautiful flock-papers with which our rooms are decorated. They are also used largely for manure. The lands for cultivating the early broccoli which are brought to the London market from the western part of Cornwall are dressed with woollen rags in preference to any other manure. See PAPER.

The following abstract of information included in Reports respecting the Export Duty on Rags in foreign countries will be of interest in connection with our paper-manufactories:—

			Value
			£
Austria, rags and paper-pulp exported in 1872 in Zoll. centners of 110·25 lbs.		26,734	18,713
Denmark, in 1872	lbs.	2,046,580	
Italy, rags of vegetable substances	kilos.	12,537,000	
„ of other substances	„	1,183,000	
Portugal, rags for making paper, 1871	„	14,341	
woollen rags	„	7,802	Roubles
Russia,	pouds of 36 lbs.	658,018	658,018
Spain, 1873	kilos.	155,403	
Switzerland	cwts.	2,987	
Ottoman Empire	okes	2,652,992	

RAG-STONE. A variety of hone-slate used for sharpening steel instruments upon. The Norway rag-stone is well known.

RAG-WOOL. The wool obtained by tearing up in a machine constructed for the purpose. Woollen rags, called also SHODDY.

RAILS. The manufacture of iron and steel rails has, with the extension of our railway system, increased in a remarkable manner. This is, however, rather a subject for a treatise on mechanical engineering, than for a Dictionary of Manufactures.

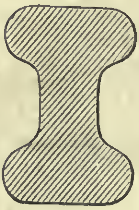
Rails are made by passing bars of iron, when red hot, through rollers with indentations or grooves in their peripheries, corresponding with the intended shape of the rails; the rails thus formed present the same surface to the bearing of the wheels, and their depths being regulated according to the distance from the point of bearing, they also present the strongest form of section with the least material.

Malleable iron rails were formerly always employed. An objection has been urged against these rails on the ground that the weight on the wheels rolling on them expanded their upper surface, and caused it to separate in thin laminæ. In many of our large stations rails may be frequently seen in this state; layer after layer breaking off, but this may be regarded rather as an example of defective manufacture than anything else. It is true, Professor Tyndall has referred to those laminating rails, as examples in proof of his hypothesis, that lamination is always due to, and is always produced by, mechanical pressure upon a body which has freedom to move laterally. Careful examination, however, shows that whenever lamination of the rail becomes evident, it can be traced to the imperfect welding together of the bars of which the rail is formed.

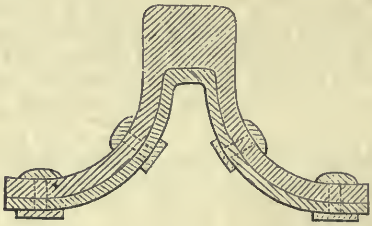
The weight of railway bars varies according to section and length. There are some of 40 pounds per yard, and some of 80 pounds, almost every railway company employing bars of different weight. Beside flat rails, which are occasionally still used, we have bridge rails employed, which have the form of a reversed U. These have sometimes parallel sides, or, as in dovetail rails, the sides are contracted. The ∩-rails are more easily manufactured than the ⌶-rails, the difficulty of filing the flanges not being so great as in the latter rail.

Fig. 1700 represents the old rail, and *fig.* 1701 Mr. W. H. Barlow's patent rail, which is made to form its own continuous bearing. In section this rail somewhat resembles an inverted V, with its ends considerably turned outwards. This portion forms the surface by which the rail bears upon the ballasting, the apex of the Λ being formed with flanges in the ordinary form of rails: and the rail, therefore, beds

1700



1701



throughout on the ballast. Rails of Vignole's section are now extensively employed. Steel rails, especially those made from Bessemer steel, are becoming very generally used. They are found to wear very much longer than the iron rail, and are specially useful at points, crossings, and stations where the wear is exceptionally heavy.

RAISINS are grapes allowed to ripen and dry upon the vine. The best come from the south of Europe, as from Roqueviaro in Provence, Calabria, Spain, and Portugal. Fine raisins are also imported from Smyrna, Damascus, and Egypt. Sweet fleshy grapes are selected for maturing into raisins, and such as grow upon the sunny slopes of hills sheltered from the north winds. The bunches are pruned, and the vine is stripped of its leaves, when the fruit has become ripe; the sun then beaming full upon the grapes completes their saccharification, and expels the superfluous water. These are *muscatels* or *blooms.* The raisins called *lexias* are plucked, cleansed, and dipped for a few seconds in a boiling lye of wood-ashes and quicklime, at 12° or 13° of Beaumé. The wrinkled fruit is lastly drained, dried, and exposed in the sun upon hurdles of basket-work during 14 or 15 days.

The finest raisins are those of the sun, so called; being the plumpest bunches, which are left to ripen fully upon the vine, after their stalks have been half cut through.

Valentia raisins are prepared by steeping them in boiling water, to which a lye of vine stems has been added.

Corinthian raisins or *currants* are obtained from a remarkably small variety of grape called the *black Corinth.* They are now grown in Zante, Cephalonia, and Patras.

RAKE VEIN, *in mining.* A vein cutting indifferently through all the strata; under some circumstances they are known as *gash veins* and *slip veins.*

RAM, HYDRAULIC. Originally invented by Montgolfier, in France, and patented by him in 1797.

This machine, which is self-acting, is composed of an air-vessel and 3 valves, 2 for the water and 1 for keeping up the supply of air. Upon pressing down the valve in the conducting tube, which opens downwards, the water escapes from it, until this momentum is sufficient to overcome the weight, when the valve immediately rises and closes the aperture. The water, having then no other outlet than the inner valve, rushes through it by its general force, compressing the air in the air-vessel until equilibrium takes place, when the air reacts by its expansive force, closing the inner valve, which retains the water above it, and driving it up the ascending tube. By this reaction the water is forced back along the conducting-pipe, producing a partial vacuum beneath the outer valve, which immediately falls by its own weight. The water thus escapes until it has acquired sufficient force to close this, when the action proceeds as before. It is best adapted for raising moderate quantities of water, as for household or farming purposes.

RAMMERS. *In mining,* an instrument used for compressing the powder in the hole for blasting. *In engineering,* the tool used for ramming earth, clay, or loam, in making dams and the like.

RAPE-SEED. (*Brassica campestris oleifera.*) Summer Rape, Wild Navew, or Colza. This and the winter rape (*B. Napus*) are the only sorts cultivated to any extent in Britain for the manufacture of oil, and growers generally agree that the former of these is to be preferred from its yielding a greater quantity of seed, in the proportion of 955 to 700. (*Lawson.*) See Colza.

RAPE-SEED OIL. See Oils.

RASPS AND FILES. File-making is a manufacture which is still in a great measure confined to Sheffield. It is remarkable that hitherto no machine has been constructed capable of producing files which equal those cut by the human hand. Machine-made files have not the 'bite' which hand-cut files have: this is accounted for by the peculiar facilities of the human wrist to accommodate itself to the particular angle suitable to produce the proper 'cut.' Small files are made out of the best cast steel; those of a larger size from ordinary steel; flat files are forged on an ordinary study; other forms on bolsters, with the indentature corresponding to the shape required being thereon impressed: a chisel wider than the blank to be cut is used as the only instrument to form the teeth; it is moved by the hand with the greatest nicety. After cutting, and previous to hardening, the file is immersed in some adhesive substance, such as ale-grounds, in which salt has been dissolved; this protects the teeth from the direct action of the fire; it is then immersed perpendicularly in water; cleaned, and finished.

The manufacture of rasps and files does not belong to this work. Those interested in it will find an elaborate description of all the varieties of files, and of their manufacture, in 'Turning and Mechanical Manipulation,' by Holtzapffel; and in 'Manufactures in Metal,' vol. i., *Iron and Steel,* revised by Mr. Robert Hunt.

RASP, MECHANICAL, is the name given by the French to an important machine much used for mashing beet-roots. See Sugar.

RATAFIA is the generic name, in France, of *liqueurs* compounded with alcohol, sugar, and the odoriferous or flavouring principles of vegetables. Bruised cherries with their stones are infused in spirit of wine to make the ratafia of Grenoble *de Teyssère.* The liquor being boiled and filtered, is flavoured when cold with spirit of *noyeau,* made by distilling water off the bruised bitter kernels of apricots, and mixing it with alcohol. Syrup of bay laurel and galango are also added. See Liqueurs.

RATTANS. The stems of the *Calamus rotang,* of *C. rudentum,* and various species of palms. They are used for caning chairs, as a substitute for whalebone, for walking-sticks, and many other purposes.

RAZORS. The manufacture of razors differs from the manufacture of the finer varieties of cutting instruments, only in the degree of care which is required to produce a perfect instrument.

Two workmen are always engaged in razor-making. The rod of steel of which they are made is about half an inch in breadth, and of sufficient thickness to form the back. The stake upon which they are forged is rounded on both sides of the tops, which is instrumental in thinning the edge, and much facilitates the operation of grinding. The blades are then hardened and tempered in the ordinary way, with the exception that they are placed on their back on an iron plate, and the moment they assume a straw colour of a deep shade they are removed.

The grinding follows, on a stone revolving in water; then glazing on a wooden disc. The fine polish is given by a wooden wheel, having its circumference covered with buff leather, which is covered with crocus. The ornamentation of the blade by etching with acid and gilding, if such be required, is the last process. See 'Manufactures in Metal,' as revised by Mr. Robert Hunt; and 'Mechanical Manipulation,' by Holtzapffel.

RAZOR-HONE. In the manufacturing of the razor, for the first process of setting, the Charnley-Forest stone is used, but the principal part of the setting is accomplished almost invariably on the German hone. Various kinds of hones are, however, sold under this name, and they are of course of various qualities. See HONES.

RAZOR-STROP. 'Perhaps for the razor-strop a fine smooth surface of calf-skin, with the grained or hair side outwards, is best. It should be pasted or glued down flat on a slip of wood, and for the dressing almost any extremely fine powder may be used—such as impalpably fine emery, crocus, natural and artificial specular iron, black lead, or the charcoal of wheat-straw; . . . combinations of these and other fine powders, mixed with a little grease and wax, have been with more or less mystery applied to the razor-strop. The choice appears nearly immaterial, provided the powders are exceedingly fine, and they are but sparingly used.

'One side of the strop is generally charged with composition; on the other side the leather is left in the natural state, and the finishing stroke is in general given on the plain side' (*Holtzapffel*). The razor-strop requires to be kept very clean, and it should be very sparingly used.

REALGAR, *Red sulphide of arsenic.* (*Arsenic rouge sulfuré*, Fr.; *Rothes Schwefelarsenik*, Ger.) This ore occurs in crystalline rocks, under the form of veins, as also in volcanic districts; for example, at the Solfatara near Naples; or sublimed in the shape of stalactites, in the rents and craters of Etna, Vesuvius, and other volcanoes. Specific gravity varies from 3·3 to 3·6. It has a fine scarlet colour in mass, but orange-red in powder, whereby it is distinguishable from cinnabar. It is soft, sectile, readily scratched by the nail; its fracture is vitreous and conchoïdal. It volatilises easily before the blowpipe, emitting the garlic smell of arsenic, along with that of sulphurous acid. It consists of 70 parts of arsenic and 30 parts of sulphur.

Nearly all the commercial realgar is an artificial product, prepared by submitting arsenical pyrites to distillation, or by heating arsenious acid and sulphur in due proportions. It is an energetic poison, more so than the native realgar, from the fact of its containing free arsenious acid. The principal use of realgar is for fireworks. *White Indian fire*, often used as a signal-light, contains 7 parts sulphur, 2 parts realgar, and 24 parts nitre. See ARSENIC and PYROTECHNY.

REAL VALUE. See IMPORTS and EXPORTS.

RÉAUMUR'S PORCELAIN. Glass in the process of working will often acquire a peculiar opacity. This appears to depend on a physical change, since by a carefully-constructed process a kind of crystallisation may be set up, producing this porcellanous appearance. Réaumur endeavoured to introduce a material of this description in the place of pottery: hence the name.

RECTIFICATION is a second distillation of alcoholic liquors, to free them from whatever impurities may have passed over in the first. See ALCOHOL and DISTILLATION.

RED, ANILINE. See ANILINE RED and ROSANILINE.

RED CHALK. An earthy ore of iron, used as a drawing material.

REDDLE. One of the ores of iron, having an earthy texture. It is found more or less mixed with earthy matter, and is used for marking sheep in some of the western counties. A fine variety occurs not far from Rotheram in Yorkshire, and at Wastwater in Cumberland. See IRON.

RED EBONY. See GRENADA CROCUS.

RED HÆMATITE. Native anhydrous oxide of iron. See HÆMATITE; IRON.

RED LEAD. *Minium or saturnine red.* A pigment formed by exposing litharge to the action of the air at a temperature of about 560°, by which it absorbs oxygen. See LEAD.

RED LIQUOR, when prepared by the dyer or printer, is a liquid compound of acetate of alumina, having in it a little sulphate of alumina and potash; and is prepared by dissolving 8 pounds of alum in boiling water, and adding to this a solution of 6 pounds of acetate of lead, and stirring the whole well together. Sulphate of lead is formed and deposited as a heavy mass at the bottom of the liquid. The clear supernatant liquid is red liquor.

Red liquor of commerce is a crude acetate of alumina, prepared from pyroligneous acid. See CALICO-PRINTING.

RED MARL. A *geological term*, designating the upper members of the New Red Sandstone formation.

RED OCHRE. An earthy oxide of iron. See IRON.

RED ORPIMENT. A pigment of a deep scarlet colour, prepared by burning the yellow native orpiment, a trisulphide of arsenic. See ARSENIC.

REDRUTHITE. A name given by Brooke and Miller to the *vitreous copper* of Phillips, from the circumstance that some fine varieties have been found in the mines near Redruth, although much finer are produced by the St. Just mines. It is the *chalcosine* of Greg and Lettsom, *cuivre sulfuré* of Haüy, and the *Kupferglanz* of Haidinger and Naumann. Redruthite is a disulphide of copper. See COPPER.

RED SANDERS WOOD. A hard and heavy wood, which is imported from Calcutta in logs. It is much used as a dye-wood, and occasionally for turning.

RED-SHORT. When iron is brittle at a red heat, it is said to be *red-short.*

REDUCING AGENTS. The agents used to separate the metal in the smelting processes. See METALLURGY.

REDUCTION. When the metal is separated from the substances—sulphur, oxygen, arsenic, &c.—with which it is combined, it is said to be reduced; reduction is the process employed.

RED WOOD. A wood used by dyers, which is obtained from the Siberian buckthorn, *Rhamnus erythroxylon.*

REED is the well-known implement of the weaver, made of parallel slips of metal or reeds, called dents. A thorough knowledge of the adaptation of yarn of a proper degree of fineness to any given measure of reed, constitutes one of the principal objects of the manufacturer of cloth; as upon this depends entirely the appearance, and in a great degree the durability, of the cloth when finished. The art of performing this properly is known by the names of *examining, setting,* or *sleying,* which are used indiscriminately, and mean exactly the same thing. The reed consists of two parallel pieces of wood, set a few inches apart, and they are of any given length, as a yard, a yard and a quarter, &c. The division of the yard being into halves, quarters, eighths, and sixteenths: the breadth of a web is generally expressed by a vulgar fraction, as $\frac{1}{4}$, $\frac{4}{4}$, $\frac{5}{5}$, $\frac{6}{5}$; and the subdivision by the eighths or sixteenths, or *nails,* as they are usually called, as $\frac{7}{8}$, $\frac{9}{8}$, $\frac{11}{8}$, &c., or $\frac{13}{16}$, $\frac{15}{18}$, $\frac{19}{16}$, &c. In Scotland, the splits of cane which pass between the longitudinal pieces or ribs of the reed are expressed by hundreds, porters, and splits, the porter is 20 splits, or $\frac{1}{5}$th of a hundred.

In Lancashire and Cheshire a different mode is adopted, both as to the measure and divisions of the reed. The Manchester and Bolton reeds are counted by the number of splits, or, as they are there called, dents, contained in 24$\frac{1}{4}$ inches of the reed. These dents, instead of being arranged in hundreds, porters, and splits, as in Scotland, are calculated by what is there termed *hares* or *bears,* each containing 20 dents, or the same number as the porter in the Scotch reeds. The Cheshire or Stockport reeds, again, receive their designation from the number of ends or threads contained in one inch, two ends being allowed for every *dent,* that being the almost universal number in every species and description of plain cloth, according to the modern practice of weaving, and also for a great proportion of fanciful articles.

Comparative Table of 37-inch reeds, being the standard used throughout Europe, for inens, with the Lancashire and Cheshire reeds, and the foreign reeds used for holland and cambric.

Scotch	Lancashire	Cheshire	Dutch holland	French cambric
600	20	34	550	653
700	24	38	650	761
800	26	44	740	870
900	30	50	832	979
1000	34	54	925	1089
1100	36	60	1014	1197
1200	40	64	1100	1300
1300	42	70	1222	1414
1400	46	76	1295	1464
1500	50	80	1387	1602
1600	52	86	1480	1752
1700	56	92	1571	1820
1800	58	96	1665	1958
1900	62	104	1757	2067
2000	66	110	1850	2176

In the above table, the 37-inch is placed first. It is called Scotch, not because it either originated or is exclusively used in that country; it is the general linen reed of all Europe; but in Scotland it has been adopted as the regulator of her cotton-manufactures.

The number of threads in the warp of a web is generally ascertained with considerable precision by means of a small magnifying glass, fitted into a socket of brass, under which is drilled a small round hole in the bottom plate of the standard. The number of threads visible in this perforation ascertains the number of threads in the standard measure of the reed. Those used in Scotland have sometimes four perforations, over any one of which the glass may be shifted. The first perforation is $\frac{1}{4}$ of an inch in diameter, and is therefore well adapted to the Stockport mode of counting; that is to say, for ascertaining the number of ends or threads per inch, the second is adapted for the Holland reed, being $\frac{1}{200}$th part of 40 inches; the third is $\frac{1}{700}$th of 37 inches, and is adapted for the now almost universal construction of Scotch reeds; and the fourth, being $\frac{1}{200}$th of 34 inches, is intended for the French cambrics. Every thread appearing in these respective measures, of course, represents 200 threads or 100 splits, in the standard breadth; and thus the quality of the fabric may be ascertained with considerable precision, even after the cloth has undergone repeated wettings, either at the bleaching-ground or dye-work. By counting the other way, the proportion which the woof bears to the warp is also known, and this forms the chief use of the glass to the manufacturer and operative weaver, both of whom are previously acquainted with the exact measure of the reed.

REFINERY SLAG. The cinders produced in the process of refining iron. See Iron.

REFINING. *In metallurgy*, the process of partially decarbonising pig-iron. The processes employed to obtain pure metals from regulus, or impure mixtures.

REFINING GOLD AND SILVER. See Gold.

REFRACTORY MINERALS. Such minerals as graphite or plumbago, mica, steatite, fire-clays, and the like, which endure without fusion a very high temperature. See Fire-Clay.

REFRIGERATION OF WORTS, &c. It is of great importance to effect the cooling of worts as rapidly as possible. The simplest mode of refrigeration is by exposing the hot liquor or wort in shallow vessels, called coolers, to the action of the atmosphere or a current of air, sometimes accelerated by fans rotating horizontally just above the surface of the liquor; but sometimes utensils called refrigerators are employed, and so constructed that a quantity of cold water should be brought into contact with the heated fluid.

A simple form of refrigerator is that of the worm used by distillers; and the reverse process is commonly used by brewers, viz. a stream of cold water passing through pipes in a zigzag form, laid horizontally in the shallow cooler. But in every construction of refrigerator heretofore used, the quantity of cold water necessarily employed in the operation, greatly exceeded the quantity of the fluid cooled, which, in some situations, where water cannot be readily obtained, was a serious impediment and objection to the use of such apparatus.

In August 1826, Mr. Yandall obtained a patent for an apparatus designed for cooling worts and other hot fluids, without exposing them to evaporation; and contrived a mode of constructing a refrigerator so that any quantity of wort or other hot fluid may be cooled by an equal quantity of cool water; the process being performed with great expedition, simply by passing the two fluids through very narrow passages, in opposite directions, so that a thin stratum of hot wort is brought into contact over a large surface with an equally thin stratum of cold water, in such manner that the heated water, when about to be discharged, still absorbs heat from the hottest portion of the wort, which as it flows through the apparatus is continually parting with its heat to water of a lower temperature flowing in the contrary direction; and however varied may be the form, the same principle should be observed.

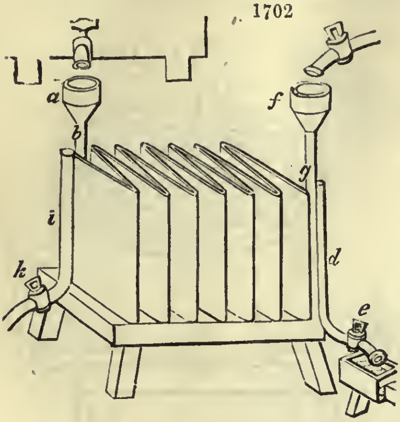
Figs. 1702, 1704, 1705, represent different forms in which the apparatus might be made; the two first having zigzag passages; the third, channels running in convolute curves. These channels or passages are of very small capacity in thickness, but of great length, and of any breadth that may be required, according to the quantity of fluid intended to be cooled or heated.

Fig. 1703 is the section of a portion of the apparatus shown at *figs.* 1702 and 1705 upon an enlarged scale; it is made by connecting three sheets of copper or any other thin metallic plates together, leaving parallel spaces between each plate for the passage of the fluids, represented by the black lines.

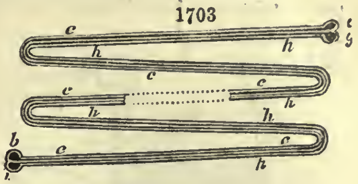
These spaces are formed by introducing between the plates thin straps, ribs, or portions of metal, to keep them asunder, by which means very thin channels are produced, and through these channels the fluids are intended to be passed, the cold liquor running in one direction, and the hot in the reverse direction.

Supposing that the passages for the fluids are each one-eighth of an inch thick, then the entire length for the run of the fluid should be about 80 feet, the breadth of the apparatus being made according to the quantity of fluid intended to be passed

1702



1703



through it in a given time. If the channels are made a quarter of an inch thick, then their length should be extended to 160 feet; and any other dimensions in similar proportions; but a larger channel than a quarter of an inch the patentee considered would be objectionable. It is, however, to be observed, that the length here recommended is under the consideration that the fluids are driven through the apparatus by some degree of hydrostatic pressure from a head in the delivery-vats above; but if the fluids flow without pressure, then the lengths of the passage need not be quite so great.

In the apparatus constructed as shown in perspective in *fig.* 1702, and further developed by the section, *fig.* 1703, cold water is to be introduced at the funnel *a*, whence it passes down the pipe *b*, and through a long slit or opening in the side of the pipe, into the passage *c*, *c* (*fig.* 1703), between the plates, where it flows in a horizontal direction through the channel towards the discharge-pipe *d*. When such a quantity of cold water has passed through the funnel *a*, as shall have filled the channel *c*, *c*, up to the level of the top of the apparatus, the cock *c*, being shut, then the hot wort or liquor intended to be cooled, may be introduced at the funnel *f*, and which descending in the pipe *g*, passes in a similar manner to the former, through a long slit or opening in the side of the pipe *g*, into the extended passage *h*, *h*, and from thence proceeds horizontally into the discharge-pipe *i*.

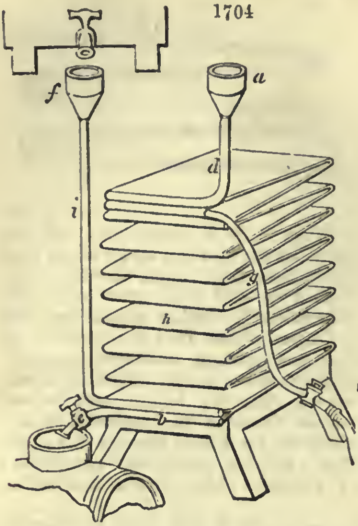
The two cocks *e* and *k*, being now opened, the wort or other liquor is drawn off, or otherwise conducted away through the cock *k*, and the water through *e*. If the apertures of the two cocks, *e* and *k*, are equal, and the channels equal also, it follows that the same quantity of wort, &c., will flow through the channel *h*, *h*, *h*, in a given time, as of water through the channel *c*, *c*; and by the hot fluid passing through the apertures in contact with the side of the channel which contains the cold fluid, the heat becomes abstracted from the former, and communicated to the latter; and as the hot fluid enters the apparatus at that part which is in immediate contact with the part where the cooling fluid is discharged, and the cold fluid enters the apparatus at that where the wort is discharged, the consequence is, that the wort or other hot liquor becomes cooled down towards its exit-pipe nearly to the temperature of cold water; and the temperature of the water, at the reverse end of the apparatus, becomes raised nearly to that of the boiling wort.

It only remains to observe, that by partially closing either of the exit-cocks, the quantity of heat abstracted from one fluid, and communicated to the other, may be regulated; for instance, if the cock *e* of the water-passage be partially closed, so as to diminish the quantity of cold water passed through the apparatus, the wort or other hot fluid conducted through the other passages will be discharged at a higher temperature, which in some cases will be desirable, when the refrigerated liquor is to be fermented.

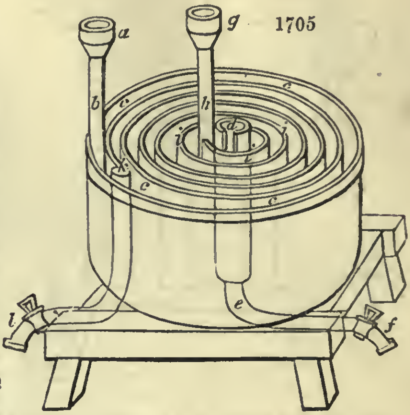
Fig. 1704 exhibits an apparatus precisely similar to the foregoing, but different in its position; for instance, the zigzag channels are made in obliquely descending planes. *a* is the funnel for the hot liquor, whence it descends through the pipe *d* into the channel *c*, *c*, *fig.* 1703, and ultimately is discharged through the pipe *b*, at the cock *e*. The cold water being introduced into the funnel *f*, and passing down the pipe *i*, enters the zigzag channel *h*, *h*, and, rising through the apparatus, runs off by the pipe *g*, and is discharged at the cock below.

The passages of this apparatus for heating and cooling fluids, may be bent into various contorted figures; and one of the most convenient forms, being very compact and easily cleaned, is that represented in *fig.* 1705, which consists of only two sheets of

1704



1705



thin copper, soldered together at their edges, forming a continuous spiral chamber for the passage of a thin stratum of water, and contained in a cylindrical case. The passages here run in convolute curves, the one winding in a spiral to the centre, the other receding from the centre.

The wort or other hot liquor intended to be cooled, is to be introduced at the funnel *a*, and passing down the pipe *b*, is delivered into the open passage *c*, which winds round to the central chamber *d*, and is thence discharged through the pipe *e*, at the cock *f*. The cold water enters the apparatus at the funnel *g*, and proceeding down the pipe *h*, enters the closed channel *i*, and after traversing round through the apparatus, is in like manner discharged through the pipe *k*, at the cock *l*. Or the hot liquor may be passed through the closed channel, and the cold through the open one; or these chambers may be both of them open at top, and the apparatus covered by a lid when at work, the principal design of which is to afford the convenience of cleaning them more readily than could be done if they were closed; or they may be both closed.

A similar ingenious apparatus for cooling brewers' worts, or wash for distillers, and also for condensing spirits in place of the ordinary worm-tub, is called by the inventor Mr. Wheeler, an Archimedes condenser, or refrigerator, the peculiar feature of which consists in forming the chambers for the passage of the fluids in spiral channels, winding round a central tube, through which spiral channels the hot and cold fluids are to be passed in opposite directions.

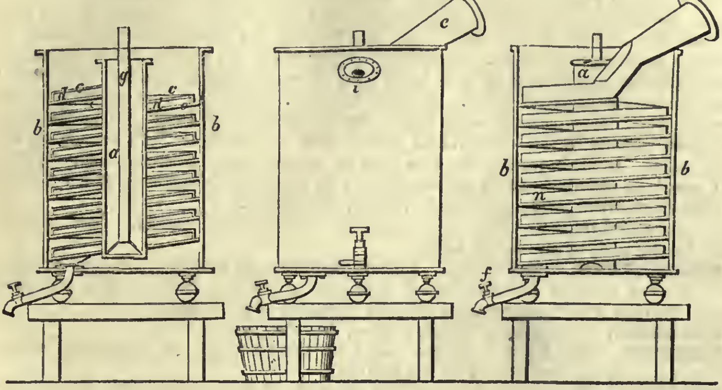
Fig. 1706 represents the external appearance of the refrigerator, enclosed in a cylindrical case; *fig.* 1707, the same, one-half of the case being removed to show the form of the apparatus within; and *fig.* 1708, a section cut through the middle of the apparatus perpendicularly, for the purpose of displaying the internal figure of the spiral channels.

In *figs.* 1707, 1708, *a*, *a*, is the central tube or standard (of any diameter that may be found convenient), round which the spiral chambers are to be formed; *b*, *b*, are the sides of the outer case, to which the edges of the spiral fit closely, but need not be attached; *c*, *c*, are two of the circular plates of copper, connected together by rivets at the edges, in the manner shown, or by any other suitable means; *d*, is the chamber, formed by the two sheets of copper, and which is carried round from top to bottom in a spiral or circular inclined plane, by a succession of circular plates connected to each other.

The hot fluid is admitted into the spiral chamber *d*, through a trumpet or wide-mouthed tube *e*, at top, and is discharged at bottom by an aperture and cock *f*. The cold water which is to be employed as the cooling material is to be introduced through the pipe *g*, in the centre, from whence, discharging itself by a hole at bottom, the cold water occupies the interior of the cylindrical case *b*, and rises in the spiral passage *n*, between the coils of the chamber, until it ascends to the top of the vessel, and then it flows away by a spout *i*, seen in *fig.* 1706.

It will be perceived that the hot fluid enters the apparatus at top, and the cold fluid at bottom, passing each other, by means of which an interchange of temperature takes

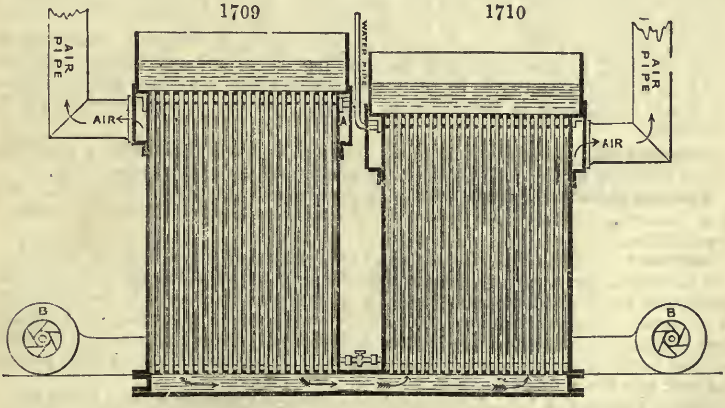
1708 1706 1707



place through the plates of copper, the cooling fluid passing off at top in a heated state, by means of the caloric which it has abstracted from the hot fluid ; and the hot fluid passing off through the pipe and cock at bottom, in a very reduced state of temperature, by reason of the caloric which it held having been given out to the cooling fluid.

Hodge's Patent Refrigerator for reducing the temperature of liquids.—This refrigerator is stated to be more effectual than anything yet offered to the public for cooling brewers' worts. The worts are passed down through the tubes in *fig.* 1709, and ascend through the tubes in *fig.* 1710. These tubes are of copper, and are encased in

1709 1710



a chamber; water is let on under a head through the pipes A, sprinkling the outer surface of the tube with a jet, keeping them moist ; at the same time a blast of cold air is blown into the chambers by the fans B B impinging on the surface, carrying away the caloric as fast as it is transmitted. Worts can be brought down from 212° to the desired temperature by this process cheaper and quicker than any other refrigerator; in fact, worts may be brought down to freezing temperature.

REFRIGERATOR. See REFRIGERATION OF WORTS.

REGENERATING FURNACE. See IRON and STEEL.

REGENERATORS. A name given to arrangements for absorbing the heat, as it passes from the furnace, or place of combustion, and for parting with that heat to fresh air admitted to supply the furnace. By alternating the direction of circulation a saving of heat is effected. Dr. Percy suggests that *accumulators* would be a better term.

REGULUS. A name introduced by the alchemists, and applied by them in the first instance to antimony; it signifies *the little king;* and from the facility with which antimony alloyed with gold, these empirical philosophers had great hopes that this metal *antimony* would lead them to the discovery of the philosopher's stone.

'In the smelting of certain sulphuretted ores the product obtained in the first instance is a *sulphide* of the metal; and this product has received different names in different metallurgical works. In English copper works the word *metal* is commonly used to denote compounds of this kind, that of *regulus* being applied in a specific sense to certain kinds of *metal.* I shall, however, adopt the word *regulus* in the present work as a generic appellation for all similar products. The Germans designate regulus by the synonymous terms *Stein* and *Lech,* and the French by the term *matte.* It is frequently the case that in one smelting operation, *slag, regulus,* and *metal* are obtained, which are superposed in the order mentioned, which is that of their respective specific gravities.' (Percy, *Metallurgy.*)

In our metal-imports 'ore' and 'regulus' are commonly named. The regulus must be regarded as an impure metal.

REHEATING, *in metallurgy.* In iron manufacture, puddled bars are brought to a welding heat in furnaces, called *Reheating* or *Welding* furnaces, they are then passed through rolls to bring them into the condition of merchant iron.

REISNER. A process of inlaying wood, like Parquetry.

RELBUN. The South-American name for the roots of the *Calceolaria arachnoidea,* used for dyeing crimson by the natives.

RENNET. The gastric juice of the stomach of the sucking calf, which, being extracted by infusion immediately after the death of the animal, serves to curdle milk. As the juice passes rapidly into putrefaction, the stomach must be salted after the outer skin has been scraped off, and all the fat and useless membranes carefully removed. It is only the inner coat which is to be preserved after it is freed from any curd or other extraneous matter in the stomach. The serum left in it should be pressed out with a cloth, and is then to be replaced in the stomach with a large quantity of the best salt. The skins, or vells, as they are called, are next put into a pan and covered with a saturated solution of salt, and soaked for some hours; but there should be no more brine than covers the vells. They are afterwards hung up to dry, a piece of wood being put crosswise into each to stretch them out. They should be perfectly dried, and look like parchment. In this state they may be kept in a dry place for any length of time, and are always ready for use.

Pieces of vell are cut off and soaked for some hours in whey or water, and the whole is added to the warm milk for curdling it, its strength having been first tested on a small quantity. By the rapidity with which it curdles, and the form of the flakes, a judgment is formed of its strength, and the quantity required for the whole milk.

REPOUSSÉ. Metal-work in relief. The metal plate is placed upon a wax block, and by means of a punch and hammer, the ornamental design is hammered up.

RESIN, KAURI or **COWDEE,** is a peculiar resinous substance, imported from New Zealand. It oozes from the trunk of a noble tree called *Dammara Australis.* See DAMMAR.

RESINS (*Résines,* Fr.; *Harze,* Ger.) are principles found in most vegetables, and in almost every part of them; but the only resins which merit a particular description are those which occur naturally in such quantities as to be easily collected or extracted. They are obtained chiefly in two ways, either by spontaneous exudation from the plants, or by extraction by heat and alcohol. In the first case, the discharge of resin in the liquid state is sometimes promoted by artificial incisions made through the bark into the wood of the tree.

Resins possess the following general properties:—They are soluble in alcohol, in ether and the volatile oils, and with the aid of heat, combine with the unctuous oils. They may be combined by fusion with sulphur, and with a little phosphorus. They are insoluble in water, and melt by the application of heat, but do not volatilise without partial decomposition. They are almost all translucid, not often colourless, but generally brown, occasionally red or green. Any remarkable taste or smell, which they sometimes possess, may be ascribed to some foreign matter, commonly an essential oil. Their specific gravity varies from 0·92 to 1·2. Their consistence is also very variable. The greater part are hard, with a vitreous fracture, and so brittle as to be readily pulverised in the cold. Some of them are soft, a circumstance probably dependent upon the presence of a heterogeneous substance. The hard resins do not conduct electricity, and they become negatively electrical by friction. When heated they melt more or less easily into a thick viscid liquid, and concrete, on cooling, into a smooth shining mass, of a vitreous fracture, which occasionally flies off into pieces, like Prince Rupert's drops, especially after being quickly cooled, and scratched with a sharp point. They take fire by contact of an ignited body, and burn with a bright flame, and the diffusion of much sooty smoke. When distilled by themselves in close vessels, they afford carbonic acid and carburetted gases, empyreumatic oil of a less disagreeable smell than that emitted by other such oils, a little acidulous water, and a very little shining charcoal. See Gas, Coal.

Resins are little acted upon by acids, except by the nitric, which converts them into artificial tan. They combine readily with the alkalis and alkaline earths, and form what were formerly reckoned soaps; but the resins are not truly saponified; they rather represent the acid constituents themselves, and, as such, saturate the salifiable bases.

Every resin is a natural mixture of several other resins, as is the case also with oils; one principle being soluble in cold alcohol, another in hot, a third in ether, a fourth in oil of turpentine, a fifth in naphtha, &c. The soft resins, which retain a certain portion of volatile oil, constitute what are called balsams. Certain other balsams contain benzoic acid. The solid resins are, *amber*, *animé*, *benzoin*, *colophony* (common rosin), *copal*, *dammar*, *dragon's blood*, *elemi*, *guaiac*, *lac*, resin of *jalap*, *labdanum*, *mastic*, *sandarach*, *storax*, *takamahac*.

1. *The hard copal* of India and Africa, especially Madagascar, is the product of the *Hymenæa verrucosa*. It is transparent and vitreous within, whatever may be its appearance outside; nearly colourless, or of a tawny yellow; without taste or smell in the cold, and almost as hard as amber, which it much resembles, but from which it may be distinguished, 1st, by its melting and kindling at a candle-flame, and running down in drops, while amber burns and swells up without flowing; 2ndly, this hard copal when blown out and still hot, exhales a smell like balsam copaiva or capivi; while amber exhales an unpleasant bituminous odour; 3rdly, when moistened by alcohol of 85 per cent., copal becomes sticky, and shows, after drying, a glazed opaque surface, while amber is not affected by alcohol; 4thly, the copal affords no succinic acid, as amber does, on distillation.

Ether, boiling hot, dissolves 39·17 per cent. of copal.

Essence (spirits) of turpentine does not dissolve any of the copal, but it penetrates and combines with it at a heat of 212° Fahr.

2. *Resin of courbaril* of Rio Janeiro, the English gum-animé, and the semi-hard copal of the French. It is characterised by forming, in alcohol, a bulky, tenacious, elastic mass. It occurs in rounded tears, has a very pale glassy aspect, transparent within, covered with a thin white powder, which becomes glutinous with alcohol. Another variety is soft, and dissolves, for the most part, in alcohol; and a third resembles the oriental copal so much as to indicate that they may both be produced from the same tree. 100 parts of the oriental and the occidental animé yield respectively the following residua:—

	With alcohol	With ether	With essence
Oriental . . .	65·71	60·83	71
Occidental . . .	43·53	27·50	75·76

The hard and soft copals possess the remarkable property in common of becoming soluble in alcohol, after being oxygenated in the air.

3. *Dammar puti, or Dammar batu.*—This resin, soft at first, becomes eventually like amber, and as hard. It is little soluble in alcohol and ether, but more so in essence of turpentine.

4. *Aromatic dammar.*—This resin occurs in large orbicular masses. It is pretty soluble in alcohol. Only small samples have hitherto been obtained. Of 100 parts, 3 are insoluble in alcohol, none in ether, and 93 in essence of turpentine. M. Guibourt thinks that this resin comes from the Molucca isles. Its ready solubility in alcohol and great hardness render it valuable for varnish-making.

5. *Slightly aromatic dammar* leaves, after alcohol, 37 per cent.; and after ether 17 per cent.; and after essence, 87 per cent.

6. *Tender and friable dammar selan.*—This resin occurs in considerable quantity in commerce (at Paris). It is in round or oblong tears, vitreous, nearly colourless, and transparent within, dull whitish on the surfaces. It exhales an agreeable odour of olibanum, or mastic, when it is heated. It crackles with the heat of the hand, like roll-sulphur. It becomes fluid in boiling water, but brittle when cooled again. It sparkles and burns at the flame of a candle; but this being the effect of a volatile oil, the combustion soon ceases.—*Guibourt.*

RESINS, MINERAL. Petroleum, bitumen, asphalt, amber, and other mineral hydrocarbons are so called. See descriptions under the respective names.

RESIST. A paste used in calico-printing to keep portions white when the cloth is dipped into the dye. See CALICO-PRINTING.

RETENE. A hydrocarbon, similar to benzine, obtained from the resinous matter found on pine-stems in peat-bogs. It has also been obtained by the dry distillation of resinous pine-wood.

RETINITE. A mineral resin found in rounded or irregular lumps. It is soluble in alcohol, leaving an unctuous residue. It is found in the lignite beds of Bovey Tracey, in similar deposits in Hanover, and in the coal-mines of Moravia.

RETINOLE. A hydrocarbon, obtained from the turpentine-resins.

RETORT. Retorts may be of various shapes, and made of very different materials, according to the requirements. Some are of glass; others of clay. They may be made of any of the metals. Retorts are employed to effect the decomposition of compound bodies by the action of heat; sometimes alone, and sometimes aided by the action of other furnaces. They vary in shape; but generally may be regarded as consisting of a bulb and a beak. For producing coal-gas there are many modifications, varying in dimensions and shape with the caprice of the constructor.

RETURN AIR. In *coal-mining*, the air which ascends after having passed through the workings of a colliery.

RETURNS. A light-coloured and mild kind of tobacco.

REVALENTA ARABICA. The commercial name for the flour obtained from the lentil, *Ervum lens*. It was first called *Ervalenta*, then by transposing the letters of the first portion of the name, *revalenta* was obtained.

REVERBERATORY FURNACE. A furnace in which the flame passes over a bridge, and plays down—or reverberates against the hearth on which the materials are placed. See METALLURGY, COPPER, IRON, SODA, &c.

RHATANY ROOT. *Krameria triandra*, a native of Peru. The root is horizontal, very long and branched. It is used as an astringent, and in powder as a dentifrice.

RHODIUM. A metal discovered by Dr. Wollaston in 1803, in the ore of platinum. It is contained to the amount of 3 per cent. in the platinum-ore of Antioquia in Columbia, near Barbacoas; it occurs in the Ural ore, and alloyed with gold in Mexico. The palladium having been precipitated from the muriatic solution of the platinum-ore previously saturated with soda by the cyanide of mercury, muriatic acid is to be poured into the residuary liquid, and the mixture is to be evaporated to dryness, to expel the hydrocyanic acid, and convert the metallic salts into chlorides. The dry mass is to be reduced to a very fine powder, and washed with alcohol of specific gravity 0·837. This solvent takes possession of the double chlorides which the sodium forms with the platinum, iridium, copper, and mercury, and does not dissolve the double chloride of rhodium and sodium, but leaves it in the form of a powder of a fine dark-red colour. This salt being washed with alcohol, and then exposed to a very strong heat, affords the rhodium. But a better mode of reducing the metal upon the small scale consists in heating the double chloride gently in a glass tube, while a stream of hydrogen passes over it, and then to wash away the chloride of sodium with water.

Rhodium resembles platinum in appearance. According to Wollaston, the specific gravity of rhodium is 11. It is insoluble by itself in any acid; but when an alloy of it with certain metals, as platinum, copper, bismuth, or lead, is treated with aqua regia, the rhodium dissolves with the other metals; but when alloyed with gold or silver, it will not dissolve along with them. It may, however, be rendered very soluble by mixing it in the state of a fine powder with chloride of potassium or sodium, and heating the mixture to a dull red-heat, in a stream of chlorine gas. It thus forms a triple salt, very soluble in water. The solutions of rhodium are of a beautiful rose colour, whence its name. Its chief use at present is for making the unalterable nibs of the so-named rhodium pens.

The following remarks from a recent paper by Deville and Debray, '*On some properties of the so-called Platinum Metals*,' are full of interest. These chemists prepare rhodium by fusing platinum-residues with an equal weight of lead and twice its weight of litharge. When the crucible has attained a bright red heat, and the litharge is thoroughly liquid, the crucible is shaken once or twice, and is then allowed to cool slowly. The button of lead, which contains all the metals in the residue less oxidisable than lead, is treated with nitric acid, diluted with an equal volume of water, which removes, besides the lead, the copper and the palladium. The insoluble powder which remains is mixed with five times its weight of binoxide of barium, weighed exactly, and is heated to redness in a clay crucible for one or two hours. After this it is first treated with water, and then with aqua regia to remove the osmic acid. When the liquor has lost all smell, sufficient sulphuric acid is added to exactly precipitate the baryta. It is then boiled, filtered, and evaporated, first adding to it a little nitric acid and then a great excess of sal-ammoniac. The evaporation is carried to dryness at 212°, and the residuum is washed with a concentrated solution of sal-ammoniac, which removes all the rhodium. When the washings are no longer coloured, the liquor is evaporated with a great excess of nitric acid, which destroys the sal-ammoniac, and when only the salt of rhodium is left, the evaporation is finished in a porcelain crucible. The rhodium salt is now moistened with hydrosulphide of ammonia, mixed with three or four times its weight of sulphur, and the crucible is heated to bright redness, after which metallic rhodium is left in the crucible. So obtained rhodium may be considered almost pure, after it has been boiled for some time, first in aqua regia, and then in concentrated sulphuric acid. To obtain it perfectly pure it must be melted with four times its weight of zinc. The alloy is treated with concentrated hydrochloric acid, which dissolves most of the zinc, but leaves a crystalline matter which is really an alloy of rhodium and zinc in definite proportions. This is dissolved in aqua regia, and the solution is treated with ammonia until the precipitate first formed is redissolved. The solution is boiled and evaporated, by which is obtained the yellow salt, or chloride of rhodium. This is purified by repeated crystallisation, and then calcined with a little sulphur, by which means rhodium is procured absolutely pure.

Rhodium melts less easily than platinum, so much so that the same fire which will liquefy 300 grammes of platinum only will melt 40 or 50 grammes of rhodium. It is not volatilised, but it oxidises on the surface like palladium. Less white and lustrous than silver, it has about the same appearance as aluminium. When perfectly pure it is ductile and malleable, at least after fusion. Its density is 12·1.

The alloys of rhodium, those at least which have been examined, are true chemical combinations, as is shown by the high temperature developed at the moment of their formation. The alloy with zinc already described resists the action of muriatic acid, but in contact with air and the acid there is soon a well-marked rose-coloration which reveals an oxidation of the two metals under the double influence of the air and acid. The alloy with tin is crystallised, black, brilliant and fusible at a very high temperature.

RHODONITE. A silicate of manganese, sometimes containing iron, magnesium and calcium, found chiefly in Sweden.

RHOMB SPAR. Native carbonate of magnesia.

RHUBARB (*Rheum*). Thirteen species of plants have been named as yielding the medicinal rhubarb; it has, however, been recently determined that the *Rheum officinale* is the true rhubarb plant. The best rhubarb is called Turkey rhubarb, and only procured by the Russians, at Kiachta, from the Chinese. Several species of rhubarb are cultivated in this country, for the agreeable acidity of their stems.—See *Elements of Materia Medica*, by Bentley and Redwood.

RHUS. The SUMACH, which see.

RHUSMA. *Rhusma turcorum.* Used as a depilatory.

RIABOCCA WOOD, or *Kiabocca wood*, an ornamental wood obtained from the East Indies. It is not known what tree produces it. It is much used for making ornamental boxes, desks, and the like.

RIBBON MANUFACTURE. This differs in no particular respect from the manufacture of woven fabrics in similar materials. See SILK, and WEAVING.

RICE. (*Oryza sativa*, Linn.) This plant, originally a native of Asia, is now extensively cultivated in India, China, the islands of the Eastern Archipelago, in the West Indies, Central America, and the southern of the United States. Roxburgh informs us that there are above forty different varieties. Carolina and Patna rice are the kinds most esteemed in this country. Braconnot (*Ann. Chim. Phys.*) has given the following analyses of two varieties of rice:—

	Carolina rice	Piedmont rice
Starch	85·07	83·80
Woody fibre	4·80	4·80
Gluten	3·60	3·60
Tallowy oil	0·13	0·25
Sugar (uncrystallisable)	0·29	0·25
Gum	0·71	0·10

The inorganic constituents being, as estimated from the ash of the grain, as follows:—Potash, 18·48; soda, 10·67; lime, 1·27; magnesia, 11·69; oxide of iron, 0·45; phosphoric acid, 53·36; chlorine, 0·37; silica, 3·35.

Rice is used as food by a hundred millions of the inhabitants of the earth, and it is employed as an agreeable and nutritive diet in various forms by ourselves.

Rice imported in 1873.

RICE CLEANING. Various machines have been contrived for effecting this purpose, of which that invented by Mr. Melvil Wilson may be regarded as a good example. It consists of an oblong hollow cylinder, laid in an inclined position, having a great many teeth stuck in its internal surface, and a central shaft also furnished with teeth. By the rapid revolution of the shaft, its teeth are carried across the intervals of those of the cylinder with the effect of parting the grains of rice, and detaching whatever husks or impurities may adhere to them. A hopper is set above to receive the rice, and conduct it down into the cleansing cylinder.

About 80 teeth are supposed to be set in the cylinder, projecting so as to reach very nearly the central shaft, in which there is a corresponding number of teeth, that pass freely between the former.

RICE-PAPER. A name given to the material on which the Hindoos and Chinese paint flowers, &c. It is the pith of the *Aralia papyrifera.* See PAPER.

RICE-STARCH. See STARCH.

RIDDING. *In mining,* a term used in the Newcastle coal-field for the operation of separating the iron ore from the coal-shale.

RIDER. *In mining,* a projecting piece of rock crossing a fissure or mineral vein, and thus dividing it.

RIFLES. *Rifled Ordnance* and *Fire-arms* are described under ARTILLERY and FIRE-ARMS.

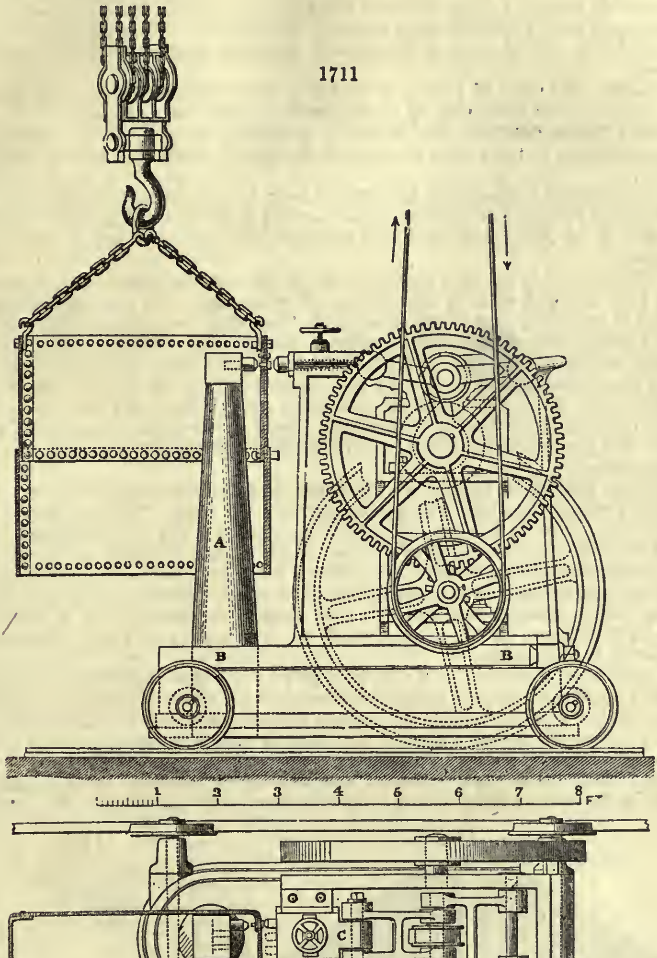
RINMANN'S GREEN. Oxide of cobalt and oxide of zinc.

RIVETING MACHINE *of Fairbairn.* The invention of the riveting machine originated in a turn-out of the boiler-makers in the employ of that engineer about thirty years ago. On that occasion the attempt was made to rivet two plates together by compressing the red-hot rivet in the ordinary punching-press. The success of this experiment immediately led to the construction of the original machine, in which the moveable die was forced upon the rivet by a powerful lever acted upon by a cam. A short experience proved the original machine inadequate to the numerous requirements of the boiler-maker's trade, and the present form was therefore adopted some years afterwards.

The large stem A (*fig.* 1711) is made of malleable iron, and having an iron strap, B B, screwed round the base, it renders the whole perfectly safe in case of the dies coming in contact with a cold rivet, or any other hard substance during the process. Its construction also allows the workmen to rivet angle-iron along the edges, and to finish the corners of boilers, tanks, and cisterns; and the stem being now made 4 feet 6 inches high, it renders the machine more extensive in its application, and allows of its riveting the fire-box of a locomotive boiler or any other work within the given depth.

In addition to these parts, it has a broad moving slide, C, in which are three dies corresponding with others in the wrought-iron stem. By using the centre die, every description of flat and circular work can be riveted, and by selecting those on the sides, it will rivet the corners, and thus complete vessels of almost every shape. This machine is in a portable form, and can be moved off rails with care to suit the article suspended from the shears.

1711



The introduction of the knee-joint gives to the dies a variable motion, and causes the greatest force to be exerted at a proper time, viz. at the closing of the joint and finishing of the head of the rivet.

In other respects the machine operates as before, effecting by an almost instantaneous pressure what is performed in the ordinary mode by a long series of impacts. The machine fixes in the firmest manner and completes eight rivets of $\frac{3}{4}$-inch diameter in a minute, with the attendance of two men and boys to the plates and rivets; whereas the average work that can be done by two riveters, with one 'holder on' and a boy, is 40 $\frac{3}{4}$-inch rivets per hour; the quantity done in the two cases being in the proportion of 40 to 480, or as 1 to 12, exclusive of the saving of one man's labour. The cylinder of an ordinary locomotive-engine boiler 8 feet 6 inches long and 3 feet diameter can be riveted and the plates fitted completely by the machine in 4 hours; whilst to execute the same work by hand would require with an extra man 20 hours. The work produced by the machine is likewise of a superior kind to that made in the ordinary manner; the rivets being found stronger, and the boilers more free from leakage, and more perfect in every respect. The riveting is done without noise, and thus is almost entirely removed the constant deafening clamour of the boiler-maker's hammer.

ROAN. The name of a common leather used for book-binding, and for slippers. It is prepared from sheep-skin by tanning with sumach. See LEATHER.

ROASTING ORES. The operation of roasting is executed by various processes, relatively to the nature of the ores, the quality of the fuel, and to the object in view.

Three principal methods may be distinguished: 1, the roasting in heaps in the open air, the most simple of the whole; 2, the roasting executed between little walls, and which may be called case-roasting (*Röst-stadel* in German); and 3, roasting in furnaces.

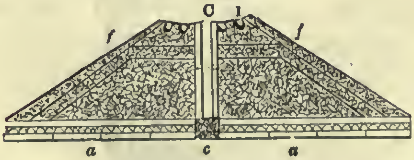
1. The roasting in the open air, and in heaps more or less considerable, is practised upon iron ores, and such as are pyritous or bituminous. The operation consists in general in spreading over the plane area, often bottomed with beaten clay, billets of wood arranged like the bars of a gridiron, and sometimes laid crosswise over one another, so as to form a uniform flat bed. Sometimes wood-charcoal is added, so as to fill up the interstices, and to prevent the ore from falling between the other pieces of fuel. Coal is also employed in moderately small lumps; and even occasionally turf. The ore, either simply broken into pieces, or sometimes under the form of *schlich* (fine pyritous sand), is piled up over the fuel; usually alternate beds of fuel and ore are formed.

The fire, kindled in general at the lower part, but sometimes, however, at the middle, gradually spreads, putting the operation in train. The combustion must be so conducted as to be slow and suffocated, to prolong the ustulation, and let the whole mass be equably penetrated with heat. The means employed to direct the fire, are to cover outwardly with earth the portions where too much activity is displayed, and to pierce with holes or to give air to those where it is imperfectly developed. Rains, winds, variable seasons, and especially good primary arrangements of a calcination, have much influence on this process, which requires besides an almost incessant inspection at the beginning.

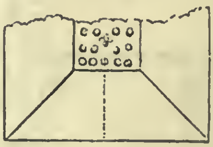
It may be laid down as a good rule, to employ no more fuel than is strictly necessary for the kind of calcination in hand, and for supporting the combustion; for an excess of fuel would produce, besides an expense uselessly incurred, the inconvenience, at times very serious, of such a heat as may melt or vitrify the ores: a result entirely the reverse of a well-conducted ustulation.

Figs. 1712, 1713, 1714, represent the roasting in mounds, as practised near Goslar in the Hartz, and at Chessy in the Department of the Rhône. *Fig.* 1712 is a

1712



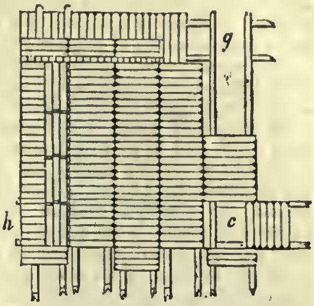
1713



vertical section, in the line *h c*, of *fig.* 1714. In *fig.* 1713 there is shown in plan, only a little more than one-half of the quadrangular truncated pyramid, which constitutes the heap. *Fig.* 1714 shows a little more than one-fourth of a bed of wood, arranged at the bottom of the pyramid, as shown by *a a*, *fig.* 1712, and *c g h*, *fig.* 1714. C is a wooden chimney, formed within the heap of ore, at whose bottom, *c*, there is a little parcel of charcoal; *d d* are large lumps of ore distributed upon the wooden pile *a a*; *e e* are smaller fragments to cover the larger; *f f* is rubbish and clay laid smoothly in a slope over the whole. *g*, *fig.* 1714, a passage for air left under the bed of billets, of which there is a smaller one in each of the four sides of the base *a a*, so that two principal currents of air cross under the upright axis *c c*, of the truncated pyramid indicated in *fig.* 1712.

Burning wood is thrown in by the chimney C. The charcoal and the wood take fire; the sulphurous ores, *d e f*, are heated to such a high temperature as to vaporise the sulphur. In the Lower Hartz, a heap of this kind continues roasting during four months

1714



2. The second method. The difficulty of managing the fire in the roasting of substances containing little sulphur, with the greater difficulty of arranging and supporting in their place the fine ores to be roasted, and last of all, the necessity of giving successive fires to the same ores, or to inconsiderable quantities at a time, have led to the contrivance of surrounding the area on which the roasting takes place with three or four little walls, leaving a door in the one in front. This is what is called a *walled area*, and sometimes, improperly enough, a roasting-furnace. Inside of these walls, about 3 feet high, there are often vertical conduits or chimneys made to correspond with an opening on the ground level, in order to excite a draught of air in the adjacent parts. When the roasting is once set going, these chimneys can be opened or shut at their upper ends, according to the necessities of the process.

Several such furnaces are usually erected in connection with each other by their lateral walls, and all terminated by a common wall, which forms their posterior part; sometimes they are covered with a shed supported partly by the back wall, built sufficiently high for this purpose. These dispositions are suitable for the roasting of *schlichs*, or pyritic sands, and in general of all matters which are to have several fires; a circumstance indispensable to a due separation of the sulphur, arsenic, &c.

3. The furnaces employed for roasting the ores and *mattes* differ much, according to the nature of the ores, and the size of the lumps. We shall content ourselves with referring to the principal forms.

When iron ores are to be roasted, which require but a simple calcination to disengage the combined water and carbonic acid, egg-shaped furnaces, similar to those in which limestone is burned in contact with fuel, may be conveniently employed; and they present the advantage of an operation which is continuous with a never-cooling apparatus. See Iron.

It has been attempted to employ the same method a little modified, for the roasting of ores of sulphide of copper and pyrites, with a view of extracting a part of the sulphur. More or less success has ensued, but without ever surmounting all the obstacles arising from the great fusibility of the sulphide of iron. For it sometimes runs into one mass, or at least into lumps agglutinated together in certain parts of the furnace, and the operation is either altogether stopped, or becomes more or less languid; the air not being able to penetrate into all the parts, the roasting becomes consequently imperfect. This inconvenience is even more serious than might at first sight appear; for, as the ill-roasted ores now contain too little sulphur to support their combustion, and as they sometimes fall into small fragments in the cooling, they cannot be passed again through the same furnace, and it becomes necessary to finish the roasting in a reverberatory hearth, which is much more expensive.

In the Pyrenees, the roasting of iron ores is executed in a circular furnace, so disposed that the fuel is contained and burned in a kind of interior oven, above which lie the pieces of ore to be calcined. Sometimes the vault of this oven which sustains the ore, is formed of bricks, leaving between them openings for the passage of the flame and smoke, and the apparatus then resembles certain pottery-kilns: at other times the vault is formed of large lumps of ore, carefully arranged as to the intervals requisite to be left for draught over the arch. The broken ore is then distributed above this arch, care being taken to place the larger pieces undermost. This process is simple in the construction of the furnace, and economical, as branches of trees, without value in the forests, may be employed in the roasting. See Kiln.

In some other countries, the ores are roasted in furnaces very like those in which porcelain is baked; that is to say, the fuel is placed exteriorly to the body of the furnace in a kind of brick shafts, and the flame traverses the broken ore with which the furnace is filled. In such an apparatus the calcination is continuous.

When it is proposed to extract the sulphur from iron pyrites, or from pyritous minerals, different furnaces may be employed, among which that used in Hungary deserves notice. It is a rectangular parallelopiped of four walls, each of them being perforated with holes and vertical conduits which lead into chambers of condensation, where the sulphur is collected. The ore placed between the four walls on billets of wood arranged as in *fig.* 1714, for the great roastings in the open air, is calcined with the disengagement of much sulphur, which finds more facility in escaping by the lateral conduits in the walls, than up through the whole mass, or across the upper surface covered over with earth; whence it passes into the chambers of condensation. In this way upwards of a thousand tons of pyrites may be roasted at once, and a large quantity of sulphur obtained. See PYRITES.

The reverberatory furnace affords one of the best means of ustulation where it is requisite to employ the simultaneous action of heat and atmospheric air to destroy certain combinations, and to decompose the sulphides, arsenides, &c. See COPPER.

In every case where it is desired to have a very perfect roasting, as for blende from which zinc is to be extracted, for sulphide of antimony, &c., or even for ores reduced to a very fine powder and destined for amalgamation, it is proper to perform the operation in a reverberatory furnace. When very fusible sulphurous ores are treated, the workmen charged with the calcination must employ much care and experience, chiefly in the management of the fire. It will sometimes, indeed, happen that the ore partially fuses, when it becomes necessary to withdraw the materials from the furnace, to let them cool and grind them anew, in order to recommence the operation. The construction of these furnaces demands no other attention than to give to the sole or laboratory the suitable size, and so to proportion to this the grate and chimney that the heating may be effected with the greatest economy.

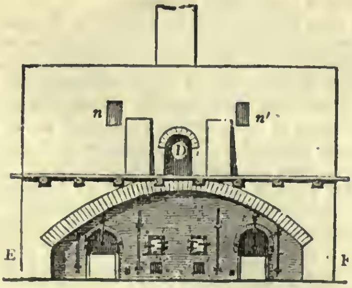
The reverberatory furnace is always employed to roast ores of the precious metals, and especially those for amalgamation; as the latter often contain arsenic, antimony, and other volatile substances, they must be disposed of in a peculiar manner.

The sole, usually very spacious, is divided into two parts, of which the one farthest off from the furnace is a little lower than the other. Above the vault there is a space or chamber in which the ore is deposited, and which communicates with the laboratory by a vertical passage, which serves to allow the ore to be pushed down when it is dried and a little heated. The flame and the smoke which escape from the sole or laboratory pass into condensing chambers before entering into the chimney, so as to deposit in them the oxide of arsenic and other substances. When the ore on the part of the sole farthest from the grate has suffered so much heat as to begin to be roasted, has become less fusible, and when the roasting of that in the nearer part of the sole is completed, the former is raked towards the fire-bridge, and its ustulation finished by stirring it over frequently with a paddle, skilfully worked, through one of the doors left in the side for this purpose. The operation is considered to be finished when the vapours and the smell have almost wholly ceased; its duration depending obviously on the nature of the ores.

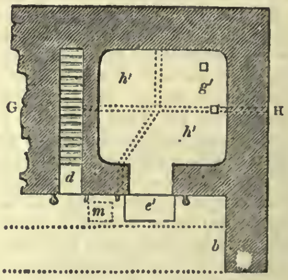
When this furnace is employed to roast very arsenical ores, the chambers of condensation for the arsenious acid are much more extensive than in furnaces commonly used.

Compared with the German *Röstöfen*, the mechanical furnaces are less efficient for the calcination of silver ores, particularly when the ores operated on are very damp and contain much sulphur; in which case the excessive production of lumps becomes a serious inconvenience to contend with.

1715

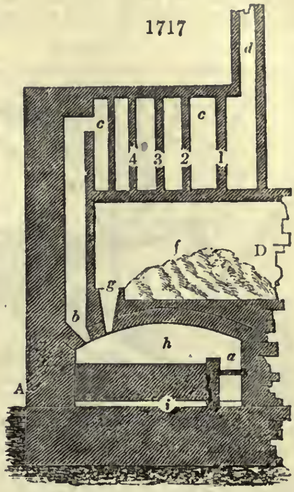


1716



But in the treatment of the silver ores of Hiendelaencina, they possess the advantage of calcining a large quantity of ore in a given time, and require no further attendance than is necessary for supplying them with ore and fuel. The supply of fuel is, however, subject to great neglect. The management of the fires is nevertheless a matter of much importance, for should they be forgotten, and the heat get much reduced, the mineral, from continuing to pass at the same rate through the furnace, cannot be properly calcined.

To prevent the fires getting low, and to raise them after being neglected, the workmen often load the grate with fuel, the result of which is to overheat the ore and cause a great waste of wood.



Figs. 1715, 1716, and 1717 represent a reverberatory furnace employed in the smelting works of Lautenthal, in the Hartz, for roasting the *schlichs* of lead ores, which contain much blende or sulphide of zinc. In *fig.* 1715 we see that the two sides, are absolutely like, the two furnaces being built in one body of brickwork. *Fig.* 1716 is the plan of the furnace B C, taken at the level E F of *fig.* 1715. *Fig.* 1717 is a vertical section of the similar furnace A B, taken in the prolongation of the line G H in *fig.* 1716.

a is the fireplace of the furnace, its grate, and ash-pit. *b* is the conduit of vaporisation, which communicates with the chambers *c*; into which the vaporised substances are deposited; *d*, chimney for the escape of the smoke of the fireplace *a*, after it has gone through the space *b c c*; *e'* is the charging door, with a hook hanging in front to rest the long iron rake upon, with which the materials are turned over; *f*, chamber containing a quantity of *schlich* destined for roasting; this chamber communicates with the vaulted corridor (gallery) D, seen in *fig.* 1715; *g*, orifice through which the *schlich* is thrown into the furnace; *h*, area or hearth of the reverberatory furnace, of which the roof is certainly much too high; *i*, channels for the escape of the watery vapours; *k l*, front arcade, between which and the furnace, properly speaking, are the two orifices of the conduits, which terminate at the channels *m m'*. *m* is the channel for carrying towards the chimney, *d*, the vapours which escape by the door *e'*. *n* is a walled-up door, which is opened from time to time, to take out of the chambers *c*, *c*, the substances that may be deposited in them.

At the smelting-works of Lautenthal, in such a roasting-furnace, from 6 to 9 quintals (cwts.) of *schlich* are treated at a time, and it is stirred frequently with an iron rake upon the altar *h*. The period of this operation is from 6 to 12 hours, according as the *schlich* may be more or less dry, more or less rich in lead, or more or less charged with blende. When the latter substance is abundant, the process requires 12 hours, with about 60 cubic feet of cleft billets for fuel.

In such furnaces are roasted the cobalt ores of Schneeberg in Saxony, the tin ores of Schlackenwald in Bohemia, of Ehrenfriedersdorf in Saxony, and elsewhere; as also the arsenical pyrites at Geyer in Saxony. But there are poison towers and extensive condensing chambers attached in the latter case.

For a description of Gerstenhöfer's furnace for roasting metallic sulphides, see Copper.

ROCCELLA, from the Italian *rocca*, 'a rock;' a genus of lichens. See Archil; Lichens.

ROCCELLIC ACID. A fatty acid obtained from the *Roccella tinctoria*.

ROCHELLE SALT. A double tartrate of soda and potash: mixed with some carbonate of soda, and an equivalent of tartaric acid being added, after the salt is dissolved, it forms the artificial seidlitz-water.

ROCH or **ROCK ALUM.** A factitious article consisting of crystalline fragments of alum not larger than almonds, coloured with Venetian red. See Alum.

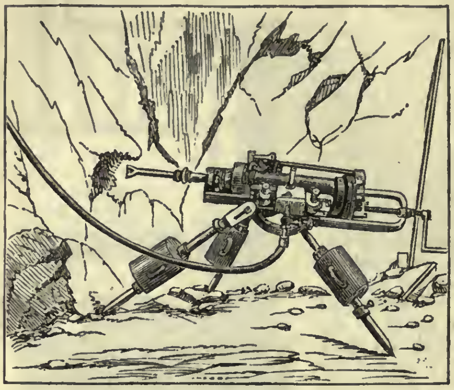
ROCK. A term used in South Staffordshire by miners to denote any hard sandstone.

ROCK CRYSTAL. A very fine transparent and colourless variety of quartz.

ROCK-DRILL or **PERFORATOR.** The rock-drill invented by Mr. Ingersol has achieved a high reputation in the mines of America. It has been introduced to this country by Messrs. Le Gros and Silva, and having excited much attention must be briefly described.

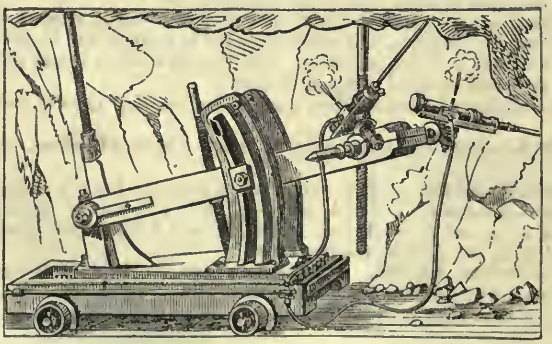
The chief principles and characteristic features of this rock-drill are, that the motive pressure is continued until the stroke of the piston takes effect in a blow on the rock (in lieu of being cut off at a point antecedent to the rock being struck), whereby an important accession of speed in penetration is attained; and that the feed or forward motion of the machine is strictly and completely automatic, dependent solely upon, and proceeding *pari passu* with, the actual work done, so that however variable may be the hardness of the rock on which it is operating, the piston acts on the feed-motion only when and so long as adequate penetration has been effected, thereby conducing to rapid and regular drilling, and steady progress and work. It appears to be an economical and effective machine, for all the operations of quarrying and mining, for rock excavations and removal by blasting, for shafts, sewerage works, tunnels, drift-ways, headings, &c., in mines, quarries, and various other engineering and constructive works. It may be worked by steam or compressed air, and so mounted as to drift bore-holes horizontally, vertically, or at any required angle. For example, as shown in the engravings, the ordinary tripod form (*fig.* 1718) is suitable for ordinary vertical drilling, and for boring holes in very narrow and irregular places, driftways, &c.; for railway tunnels, and the heavier class of operations, a car is employed with several drills mounted thereon (*fig.* 1719); and, again, *fig.* 1720 shows the ordinary form of 'gadding car,' designed for boring horizontal as well as vertical holes, to enable blocks of stone of any desired dimensions to be taken out of a quarry.

1718



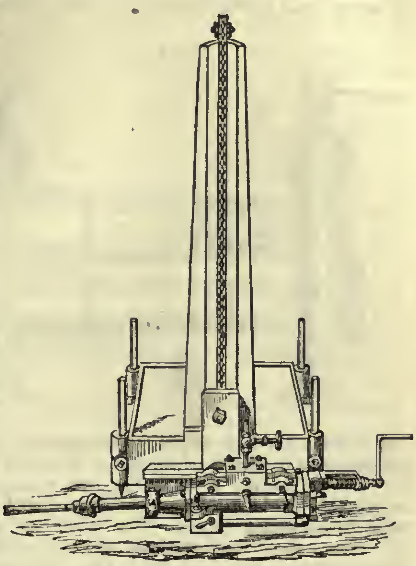
The mechanical construction and details are as follow:—It is one of the class of machines known as a percussive rock-drill, comprising a cylinder with a double-action reciprocating and rotating piston, with a piston-rod terminating at its outer extremity in a drilling or cutting tool. The drill-bar is raised by the upward pressure of the expansive fluid employed, upon the piston, and falls on that being withdrawn, the impulse of the downward stroke being aided and intensified by the expansive pressure when admitted, in alternation, to act upon the upper side of the piston; this in case of vertical downward drilling; in horizontal and overhead drilling, the weight of the piston, rod, and drill-bar is overcome, and the tool propelled against the rock to be bored, like a projectile from a gun, by the expansive force employed. The reciprocating motion of the piston itself is the automatic agent in effecting the alternate opening of the ports and the change of steam, induction, and eduction. Attached to the cylinder is a steam-chest and common D slide-valve, actuated by two short valve-stems, one at each end, which are worked by tappets having rounded shoulders, projecting into the cylinder, and so situated that the piston strikes against them at the completion of its stroke in either direction; on contact with either of the tappets, the piston thus not only effects a suitable change of steam by means of the valves, but at the same time restores the other tappet, at the opposite end, to its due projecting posi-

1719



tion, so that it may be acted upon at the return stroke. At each change the steam is admitted to the same end of the cylinder as the piston and the tappet struck, and, there being a sufficient clearance allowed, rushes in to cushion the piston and arrest and reverse the motion.

1720



The self-acting feed-motion, whereby the penetration of the rock, resulting from the rapid succession of blows, is mechanically accompanied by a corresponding advance in the boring machine itself, is actuated by means of another tappet, attached to the opposite side of the cylinder, so as to project into the cylinder at a point in the lower clearance below the valve-tappet and fitted with a spring for returning it into position after being struck; this feed-tappet is carried on to the external spindle, extending the opposite or upper end of the cylinder, and there acting by means of a pawl upon a ratchet-wheel or collar, attached to the cylinder so as to work round the feed-screw; and the action of this device is such that the feed is exactly proportioned to the progress of the work. If from excessive hardness or any other cause, the blow is ineffective, and the penetration deficient, *i.e.*, less than the distance between the valve and feed-tappets, or $\frac{3}{16}$ths of an inch, the piston fails to actuate the feed-motion, and the cylinder remains stationary for the time. It will readily be understood that the cylinder is fitted so as to slide in the frame, which is a semi-cylindrical shell, provided with V-shaped projections fitting into external grooves on the cylinder; the feed-screw is attached by a collar to the curved arm or bar on the head of the frame, and has a square head on which a winch-handle fits, whereby, when the cylinder has been fed forwards by the ratchet-and-pawl motion to the end of the guides or slides, it may be brought back by hand, ready for further operations, for which a longer drill-bar would have to be attached.

There remains to be noted another speciality in the mechanism, viz., the device whereby the necessary continuous, step-by-step, and partial rotation of the drill-rod, and piston is effected at each return stroke. This is effected by a peculiar rifling arrangement, which is brought to bear upon the interior and upper part of the piston and rod. For this purpose a suitably-rifled round steel-bar is attached by a collar to the top cylinder cover, and provided with a ratchet and pawls, so that it is free to rotate in one direction only; this bar has eight spiral grooves, one complete turn in 7 feet being the pitch, and projects downward into a corresponding hole bored in the piston and rod, which are fitted with a brag-nut fitted thereto, and rifled to correspond. By this means the rifled-bar and the piston and drill-bar are alternately made to make $\frac{1}{12}$th of a complete revolution at each stroke; on the down-stroke of the piston, which is straight, the rifled-bar is caused partially to rotate; but as it cannot go back on the upstroke, the piston takes the rifling and rotates partially in its turn; and the stroke and pitch are so proportioned that one entire revolution is made in about twelve complete strokes.

The smallest size of these rock-drills has a $2\frac{1}{2}$-inch cylinder, and weighs only 173 lbs. (cylinder 123 lbs.); its piston-stroke is $3\frac{1}{2}$ inches, and it is capable of boring holes from $\frac{5}{8}$-inch to $1\frac{3}{4}$-inch diameter to 10 feet deep, averaging, in the hardest crystalline trap-rock, about 35 feet linear of 1-inch bore-hole in a day of ten hours. In the largest size, weighing 818 lbs. (cylinder 558 lbs.), 5-inches cylinder, the stroke is variable, 8 inches for soft, and $5\frac{1}{2}$ inches for hard rock. The drill-holes may be from $1\frac{3}{4}$ to 5 inches, and to a depth of 40 feet. With this machine a day's work of ten hours would average 25 feet of $3\frac{3}{4}$-inches bore-hole in the hardest trap. The small size delivers 800, and the large one 400 blows per minute.

ROCKETS. See PYROTECHNY.

ROCK FAT. See ADIPOCERE.

ROCK OIL. A name for petroleum. See NAPHTHA; PARAFFINE; PETROLEUM.

ROCK SALT. See Salt.

ROE STONE. A name for *oolite*, from its being like the roe of fish. See Oolite.

ROLLERS, ELASTIC, for printing. See Printing Rollers.

ROLLING MILLS. These useful aids to many of our metallurgical processes appear to have been introduced to this country in the seventeenth century; but it was not until 1784, when Mr. Cort patented 'a new mode and art of shingling, welding, and manufacturing iron and steel into bars, plates, &c.,' that much attention was directed to the value of the rolling mill.

1721

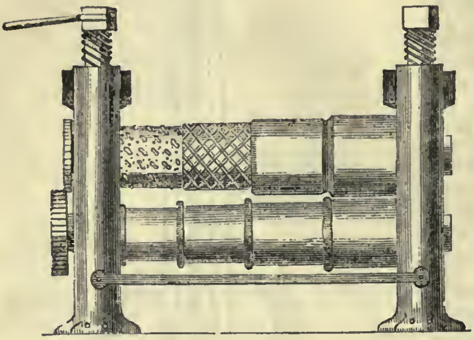


Fig. 1721 is a front view of a pair of rollers, used in the manufacture of iron in connection with the puddling furnace. They are about 4 feet long, divided into four parts, the largest being about 20 inches in diameter. The portion of the upper roller under which the metal is first passed, is cut in a deep and irregular manner, resembling that chiselling in stone called 'mosaique-work,' that it may the more easily get hold of and compress the metal when almost in a fluid state. The plate is next passed under the cross-cut portion of the roller, and successively through the flat sections. The lower roller, it will be observed, is formed with raised collars at intervals, to keep the metal in its proper course. The rollers are connected by cog-wheels placed upon their axes; upon the lowermost of these, works also the wheel by means of which the revolution is communicated. The cheeks are of cast iron, very massive, that they may bear the violent usage to which they are subjected.

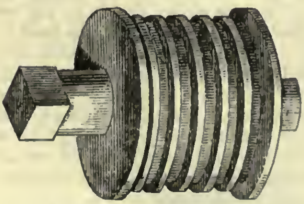
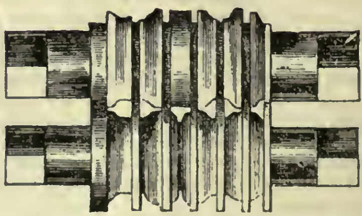
We cannot go into the numerous purposes to which rolling mills of this kind are applied; a few may however be mentioned.

The practice of 'slitting' sheets of metal into light rods, either for the use of the wire-drawers or of nail-makers, is carried out by means of two large steel rollers, channelled circularly, as in *fig.* 1722. These are so placed that the cutters or raised parts of one roller, which are exactly turned for that purpose, shall work in corresponding channels of the other roller, thus forming what may be called revolving shears, for the principle is that of clipping; so that a sheet of metal on being passed through this machinery, is separated into slips agreeing in size with the divisions of the rollers.

1722



1723



For the manufacture of rails, rolling mills are also employed, *fig.* 1723 representing a rolling mill as constructed for rolling Birkinshaw's rails. The open spaces along the middle of the figure, and which owe their figure to the moulding on the periphery of the rollers, indicate the form assumed by the iron rail as it is passed successively from the larger to the smaller apertures, till it is finished at the last.

For a further description, and for the arrangement of rolling mills and slitters, see Iron. Beyond these few notices the character of this Dictionary will not admit of our going; the reader is therefore referred to the works which have been published on the Metallurgy of Iron and Steel, for further information.

Rolling mills have been patented for rolling tubes for gas and other purposes. See Tubes.

ROMAN ALUM. An alum extracted from the volcanic rocks of the Solfatara; it contains more alumina than the common alum. See Alum.

ROMAN CEMENTS. Under the name of Roman cement, some hydraulic mortars, varying considerably in their chemical composition, though physically possessing the same general character, are sold. Like all the hydraulic cements, it is an argillaceous lime. It is usually manufactured from a dark brown stone—a carbonate of lime with much alumina—found in the Island of Sheppy. This stone is calcined and mixed with a certain proportion of sand.

Any hydraulic limestone, that is, one containing from 15 to 20 per cent. of clay, will, when properly prepared, form this cement. Calcine any ordinary clay, and mix it with two-thirds its quantity of lime, grind to powder and calcine again; this makes a very beautiful cement, improperly called Roman, since the preparation was entirely unknown to the Romans. See Hydraulic Cement.

ROMAN OCHRE. A deep and powerful orange-yellow colour, transparent and durable. It is used both raw and burnt by artists. The colouring-matter is oxide of iron mixed with earthy matter. See Ochre.

ROMAN VITRIOL. See Copper.

ROOFING, ASPHALTE. Patent asphalte roofing felt, particularly applicable for warm climates. It is a non-conductor. It is portable, being packed in rolls, and not being liable to damage in carriage, it effects a saving of half the timber usually required. It can be easily applied by any unpractised person. From its lightness, weighing only about 42 lbs. to the square of 100 feet, the cost of cartage is small. The felt can be laid on from gable to gable, or across the roof from eaves to eaves. It is essential that it should be stretched tight and smooth, overlapping full one inch at the joinings, and closely nailed through the overlap with twopenny fine clout nails (heated in a shovel and thrown when hot into grease to prevent rust), about 1½ inch apart, but copper nails are preferable.

The whole roof must have a good coating of coal-tar and lime (about two gallons of the former to six pounds of the latter), well boiled together, kept constantly stirring while boiling, and put on hot with a common tar mop, and while it is soft, some coarse sharp sand may be sifted over it. The coating must be renewed every fourth or fifth year, or more or less frequently according to the climate. The gutters should be made of two folds, one over the other, cemented together with the boiling mixture.

ROOFING-SLATE. See Slate.

ROPE-MAKING. The fibres of hemp which compose a rope seldom exceed in length 3½ feet at an average. They must, therefore, be twined together so as to unite them into one; and this union is effected by the mutual circumtorsion of the two fibres. If the compression thereby produced be too great, the strength of the fibres at the points where they join will be diminished; so that it becomes a matter of great consequence to give them only such a degree of twist as is essential to their union.

The first part of the process of rope-making by hand, is that of spinning the yarns, or threads, which is done in a manner analogous to that of ordinary spinning. The spinner carries a bundle of dressed hemp round his waist; the two ends of the bundle being assembled in front. Having drawn out a proper number of fibres with his hand, he twists them with his fingers, and fixing this twisted part to the hook of a whirl, which is driven by a wheel put in motion by an assistant, he walks backwards down the rope-walk, the twisted part always serving to draw out more fibres from the bundle round his waist, as in the flax spinning-wheel. The spinner takes care that these fibres are equally supplied, and that they always enter the twisted parts by their ends, and never by their middle. As soon as he has reached the termination of the walk, a second spinner takes the yarn off the whirl, and gives it to another person to put upon a reel, while he himself attaches his own hemp to the whirl-hook, and proceeds down the walk. When the person at the reel begins to turn, the first spinner, who has completed his yarn, holds it firmly at the end, and advances slowly up the walk, while the reel is turning, keeping it equally tight all the way, till he reaches the reel, where he waits till the second spinner takes his yarn off the whirl-hook, and joins it to the end of that of the first spinner, in order that it may follow it on the reel.

The next part of the process is that of warping the yarns, or stretching them all to one length, which is about 200 fathoms in full-length rope-grounds, and also in putting a slight turn or twist into them.

The third process in rope-making is the tarring of the yarn. Sometimes the yarns are made to wind off one reel, and, having passed through a vessel of hot tar, are wound upon another, the superfluous tar being removed by causing the yarn to pass through a hole surrounded with spongy oakum; but the ordinary method is to tar it in skeins or hanks, which are drawn by a capstan with a uniform motion through the tar-kettle. Yarn for cables requires more tar than for hawser-laid ropes; and for standing and running rigging, it requires to be merely well covered. Tarred cordage has been found to be weaker than what is untarred, when it is new; but the tarred rope is not so easily injured by immersion in water.

The last part of the process of rope-making is to lay the cordage. For this purpose two or more yarns are attached at one end to a hook. The hook is then turned the contrary way from the twist of the individual yarn, and thus forms what is called a strand. Three strands, sometimes four, besides a central one, are then stretched at length, and attached at one end to three contiguous but separate hooks, but at the other end to a single hook; and the process of combining them together, which is effected by turning the single hook in a direction contrary to that of the other three, consists in so regulating the progress of the twists of the strands round their common axis, that the three strands receive separately at their opposite ends just as much twist as is taken out of them, by their twisting the contrary way, in the process of combination.

Large ropes are distinguished into the *cable-laid* and the *hawser-laid*. The former are composed of nine strands, namely, three great strands, each of these consisting of three smaller secondary strands, which are individually formed with an equal number of primitive yarns. A *cable-laid* rope, 8 inches in circumference, is made up of 333 yarns, or threads, equally divided among the nine secondary strands. A *hawser-laid* rope consists of only three strands, each composed of a number of primitive yarns, proportioned to the size of the rope; for example, if it be 8 inches in circumference, it may have 414 yarns, equally divided among three strands. Thirty fathoms of yarn are reckoned equivalent in length to 18 fathoms of rope cable-laid, and to 20 fathoms hawser-laid. Ropes of from 1 inch to 2½ inches in circumference are usually hawser-laid; of from 3 to 10 inches, are either hawser- or cable-laid; but when more than 10 inches, they are always cable-laid.

Every hand-spinner in the dockyard is required to spin, out of the best hemp, six threads, each 160 fathoms long, for a quarter of a day's work. A hawl of yarn, in the warping process, contains 336 threads.

The following are Captain Huddart's improved principles of the rope manufacture:—

1. To keep the yarns separate from each other, and to draw them from bobbins revolving upon skewers, so as to maintain the twist while the strand, or primary cord, is forming.

2. To pass them through a register, which divides them by circular shells of holes; the number in each concave shell being conformable to the distance from the centre of the strand, and the angle which the yarns make with a line parallel to it, and which gives them a proper position to enter.

3. To employ a tube for compressing the strand, and preserving the cylindrical figure of its surface.

4. To use a gauge for determining the angle which the yarns in the outside shell make with a line parallel to the centre of the strand, when registering; because, according to the angle made by the yarns in this shell, the relative lengths of all the yarns in the strand will be determined.

5. To harden up the strand, and thereby increase the angle in the outside shell; which compensates for the stretching of the yarns, and the compression of the strands.

The improvements in the manufacture of cordage at present in use either in Her Majesty's yards or in private rope-grounds, owe their superiority over the old method of making cordage to Captain Huddart's invention of the register-plate and tube.

Captain Huddart invented and took a patent for a machine, which, by registering the strand at a short length from the tube, and winding it up as made, preserved an uniformity of twist, or angle of formation, from end to end of the rope, which cannot be accomplished by the method of forming the strands down the ground, where the twist is communicated from one end to the other of an elastic body upwards of 300 yards in length. This registering-machine was constructed with such correctness, that when some were afterwards required, no alteration could be made with advantage.

A number of yarns cannot be put together in a cold state, without considerable vacancies, into which water may gain admission; Captain Huddart, therefore, formed the yarns into a strand immediately as they came from the tar-kettle, which he was enabled to do by his registering-machine, and the result was most satisfactory. This combination of yarns was found by experiment to be 14 per cent. stronger than the cold register; it constituted a body of hemp and tar impervious to water, and had great advantage over any other cordage, particularly for shrouds, as, after they were settled on the mast-head, and properly set up, they had scarcely any tendency to stretch, effectually secured the mast, and enabled the ship to carry the greatest press of sail.

In order more effectually to obtain correctness in the formation of cables and large cordage, Captain Huddart constructed a laying machine, which has carried his inventions in rope-making to the greatest perfection, and which, founded on true mathematical principles, and the most laborious calculations, is one of the noblest monuments of mechanical ability since the improvement of the steam-engine by Watt. By this machine, the strands receive that degree of twist only which is necessary, and are laid at any angle with the greatest regularity; the pressure is regulated to give the required elasticity, and all parts of the rope are made to bear equally.

The following description of one of the best modern machines for making ropes on Captain Huddart's plan, may be useful to the reader:—

1724

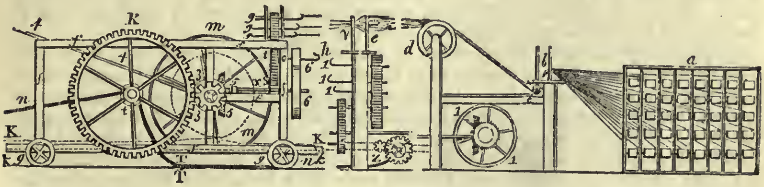


Fig. 1724 exhibits a side elevation of the tackle-board and bobbin-frame at the head of the ropery, and also of the carriage or rope-machine in the act of hauling-out and twisting the strands.

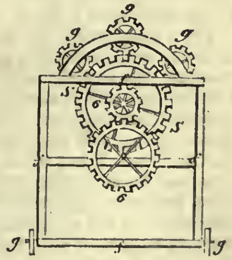
Fig. 1725 is a front elevation of the carriage.

Fig. 1726 is a yarn-guide, or board, or plate, with perforated holes for the yarns to pass through before entering the nipper.

Figs. 1727 and 1728 are side and front views of the nipper for pressing the rope-yarns.

a is the frame for containing the yarn-bobbins. The yarns are brought from the frame, and pass through a yarn-guide at *b*. *c* is a small roller, under which the rope-yarns pass; they are then brought over the reel *d*, and through another yarn-guide *e*, after which they enter the nippers at *v*, and are drawn out and formed into strands by the carriage. The roller and reel may be made to traverse up and down, so as to regulate the motion of the yarns.

1725



1726

1727  1728

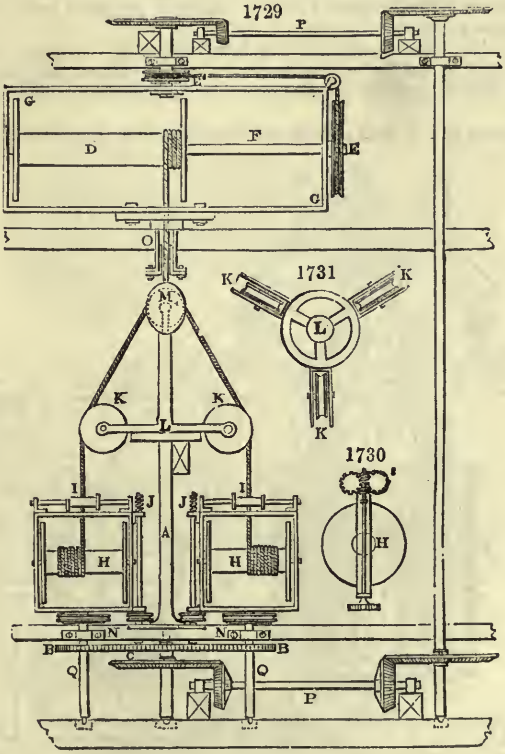
The carriage runs on a railway. *f*, *f*, is the frame of the carriage; *g*, *g*, are the small wheels on which it is supported; *k*, *k*, is an endless rope reaching from the head to the bottom of the railway, and is driven by a steam-engine; *m*, *m*, is a wheel with gubs at the back of it, over which the endless rope passes, and gives motion to the machinery of the carriage. *n* is the ground-rope for taking out the carriage, as will be afterwards described. On the shaft of *m*, *m*, are two bevel-wheels, 3, 3, with a shifting catch between them; these bevel-wheels are loose upon the shaft, but when the catch is put into either of them, this last then keeps motion with the shaft, while the other runs loose. One of these wheels serves to communicate the twist to the strand in drawing out; the other gives the opposite or after-turn to the rope in closing. 4, 4, is a lever for shifting the catch accordingly. 5 is a third bevel-wheel, which receives its motion from either of the other two, and communicates the same to the two spur-wheels 6, 6, by means of the shaft *x*. These can be shifted at pleasure; so that by applying wheels of a greater or less number of teeth above and beneath, the twist given to the strands can be increased or diminished accordingly. The upper of these two communicates motion, by means of the shaft *o*, to another spur-wheel 8, which working in the three pinions above, 9, 9, gives the twist to the strand-hooks. The carriage is drawn out in the following manner:—On the end of the shaft of *m*, *m*, is the pinion 3, which, working in the large wheel R, gives motion to the ground-rope shaft upon its axis. In the centre of this shaft is a curved pulley or drum *t*, round which the ground-rope takes one turn. This rope is fixed at the head and foot of the ropery, so that when the machinery of the carriage is set agoing by the endless rope, *k*, *k*, and gives motion to the ground-rope shaft, as above described, the carriage will necessarily move along the railway; and the speed may be regulated either by the diameter of the circle formed by the gubs on the wheel *m*, *m*, or by the number of teeth in the pinion 3. At T, is a small roller, merely for preventing the ground-rope from coming up among the machinery. At the head of the railway, and under the tackle-board, is a wheel and pinion Z, with a crank for tightening the ground-rope. The fixed machinery at the head, for hardening or tempering the strands, is similar to that on the carriage, with the exception of the ground-rope gear, which is unnecessary. The motion is communicated by another endless rope (or short band, as it is called, to distinguish it from the other), which passes over gubs at the back of the wheel 1, 1.

When the strands are drawn out by the carriage to the requisite length, the spur-wheels 3, R, are put out of gear. The strands are cut at the tackle-board, and fixed to the hooks 1, 1, 1; after which they are hardened or tempered, being twisted at both ends. When this operation is finished, three strands are united on the large hook *h*, the top put in, and the rope finished in the usual way.

In preparing the hemp for spinning an ordinary thread- or rope-yarn, it is only heckled over a large keg or clearer, until the fibres are straightened and separated, so as to run freely in the spinning. In this case the hemp is not stripped of the tow, or cropped, unless it is designed to spin beneath the usual grist, which is about 20 yarns for the strand of a 3-inch strap-laid rope. The spinning is still performed by hand, being found not only to be more economical, but also to make a smoother thread than has yet been effected by machinery. Various ways have been tried for preparing the yarns for tarring. That which seems now to be most generally in use is, to warp the yarns upon the stretch as they are spun. This is accomplished by having a wheel at the foot, as well as the head of the walk, so that the men are able to spin both up and down, and also to splice their threads at both ends. By this means they are formed into a haul, resembling the warp of a common web, and a little turn is hove into the haul, to preserve it from getting foul in the tarring. The advantages of warping from the spinners, as above, instead of winding on winches, as formerly, are, 1st, the saving of this last operation altogether; 2ndly, the complete check which the foreman has of the quantity of yarn spun in the day; 3rdly, that the quality of the work can be subjected to the minutest inspection at any time. In tarring the yarn, it is found favourable to the fairness of the strip, to allow it to pass around or under a reel or roller in the bottom of the kettle while boiling, instead of coiling the yarn in by hand. The tar is then pressed from the yarn, by means of a sliding nipper, with a lever over the upper part, and to the end of which the necessary weight is suspended. The usual proportion of tar in ordinary ropes is something less than a fifth. In large strap-laid ropes, which are necessarily subjected to a greater press in the laying of them, the quantity of tar can scarcely exceed a sixth, without injuring the appearance of the rope when laid.

For a long period the manner of laying the yarns into ropes was by stretching the haul on the rope-ground, parting the number of yarns required for each strand, and twisting the strands at both ends, by means of hand-hooks, or cranks. It will be obvious that this method, especially in ropes of any considerable size, is attended with serious disadvantages. The strand must always be very uneven; but the principal disadvantage, and that which gave rise to the many attempts at improvement, was, that the yarns being all of the same length before being twisted, it followed, when the rope was finished, that while those which occupied the circumference of the strand were perfectly tight, the centre yarns, on the other hand, as they were now greatly slackened by the operation of hardening or twisting the strands, actually would bear little or no part of the strain when the rope was stretched, until the former gave way. The method displayed in the preceding figures and description is among the most improved processes. Every yarn is given out from the bobbin-frame as it is required in twisting the rope; and the twist communicated in the out-going of the carriage can be increased or diminished at pleasure. In order to obtain a smooth and well-filled strand, it is necessary also, in passing the yarns through the upper board, to proportion the number of centre to that of outside yarns. In ordinary-sized ropes, the strand seems to have the fairest appearance when the outside yarns form from two-thirds to three-fourths of the whole quantity, in the portion of twist given by the carriage in drawing out and forming the strands.

In laying cables, torsion must be given both behind and before the laying-top. *Figs.* 1729 to 1732 represent the powerful patent apparatus employed for this purpose. A, is a strong upright iron pillar, supported upon the great horizontal beam N, N, and bearing at its upper end the three-grooved laying-top M. H, H, are two of the three great bobbins or reels round which the three secondary strands or small hawsers are wound. These are drawn up by the rotation of the three feeding rollers I, I, I, thence proceed over the three guide-pulleys K, K, K, towards the laying-top M, and finally pass through the tube O, to be wound upon the cable-reel D. The frames of the three bobbins H, H, H, do not revolve about the fast pillar A, as a common axis; but each bobbin revolves round its own shaft Q, which is steadied by a bracing collet at N, and a conical step at its bottom. The three bobbins are placed at an angle of 120 degrees apart, and each receives a rotatory motion upon its axis from the toothed spur-wheel B, which is driven by the common central spur-wheel C. Thus each of the three secondary cords has a proper degree of twist put into it in one direction, while the cable is laid, by getting a suitable degree of twist in an opposite direction, from the revolution of the frame or cage G, G, round two pivots, the one under the pulley E, and the other over O. The reel D has thus, like the bobbins H, H, two movements; that in common with its frame, and that upon its axis, produced by the action of the endless band round the pulley E, upon one of its ends, and the pulley E′ above its centre of rotation. The pulley E is driven by the bevel mill-gearing P, P, P, as also the under spur-wheel C. L, in *fig.* 1729, is the place of the ring L, *fig.* 1731, which bears the three guide-pulleys K, K, K. *Fig.* 1734 is an end view of the bobbin H, to show the worm or endless screw J, of *fig.* 1729 working into the two snail-toothed



wheels, upon the ends of the two feed-rollers I, I, which serve to turn them. The upright shafts of J, J, receive their motion from pulleys and cords near their bottom. Instead of these pulleys, and the others, E E′, bevel-wheel gearing has been substituted with advantage, not being liable to slip, like the pulley-band mechanism. The axis of the great reel is made twice the length of the bobbin D, in order to allow of the latter moving from right to left, and back again alternately, in winding on the cable with uniformity as it is laid. The traverse mechanism of this part is, for the sake of perspicuity, suppressed in the figure.

Mr. William Norvell, of Newcastle, obtained a patent for an improvement adapted to the ordinary machines employed for twisting hempen yarns into strands, affording, it is said, a simpler and more eligible mode of accomplishing that object, and also of laying the strands together, than had been theretofore effected by machinery.

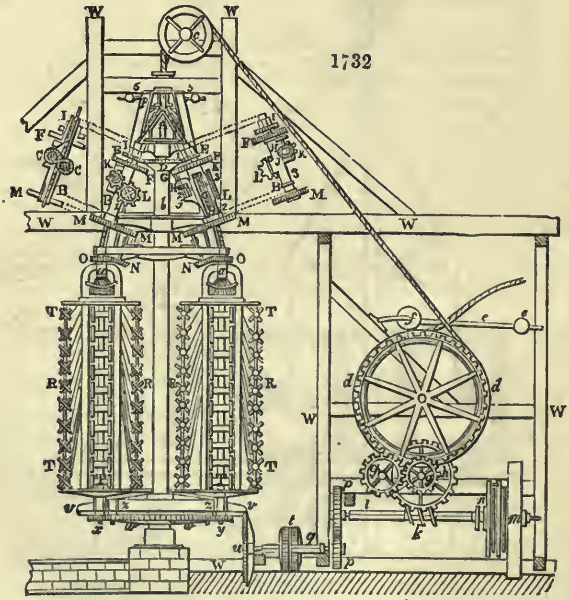
His improvements consisted, first, in the application of three or more tubes, two of which are shown in *fig.* 1732, placed in inclined positions, so as to receive the strands immediately above the press-block *a*, *a*, and nearly in a line with A, the point of closing or laying the rope. B[1] and B[3] are opposite side views; B[2], an edge view; and B, a side section of the same. He did not claim any exclusive right of patent for the tubes themselves, but only for their form and angular position.

Secondly, in attaching two common flat sheaves, or pulleys, C, C, *fig.* 1732, to each of the said tubes, nearly round which each strand is lapped or coiled, to prevent it from slipping, as shown in the section B[1]. The said sheaves or pulleys are connected by a crown or centre-wheel, D, loose upon *b*, *b*, the main or upright axle; E, E, is a smaller wheel upon each tube, working into the said crown or centre-wheel, and fixed upon the loose box I, on each of the tubes.

F, F, is a toothed or spur-wheel, fixed also upon each of the loose boxes I, and working into a smaller wheel, G, upon the axis 2 of each tube; H is a bevel-wheel fixed upon the same axis with G, and working into another bevel-wheel, *j*, fixed upon the cross axle 3 of each tube; K is a spur-wheel attached to the same axis with *j*, at the opposite end, and working into L, another spur-wheel of the same size upon each of the tubes. By wheels thus arranged and connected with the sheaves or pulleys, as above described, a perfectly equal strain or tension is put upon each strand as drawn forward over the pulley C.

Thirdly, the invention consists in the introduction of change-wheels, M, M, M, M, *fig.* 1732, for putting the forehard or proper twist into each strand before the rope is laid; this is effected by small spindles on axles, 4, 4, placed parallel with the line of each tube B.

Upon the lower end of each spindle the bevel-wheels N, N, are attached, and driven



by other bevel-wheels, O, O, fixed immediately above each press-block, *a*, *a*. On the top end of each spindle or axle, 4, 4, is attached one of the change-wheels, working into the other change-wheel fixed upon the bottom end of each of the tubes, whereby the forehard, or proper twist in the strands for all sizes of ropes, is at once attained, by simply changing the sizes of those two last-described wheels, which can be very readily effected, from the manner in which they are attached to the tubes B, B, and 4, 4.

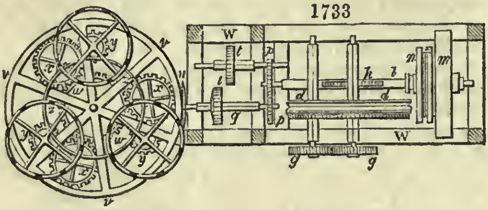
From the angular position of the tubes towards the centre, the strands are nearly in contact at their upper ends, where the rope is laid, immediately below which the forehard or proper twist is given to the strands.

Fourthly, in the application of a press-block, P, of metal, in two parts, placed directly above and close down to where the rope is laid at A, the insdie of which is polished, and the under end is bell-mouthed; to prevent the rope from being chafed in entering it, a sufficient grip or pressure is put upon the rope by one or two levers and weights, 5, 5, acting upon the press-block, so as to adjust any trifling irregularity in the strand or in the laying; the inside of which, being polished, gives smoothness, and by the said levers and weights, a proper tension to the rope, as it is drawn forward through the press-block. By the application of this block, ropes may be made at once properly stretched, rendering them decidedly preferable and extremely advantageous particularly for shipping, inclined planes, mines, &c.

The preceding description includes the whole of Mr. Norvell's improvements; the remaining parts of the machine may be briefly described as follow:—A wheel or pulley, *c*, is fixed independently of the machine, over which the rope passes to the drawing motion represented at the side; *d*, *d*, is a grooved wheel, round which the rope is passed, and pressed into the groove by means of the lever and weight *e*, *e*, acting upon the binding-sheaf *f*, to prevent the rope from slipping. After the rope leaves the said sheaf, it is coiled away at pleasure. *g*, *g*, are two change-wheels, for varying the speed of the grooved wheel *d*, *d*, to answer the various sizes of ropes; *h*, is a spiral wheel, driven by the screw *k*, fixed upon the axle *l*; *m* is a band-wheel, which is driven by a belt from the shaft of the engine, or any other communicating power; *n*, *n*, is a friction-strap and striking-clutch. The axle *q* is driven by two change-wheels *p*, *p*; by changing the sizes of those wheels, the different speeds of the drum R, R, for any sizes of ropes, are at once effected.

The additional axle *s*, and wheels *t*, *t*, shown in *fig.* 1733, are applied occasionally

1733



for reversing the motion of the said drums, and making what is usually termed left-hand ropes; *u*, *figs.* 1732, 1733, shows a bevelled pinion, driving the main crown-wheel *v*, *v*, which wheel carries and gives motion to the drums R, R; *w*, *w*, is a fixed or sun-wheel, which gives a reverse motion to the drums, as they revolve round the same, by means of the intervening wheels *x*, *x*, *x*, whereby the reverse or retrograding motion is produced, which gives to the strands the right twist. The various retrograding motion or right twist for all sizes and descriptions of ropes, may be obtained by changing the diameters of the pinions *y*, *y*, *y*, on the under ends of the drum spindles; the carriages of the intervening wheels *x*, *x*, *x*, being made to slide round the ring *z*, *z*; W, W, is the framework of the machine and drawing motion; T, T, T, are the bobbins containing the yarns; their number is varied to correspond with the different sizes of the machine.

Messrs. Chapman, of Newcastle, having observed that rope-yarn is weakened by passing through the tar-kettle, that tarred cordage loses its strength progressively in cold climates, and so rapidly in hot climates as to be scarcely fit for use in three years, discovered that the deterioration was due to the reaction of the mucilage and acid of the tar. They accordingly proposed the following means of amelioration: 1. Boiling the tar with water, in order to remove these two soluble constituents. 2. Concentrating the washed tar by heat, till it becomes pitchy, and then restoring the plasticity which it thereby loses, by the addition of tallow, or animal or expressed oils.

The same engineers patented a method of making a belt or flat band, of two, three, or more strands of shroud or hawser-laid rope, placed side by side, so as to form a band of any desired breadth, which may be used for hoisting the kibbles and corves in mine-shafts, without any risk of its losing twist by rotation. The ropes should be laid with the twist of the one strand directed to the right hand, that of the other to the left, and that of the yarns the opposite way to the strands, whereby perfect flatness is secured to the band. This parallel assemblage of strands has been found also to be stronger than when they are all twisted into one cylinder. The patentees at the same time contrived a mechanism for piercing the strands transversely, in order to brace them firmly together with twine. Flat ropes are usually formed of hawsers with three strands, softly laid, each containing thirty-three yarns, which with four ropes compose a cordage 4½ inches broad and 1¼ inch thick, being the ordinary dimensions of the grooves in the whim-pulleys round which they pass.

The above statement is the result of several hundred experiments.

ROPE, WIRE. See Wire Rope.

ROSANILINE. The name given by Dr. Hofmann to a compound which plays the part of a well-defined base in the formation of the aniline reds. It may now be considered as demonstrated that the aniline reds are salts of a peculiar and extremely remarkable compound, called *rosaniline.* See Aniline.

Rosaniline in the anhydrous state is represented by the formula $C^{40}H^{19}N^{3}$ ($\mathbf{C^{20}H^{19}N^{3}}$), and in the hydrated state, such as it assumes when isolated from its compounds, by the formula $C^{40}H^{19}N^{3}.2HO$ ($\mathbf{C^{20}H^{19}N^{3}.H^{2}O}$).

It is a triamine capable of combining with one, two, and three equivalents of acid. The pure aniline reds are saline compounds of rosaniline with one equivalent of acid.

It is very interesting that rosaniline itself, when freshly prepared, is a colourless compound. It is nearly insoluble in water, slightly soluble in ammonia, more soluble in ether. When exposed to the action of the air, rosaniline becomes rapidly rose-coloured, and finally of a deep red, probably in consequence of the formation of a carbonate. It is a rather powerful base, forming salts, almost all of which are remarkable for their beauty, and the facility with which they crystallise.

The salts containing one equivalent of acid exhibit, for the most part, in reflected light, the lustrous metallic green of the wings of the rose-beetle; in transmitted light the crystals are red, becoming opaque when they acquire certain dimensions. The solutions of these salts in water or alcohol possess the magnificent crimson colour which characterises rosaniline-compounds. According to M. Chevreul, who, in the extensive course of his memorable researches on the theory of dyeing, examined the colouring-matters derived from coal-tar, the green colour reflected from the salts of rosaniline is exactly complementary to the colour which these salts impart to wool or silk.

The salts with three equivalents of the stronger acids, on the other hand, are yellowish-brown, both in the solid state and in solution. They are much more soluble in water and alcohol than the monacid salts, which, for the most part, are comparatively sparingly soluble.

Both classes of rosaniline salts crystallise readily, more especially the monacid compounds, some of which Mr. Nicholson has obtained in perfectly well-formed crystals.

The formula of rosaniline has been corroborated by the examination and analysis of its salts, the most important of which are the following:—

Hydrochlorate.—Prepared either by the action of hydrochloric acid, or of chloride of ammonium, upon the free base, the monacid salt is deposited from its boiling solution in well-defined rhombic plates, frequently in stellar forms. This chloride is difficultly soluble in water, more soluble in alcohol, and insoluble in ether.

The salt retains a little water at 100° C., but becomes anhydrous at 130° C.

Like most of the rosaniline salts, this salt is very hygroscopic. The monacid chloride dissolves more readily in moderately strong hydrochloric acid than in water. If this solution, gently warmed, be mixed with very concentrated hydrochloric acid, it solidifies on cooling into a network of beautiful brown-red needles, which have to be washed with concentrated hydrochloric acid and dried *in vacuo* over sulphuric acid and lime, since water decomposes them with reproduction of the monacid compound. The salt obtained by the action of concentrated hydrochloric acid is a compound with three equivalents of acid.

Exposed to 100° C., this salt gradually loses acid, the brown crystals becoming indigo-blue; and if the exposure be continued until the weight becomes constant, the original green-salt with one equivalent of acid is reproduced.

Sulphate of Rosaniline is readily obtained by dissolving the free base in boiling dilute sulphuric acid. On cooling, the salt is deposited in green metal lustrous crystals, which by one recrystallisation become perfectly pure.

Acetate of Rosaniline.—This is probably the finest salt of the series. Mr. Nicholson obtained it in crystals an inch in diameter, which, on analysis, were found to be the pure monacid acetate. The crystals of this salt, when freshly prepared, exhibit in a marked manner a beautifully green metallic lustre; on protracted exposure to the light this lustre disappears, and the crystals assume a dark reddish-brown tint.

The acetate is one of the more soluble salts both in water and in alcohol; on a smaller scale it cannot be conveniently recrystallised.

Nitrate of Rosaniline is easily formed by dissolving the base in warm dilute nitric acid. On cooling, the salt crystallises in small crystals resembling the other salts of rosaniline.

Of the remaining salts of this base we may mention the *chromate*, which is obtained by adding chromate of potash to a solution of the acetate, in the form of a brick-red precipitate, becoming a green crystalline, almost insoluble, powder on ebullition with water.

The *Tannates of Rosaniline*, described by M. E. Kopp, are also very beautiful salts; they are true carmine lakes which rival the renowned carmine-lake obtained from cochineal. They are entirely insoluble in water, but soluble in alcohol, wood-spirit, and acetic acid. In the dry state they do not present the green metallic appearance of the other salts of rosaniline, but preserve their beautiful carmine-red colour.

The tannate of rosaniline is of considerable importance to industry, not only because it is formed in nearly all the cotton fabrics dyed and printed in red or rose with rosaniline, but also because, by reason of its insolubility, it enables the manufacturer to make use of very dilute aqueous solutions of aniline red, which are often obtained in the factories during the purification of rosaniline. In fact, the best manner of treating these solutions, which are too poor in colouring-matter to be advantageously employed in any other way, consists in precipitating them with a fresh solution of nut-galls; after a very short time all the rosaniline is precipitated in a state of magnificent red lake, the mother-liquors becoming almost entirely colourless.

Iodide of Rosaniline.—Hobrecker, of Crefeld, discovered a violet colouring-matter, derived from rosaniline, which crystallises easily, and is characterised by its rich reddish tone. This colouring-matter is obtained by the action of a mixture of chloride of benzyl and iodide of methyl upon rosaniline, dissolved in methylic alcohol. The mixture is digested for some time in a water-bath. As the deep violet solution cools, needles of a green metallic lustre separate out, and can be obtained completely pure by re-solution in alcohol and re-crystallisation. The compound—an iodide—is almost insoluble in water, sparingly soluble in cold alcohol, but more soluble in the same liquid when hot. The iodide, dried at 100° C., was analysed by Hofmann, with the following results:—Carbon, 70·56; hydrogen, 6·0; nitrogen, 5·89; iodine, 17·67: total, 100·12.

ROSEINE. See ANILINE RED.

ROSELET. The fur of the ermine *Mustela erminea*, as it is taken from the animal in the summer. See ERMINE.

ROSEMARY. The *Rosmarinus officinale* contains a volatile oil, and is used in perfumery.

ROSENSTIEHL'S GREEN, known also as *Cassel green*. This is a *baryta* green, or a *manganate of baryta*. The best mode of preparing it is as follows, according to M. E. Fleischer:—On precipitating a green boiling solution of manganate of potash with chloride of barium, there is formed a deposit strongly granular, but not crystalline. This precipitate is of a violet colour, bordering on blue. It is well washed by decantation, and then filtered. When dried, its colour becomes paler as the temperature rises. At a dark red heat it is white, with a slight greyish-blue tinge. If heated higher, with access of air, it becomes by degrees completely green, then of a fine blue, and at very elevated temperatures it is converted into a dirty brown-grey. If a solution of permanganate of potash is precipitated with chloride of barium, and allowed to boil, there is slowly formed a reddish-violet deposit (colour of peach-blossom), and the liquid retains an intense violet colour. The precipitate may be washed by decantation, and filtered without decomposition. It can even be dried at 100° without losing its colour. When gradually heated, the permanganate of baryta loses its colour, like the manganate, but at very high temperatures it behaves differently. When its colour has once been destroyed by a moderate heat, it does not become either green or blue by farther heating with access of air. The whole becomes at once of a greyish-brown. The finest barytes green is formed by calcining the manganate of baryta. Rosenstiehl's process—the fusion of hydrate of baryta with chlorate of potash and peroxide of manganese—yields an inferior colour.

ROSE OIL. See OTTO OF ROSES.

ROSE-PINK. A coarse and common colour, much used in the cheaper kinds of paper-staining, and for distemper painting. It is prepared by saturating chalk with a strong infusion of Brazil-wood.

ROSETTA WOOD. An East-Indian wood of a lively red-orange colour, and handsomely veined with darker marks. It is occasionally used in fine cabinet-work.

ROSEWOOD. This well-known wood, which has long been fashionable for drawing-room and library furniture, is a native of the Brazils, the East Indies, the Canary Islands, and some parts of Africa. The best rosewood comes from Rio de Janeiro, and is believed to be yielded by a species of *Dalbergia.*

'Rosewood is a term as generally applied as iron-wood, and to as great a variety of plants in different countries, sometimes from the colour, and sometimes from the smell of the woods. The rosewood of Bahia and Rio Janeiro, called also Jacaranda, is so named, according to Prince Maximilian, as quoted by Dr. Lindley, because when fresh it has a faint but agreeable smell of roses, and is produced by a mimosa in the forests of Brazil. Mr. G. Loddiges informs me it is the *Mimosa jacaranda.*'—*Holtzapffel.*

Rosewood is imported in large slabs, or the halves of trees, some of these logs producing as much as 150*l.* when cut into veneers.

ROSIN, or *common resin.* The residue of the process for obtaining oil of turpentine. While liquid it is run into metallic receivers coated with whiting to prevent adhesion, and from these laded into casks. See TURPENTINE.

Rosin imported in 1873.

	Cwts.	Value
From France	61,793	£32,954
,, United States of America	888,025	434,085
,, Other countries	5,971	4,569
Total	955,789	471,608

Rosin imported in 1874, 1,066,681 cwts.; value 442,700*l.*

When the distillation is not carried too far, the product is called *yellow rosin*; it then contains a little water. The heat being continued, the water is expelled, and *transparent rosin* is the result.

If the process be continued up to a point short of producing the decomposition of the rosin, it acquires a deep colour, and becomes *brown* or *black* rosin, sometimes called *colophony.*

Rosin is insoluble in water, but soluble in alcohol, ether, and the volatile oils. It unites with wax and the fixed oils by heat, forming the *Emplastrum rosinæ* of the London Pharmacopœia.

Rosin is employed in common varnishes; it is united with tallow in the preparation of common candles. It has been proposed to employ rosin as a source from which gas might be obtained. The experiments made were not, however, of so successful a kind as to warrant the general adoption of the process.

ROSIN OIL. By distillation rosin separates into rosin oil and tar. (See TAR.) This oil is a mixture of four carbides of hydrogen: $C^{14}H^{8}$; $C^{10}H^{12}$; $C^{32}H^{16}$; and $C^{20}H^{8}$. The rosin oil, which distils over at about 300° Fahr., is sometimes used in the arts as a substitute for the oil of turpentine. The part which boils at 464° Fahr., called *retinole,* $C^{32}H^{16}$, enters into the composition of some printing inks.

ROSIN TIN. A pale-coloured oxide of tin with a resinous lustre is so called by the miner.

ROSOLANE. See ANILINE VIOLET.

ROSOLIC ACID, discovered by Rungé, and more fully examined by Hugo Müller. Obtained by exhausting the crude carbonate of lime from the gas-purifiers with a dilute boiling solution of carbonate of ammonia; evaporating to dryness, ammonia is evolved, and a dark resinous body separates, which is the crude rosolic acid. The crude acid thus obtained is purified by conversion into a lime salt, and the acid is again liberated by acetic acid.

ROTCH, or **ROCHE.** A local term used by quarrymen and miners in South Staffordshire for a soft and friable sandstone.—H.W.B.

ROTTEN-STONE. A polishing-powder which is much used for giving lustre to brass, silver, and even to glass surfaces. According to the analysis of Richard Philips, the rotten-stone of Ashford in Derbyshire consists of, carbon, 10; alumina, 86·0; silica, 4·0. Rotten-stone is nearly peculiar to this country, being found principally in Derbyshire, near Bakewell, and in Carmarthenshire and Breconshire, South Wales.

It is thought by geologists to be derived in Derbyshire from the siliceous limestone, 'the lime being decomposed, and the silex remaining as a light earthy mass.' This does not, however, agree with the above analysis, in which alumina occupies so large a proportion. The total annual produce of the country is under 300 tons.

ROUGE. (*Fard*, Fr.) A cosmetic employed to brighten a lady's complexion. See CARMINE.

ROUGE, JEWELLERS'. An oxide of iron prepared with much care. See OXIDES FOR POLISHING.

ROUND ORE. *In Lead mining*, the largest pieces of lead ore selected free from the carbonate of lime or quartz, with which it may be associated in the lode.

ROWLEY RAG. A peculiar augitic trap, forming the chief portion of the Rowley Hills, near Dudley. Attempts have been made to fuse it, and then casting it into ornamental shapes in moulds, to use it for architectural purposes; but the experiments have not been successful.

ROYAL BLUE. (*Bleu de Roi*, Fr.) A fine deep blue prepared from cobalt, and used for enamel and porcelain painting.

The term *Bleu de Roi*, or *Royal Blue*, has of late been applied to one of the finest of the aniline blues.

RUBBLE. A local term used by quarrymen and miners for loose angular gravel, or a slightly-compacted brecciated sandstone.—H.W.B.

RUBIACIN. *Madder-orange; Krapp-orange.* A yellow colouring-matter discovered by Rungé. See MADDER.

RUBIAN. A deep-yellow matter discovered by Schunk in madder. For the analogous substances to, and derivatives of, rubian, consult 'Dictionary of Chemistry,' by Watts. See MADDER.

RUBICELLE. The yellow or orange-red varieties of spinel. See RUBY.

RUBIDIUM. (See also CÆSIUM and THALLIUM.) Prof. Bunsen, in examining, by means of the spectrum, the alkalis of a mineral spring at Dürkheim, in the Palatinate, noticed the appearance of some bright lines which he had not observed in any previous investigation of like kind; and, as he had, by well-established chemical methods, separated all the non-alkaline metals, he concluded that these lines must be caused by the presence of some new alkaline metal. Although he had obtained only $\frac{1}{15000}$ part of a gramme of the substance, he did not doubt the accuracy of his conclusion; so delicate and so reliable are the indications of the spectroscope. He resolved, therefore, to obtain for examination a larger quantity of the presumed new body; and, with this view, he proceeded at once to evaporate 40 tons of the mineral water. It soon became evident that *two* new alkalis were present; and from the 40 tons of water Bunsen succeeded in preparing about 7 grammes of the chloride of the one metal, and 9 grammes of the chloride of the other. To the first of these substances he gave the name of *Cæsium*, from *cæsius*, bluish-grey, on account of its spectrum being characterised by two bright blue lines. For the second he proposed the name *Rubidium*, from *rubidis*, dark red, because of the existence in its spectrum of two red bands. Cæsium and rubidium, in their chief chemical properties, closely resemble potassium; so closely indeed that their existence would probably have escaped notice, had it not been for the peculiarities which their spectra exhibit. For the purpose of separating the two new metals from sodium- and potassium-compounds, Bunsen took advantage of the fact that the chlorides of rubidium and cæsium form, with bichloride of platinum, double salts, much more sparingly soluble in water than the corresponding double salt. By washing the precipitate containing the platinum salts of rubidium, cæsium and potassium, the whole of the latter salt is easily removed. The absence of the well-known potassium line in the spectrum of the salt serves as a test to indicate the absolute purity of the new metals. It was, however, much more difficult to separate cæsium from rubidium, so closely do they resemble one another in their properties. But carbonate of cæsium was found to be soluble in alcohol, in which carbonate of rubidium, like the other alkaline carbonates, is insoluble. The metals thus isolated have been carefully studied by Bunsen; and small as were the quantities at his disposal, he soon succeeded in determining the composition, crystalline form, and general properties of many of their salts, besides establishing their numerical equivalents. Both metals form salts strictly isomorphous with the salts of potassium. The equivalent of rubidium, Rb, is 85·36; that of cæsium, Cs, 133. After the publication of the memoir on the new alkalis, M. Bunsen examined the water of a large number of German saline springs, and in almost all he found cæsium and rubidium in quantities more or less minute. The solid sources of rubidium are much more prolific; several varieties of lepidolite, in particular, containing it in notable proportions, so that from this mineral it may now be prepared by the pound. Dr. Struve, the well-known manufacturer of artificial mineral waters, is now selling (at six thalers per kilo.) the residue from the preparation of lithia, which residue contains about fifteen per cent. of chloride of rubidium. M. Grandeau of Paris tested many of the French mineral waters for the new metals, and with very frequent success. The waters of Bourbonnes-les-Bains, in particular, proved to be rich in rubidium and cæsium; ten litres of the water having yielded M. Grandeau no less than two grammes of the double chlorides of the new metals and platinum. M. Grandeau has likewise shown that rubidium occurs in the mother-liquor left after the extraction of the alkalis from beet-root *vinasses*. From one kilogramme of the mother-liquor M. Grandeau obtained no less than 4·7 grammes of chloride of rubidium, or exactly 0·47 per cent. Hence it appears that rubidium is a notable constituent of certain soils; so that the question arises whether the new alkalis take part, like potash and soda, in the nutrition of plants; and if so, whether as merely accidental or substitution constituents of ash, or (in certain cases) as essential ingredients thereof.—(*Hofmann.*) For the salts of rubidium, see Watts's 'Dictionary of Chemistry.'

RUBIRETINE. See MADDER.

RUBY. A beautiful and favourite gem. The true ruby is a red sapphire, an almost pure form of alumina. (See SAPPHIRE.) This extremely valuable gem is found chiefly in the kingdom of Ava, and is frequently known as *Oriental Ruby*, in order to distinguish it from the commoner stone called *Spinel Ruby*.

Ruby spinel, or *Spinel ruby*, is of a light or dark red, and, if held near the eye, a rose-red colour. Its hardness is 8; specific gravity 3·523. Its fundamental form is the cube or hexahedron, but it occurs crystallised in many secondary forms, such as octahedrons and tetrahedrons. Fracture conchoïdal; lustre vitreous; colour red, passing into blue and green, yellow, brown, and black; and sometimes it is nearly white. Pure spinel is a compound of alumina and magnesia, usually in the proportions of about 28 magnesia and 72 alumina, although we sometimes find the magnesia partially replaced by lime, and the alumina by oxide of iron. Vauquelin discovered 6·18 per cent. of chromic acid in the red spinel. The red varieties exposed to heat become black and opaque; on cooling, they appear first green, then almost colourless, but at last resume their red colour.

Pleonaste is a black variety which yields a deep green globule with borax.

Balas ruby. Pale red or rose-red spinel, with sometimes a tinge of brown or violet.

Rubicelle. Yellow or orange-coloured spinel.

Almandine ruby, which is of a violet-red colour.

Crystals of spinel from Ceylon have been observed embedded in limestone, mixed with mica, or in rocks containing adularia, which seem to have belonged to a primitive district. Other varieties, like the pleonaste, occur in the drusy cavities of rocks ejected by Vesuvius. Crystals of spinel are often found in diluvial and alluvial sand and gravel, along with true sapphires, pyramidal zircon, and other gems, as also with magnetic iron ore, in Ceylon. Blue and pearl grey varieties occur in Südermannland in Sweden, embedded in granular limestone. Pleonaste is met with also in the diluvial sands of Ceylon. Clear and finely-coloured specimens of spinel are highly prized as ornamental stones. When the weight of a good spinel exceeds 4 carats, it is said to be valued at half the price of a diamond of the same weight. M. Brard has seen one at Paris which weighed 215 grains. As a gem, the ruby is cut in the same form as the diamond, and may be set with a foil of copper or gold.

RUBY, ORIENTAL. The red sapphire. See RUBY.

RUBY SILVER. See PYRARGYRITE; SILVER.

RUBY, SPINEL. See RUBY.

RUE (*Ruta graveolens*) produces a yellow colouring-matter similar to that obtained from BUCKWHEAT, which see.

RUM is a variety of ardent spirits distilled in the West Indies from the fermented skimmings of the sugar-waste, mixed with molasses, and diluted with water to the proper degree. A sugar plantation in Jamaica or Antigua, which makes 200 hogsheads of sugar, of about 16 cwts. each, requires for the manufacture of its rum two copper-stills; one of 1,000 gallons for the wash, and one of 600 gallons for the low wines, with corresponding worm-refrigerators. It also requires two cisterns, one of 3,000 gallons for the lees or spent wash of former distillations, called dunder (*quasi redundar*, Span.), another for the skimmings of the clarifiers and teaches of the sugar-house, along with twelve or more fermenting cisterns or tuns.

Our *Importation* of Rum was as follows in 1873 :—

	Proof gallons	Value
		£
From Spanish West India Islands . .	621,597	55,803
„ Dutch „ „ . .	102	12
„ „ Guiana	156,422	15,297
„ Mauritius.	390,350	31,112
„ Straits Settlements	2,063	101
„ British West India Islands . .	2,313,665	304,416
„ „ Guiana.	3,341,847	325,222
„ Other countries	105,265	10,733
Total	6,931,311	742,696

Entered for home consumption . . 5,029,033 proof gallons
Gross amount received for duty . . £2,556,194

The wort is made, in Jamaica, by adding to 1,000 gallons of dunder, 120 gallons of molasses, 720 gallons of skimmings (=120 of molasses in sweetness), and 160 gallons of water; so that there may be in the liquid nearly 12 per cent. of solid sugar. The formula prescribes so much spent wash as would be apt to communicate an unpleasant flavour to the spirits. Both the fermenting and flavouring principles reside chiefly in the fresh cane-juice, and in the skimmings of the clarifier; because, after the syrup has been boiled, they are in a great measure dissipated.

The fermentation goes on most uniformly in very large masses, and requires from 9 to 15 days to complete; the difference of time depending upon the strength of the wort, the condition of its fermentable stuff, and the state of the weather. The progress of the attenuation of the wash should be examined from day to day with a hydrometer. When it has reached nearly to its *maximum*, the wash should be as soon as possible transferred by pumps into the still, and worked off by a properly-regulated heat; for if allowed to stand over, it will deteriorate by acetification.

About 115 gallons of proof rum are usually obtained from 1,200 gallons of wash. The proportion which the product of rum bears to that of sugar, in very rich, moist plantations, is rated, by Edwards, at 82 gallons of the former to 16 cwts. of the latter; but the more usual ratio is 200 gallons of rum to 3 hogsheads of sugar. But this proportion will necessarily vary with the value of rum and molasses in the market. In one considerable estate in the island of Grenada, 92 gallons of rum were made for every hogshead (16 cwts.) of sugar.

Rum is largely used in the Navy. Its general consumption will, however, be shown by the quantities imported, as given above.

The duty now fixed, if from British Possessions and from the country of its production (July 17, 1860), is 10*s.* 2*d.* per gallon; not from the country of production is 10*s.* 5*d.* per gallon. Rum Shrub is imported at the same rate of duties.

RUNNING-OUT-FIRE, *in metallurgy.* A name given to the refinery furnace. See Iron.

RUSH. A common plant, extensively employed in the manufacture of mats, baskets, &c. The Rush family—*Juncaceæ*—are natives of all parts of the world, though they belong chiefly to the colder regions. Under the equator they occur as alpine plants, while in the northern climates they are found in the marshes. Upwards of 100 species of rush are described. The long leaves of many of the species are used for tying plants in gardens, and for making the bottoms of chairs, mats, and the like. The central cellular tissue, or pith, is used for candles, called *Rushlights.* Bulrushes are a different plant (*Typha*); these are used for polishing wood, and also by coopers. The Dutch rush (*Equisetum hyemale*) is also much used for polishing metals and stone.

RUSSET. *Madder Brown* or *Field's Russet,* a pure rich transparent brown, prepared from the madder-root.

RUSSIAN LEATHER. See Leather, Russian.

RUST is the orange-yellow coat of peroxide which forms upon the surface of iron exposed to moist air. Oil, paint, varnish, plumbago, grease, or indeed any body which will shield the metal from the moist air, may be employed, according to circumstances, to prevent the rusting of iron utensils.

Iron under all ordinary circumstances effects the decomposition of water, abstracting the oxygen, and combining with it. The rusting of iron is one of the many instructive examples of chemical affinity which are constantly occurring around us.

The Messrs. Myers have patented a composition for preventing rust on bright steel, iron, brass, or other metal surfaces. For this purpose they take: Gutta-percha, 10 lbs.; mutton-suet, 20 lbs.; beef-suet, 30 lbs.; neats-foot oil, 2 gallons; rape oil, 1 gallon.

These materials are melted together until thoroughly dissolved, and then coloured with a small portion of rose-pink; oil of thyme, or other perfuming matter, being at the same time added. When cold, the composition is ready to be applied by rubbing upon the metallic surfaces which require protection.

RUTACEÆ. The only plant in this natural order which is employed in manufacture is the false Dittany (*Dictamnus fraxinella*). Perfumers obtain from the flowers of this shrub a very odorous distilled water, which is used as a cosmetic. It is also employed in giving flavour to some liqueurs.

RUTE, *in mining*. Used in some lead mines to distinguish very small strings of ore.

RUTHENIUM (*Symb.* Ru.; *At. wt.* 52·11). After osmium, ruthenium is the most refractory metal known. It requires a very extreme heat to melt the smallest quantity. When melting, there is formed the oxide of ruthenium, which is volatilised, and which smells something like osmic acid. When removed from the flame, ruthenium is blackish-brown on the surface, and is brittle and hard like iridium. It is only distinctly separated from this last metal by its density, which is obviously half that of iridium. The purest ruthenium obtained has a density of 11 to 11·4.

To prepare the metal mix the osmide in fine powder with 3 parts of binoxide of barium and 1 part of nitrate of baryta, and heat them to redness in a clay crucible for an hour. The black friable mass which remains is powdered with great care and introduced into a flask in which has been previously mixed 20 parts of water and 10 parts of ordinary muriatic acid. The flask must be placed in cold water to avoid the elevation of temperature which would ensue from the violent reaction which takes place. This operation should be conducted under a good chimney to avoid the escape of the osmic-acid vapour into the laboratory.

When this reaction is finished, 1 part nitric acid is added, and then 2 parts ordinary strong sulphuric acid. The flask is now well shaken, and the sulphate of baryta is allowed to deposit. The supernatant liquid is then poured off, the precipitate is washed by decantation, and the liquid and the washings are distilled together in a tubulated retort, until about a fourth of their volume of a liquid very rich in osmic acid has passed over. The red liquor which is left in the retort is evaporated to a small volume, 2 or 3 parts of sal-ammoniac in small pieces are added, and a small quantity of nitric acid. The whole is now evaporated to dryness at the temperature of boiling water. A crystalline violet-black precipitate remains in the capsule, which is treated with a small quantity of water partly saturated with sal-ammoniac, and washed with the same solution until it is no longer coloured. The insoluble salt left (chloro-iridate of ammonia containing ruthenium) is heated by degrees to redness in a porcelain crucible. The mixture of iridium and ruthenium thus obtained is fused in a silver crucible with an equal weight of hydrated potash and twice its weight of nitre, and when cold the rutheniate of potash is dissolved out with cold water; the solution, which is yellow, is decomposed by means of carbonic or nitric acid, and the precipitated oxide of ruthenium is strongly calcined in a charcoal crucible. The ruthenium is then reduced in the apparatus before described. Iridium and ruthenium present many analogies; their coloured reactions are the same, and the oxide of iridium dissolves in a mixture of nitre and potash.

Ruthenium forms with zinc an alloy which will burn in the air; it crystallises in hexagonal prisms. With tin there is formed an alloy $RuSn^2$, which crystallises in cubes as beautiful in their form and lustre as crystallised bismuth.—*Deville and Debray on the Platinum Metals.*

RUTILE. Native oxide of titanium.

Rutile occurs in granite, gneiss, mica-slate, and Syenitic rocks, and occasionally in granular limestone. It has sometimes been met with in specular iron. The way in which it occurs in masses of quartz or felspar, the acicular crystals being imbedded, is very curious. The following localities are given by Dana: 'Brazil affords acicular crystals in limpid quartz; also occurs in Arendal in Norway; Sau-alpe, Carinthia; in the Urals; in the Tyrol; at St. Gotthard; at St. Yrieix, in France; Krummhennersdorf near Freiberg; in Castile, in geniculated crystals, often very large. At Ohlapian in Transylvania, *Nigrine* in pebbles; in large crystals in Perthshire; at Cairngorm, Scotland; at Craig Cailleach near Killin, and in Bengloe; in Isles of Burray, Shetland. A variety from Karingsbricka in Sweden contains a small percentage of chrome, and is the *titane oxydé chromifère* of Haüy. Rough octahedrons, reticulated within, from Brazil, are supposed to be pseudomorphs after anastase.' Besides these, Dana gives at least twenty localities in America.

The oxide of titanium is employed for a yellow colour, in painting porcelain; and it is often employed to give the requisite tint to artificial teeth. Rutile is so named from the Latin *rutilus*, which signifies 'a shining red.'

RYE (*Seigle*, Fr.; *Roggen*, Ger.) is a cereal grain (*Secale cereale*), supposed to be a native of Crete, and apparently used at a very early period by man. The culture of rye is confined to the temperate zones. Rye consists, according to the analysis of Einhof, of 24·2 of husk, 65·6 of flour, and 10·2 of water, in 100 parts. This chemist found in 100 parts of the flour, 61·07 of starch, 9·48 of gluten, 3·28 of vegetable albumen, 3·28 of uncrystallisable sugar, 11·09 of gum, 6·38 of vegetable fibre, and the loss was 5·62, including a vegetable acid not investigated. Some phosphate of lime and magnesia is also present.

Rye-straw has been long used and celebrated for the manufacture of straw-plait.

RYE, ERGOT OF. (*Secale cornutum*). The grain rye is subject to a disease (*Spermedia clavis*) commonly known as *ergot*, which causes the grain to turn black. It is produced by the attack of a fungus known as *Cordyceps purpurea*. The ergot is used medicinally. See Pereira's *Materia Medica.*

S

SABICA WOOD. A wood grown in Cuba, and used for ship-building. It is the produce of *Lysdonia Sabica.*

SABLE. A valuable fur obtained from the marten. See Fur.

SABOT. A wooden shoe. The manufacture of these in France is very important.

SABOTIÈRE. An apparatus for making ices; it is composed of two principal parts—a pail which is indented towards the top and covered, and the *sabôtière*, or inner vessel, slightly conical, which is inserted in the pail, on which it rests by a projecting border or rim; this vessel is closed at the bottom like a cup, and open at the top to admit the creams to be iced. The freezing-mixture is turned into the pail, and the creams to be iced into the inner vessel; its cover is then fastened by the hook, and the vessel is set into the pail among the freezing liquid; then taking the whole by the handle of the sabotière, an alternate motion of rotation is given to it for about a quarter of an hour, when the cream is sufficiently frozen. See Freezing Mixture.

SACCHAROMETER is the name of a hydrometer, adapted by its scale to point out the proportion of sugar, or the saccharine matter of malt, contained in a solution of any specific gravity. Brewers, distillers, and the Excise, sometimes denote by the term 'gravity' the excess of weight of 1,000 parts of a liquid by volume above the weight of a like volume of distilled water, so that if the specific gravity be 1045, 1070, 1090, &c.; the gravity is said to be 45, 70, or 90; at others, they thereby denote the weight of saccharine matter in a barrel (36 gallons) of worts; and again, they denote the excess in weight of a barrel of worts over a barrel of water, equal to 36 gallons, or 360 pounds. This and the first statement are identical, only 1,000 is the standard in the first case, and 360 in the second.

The saccharometer used by the Excise, and by the trade, is that constructed by the late Mr. R. B. Bate. The instrument is composed of brass; the ball or float being a circular spindle, in the opposite ends of which are fixed a stem and a loop. The stem bears a scale of divisions, numbered downwards from the first to 30; these divisions, which are laid down in an original manner, observing a diminishing progression according to true principles; therefore each division correctly indicates the one-thousandth part of the specific gravity of water; and further, by the alteration made in the bulk of the saccharometer at every change of poise, each of the same divisions continues to indicate correctly the said one-thousandth part throughout.

The following Table shows the quantities of sugar contained in syrups of the annexed specific gravities. It was the result of experiments carefully made by the late Dr. Ure:—

Experimental spec. gravity of solution at 60° F.	Sugar in 100· by weight	Experimental spec. gravity of solution at 60° F.	Sugar in 100· by weight
1·3260	66·666	1·1045	25·000
1·2310	50·000	1·0905	21·740

N.B. The column in the table on p. 728, marked *extract by weight in* ·100, is Mr. Bate's; it may be compared with the preceding short table on p. 727, and also with the table of Malt Infusions in this Dictionary. See BEER; MALT; FERMENTATION.

If the decimal part of the number denoting the specific gravity of syrup be multiplied by 26, the product will denote very nearly the quantity of sugar per gallon in pounds at the given specific gravity.

SACK. A general name for a large bag. Its capacity varies much; it may therefore be useful to give a few examples of its capacity in different places:—

		Winchester bushels
France:	the minimum French sack is	2·012
	maximum ditto	4·256
Brussels:	the sack is	6·90.
America:	the miller's sack is	2·00.
	ordinary sack of salt	215 lbs.
England:	the sack of wool	2 weys. 13 tods. 364 lbs.
	sack of flour or corn	280 lbs., or 2 cwts. 2 qrs.
	sack of coals formerly	3 bushels.
	do. recent	2 cwts.
	sack of dry goods	3 heaped bushels. 4 strike bushels.

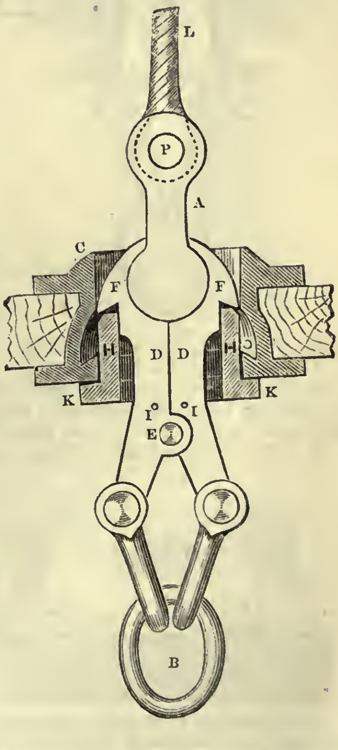
Sack is also a loose robe. A name formerly given to sherry.

SACKCLOTH. A coarse baling or wrapping.

SACKING. A coarse kind of hemp fabric, made chiefly in Dundee and in the north of Ireland.

SAFETY APPARATUS, *for the prevention of over-winding in mines.* Numerous arrangements—many of them very ingenious—have been introduced from time to time, to prevent the accidents which have very often arisen from winding the cage, containing men, over the pulley, or the load, which, breaking away, falls of course to the bottom of the shaft.

1734



Two of the latest inventions for this purpose are all that can be admitted with the space at disposal. The first of these is Walker's Detaching Hook, and the second King's Safety Apparatus.

The principle in each invention is the same, and the safety in either case is obtained from the fact, that if the load is raised above a certain point, the weight of the load compels the rope to become detached, which detaching cannot take place until the 'jaw hooks' have a firm hold on the supporting ring.

Fig. 1734 is the front view of Walker's detaching hook, with the supporting ring and clamp in section, and *fig.* 1735 is another view of the same after the hook is detached.

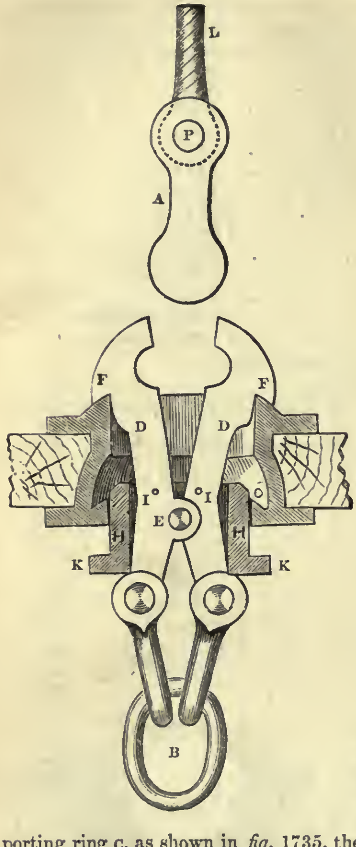
The lifting rope is attached to the shackle A, and the load to the connecting link B.

The supporting ring, C (through which the rope is constantly working), is a fixture in a baulk of timber, or iron girder, at the pit top.

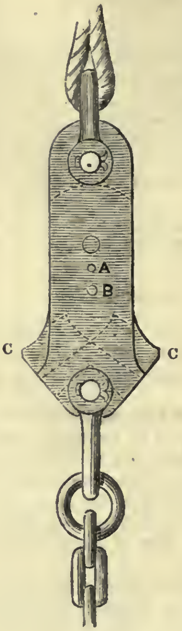
The hook consists of a pair of jaws, D, D, working on a centre-pin, E, in such a manner that the weight of the load has a tendency to open the upper limbs, which clip the strong centre-pin of the shackle A. The upper limbs are formed externally with jaw hooks, F, F. The jaws are kept together, and made to retain the shackle-pin by means of the clamp H, which is held in position by the pins I, I.

In case of overwinding, the jaw hooks (held together by the clamp) pass freely into the ring C, but the projections, K, K, of the clamp coming into contact with the bottom flange of the said ring hold the clamp stationary, while the jaws are being pulled through, the result being that the pins, I I, are sheared off, and the jaw hooks released from the restraint of the clamp. The internal diameter of the ring being the same as

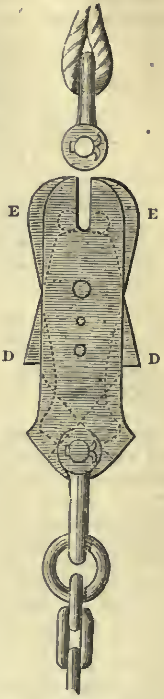
1735



1736



1737

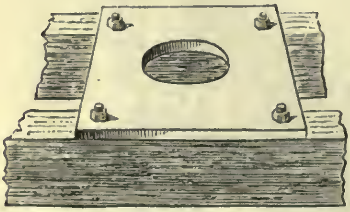


the width across the jaw hooks, F, F, the rope remains secure, until the jaw hooks reach the top of the ring, when, by the action of the weight of the load, they are forced open, and so hook on to the top of the supporting ring C, as shown in *fig.* 1735, the rope passing harmlessly over the pulley.

The recess O, in the ring C, is intended to meet an imaginary case that experiment shows to be almost impossible, namely, that if the engine is reversed after the pins I, I, are cut, and before the hooks reach the top of the ring, the jaws will then hook into the recess, and the load remain suspended in perfect safety.

It will be observed that the upper edge of the ring C is curved to match the sweep of the jaw hooks when opening. By this arrangement all shock is avoided.

1738



King's Safety Apparatus will be perfectly understood from the accompanying figures.

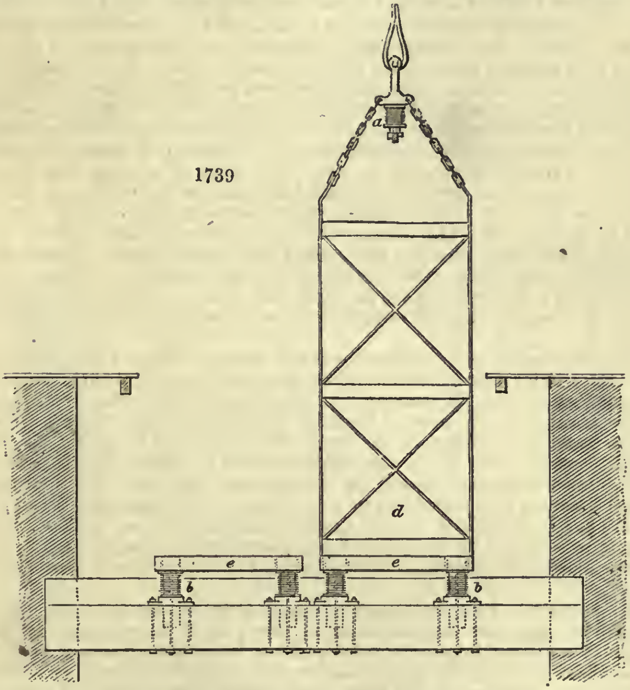
Fig. 1738 is a plan showing plate fixed on top side of beams, which must be of good strong oak, strong enough to hold three times the weight it has to carry; the two pieces of timber to be as far apart as the ring is wide; the plate to be strongly bolted with four pins.

Figs. 1736 and 1737 show the inside of plates when in work; C C, when drawn up to the plate, are compressed, which forces D D out on the opposite side, and opens the jaws of E E, which releases top shackle and leaves D D secure on the top side of plate. A is a small hole in centre of hook for a ½-inch pin to be rivetted in for holding the plates secure when in work—*care must be taken not to work without it*; when drawn up to C C it is sheared in four parts; the hole B is to put a drift in for holding the plates square, so as to punch the sheared pin out.

The detaching hook is simple in construction, and it appears to be effectual and certain in action, and is said not to be very liable to get out of order.

SAFETY CAGE. In all our collieries the men descend to their labour and are raised from the depth of the mines by winding machinery. This may be described in general terms as a stage travelling in guides fixed to the sides of the shafts. The rapidity with which these stages are moved up or down is very great, and consequently, if anything occurs to engage the attention of the man in charge of the winding-engine, the stage with its living load is either landed with injurious violence at the bottom of the pit, or it is carried over the pulley, and thus the lives of the men are sacrificed. The engraving, *fig.* 1739, shows an ingenious contrivance for obviating the blow which arises from reaching the bottom at too great a speed. *e e*, are

1739



platforms placed on india-rubber springs *b b* (see CAOUTCHOUC), on the landing at the bottom of the pit; *d*, is one of the cages which has descended, the other being supposed to be at the surface. The elasticity of these springs certainly serves to protect the men from the violence of the concussion in the event of the rope breaking, or if from any other cause they suddenly reach the bottom.

Many safety cages, have been invented, in which the principles are to allow them to travel freely on their guides, so long as the rope by which they are suspended remains entire; but, in the event of its breaking, arms, levers, or catches, are released; these seize the guide-rods, and thus suddenly stop the cage. Experience has not satisfactorily confirmed the value of these arrangements.

The remarks made by the reporter on the Safety Cages exhibited in the International Exhibition of 1862 are well worthy of consideration:—

'The jury gave careful attention to all the varieties of this apparatus, and were strongly impressed with the merits of several of them, and with the desirableness of enlisting in this cause the interest of the intelligent mechanician. But they share in the repugnance of colliery viewers to trust to the action of a spring, on which most of them depend; and which, of whatever substance it is made, is sure, by degrees, to lose its elasticity, and is thus liable, unless frequently looked after, to fail at the moment when required. They are also aware that a great inconvenience, not to say danger, has been introduced by all those hitherto employed, in consequence of the apparatus being brought into play by a plunge during the rapid descent of the cage, and that hence several of those inventions, after being fairly tried for one, two, or three years, have been ultimately removed. Nor is it too much to say, although an insufficient argument if taken alone, that the employment of this apparatus has a tendency to make people careless about the examination and renewal of ropes.'

SAFETY FUSE. A woven cylinder containing gunpowder, employed in blasting rocks, especially in our mines. The safety fuse is also prepared for blasting under water. See FUSE, SAFETY.

SAFETY LAMP. The dangerous nature of the accumulation of fire-damp in a colliery renders it necessary that some means should be employed to produce light under such circumstances that the risks of explosion are greatly reduced.

The contrivance of a *steel mill* was formerly used, but it afforded only a gleam of light. It consisted of a small frame of iron, mounted with a wheel and pinion, which gave rapid rotation to a disk of hard steel placed upright, to whose edge a piece of flint was applied. The use of this machine entailed on the miner the expense of an attendant, called the 'miller.' Nor was the light altogether safe, for occasionally the ignited shower of steel particles attained to a sufficient heat to inflame the fire-damp.

At length the attention of the scientific world was powerfully attracted to the means of lighting the miner with safety, by an awful catastrophe which happened at Felling Colliery, near Newcastle, on May 25, 1812. This mine was working with great vigour, under a well-regulated system of ventilation, set in action by a furnace and air-tube, placed over a rise-pit in elevated ground. The depth of winning was above 100 fathoms; 25 acres of coal had been excavated, and one pit was yielding at the rate of 1,700 tons per week. At eleven o'clock in the forenoon the night shift of miners was relieved by the day shift; 121 persons were in the mine, at their several stations, when, at half-past eleven, the gas fired, with a most awful explosion, which alarmed all the neighbouring villages. Of the 121 persons in the mine at the time of the explosion, only 32 were drawn up the pit alive, 3 of whom died a few hours after the accident. Thus no less than 92 valuable lives were instantaneously destroyed by the fire-damp.

Dr. W. Reid Clanny, of Sunderland, was the first to contrive a lamp which might burn in explosive air without communicating flame to the gas in which it was plunged. This he effected, in 1813, by means of an air-tight lamp, with a glass front, the flame of which was supported by blowing fresh air from a small pair of bellows through a stratum of water in the bottom of the lamp, while the heated air passed out through water by a recurved tube at top. By this means the air within the lamp was completely insulated from the surrounding atmosphere. This lamp was the first ever taken into a body of inflammable air in a coal-mine, at the exploding point, without setting fire to the gas around it. Dr. Clanny made another lamp upon an improved plan, by introducing into it the steam of water generated in a small vessel at the top of the lamp, heated by the flame. The objection to these lamps was their inconvenience in use.

In the course of a long and laborious investigation on the operation of the fire-damp, and the nature and communication of flame, Sir H. Davy ascertained that the explosions of inflammable gases were incapable of being passed through long narrow metallic tubes; and that this principle of security was still obtained by diminishing their length and diameter at the same time, and likewise diminishing their length and increasing their number, so that a great number of small apertures would not allow an explosion to pass, when their depth was equal to their diameter. This fact led him to trials upon sieves made of wire-gauze, or metallic plates perforated with numerous small holes; and he found that ignited gases would not pass through them.

The apertures in the gauze should never be more than $\frac{1}{20}$th of an inch square. In the working models, sent by Sir H. Davy to the mines, there were 748 apertures in the square inch, and the wire was about $\frac{1}{40}$th of an inch diameter. The cage or cylinder of wire-gauze should be made by double joinings, the gauze being folded over in such a manner as to leave no apertures. It should not be more than 2 inches in diameter, or in large cylinders the combustion of the fire-damp renders the top inconveniently hot; and a double top is always a proper precaution, fixed at a distance of about half an inch above the first top.

The principles upon which these lamps are constructed, dependent as they are upon some of the most refined researches of science, must be briefly described. Flame is gaseous matter in a state of combustion, that is, it is under the ordinary circumstances carburetted hydrogen gas in active combination with oxygen. During the intense chemical action there is a great increase of volume, carbonic acid and water-vapour escaping. Fire-damp is for the most part light carburetted hydrogen or marsh-gas.

This is formed by the changes which go on in the carbonaceous compounds of which coal is constituted, and it is condensed in the coal.

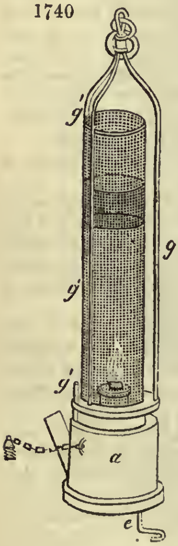
A few of the analyses which have been published by different chemists will show the composition of the fire-damp of our coal-mines.

	Carburetted hydrogen	Light air	Nitrogen	Oxygen	Carbonic acid	Name of chemist
Wallsend, Bensham seam	77·50	...	21·10	...	1·30	Playfair.
Jarrow, Bensham seam	83·10	...	14·20	0·40	2·10	"
Killingworth	66·30	23·35	6·52	...	4·03	Richardson.
Gateshead	94·20	...	4·50	1·30	...	Graham.

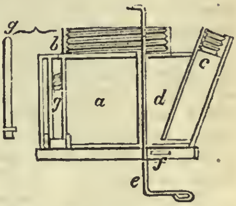
Mr. Tennant, in his 'Researches on Flame,' first noticed that burning gases would not pass through tubes of a certain diameter. Dr. Paris says, Davy was not aware of Tennant's researches. Be this as it may, he greatly extended the inquiry.

The first full account of Davy's beautiful researches was published in the 'Philosophical Transactions' for 1816, his memoir being entitled 'An account of an invention for giving light in explosive mixtures of fire-damp in coal-mines, by consuming the fire-damp.' In January 1817, the principle was announced in a paper on 'Some new experiments and observations on the combustion of gaseous mixtures, with an account of a method of preserving a continued light in mixtures of inflammable gases and air without flame.'

1740



1741



The lamp of Davy, *fig.* 1740, consists therefore of a common oil-lamp, surmounted with a covered cylinder of wire-gauze, for transmitting light to the miner without endangering the kindling of the atmosphere of fire-damp which may surround him.

The gauze-cylinder should be fastened to the lamp by a screw, *b*, *fig.* 1741, of four or five turns, and fitted to the screw by a tight ring. All joinings in the lamp should be made with hard solder; as the security depends upon the circumstance, that no aperture exists in the apparatus larger than in the wire-gauze.

The parts of the lamp are,—

1. The brass cistern *a*, *d*, *fig.* 1741, which contains the oil. It is pierced at one side of the centre with a vertical narrow tube, nearly filled with a wire which is recurved above, at the level of the burner, to trim the wick, by acting on the lower end of the wire *e* with the fingers. It is called the safety-trimmer.

2. The rim *b* is the screw neck for fixing on the gauze-cylinder, in which the wire-gauze cover is fixed, and which is fastened to the cistern by a screw fitted to *b*.

3. An aperture *c*, for supplying oil. It is fitted with a screw or a cork, and communicates with the bottom of the cistern by a tube at *f*, a central aperture for the wick.

4. The wire-gauze cylinder, *fig.* 1740, which should not have less than 625 apertures to the square inch.

5. The second top, $\frac{3}{4}$ of an inch above the first, surmounted by a brass or copper plate, to which the ring of suspension may be fixed. It is covered with a wire cap in the figure.

6. Four or six thick vertical wires, *g′ g′ g′ g′*, joining the cistern below with the top plate, and serving as protecting pillars round the cage. *g* (*fig.* 1741) is a screw-pin to fix the cover, so that it shall not become loosened by accident or carelessness. The oil-cistern, *fig.* 1741, is drawn upon a larger scale than *fig.* 1740, to show details of the smaller parts.

When the wire-gauze safety-lamp is lighted and introduced into an atmosphere gradually mixed with fire-damp, the first effect of the fire-damp is to increase the length and size of the flame. When the inflammable gas forms so much as $\frac{1}{12}$th of the volume of the air, the cylinder becomes filled with a feeble blue flame, while the flame of the wick appears burning brightly within the blue flame. The light of the wick augments till the fire-damp increases to $\frac{1}{6}$th or $\frac{1}{5}$th, when it is lost in the flame of the fire-damp, which in this case fills the cylinder with a pretty strong light. As long as any *explosive* mixture of gas exists in contact with the lamp, so long it will give light; and when it is extinguished, which happens whenever the foul air constitutes so much as $\frac{1}{3}$rd of the volume of the atmosphere, the air is no longer proper for respiration; for although animal life will continue where flame is extinguished, yet it is always with suffering. By fixing a coil of platinum-wire above the wick, ignition may be continued in the metal when the lamp itself is extinguished; and from this ignited wire the wick may be again rekindled, on carrying it into a less inflammable atmosphere. This arrangement, however, is rarely employed.

The late Mr. John Buddle, one of the most experienced of coal-miners, wrote as follows, in the 'Journal of Science,' on the general use of the safety-lamp:—'We have frequently used the lamps where the explosive mixture was so high as to heat the wire-gauze red-hot; but on examining a lamp which has been in constant use for three months, and occasionally subjected to this degree of heat, I cannot perceive that the gauze-cylinder of iron-wire is at all impaired. I have not, however, thought it prudent, in our present state of experience, to persist in using the lamps under such circumstances, because I have observed, that in such situations the particles of coal-dust floating in the air, fire at the gas burning within the cylinder, and fly off in small luminous sparks. This appearance, I must confess, alarmed me in the first instance, but experience soon proved that it was not dangerous.

'Besides the facilities afforded by this invention to the working of coal-mines abounding in fire-damp, it has enabled the directors and superintendents to ascertain, with the utmost precision and expedition, both the presence, the quantity, and correct situation of the gas. Instead of creeping inch by inch with a candle, as is usual, along the galleries of a mine suspected to contain fire-damp, in order to ascertain its presence, we walk firmly on with the safety-lamp, and, with the utmost confidence, prove the actual state of the mine. By observing attentively the several appearances upon the flame of the lamp, in an examination of this kind, the cause of accidents which happened to the most experienced and cautious miners is completely developed; and this has hitherto been in a great measure matter of mere conjecture.'

The two first safety-lamps used in a colliery are preserved in the Museum of Practical Geology.

The action of the wire-gauze has been supposed to depend upon a cooling-process; but many experiments cried by the Editor of the present work tends to convince him that the cooling hypothesis will not explain the phenomenon. He conceives the impermeability of wire-gauze to flame to be due to a repulsive power established between the hot metal and the ignited gas, similar in character, although differing in condition, to that which prevails between water and a white-hot metal.

George Stephenson, proceeding not improbably upon the data furnished by Mr. Tennant, with that peculiar aptitude in mechanical design which ever characterised that remarkable man, at once, and without any knowledge of the researches of the chemist, devised a lamp by which air was admitted to the flame through 'apertures of wire-gauze.' This lamp is said by Mr. Brandling to have been tried in 'the Killingworth pits on Saturday, October 21, 1815.' The result, however, of a very careful examination of the question as between George Stephenson and Humphry Davy by a meeting of coal-owners, was, on October 11, 1816, a decision that the merits of discovering a real safety-lamp belonged to Davy; and on September 13, 1817, a service of plate was presented by the coal-owners at Newcastle, 'as a testimony of their gratitude for the services you have rendered to them and to humanity.'

Numerous modifications of the Davy safety-lamp have been from time to time introduced. A few of the more important must be named:—

George Stephenson modified his original plan. His modified lamp consisted of a wire-gauze cylinder about 2¼ inches diameter, and about 6 inches high, with a glass shield inside. The air for combustion was admitted through a series of perforations in the bottom, and a metal chimney, full of small holes, is fixed inside on the top of the glass-cylinder. The 'Geordie,' as the Stephenson lamp is familiarly called, has been much used in fiery collieries.

Mr. Smith, of Newcastle, improved this by covering all the perforations in the metal with wire-gauze.

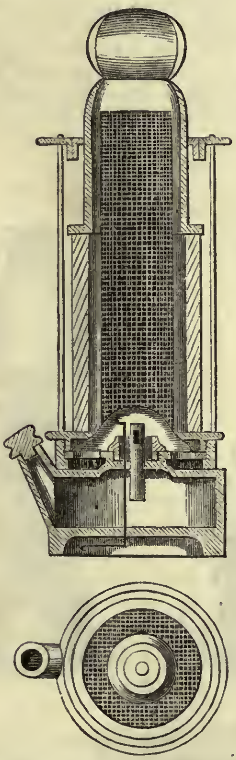
Newman, to meet the objection that strong currents of air, or of gas, could be forced through the gauze, made a lamp with a double wire-gauze, commencing from nearly the top of the flame of the lamp, leaving the lower portion with one gauze only; there was no obstruction to the light, and it has not been found possible to light a gas-flame by the Newman double gauze-lamp, whereas this may be done by suddenly driving the flame through the single gauze of the Davy.

Upton and Roberts' lamp, *fig.* 1742. This consists of a wire-gauze cylinder $5\frac{1}{2}$ inches long and $1\frac{1}{2}$ inch in diameter, which is attached to the cylinder in the usual manner. The lower half is protected by a thick glass-cylinder, and the remaining portion by one of copper, screwed to the upper ring of the frame. The air for combustion passes through a range of small openings in the upper part of the cistern into a space protected by a double shield of closely-compressed wire-gauze. A cone of sheet metal stands above this shield and conducts the air directly upon the wick.

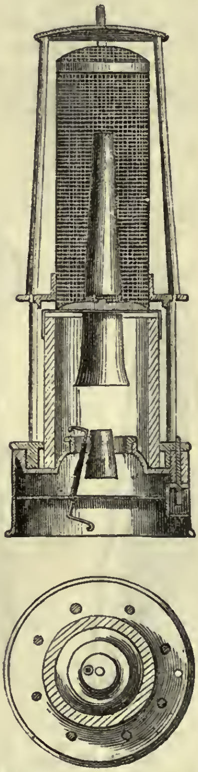
Martin's lamp was, in many respects, similar to Upton and Roberts's, but so constructed that the flame was extinguished as soon as an explosive mixture was within the glass-cylinder.

Dumesnil sought to increase the quantity of light, at the same time as he protected the flame against any rapid current. The glass shield surrounding the

1742



1743



flame is of carefully-annealed glass, and is protected from mechanical injury by curved metal bars; a chimney of sheet metal being above the glass, and all the air being compelled to pass through apertures rendered safe by the use of wire-gauze.

Dr. Clanny, already named, introduced a new lamp, with an impervious metal-shield, having glass and lenses in its sides, only open at the highest part of the gauze-cylinder for about $1\frac{1}{2}$ inch. Thus there is no admission of air to the lamp, or of the products of combustion from the lamp, except over the top of the shield. This in many respects resembles Mueseler's lamp, to be next described.

Mueseler's lamp is shown in section, *fig.* 1743. The cistern, opening for the wick, &c., are precisely the same as we find them in the Davy. A glass-shield occupies about two-fifths of the entire height, the lower edge resting in an annular recess on the upper surface of the cistern. A conical tube of metal carries off the products of combustion. Upon the bars which protect the glass rests the gauze-cylinder above it. When this lamp is first brought into an explosive mixture the flame is first lengthened, and then extinguished. It unfortunately happens that by turning the lamp on one side the flame is often put out, and in the mines of Liège boys are employed to relight the extinguished lamps. It is, however, stated that not less than 12,000 of these lamps are in daily use in Belgium.

Combe's and Boty's are modifications of the preceding.

Parish's lamp, one by Dr. Fyfe, and some others by Mr. Hewitson and by Mr. Biram, involve the use of mica in the place of glass.

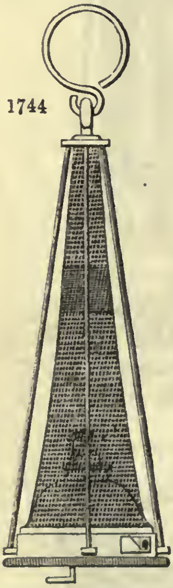
Eloin's lamp consists of a cylinder fixed upon the upper surface of the cistern and the glass-shield, which is pierced with several holes covered with wire-gauze, through which the air enters. As in Upton and Roberts's lamp, a cone assists the combustion. A copper chimney is connected with the base, pierced in the upper end with small holes, through which the products of combustion escape. The light is improved by means of a reflector, which slides upon the bars, by which the glass is protected.

Dr. Glover, Mr. Cail, and Mr. T. Y. Hall have introduced lamps which are so similar to those already named that they need not be described.

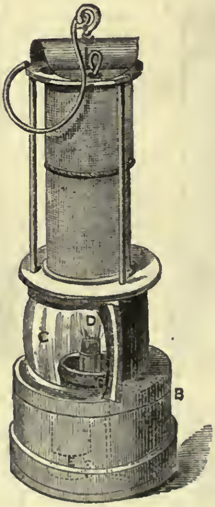
Mackworth's safety lamp was contrived by one of the Government Inspectors of Coal-mines, to meet the objections raised in resisting the general introduction of the Davy lamp into fire-damp mines. As the lamp is not used, it need not be described.

Some other lamps have been brought forward, the chief purpose being to prevent their being opened by the miner. Mr. W. P. Struve, of Swansea, constructed an ingenious safety lamp. The sketch, *fig.* 1744, will convey a better notion of it than any

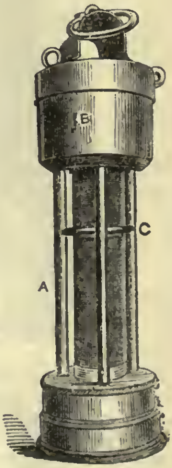
1744



1745



1746



written description; and it is only necessary to add, that although the diameter of the gauze-cylinder at its base is considerably more than that of the Davy, yet owing to the oil-box being placed within the gauze-cylinder, instead of below it, and thus occupying a considerable portion of the internal space, the cubical contents of the cylinder do not exceed that of an ordinary Davy. The greater amount of cooling surface near the flame, and the less-obstructed admission of air thus obtained, renders it practicable and perfectly safe to use a larger wick than in the Davy, whilst the combustion of the oil is much more perfect, and the smoke very considerably diminished. The light emitted from this lamp has been carefully ascertained to be equal to that from three Davys; and, owing to the conical form of the cylinder, and the shape of the oil-box, it diffuses the light both upwards and downwards, as well as in every other direction, with less shadow than any other lamp that has been offered to the miner. From the more perfect combustion, the consumption of oil in this lamp but slightly exceeds that of the Davy, while its simplicity of construction gives great facilities for keeping it in order and for repairs. It barely weighs $1\frac{1}{2}$ lb.

Mr. H. D. Plimsoll has introduced a lamp which he calls the Coal-Miners' Double Safety Lamp. It is a combination of the Davy and the Clanny, having a double gauze and a glass.

Yates's Miners' safety lamp will be understood from the annexed figure (1745). B is the body of the lamp, comprising the oil-reservoir, the fixed wick-tube, and the moveable wick-holder, shown by the dotted lines at E. This is screwed on to the upper part, comprising the wire-gauze chimney, the lens C, and the metal-reflector D. The arrangements for securing this lamp are very ingenious.

Several arrangements have from time to time been introduced, to prevent the miners from opening the lamps. Mr. Bidder inserts a magnetic bar, which is turned into staples, by the use of a powerful magnet, and the lamp cannot be opened until it is again brought to the magnet, and the poles reversed.

The 'Rowe' Safety Lamp (*fig.* 1746) is a modification of the 'Relume' signal lamp, and by the same author, Mr. J. G. Rowe of Aylesbury; its object is to prevent miners opening their safety lamps while alight.

In the larger tube A (*fig.* 1746) is placed a metal bar composed of brass and steel, having a locking stud on one side. When the lamp is lighted the heat causes the bar to expand differentially, and thereby bends in the form of a bow, so that the locking stud is forced out through the screw-threads which connect the top and bottom part of the lamp.

The chamber, B, is to retain the heat, and thus prevent miners cooling the locking bar by means of a wet handkerchief, and the small ring C is inserted to stiffen the frame and keep the tube containing the locking bar quite rigid. Where glass-cylinders are used, the locking bar is placed inside them, and not in a tube.

In practice various forms are adopted, but the principle remains the same, and may shortly be described as a safety lamp locked by heat without a key; to open them the light must be extinguished, when all danger is at an end, and the metal frame allowed to get cold.

SAFETY POWDER. See EXPLOSIVE AGENTS.

SAFFLOWER. This dye-stuff has been fully described. See CARTHAMUS.

We *imported* of safflower in 1873:—

	cwts.	value

SAFFLOWER DYEING. See CALICO-PRINTING.

SAFFRANINE. This interesting dye has been lately investigated by Hofmann and Geyger. The sample upon which they operated was obtained from the establishment of Tillman, at Crefeld. It is sometimes sold as a solid paste, and sometimes as a yellowish-red powder, containing the chloride of a colourable base in addition to carbonate of lime and chloride of calcium. The true colour is extracted by boiling the paste and filtering the solution when hot. On cooling it deposits a crystalline matter which, after repeated re-crystallisation, leaves no fixed residue. With each solution it becomes less perfectly crystalline and loses chlorine. The addition of hydrochloric acid restores the form, and is necessary to obtain normal salts. The chloride of saffranine is soluble in water and alcohol, especially when hot, but insoluble in ether and in saline solutions. The solutions are of a deep orange, and strongly fluorescent. Its composition was found to be: Carbon 68·82, hydrogen 6·09, nitrogen 15·34, chlorine 10·23. Saffranine cannot be obtained as a free base by precipitation with alkalis, as it is re-dissolved on diluting with water. It is best prepared by treating its chloride with the oxide of silver: it is thus obtained as an orange liquid, giving on concentration reddish-brown crystals. When dried at 212° they have a green metallic lustre. They dissolve in water and alcohol, but not in ether. On adding strong hydrochloric or sulphuric acid to the solutions of its salts, the red-brown colour of the liquid changes to a fine violet, which on adding more acid changes to a deep blue, then to a deep green, and lastly to a light green. Anilines of a high boiling-point are best adapted for its preparation. It may be obtained by treating them with a mixture of nitrous and arsenic acids, but the yield is small. The best results were obtained by the authors with chromic acid acting upon a liquid toluidine at 198°.

SAFFRON. (*Safran*, Fr. and Ger.) The leaves of the saffron crocus. *Hay saffron* is the only kind now found in the shops; *cake saffron* rarely containing any of that flower. *Hay saffron* consists of the stigmas with part of the style of the flowers, which have been very carefully dried. Spanish saffron is the best which is imported. It is stated that 4,320 flowers are required to produce an ounce of saffron. True cake saffron, no longer to be found, was a filamentous cake, composed of the stigmas of the flowers of the *Crocus sativus*. It is now, however, generally the leaves of the safflower (*Carthamus tinctorius*). True saffron contains a yellow matter, called *polychroïte*, because of its being susceptible of numerous changes of colour. This is obtained by evaporating the watery infusion of saffron to the consistence of an extract, digesting the extract with alcohol, and concentrating the alcoholic solution. The polychroïte remains in the form of a brilliant mass, of a scarlet red colour, transparent, and of the consistence of honey. It has no smell, with the bitter pungent taste of saffron. It is slightly soluble in water; and if it be stove-dried it deliquesces speedily in the air. According to M. Henry *père*, polychroïte consists of 80 parts of colouring-matter, combined with 20 parts of a volatile oil, which cannot be separated by distillation till the colouring-matter has been combined with an alkali. Light blanches the reddish-yellow of saffron, even when it is contained in a full phial well corked. Polychroïte, when combined with fat oils, and subjected to dry distillation, affords ammonia, which shows that nitrogen is one of its constituents. Sulphuric acid colours the solution of polychroïte indigo-blue with a lilac cast; nitric acid turns it green, of various shades, according to the state of dilution. Protochloride (muriate) of tin produces a reddish precipitate.

Saffron is employed in cookery. It is also used to colour confectionery articles, liqueurs, varnishes, and especially cakes in the west of England. It was formerly used to such an extent in Cornwall, that that one county consumed more saffron than all the rest of England.

SAGAPENUM. A gum-resin derived from an umbelliferous plant supposed to be a native of Persia. It is occasionally used instead of gum galbenum. See Dr. Pereira's 'Elements of Materia Medica.'

SAGGER. A clay case of a cylindrical shape, in which porcelain or earthenware goods are placed in the kiln to protect them from the immediate contact of the flame and smoke. See POTTERY.

SAGO (*Sagou*, Fr.; *Sago*, Ger.) is a species of starch extracted from the pith of the sago-palm, a tree which grows to the height of 30 feet in the Moluccas and the Philippines. The tree is cut down, cleft lengthways, and deprived of its pith, which being washed with water upon a sieve, the starchy matter comes out, and soon forms a deposit. This is dried to the consistence of dough, pressed through a metal sieve to corn it (which is called *pearling*), and then dried over the fire with agitation in a shallow copper pan. Sago is sometimes imported in the pulverulent state, in which it can be distinguished from arrowroot only by microscopic examination of its particles. These are uniform and spherical, not unequal and ovoïd, like those of arrowroot. In this state it is known as *sago-meal*. A factitious sago is prepared in France and Germany with potato-starch.

Of sago and sago-flower we *imported* in 1873:—

	cwts.	value
From Borneo	10,137	£ 8,892
Straits Settlements	279,766	221,798
Other countries	8,276	6,367
Total	298,179	£237,057

SAIL CLOTH. A hemp fabric, manufactured largely at Dundee.

SAINT IGNATIUS'S BEANS. The seeds of a climbing plant, native of the Philippine Islands, supposed to be a species of *Strychnos*. These beans are sometimes used instead of Nux vomica. See Dr. Pereira's 'Elements of Materia Medica.'

SAL AERATUS. A mixture of carbonate of soda and salt is so called in the United States. It is employed in making pastry and bread, mixed with a little cream of tartar or tartaric acid.

SAL-AMMONIAC. See AMMONIUM, CHLORIDE OF.

SALAMSTONE. A variety of corundum. See SAPPHIRE.

SALANGANA. See ALGÆ and SWALLOW, ESCULENT.

SALENIXON. Crude sulphate of potash obtained in the manufacture of nitric acid.

SALEP, or **SALOUP,** is the name of the dried tuberous roots of the *Orchis*, imported from Persia and Asia Minor, which are the product of a great many species of the plant, but especially of the *Orchis mascula*. Salep occurs in commerce in small oval grains, of a whitish-yellow colour, at times semi-transparent, of a horny aspect, very hard, with a faint, peculiar smell, and a taste like that of gum-tragacanth, but slightly saline. These are composed almost entirely of starchy matter, well adapted for making a thick pap with water or milk, and are hence in great repute in the

Levant, as restorers of the animal forces. Semolina is sometimes sold under this name.

SALICINE is a substance which may be obtained in white pearly crystals from the bark of the white willow (*Salix alba*), of the aspen tree (*Salix helix*), as also of some other willows. It has a very bitter taste. It has been employed for the purpose of adulterating the sulphate of quinine. Its composition is $C^{26}H^{18}O^{14}$ ($\mathbf{C^{13}H^{18}O^{7}}$), quinine being $C^{40}H^{24}N^{2}O^{4}$. The presence of nitrogen in the latter renders the salicine essentially different in its chemical as in its medicinal relations. It is said to be almost a specific against sea-sickness.

SAL MARINE is common salt (chloride of sodium). See SALT, SEA.

SAL MARTIS is protosulphate of iron.

SAL MIRABILE is sulphate of soda.

SAL PRUNELLA is fused nitre cast into cakes or balls.

SAL VOLATILE is carbonate of ammonia.

SALT, EPSOM, is sulphate of magnesia.

SALT, FUSIBLE, is phosphate of ammonia.

SALT, GLAUBER'S, is sulphate of soda.

SALT, GLAZIER'S, is sulphate of potash.

SALT, MICROCOSMIC, is the triple phosphate of soda and ammonia.

SALT OF AMBER is succinic acid.

SALT OF LEMERY is sulphate of potash.

SALT OF LEMONS is citric acid and binoxalate of potash.

SALT OF SATURN is acetate of lead.

SALT OF SODA is carbonate of soda.

SALT OF SORREL is binoxalate of potash.

SALT OF TARTAR is carbonate of potash.

SALT OF TIN is protochloride of tin.

SALT OF VITRIOL is sulphate of zinc.

SALT PERLATE is phosphate of soda.

SALTPETRE is nitre, or nitrate of potash, which see.

SALT, ROCK, SEA, or CULINARY. (*Chlorure de sodium; Hydrochlorate de soude*, Fr.; *Salz*, *Chlornatrium*, Ger.) These terms are used to designate different forms of a substance which is composed, chemically speaking, of single equivalents of sodium and chlorine, or of 39·4 parts of sodium and 60·6 of chlorine in 100 parts by weight: it is known chemically as chloride of sodium and formerly as muriate of soda.

Chloride of sodium generally occurs crystallised in the cube, and occasionally in other forms belonging to the regular system; among these varieties, the octahedron, the cubo-octahedron, and the dodecahedron, have been observed; but there is another which at first sight appears singular, and deserves notice on account of its frequent occurrence. It is called the funnel- or hopper-shaped crystal, and is a hollow, rectangular pyramid, forming on the surface of a saline solution in the course of its evaporation: it appears to commence with the formation of a small floating cube, to the edges of the upper face of which lines of other little cubes attach themselves by the edges of their lower faces. By a repetition of this proceeding, the sides of a hollow pyramid are formed, the apex of which, the single cubical crystal, is downward: the crystal sinks by degrees as the aggregation goes on above, until a pyramidal boat of considerable size is constructed.

The crystals of chloride of sodium are anhydrous, but generally contain a little water entangled in their interstices, the expansion of which causes them to decrepitate when heated. This salt is fusible at a red heat, and at a white heat volatilises. Its crystals are white, frequently perfectly transparent, of a specific gravity of 2·13, and a hardness of 2·5. A remarkable feature in this salt is, that its solubility in water increases but slightly as the temperature of the latter is raised, for, according to the experiments of M. Gay-Lussac, 100 parts of water dissolve

35·81 parts of the salt,	at a temperature of	57·0° Fahr.
35·88 ,,	,,	62·5° ,,
37·14 ,,	,,	140·0° ,,
40·38 ,,	,,	229·5° ,,

This must be understood to apply only to the pure substance, for the presence of other salts frequently increases its solubility.

Chloride of sodium, when perfectly colourless and transparent, is perfectly diathermanous, *i.e.*, it allows the rays of heat to pass through its substance almost without perceptible interception. It stands first amongst solid bodies in this respect, all others absorbing a very considerable portion of the heat which passes through them, and some almost the whole:—

Of 100 rays of heat	Clear rock-salt transmits	92
„	Muddy ditto „ . . .	65
„	Plate glass „ . . .	24
„	Clear ice „ . . .	0

The source of heat in these experiments was red-hot platinum.

Chloride of sodium occurs in nature chiefly in two forms, either as rock-salt, forming extensive deposits, or disseminated in minute quantity through the mass of the strata which form the earth's crust. Water penetrating the layers of rock-salt, and exerting there a solvent action, gives rise to the brine springs which are found in various countries; whilst streams and rivers dissolving the same substance out of the strata through which they flow, carry it down to the sea, where it constitutes the principal saline ingredient in the waters of the ocean.

Even in mass, as rock-salt (*Sel gemme*, Fr.; *Steinsalz*, Ger.), this substance possesses a crystalline structure derived from the cube, which is its primitive form. It has generally a foliated texture, and a distinct cleavage, but it has also sometimes a fibrous structure. Its lustre is vitreous, and its streak white. It is not so brittle as nitre; its hardness =2·5, which is nearly that of alum; a little harder than gypsum, but softer than calcareous spar. Its specific gravity varies between 2·1 and 2·257. It is white, occasionally colourless, and perfectly transparent, but usually of a yellow or red, and more rarely of a blue or purple tinge. A few analyses will show the general purity of this substance.

The principal impurities occurring in rock-salt are sulphate of lime, oxide of iron and clay, but the chlorides of potassium, calcium, and magnesium, the sulphates of soda and magnesia, and bituminous matters, are sometimes found in it; and occasionally shells, and insect and infusorial remains, exist enclosed in the mass. To the presence of infusoria, indeed, is attributed the red or green colour with which some varieties are tinted, which, upon analysis, are found to be absolutely pure chloride of sodium, as in the case of the second specimen quoted in the above table. Carburetted hydrogen gas in a state of strong compression is met with in some varieties, and these when dissolved in water emit a peculiar crackling sound, caused by the expansion and escape of the confined gas.

The geological position of rock-salt is very variable; it is found in all sedimentary formations, from the palæozoic to the tertiary, and is generally interstratified with gypsum, and associated with beds of clay. When the latter is present in large quantity, the term 'saliferous clay' is applied to the deposit. The great British deposits of salt in Cheshire and Worcestershire are found in the New Red Sandstone. At Northwich, in the Vale of the Weaver, the rock-salt consists of two beds, which are not less than 100 feet thick, and are supposed to constitute large insulated masses, about a mile and a half long, and nearly 1,300 yards broad. There are other deposits of rock-salt in the same valley, but of inferior importance. The uppermost bed occurs at 75 feet beneath the surface, and is covered with many layers of indurated red, blue, and brown clay, interstratified more or less with gypsum, and interspersed with argillaceous marl. The second bed of rock-salt lies at 31½ feet below the first, being separated from it by layers of indurated clay, with veins of rock-salt running between them. The lowest bed of salt was excavated to a depth of 110 feet, several years ago. Many of the German deposits of rock-salt occur in their *Bunter Sandstein*, which is the representative of part of our New Red Sandstone, and is so called because its colours vary from red to salmon and chocolate. In the Austrian Alps salt is found in oolitic limestone; at Cardonna, in Spain, in the greensand; and the famous mines of Wieliczka, in Galicia (excavated at a depth of 860 feet, in a layer 500 miles long, 20 broad, and

1,200 feet deep), it occurs in tertiary strata. But in addition to those concealed deposits, this substance presents itself in vast masses upon many parts of the earth's surface: in the high lands of Asia and Africa are often extensive wastes, the soil of which is covered and impregnated with salt, which has never been enclosed by superimposed deposits; near Lake Oroomiah, in the N.W. of Persia, it forms hills and extended plains; it abounds in the neighbourhood of the Caspian Sea, and penetrates the entire soil of the steppes of the south of Russia.

The beds of rock-salt are sometimes so thick, as at Wieliczka and Northwich, that they have not yet been sunk through, although mined for many centuries; but in ordinary cases the thickness of the layers varies from an inch or two to ten or fifteen yards. When the strata are thin, they are usually numerous, and throughout a certain extent parallel; but when explored at several points such enlargements and diminutions are observed, as to destroy this appearance of parallelism.

It has been remarked that the plants which generally grow on the sea-shore, such as the *Triglochin maritimum*, the *Salicornia*, the *Salsola Kali*, the *Aster trifolium*, or 'farewell-to-summer,' the *Glaux maritima*, &c., occur also in the neighbourhood of salt-mines and salt springs, even of those which are most deeply buried beneath the surface. It is also generally found that the interior of salt-mines is extremely dry, so that the dust produced in the workings becomes an annoyance to the miners, though in other respects the excavations are not insalubrious.

Much discussion has been raised concerning the origin of these rock-salt deposits; some asserting that they were the result of igneous agency, and others that they have been in every case deposited from solution in water. The great argument in favour of the former view appears to rest upon the fact, that chloride of sodium and hydrochloric acid gas are among the substances erupted by volcanoes; whilst, on the other hand, it is urged that the specimens of erupted chloride of sodium which have been analysed always differ much from rock-salt, since they contain a large amount of chloride of potassium; and in addition to this, the frequent occurrence of bodies such as bitumen and organic remains, and of cavities containing liquids, and in some cases gases, in almost all varieties of rock-salt, are held to furnish indisputable proof of the deposition of this substance from its aqueous solution. The occurrence of sandstone pseudomorphs in the cubical form of rock-salt, also favours this opinion; and so also does the general character of these deposits; they are usually lenticular, or irregularly-shaped beds, having a great horizontal extension, and but rarely occur in the form of dykes, or masses filling vertical fissures, which is the usual form assumed by a molten mass projected upwards from the interior of the earth. The method of its formation was, according to those who hold the aqueous theory, somewhat as follows:—A sea, such as the Mediterranean, is, by an elevation of the land at Gibraltar, cut off from communication with the ocean; the rate of evaporation from its surface is greater than the supply of water by rain and rivers, consequently the amount of salts which it holds dissolved, increases; now chloride of sodium is the principal saline constituent of sea-water, and Bischof's experiments have shown that when a solution of this salt is allowed to be at rest, the particles of salt sink, so that the lower layers soon become more saturated than the upper; concentration is then supposed to go on until at the undisturbed bottom of this inland sea a saturated solution of chloride of sodium exists, from which masses of rock-salt are slowly deposited. Its great purity is accounted for by the fact, that the other salts existing in sea-water are either far less or far more soluble than chloride of sodium; thus the carbonate and sulphate of lime would be almost wholly precipitated before the solution became sufficiently concentrated to deposit rock-salt, whilst at that degree of concentration the sulphate and chloride of magnesium would still remain for the most part in solution.

The principal European mines of rock-salt are those of Wieliczka in Galicia, excavated at a depth of 860 feet below the soil; at Hall in the Tyrol, and along the mountain range through Aussee, in Styria, Ebensee, Ischl, and Hallstadt, in Upper Austria; Hallein in Salzburg, 3,300 feet above the sea level, and Reichenthal in Bavaria; in Hungary, at Marmoros; in Transylvania and Wallachia; at Vic and Dieuze in France; at Bex, in Switzerland; in the Valley of Cardonna, and elsewhere, in Spain; and in the region around Northwich, in Cheshire, in our own country. Some of these deposits, as at Wieliczka and Northwich, are almost pure chloride of sodium; others, again, as many of the Austrian beds, are only saliferous clay; whilst others, as at Arbonne in Savoy, elevated 7,200 feet above the level of the sea, and in the region of perpetual snow, are masses of saccharoid gypsum and anhydrite, which are imbued with chloride of sodium, and which become quite light and porous when the salt has been removed by water.

Of late years valuable saline deposits have been discovered and are actively worked in the neighbourhood of Stassfurt, in Prussian Saxony, and in the adjoining duchy of Anhalt. The rock-salt which occurs at a considerable depth from the surface, is here overlain by a great thickness of mixed salts, rich in compounds of potash and magnesia. (See ABRAUM SALTS; POTASH.) It is notable that the order in which these various salts are superposed upon each other is precisely the order of their relative solubility, and hence the conclusion that the whole deposits represent the salts left by evaporation of the waters of a great salt-lake.

The natural transition from the consideration of these strata of rock-salt is to those brine springs which generally accompany them, and which have frequently first called attention to the deposits below. It has been noticed that salt springs issue, in general, from the upper portion of the saliferous strata; cases, however, occur in which the brines are not accompanied by rock-salt, and in which, therefore, their whole saline contents must be derived from the ordinary constituents of the strata. Thus, in England, besides the strong brines of the New Red Sandstone, we have salt springs issuing from the carboniferous rocks. The purest and most saturated brines are, however, found to be those which can be traced to rock-salt beds, and in the foremost rank of these stand the English springs of the Northwich, Middlewich, and Sandbach districts in Cheshire; of Droitwich and Stoke in Worcestershire; and of Weston and Shirleywich in Staffordshire; and the continental brines of Würtemberg and Prussian Saxony. The following is the composition of these saturated brines:—

Compared with these may be some weaker and less pure brines, which rise from other geological formations. The brines in the United States come for the most part from Silurian sandstones, but those in the Alleghany Mountains spring from the coal; and the weak salt springs of Nauheim and Homburg, which can only be called brines because chloride of sodium is their largest constituent, rise from palæozoic strata. (See Table at top of next page.)

These weak salt springs are supposed to have no connection with beds of rock-salt, but to obtain their chloride of sodium, in common with the other salts which they contain, from the strata which they permeate. The singular brines of the Alleghany Mountains must obviously pass through strata containing little if any soluble sulphate, otherwise their chloride of barium would be separated as insoluble sulphate of baryta; and all indeed may be regarded as coming more under the head of ordinary mineral waters, which happen to contain rather a large quantity of chloride of sodium.

The next source of chloride of sodium which demands notice is found in the inland seas, salt lakes, pools, and marshes, which have their several localities obviously independent of peculiar geological formations. They appear to owe their origin to two causes, being due, first, to the formation of lakes upon, and the passage of rivers through, some of the surface deposits of salts already alluded to; and, secondly, by the cutting off of a portion of the ocean by the elevation of the land, and the consequent formation of an inland lake. To the former cause are probably due the existence of the Lake Oroomiah in the N.W. of Persia, the numerous brine pools of Southern Russia, and the Great Salt Lake of N. America. The lake Oroomiah is 82 miles

long by 24 wide, and elevated 4,000 feet above the level of the sea; it is surrounded, especially on the east and north, by some of the most remarkable surface-deposits of rock-salt in the world, and through these salt streams are continually flowing into the lake. The Russian brine pools are situated in the salt-impregnated steppe between the rivers Ural and Wolga, and doubtless derive their saline constituents from thence. The Great Salt Lake is a saturated solution of almost pure chloride of sodium, but whence the salt is derived appears at present to be but a matter of conjecture. To the second cause the origin of the Dead Sea is frequently attributed; its surface is about 1,300 feet below that of the Mediterranean, and it is thought to have lost a column of water of that height by evaporation. The Crimean lakes also have probably originated thus.

Bischof has shown that in proportion as chloride of magnesium increases in a solution, it renders chloride of sodium and sulphate of lime more and more insoluble; he is therefore of opinion that at the bottom of the Dead Sea, and similar lakes, an impure rock-salt deposit, interstratified also with mud, is forming, similar to the saliferous clays or clayey marls which are frequently met with on the Continent.

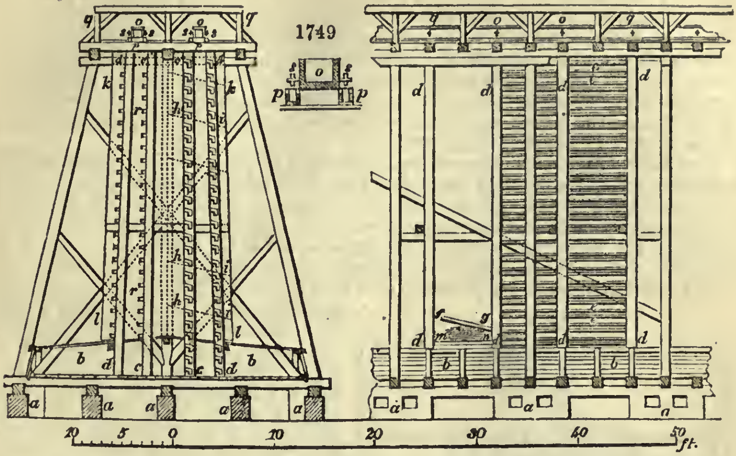
Culinary salt is prepared from each of the four sources above mentioned. It but rarely happens that rock-salt is sufficiently pure for immediate use, and when employed, as in some places on the Continent, and formerly in Cheshire, it is dissolved in water, the insoluble impurities allowed to subside, and the solution treated as a concentrated brine. From its other sources, salt is obtained by evaporation, and this is effected in two ways: 1. Entirely by the application of artificial heat; 2. By natural evaporation preceding the application of artificial heat.

The first method is employed invariably in this country, and also on the Continent when the brines contain more than 16 or 20 per cent. of chloride of sodium, the cost of fuel at different places of course regulating the application of this method. The manufacture of salt at Droitwich in Worcestershire, is said to have existed in the time of the Romans, and in Cheshire, the 'Wiches' (Nantwich, &c.) were very productive in the reign of Edward the Confessor. Some time elapsed before the method of evaporation was devised, and the original mode of obtaining the salt was by pouring the brine upon the burning branches of oak and hazel, from the ashes of which the deposited salt was afterwards collected. The process of evaporation was first conducted in small leaden vessels, which were afterwards exchanged for iron ones, having a surface of about a square yard and a depth of six inches; the size of these pans increased but slowly, for only a century since the largest pans at Northwich were but 20 feet long by 10 broad. The pans now in use in Cheshire, Worcestershire, and Staffordshire have a length of 60 or 70 feet, with a width of from 20 to 25, and a depth of about 18 inches; they are made of stout iron plates riveted together, are supported on brickwork, and have from one to three furnaces placed at one end, the flues of which are in immediate contact with the bottom of the pan. The brine is generally raised by steam-power, and its supply appears inexhaustible. The shafts are lined with wooden or iron casings to prevent the admixture of freshwater springs with the brine; the depth of the borings is in Cheshire usually from 210 to 250 feet, but at Stoke, in Worcestershire, a shaft of 225 feet was constructed, yet no satisfactory supply of brine obtained until a further boring of 348 feet was made. At Droitwich the borings are only to a depth of 175 feet, and so abundant is the supply of brine, that if the pumps cease working, it speedily rises to within nine feet of the surface, and if left unremoved soon overflows. The freedom of the brine from dilution by freshwater springs is from time to time tested by the hydrometer. From the pumps the brine is directly conveyed by means of pipes to reservoirs, from which, as the evaporation proceeds, it is admitted into the pans. As the water is vaporised, the salt is deposited and falls to the bottom of the pan; it is then drawn to the sides by the workmen, until a heap is accumulated, and from this portions are ladled out into rectangular wooden boxes with perforated bottoms, allowed to drain and solidify, removed from the boxes, and placed in the drying room; the salt of coarser grain is simply drained roughly in baskets and dried. The grain of the salt, *i.e.* its occurrence in larger or smaller crystals, is entirely the effect of temperature; the fine-grained or table salt is produced by rapid heating, and is formed at that end of the pan next the fireplace; the coarse or bay-salt is formed by the slow evaporation which goes on at the other end; whilst an intermediate variety, common salt, is produced in the middle. A pan may sometimes be slowly evaporated for the express purpose of obtaining bay-salt.

In the preparation of salt various substances have been added to the brine, with a view of improving the quality of the product: these have been chiefly bodies containing albuminous matters, which, coagulating upon the application of heat, entangle all solid impurities and carry them to the surface; blood, white-of-egg, glue, and calves' feet have thus been extensively used. There is also another class of substances employed for a different purpose. When a concentrated solution of any saline matter is evaporated, much annoyance is caused by a layer of the solid salt forming on the surface of the liquid and impeding evaporation: this is called a 'pellicle'; to obviate this, and to avoid the loss of labour entailed by constant stirring, oils, butter, or resin, have been added to the brine. The effect of the latter is said to be perfectly magical, the introduction of a very few grains being amply sufficient to clear the largest pan, and to prevent any recurrence of the 'setting over.'

When it is required to prepare salt from the weak brines which are of common occurrence in France and Germany, the second method is resorted to, and the brine is concentrated by natural evaporation previous to the application of artificial heat: this concentration was formerly effected by distributing the brine over flat inclined wooden surfaces, but it is now brought about by allowing the brine to trickle in a continuous stream through walls of thorns exposed to the sun and wind. This, which is called the method of *graduation*, is employed, among other places, at Moutiers in France, and at Nauheim, Dürrenberg, Rodenberg, and Schönebeck, in Germany. The weak brine is pumped into an immense cistern on the top of a tower, and is thence allowed to flow down the surface of bundles of thorns built up in regular walls between parallel wooden frames. At Salza, near Schönebeck, the graduation-house is 5,817 feet long, the thorn-walls are from 33 to 52 feet high, in different parts, and present a total surface of 25,000 square feet. Under the thorns, a great brine cistern, made of strong wooden planks, is placed to receive the perpetual shower of water. Upon the ridge of the graduation-house there is a long spout, perforated on each side with numerous holes, and furnished with spigots or stopcocks for distributing the brine either over the surface of the thorns or down through their mass; the latter method affording larger evaporation. The graduation-house should be built lengthwise in the direction of the prevailing wind, with its ends open. An experience of many years at Salza and Dürrenberg has shown that in the former place graduation can go on 258, and in the latter 207 days, on an average in the year; the best season being from May till August. At Dürrenberg, 3,596,561 cubic feet of water are evaporated annually. According to the weakness of the brine, it must be the more frequently pumped up, and made to flow down over the thorns in different compartments of the building, called the 1st, 2nd, and 3rd graduation. A deposit of gypsum incrusts the twigs, which requires them to be renewed at the end of a certain time. *Figs.* 1747 and 1748 represent the graduation-house of the salt-works at Dürrenberg. *a*, *a*, *a*, are low stone pillars for supporting the brine-cistern, *b*, called the *Soole-schiff*. *c*, *c*, are the inner, *d*, *d*, the outer walls of thorns; the first have perpendicular sides, the last sloping. The spars, *e*, *e*, which support the thorns, are longer than the interval between two thorn walls from *f* to *g*, *fig.* 1748, whereby they are readily fastened by their tenons and mortises. The spars are laid at a slope of 2 inches in the foot, as shown by the line *h*, *i*. The bundles of thorns are each 1½ foot thick, from 5 to 7 feet long, and are piled up in the following way:—Guide-bars are first placed in the line *k*, *l*, to define the outer surface of the thorn wall, the undermost spars *m*, *n*, are fastened upon them, and the thorns are evenly spread after the willow-withs of the bundles have been cut. Over the top of the thorn-walls are laid, through the whole length of the graduation-house, the brine-spouts *o, o*, which are secured to the upper beams; and at both sides of these spouts are the drop-spouts *p, p*, for discharging the brine by the spigots *s, s*, as shown upon a larger scale in *fig.* 1749. The drop-spouts are 6 feet long, have on each side small

1747 1749 1748



notches, 5 inches apart, and are each supplied by a spigot. The space above the ridge of the graduation-house is covered with boards, supported at their ends by binding-beams, *q*. *r, r*, show the tenons of the thorn-spars. Over the Soole-schiff *b*, inclined planes of boards are laid for conducting downwards the innumerable showers. The brine, which contains at first 7·692 per cent. of salt, indicates after the first shower, 11·473; after the second, 16·108; and after the third, 22. The brine thus concentrated to such a degree as to be fit for boiling, is kept in great reservoirs, of which the eight at Salza, near Schönebeck, have a capacity of 2,421,720 cubic feet, and are furnished with pipes leading to the sheet-iron salt-pans. The capacity of these is very different at different works. At Schönebeck there are 22, the smallest having a square surface of 400 feet, the largest of 1,250, and are enclosed within walls, to prevent their being affected by the cold external air. They are covered with a funnel-formed or pyramidal trunk of deals, ending in a square chimney to carry off the steam.

The graduation-range should be divided lengthwise into several sections: the first, to receive the water of the spring, the lake, or the sea; the second, the water from the first shower-receiver; the third, the water from the second receiver; and so on. The pumps are usually placed in the middle of the building, and lift the brine from the several receivers below into the alternate elevated cisterns. The square wooden spouts of distribution may be conveniently furnished with a slide-board attached to each of their sides, to serve as a general valve for opening or shutting many trickling orifices at once. The rate of evaporation at Moutiers is exhibited by the following table:—

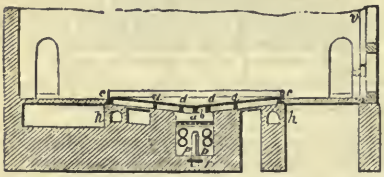
Number of showers	Total surface of the fagots	Specific gravity of the brine	Water evaporated
		1·010	...
1 and 2	5158 square feet . .	1·023	0·540
3, 4, 5, 6, 7, 8, and 9 .	2720	1·072	0·333
10	550	1·140	0·062
Total evaporation			0·935
Water remaining in the brine at the density of 1·140 .			0·065
Water assigned at the density of 1·010			1·000

From the above table it appears that no less than 10 falls of the brine have been required to bring the water from specific gravity 1·010 to 1·140, or 18° Beaumé.

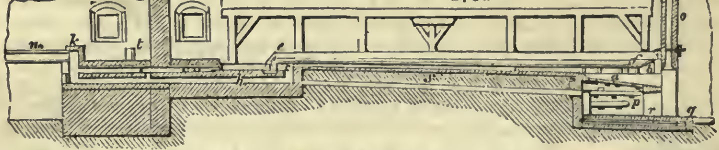
The evaporation is found to proceed at nearly the same rate with the weaker water, and with the stronger, within the above limits. When it arrives at a density of from 1·140 to 1·16, it is run off into the settling-cisterns. M. Berthier calculates, that upon an average in ordinary weather, at Moutiers, 60 kilogrammes of water (13 gallons imp.) are evaporated from the fagots, in the course of 24 hours, for every square foot of their surface. Without the aid of currents of air artificially warmed, such an amount of evaporation could not be reckoned upon in this country. In the *Schlotting*, or throwing down of the sediment, a little bullock's blood previously beaten up with some cold brine, promotes the clarification. When the brine acquires, by brisk ebullition, the density of 1·200, it should be run off from the preparation to the finishing or salting-pans. The boilers constructed at Rosenheim, in Bavaria, evaporate 3½ pounds of water for every pound of wood burnt.

Figs. 1750, 1751, 1752, represent the construction of a salt-pan, its furnace, and the salt store-room of the works at Dürrenberg: *fig.* 1752, being the ground-plan, *fig.* 1751, the longitudinal section, and *fig.* 1750, the transverse section. *a*, is the fire-grate, which slopes upwards to the back part, and is 31½ inches distant from the bottom of the pan. The ratio of the surface of the grate to that of the bottom of the pan is as 1 to 59·5; that of the air-hole into the ash-pit, as 1 to 306. The bed under the pan is laid with bricks, smoothly plastered over from *b* to *c*, in *fig.* 1750. Upon this bed the pillar *d*, *d*, &c., are built in a radiated direction, being 6 inches broad at the bottom, and tapering to 1½ inch at top. The pan is so laid that its bottom has a fall towards the middle of 2½ inches: see *e*, *f*, *fig.* 1751. The fire diffuses itself in all directions under the pan, proceeds thence through several holes, *g*, *g*, *g*, into flues, *h*, *h*, *h*, which run round three sides of the pan; the burnt air then passes through *i*, *fig.* 1752, under other pans, from which it is collected in the chimneys *k*, *k*, to be conducted into the drying-room. At *l*, *l*, there is a transverse flue, through which by

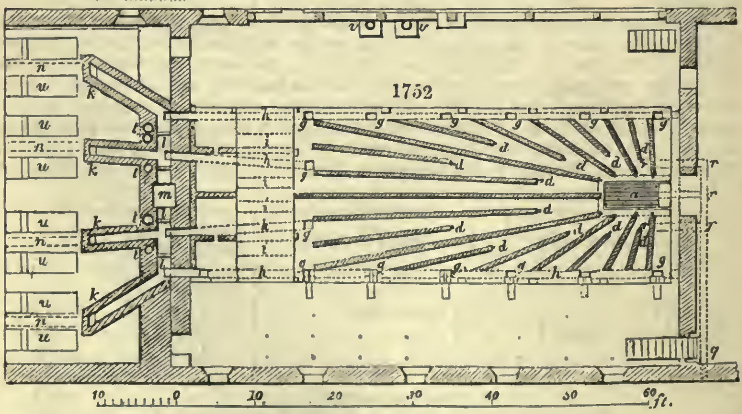
1750



1751



1752

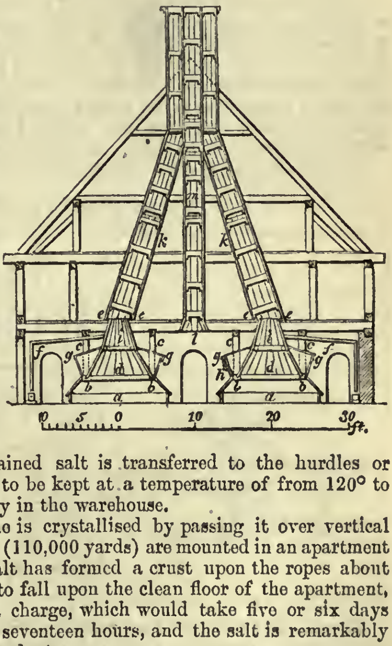


means of dampers, the fire-draught may be conducted into an extra chimney, *m*. From the flues *k*, *k*, four square iron pipes, *n*, *n*, issue and conduct the burnt air into the main chimneys in the opposite wall.

The bottoms of the several flues have a gradual ascent above the level of the fire-grate. A special chimney, *o*, rises above the ash-pit, to carry off the smoke which may chance to regurgitate in certain states of the wind. *p*, *p*, are iron pipes laid upon each side of the ash-pit (see *figs.* 1750 and 1751), into which cold air is admitted by the flue *q*, *r*, where, becoming heated, it is conducted through iron pipes, *s*, and thence escapes at *t*, into the stove-room. Upon both sides of the hot flues in the stove-room, hurdle-frames, *u*, *u*, are laid, each of which contains 11 baskets, and every basket, except the undermost, holds 60 pounds of salt, spread in a layer 2 inches thick. *v*, *v*, shows the pipes by which the pan is supplied with graduated brine.

Description of the Steam-trunk in fig. 1753.—In front of the pan *a*, *a*, there are two upright posts, upon which, and in holes of the back wall, two horizontal beams, *b*, *b*, are supported. The pillars *c*, *c*, are sustained upon the bearers, *d*, *d*. At *e*, *e*, a deep quadrangular groove is made in the beams, for fixing down the four boards which form the bottom of the steam-way. In this groove any condensed water from the steam collects, and is carried off by a pipe *f*, to prevent it falling back into the pan. Upon the three sides of the pan not in contact with the wall, there are three rows of boards hinged upon planks, *b*, *b*. Behind the upper one, a board is hung on at *g*, upon which the boiled salt is laid to drain. The two other rows of boards are hooked on so as to cover the pan, as shown at *h*. Whenever the salt is sufficiently drained, the upper shelves are placed in a horizontal position; the salt is put into small baskets, and carried into the stove-room. *i*, *k*, is the steam-trunk; *l*, *m*, is a tunnel for carrying off the steam from the middle of the pan, when this is uncovered by lifting the boards.

1753



In proportion as the brine becomes concentrated by evaporation, more is added from the settling-reservoir of the graduation-house, till finally small crystals appear on the surface. No more weak brine is now added, but the charge is worked off, care being taken to remove the scum as it appears. In some places the first pan is called a schlot-pan, in which the concentration is carried only so far as to cause the deposition of the sludge, from which the same solution is run into another pan, and gently evaporated to produce the precipitation of the fine salt. This salt should be continually raked towards the cooler and more elevated sides of the pan, and then lifted out with cullender-shovels into large conical baskets, arranged in wooden frames round the border of the pan, so that the drainage may flow back into the boiling liquor. The drained salt is transferred to the hurdles or baskets in the stove-room, which ought to be kept at a temperature of from 120° to 130° Fahr. The salt is then stowed away in the warehouse.

In summer the saturated boiling brine is crystallised by passing it over vertical ropes; for which purpose 100,000 meters (110,000 yards) are mounted in an apartment 70 meters (77 yards) long. When the salt has formed a crust upon the ropes about 2½ inches thick, it is broken off, allowed to fall upon the clean floor of the apartment, and then gathered up. The salting of a charge, which would take five or six days in the pan, is completed in this way in seventeen hours, and the salt is remarkably pure, but the mother-waters are more abundant.

The mother-water contains a large quantity of chloride of magnesium, along with chloride of sodium and sulphate of magnesia. Since the last two salts mutually decompose each other at a low temperature, and are transformed into sulphate of soda, which crystallises, and chloride of magnesium, which remains dissolved, the mother-water may with this view be exposed in tanks to the frost during winter, when it affords three successive crystalline deposits, the last being nearly pure sulphate of soda.

The chloride of magnesium, or bittern, not only deteriorates the salt very much, but occasions a considerable loss of weight. It may, however, be most advantageously removed, and converted into chloride of sodium, by the following simple expedient:—Let quicklime be introduced in equivalent quantity to the chloride of magnesium present; double decomposition will take place, resulting in the precipitation of magnesia, and the formation of chloride of calcium; the latter will then react upon the sulphate of soda in the mother-water, producing sulphate of lime and chloride of sodium, the former of which, being sparingly soluble, is almost entirely separated.

In those countries, as Portugal and the coasts of the Mediterranean, where sea-water is used as the source of salt, a peculiar method of natural evaporation is resorted to, in what are called 'Salt Gardens.' Large shallow basins, the bottom of which is very smooth, and is formed of clay, are excavated along the sea-shore; they consist of:—

1st. A large reservoir, of from 2 to 6 feet in depth, communicating with the sea by means of a channel provided with a sluice. Advantage is taken of the high tide to fill this basin; and the water is allowed to remain here for some time to deposit any suspended impurities; it is then drawn off into the brine-pits.

2ndly. The brine-pits are divided into a large number of compartments by means of little banks; these all have a communication with each other, but so arranged that the water has a long circuit to make in its passage from one set to another; it frequently flows 400 or 500 yards before it reaches the extremity of this sort of labyrinth. The various divisions are distinguished by a number of technical names. They should be exposed to the north, north-east, or north-west winds.

In the month of March the water of the sea is let into these reservoirs, where a vast surface is exposed to evaporation from the first or clearing-working; the others are refilled as their contents decrease. The salt is considered to be on the point of crystallising when the water begins to grow red; soon after this, a pellicle forms on the surface, which breaks and falls to the bottom. Sometimes the salt is allowed to subside in the first compartment; but generally, the strong brine is made to pass on to the others, where a larger surface is exposed to the air; in either case, the salt as it forms is raked out, and left upon the borders to drain and dry. To get rid of the chloride of magnesium, which is one of the principal impurities of this kind of salt, it is frequently heaped up under sheds, where it is just protected from the rain, and the chloride of magnesium being a very deliquescent salt, attracts moisture from the air and drains away. The salt thus obtained partakes of the colour of the bottom on which it is formed, and is hence white, red, or grey.

The following table shows the composition of several varieties of culinary salt:—

Analyses of several varieties of Culinary Salt.

	Cheshire stoved	Lymington cat. salt	Scotch common	Königsborn, Westphalia	St. Malo, sea-salt	Moutiers	
						Des cordes	Boilers
Chloride of sodium . .	98·250	98·8	93·55	95·90	96·00	97·17	93·59

	99·90	99·9	99·60	97·27	99·10	100·00	100·00

The specific gravity of a saturated solution of large-grained cubical salt, is 1·1962 at 60° Fahr. 100 parts of this brine contain 25·5 of salt (100 water + 34·2 salt).

In Great Britain the rock-salt mines and principal brine-springs are in Cheshire; and the chief part of the Cheshire salt, both rock-salt and manufactured, is sent by the river Weaver to Liverpool, a very small proportion of it being conveyed elsewhere, by canal or land carriage.

There are brine-springs in Staffordshire, from which Hull is furnished with white salt, and the Worcestershire salt chiefly supplies the London market.

Within the last few years, while boring for coal in the Cleveland district near Middlesbro, Messrs. Bolchow and Vaughan discovered a considerable deposit of salt. Shafts are being sunk, not only at these works, but at the Clarence Works, belonging to Messrs. Bell Brothers. In a short time we may expect to find all the soda-works upon the Tyne suppliedwith salt from those deposits in the North Riding of Yorkshire.

According to M. Clément Desormes, engineer and chief *actionnaire* of the great salt-works of Dieuze, in France, the internal consumption of that kingdom is rather more than 200,000 tons per annum, being at the rate of 6½ kilogrammes for each individual of a population estimated at 32,000,000.

The salt produce of the United Kingdom is shown in the following returns:—

The Quantities of Cheshire Rock Salt and White Salt sent down the River Weaver in each of the last five years were:

Years	Rock-salt	White salt	Total
	tons	tons	tons
1869	58,696	901,566	960,262
1870	67,410	901,158	968,568
1871	82,765	930,551	1,013,316
1872	91,084	996,381	1,087,465
1873	95,429	918,068	1,013,497

Droitwith and Stoke Prior produced about 276,000 tons each year; and the salt-mines in Ireland about 20,000 tons annually. The total produce of the United Kingdom being a little up or down of 1,500,000 tons, and of this about 700,000 tons are annually exported.

Salt *exported* in 1874:—828,964 tons; value, 663,451*l*.

SALTS. It may be sufficient to state here that the common acceptation of a salt is that of a crystallised substance. Those formed by the union of simple bodies, as chlorine and sodium, iodine and iron, or the like; or of those formed by substances already compound, as sulphuric acid (sulphur and oxygen), with soda (sodium and oxygen), &c.; or, in the case of many of the salts formed from the organic acids exhibiting a yet more complex constitution.

Modern chemists define a salt as a body obtained from an acid by replacement of its hydrogen by a metal; thus, common salt may be derived from hydrochloric acid, or chloride of hydrogen, by replacing the hydrogen by sodium.

Salts may be either *neutral*, or such as do not exhibit any acid or alkaline properties; or *acid*, *i.e.* those in which there is an excess of acid; or *basic*, in which there is present more than one equivalent of base for each equivalent of acid.

SALT, SEDATIVE, is boracic acid.

SALT WATER, DISTILLATION OF. See WATER.

SAND (Eng. and Ger.; *Sable*, Fr.) is the name given to any mineral substance in a hard granular or pulverulent form, whether strewed upon the surface of the ground, found in strata at a certain depth, forming the beds of rivers, or the shores of the sea. The siliceous sands seem to be either original crystalline formations, like the sand of Neuilly, in 6-sided prisms, terminated by two 6-sided pyramids, or the *débris* of granitic, schistose, quartzose, or other primary crystalline rocks, and are abundantly distributed over the globe; as in the immense plains known under the names of deserts, *steppes*, *landes*, &c., which, in Africa, Asia, Europe, and America, are entirely covered with loose sterile sand. Valuable metallic ores, those of gold, platinum, tin, iron, titanium, often occur in the form of sand, or mixed with that earthy substance. Pure siliceous sands are very valuable for the manufacture of glass, for ameliorating dense clay soils, for moulding, and many other purposes.

Specimens of the finer kinds of sand, from the Isle of Wight, and the neighbourhood of Lynn, are remarkably white and beautiful. Reigate also furnishes pure siliceous sand. By far the finest samples of sand ever seen in this country were in the American department of the Great Exhibition of 1851, and did not fail to attract the notice of those interested in such matters. This sand was totally free from iron and every other source of contamination. It was as white as snow; and so far as the making of glass is concerned, no sand is equal to it: considerable quantities have been imported since that period. The principal sources of sand for the manufacture of glass are Charlton, Hastings, Derbyshire, Alum Bay, Yarmouth, Isle of Wight, Reigate, and Hartwell near Aylesbury, in England; near Llandudno, in Wales; and in Limerick, Cork, and Donegal in Ireland. These sands have all more or less of a yellow topaz hue, indicating oxide of iron, and which imparts to all glass the green tinge so very perceptible in the common window variety. To remove this oxide of iron from sand, has never yet, we believe, been attempted; though if we may judge by the trouble taken to modify its influence in the manufacture of glass, an effectual process of the kind would be a lucrative discovery. When sand containing oxide of iron is mixed with a little charcoal and subjected at a red heat to the action of chlorine gas, the whole of the iron is volatilised as chloride of iron, and the silica remains pure as soon as the excess of charcoal is burnt off: this experiment seems to suggest the possibility of purifying the glass-makers' sand, by the employment of waste muriatic acid. Even at ordinary temperatures, the solution of oxide of iron by this means might be hoped for; but there can be no practical objection to the use of a reasonable amount of heat for such a purpose, if found necessary. A beautifully white sand has been used in America in the manufacture of soap.

The sand from Alum Bay, in the Isle of Wight, is composed of—

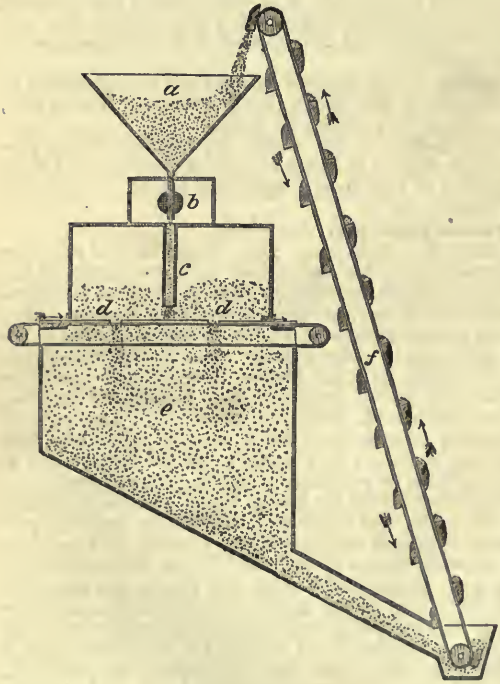
Silica	97
Alumina, with trace of oxide of iron and magnesia	2
Moisture	1
	100

The French, or Fontainebleau sand, now used in glass-making very extensively, is—

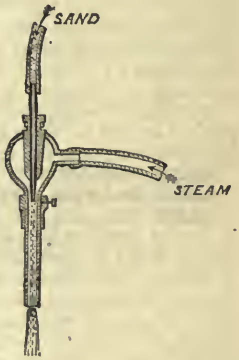
Silica	98·8
Alumina, and trace of iron	0·7
Moisture	0·5
	100

SAND-BLAST. Under the head of ENGRAVING ON GLASS, a description is given of Mr. Tilghman's process of abrading the surface of glass or stone by the action of a jet of sand driven at considerable velocity. The construction of the apparatus only will be dealt with in this place. The machine employed to direct the sand on to the

1754



1755



object to be operated upon resembles a Gifford's injector. The arrangement will be understood by examining *fig.* 1754. *a* is the sand-box, and *b* a box containing compressed air, which passes through the tube *c*, with force proportional to the pressure exerted on the air in the box; opposite to this jet of air and sand is placed the plate of glass to be operated on. The grains of sand being drawn by suction into the air, or steam, if the latter is employed, and then projected forward with a velocity proportioned to the pressure, the sand does its work and passes off into the settling chamber *e*, from which it is again lifted by the sand-elevator to be returned into the box *a*. For cutting stone, the sand is introduced into a central iron tube, about $\frac{1}{4}$th-inch bore (*fig.* 1755), and the steam issues through an annular passage surrounding the sand-tube. A tube of chilled cast iron, 6 inches long, and $\frac{7}{16}$ths-inch bore, is fixed as a prolongation of the steam passage, and serves as a tube in which the steam mixes with the sand, and imparts velocity to the latter. The central sand-tube is connected by means of a flexible tube and funnel, with a box containing dry sand, and the outer annular tube is connected by another flexible tube with a steam-boiler.

SANDAL, SANTAL, or RED SANDERS WOOD (*Santal*, Fr.; *Sandelholz*, Ger.), is the wood of the *Pterocarpus santalinus*, a tree which grows in Ceylon and on the coast of Coromandel. The old wood is preferred by dyers. Its colouring-matter is of a resinous nature, and is therefore quite soluble in alcohol, essential oils, and alkaline lyes; but sparingly in boiling water, and hardly, if at all, in cold water. The colouring-matter which is obtained by evaporating the alcoholic infusion to dryness, has been called *santalin*. See SANTALIN.

Sandal-wood is used in India, along with one-tenth of *sapan* wood (the *Cæsalpinia sapan* of Japan, Java, Siam, Celebes, and the Philippine Isles), principally for dyeing silk and cotton. Trommsdorf dyed wool, cotton, and linen a carmine hue by dipping them alternately in an alkaline solution of the sandal-wood, and in an acidulous bath. Bancroft obtained a fast and brilliant reddish-yellow, by preparing wool with an alum-and-tartar bath, and then passing it through a boiling bath of sandal-wood and sumach.

According to Togler, wool, silk, cotton, and linen mordanted with a salt of tin, and dipped in a cold alcoholic tincture of the wood, became of a superb ponceau-red colour. With alum they took a scarlet-red; with sulphate of iron a deep violet or brown-red. Unfortunately, those dyes do not resist the influence of light.

SANDERS WOOD. See SANDAL WOOD.

SANDARACH, or *Juniper-Resin,* is a peculiar resinous substance, the product of the *Thuya articulata*, a small tree of the coniferous family, which grows in the northern parts of Africa, especially round Mount Atlas. It is imported from Mogadore.

The resin comes to us in pale yellow, transparent, brittle, small tears, of a spherical or cylindrical shape. It has a faint aromatic smell, does not soften, but breaks between the teeth, fuses readily with heat, and has a specific gravity of from 1·05 to 1·09. It contains three different resins: one soluble in spirits of wine, somewhat resembling *pinic acid* (see TURPENTINE); one not soluble in that menstruum; and a third, soluble only in alcohol of 90 per cent. It is used as pounce-powder for strewing over paper erasures, as incense, and in varnishes. The *Pterocarpus Draco* is another species of the genus: from this the Dragon's blood was formerly obtained. The wood being wounded, a resinous juice of a red colour flows out, which concretes on exposure to the air. But little of this resin is now found in commerce, the reed *Calamus Draco* producing all that is imported. Gum Kino is obtained from *Pterocarpus erinaceus.*

Sandarach is softer and less brilliant than shellac, but much lighter in colour; it is therefore used for making a pale varnish for light-coloured woods. See VARNISHES.

SANDIVER. The saline scum formed on glass-pots, known also as *Glass gall.* The name is a corruption of the French '*Saint de verre.*'

SANDSTONE. A building-stone simply formed by the cohesion of sandy particles. The most durable sandstones are such as are formed of siliceous particles cemented together by silica.

SANITARY ECONOMY. This term is used to express and to include everything which is done or can be done to the preservation of health. This includes the supply of a large quantity of pure air, the maintenance of the waters of wells and rivers in as uncontaminated a state as possible, and the removal from amongst the living of all decomposable or dead matter as speedily as possible.

SANTALIN. The chemistry of this product is by no means quite complete. Pelletier was the first who discovered and isolated santalin. Meier prepares it by treating the wood with ether; the concentrated solution yields the substance in a crystalline yet impure state. The crystals are first washed with water, and next re-dissolved in alcohol; the alcoholic solution is precipitated by acetate of lead, and the ensuing precipitate washed with boiling alcohol, and next decomposed by means of sulphuric acid in the presence of alcohol. After removing the sulphate of lead, the previously-concentrated alcoholic solution deposits santalin in the shape of small crystals of a beautiful red colour, fusing at 104°. Dr. Dussance's plan of preparing santalin is by precipitating the alcoholic extract of the wood by means of hydrated oxide of lead. After washing, the precipitate is dissolved in acetic acid, and to this solution a large quantity of cold water is added, which indeed precipitates the colouring-matter, but in a rather impure state, since the edge thus obtained does not yield good results.

Santal-wood contains on an average about 16 per cent. of santalic acid. According to Wegermann and Haeffely, the composition of santalin is $C^{30}H^{14}O^{10}$ ($\mathbf{C^{15}H^{14}O^{5}}$). Dr. Bolley considers that santal-wood contains two different colouring-matters, one of which is richer in oxygen, but poorer in hydrogen; this is the material occurring in the old dark-coloured wood. The other is found in the younger and paler variety.

According to the researches of Meier and Kimmer, santalin is accompanied by divers red and brown coloured-matters, more soluble in water than santalin itself, and the products of its oxidation. This assertion is certainly substantiated by the fact, that the young twigs of the *Pterocarpus santalinus* are internally yellow-coloured, and only become red by the action of the air.

Santalin exhibits the following properties: it is a beautiful red crystalline powder, almost insoluble in water, soluble in alcohol, ether, and acetic acid; the colouring-matter is very readily withdrawn from the acetic acid solution by albuminous substances, which retain it energetically; alkalis dissolve santalin, yielding deep violet-red solutions, from which it is thrown down unaltered by acids. Santalin fuses at 104°. (See Crookes's 'Practical Handbook of Dyeing.')

SAPAN-WOOD, or *East Indian Dye Wood*, or *Buckum-Wood*, is a species of the genus *Cæsalpinia*, to which Brazil-wood belongs. It is so called by the French, because it comes to them from Japan, which they corruptly pronounce Sapan. It is imported in pieces like the Brazil-wood, to which it is far inferior for dyeing. The decoction is used in calico-printing for red colours. In general, span wood is too unsound to be employed for turning. See BRAZIL-WOOD.

SAP GREEN. The juice of the berries of the *Rhamus catharticus*, or common buckthorn.

SAPPHIRE. The *Sapphire, Ruby, Oriental Amethyst, Oriental Emerald*, and *Oriental Topaz*, are gems next in value and hardness to diamond; and they all consist of nearly pure alumina, with a minute proportion of iron as the colouring-matter. The following analyses show the affinity in composition of the most precious bodies with others in little relative estimation:—

	Sapphire	Corundum-stone	Emery
Alumina . . .	98·5	89·50	86·0
Silica	0·0	5·50	3·0
Oxide of iron . .	1·0	1·25	4·0
Lime	0·5	0·00	0·0
	100·0	96·25	93·0

Salamstone is a variety which consists of small transparent crystals, generally six-sided prisms, of pale reddish and bluish colours. The corundum of Battagammana is frequently found in large six-sided prisms: it is commonly of a brown colour, whence it is called by the natives *Curundu gallé*, cinnamon-stone. The hair-brown and reddish-brown crystals are called adamantine spar.

Sapphire and salamstone are chiefly met with in secondary repositories, as in the sand of rivers, &c., accompanied by crystals and grains of magnetic iron ore and of several species of gems.

The finest varieties of sapphire come from Pegu, where they occur in the Capelan mountains near Syrian. Some have been found also at Hohenstein in Saxony, Bilin in Bohemia, Puy in France, and in several other countries. The red variety, the ruby, is most highly valued. Its colour is between a bright scarlet and crimson. A perfect ruby above 3½ carats is more valuable than a diamond of the same weight. If it weigh 1 carat, it is worth 10 guineas; 2 carats, 40 guineas; 3 carats, 150 guineas; 6 carats, above 1,000 guineas. A deep-coloured ruby, exceeding 20 carats in weight, is generally called a carbuncle; of which 108 were said to be in the throne of the Great Mogul, weighing from 100 to 200 carats each; but this statement is probably incorrect. The largest oriental ruby known to be in the world was brought from China to Prince Gargarin, governor of Siberia. It came afterwards into the possession of Prince Menzikoff, and constitutes now a jewel in the imperial crown of Russia. See RUBY.

A good blue sapphire of 10 carats is valued at 50 guineas. If it weighs 20 carats, its value is 200 guineas; but under 10 carats, the price may be estimated by multiplying the square of its weight in carats into half a guinea; thus, one of four carats would be worth $4^2 \times \frac{1}{2}G. = 8$ guineas. It has been said that the blue sapphire is superior in hardness to the red, but this is probably a mistake arising from confounding the corundum-ruby with the spinelle-ruby. A sapphire of a barbel-blue colour, weighing 6 carats, was disposed of in Paris by public sale, for 70*l.* sterling; and another of an indigo-blue, weighing 6 carats and 3 grains, brought 60*l.*; both of which sums much exceed what the preceding rule assigns, from which we may perceive how far fancy may go in such matters. The 'sapphire' of Brazil is merely a blue tourmaline, as its specific gravity and inferior hardness show. White sapphires are sometimes so pure, that when properly cut and polished they have been passed for diamonds.

The yellow and green sapphires are much prized under the names of oriental topaz and emerald. The specimens which exhibit all these colours associated in one stone are highly valued, as they prove the mineralogical identity of these varieties.

Besides these shades of colour, sapphires often emit a beautiful play of colours, or *chatoiement*, when held in different positions relative to the eye or incident light; and some likewise present star-like radiations, whence they are called star-stones or *asterias;* sending forth 6 or even 12 rays, that change their place with the position of the stone. This property, so remarkable in certain blue sapphires, is not however peculiar to these gems. It seems to belong to transparent minerals which belong to the rhombohedral system, and arises from the combination of certain conditions in their cutting and structure. Lapidaries often expose the light-blue variety of sapphire to the action of fire, in order to render it white and more brilliant; but with regard to those found at Expailly in France, fire deepens their colour.

SARD. A variety of chalcedony of a dark reddish-brown colour, almost approaching to black by reflected light, and very deep red, inclining to blood-red, by transmitted light. It is found under the same conditions as carnelian, but is rarer and more highly esteemed, and therefore fetches a higher price. The name is derived either from *sarx* (Gr. σάρξ, 'flesh'), in allusion to its colour, or from Sardis in Lydia, whence it is said to have been first brought. It should be remarked, however, that the sard presents, in its interior and in the middle of its ground, concentric zones, or small nebulosities, which are not to be seen in the red carnelian, properly so called. The ancients certainly knew our sard, since they have left us a great many of them engraved, but they seem to have associated under the title *Sarda* both the *sardoine* of the French and our carnelians and chalcedonies. Pliny says that the sarda came from the neighbourhood of a city of that name in Lydia, and from the environs of Babylon. Among the engraved sards which exist in the collection of antiques in the Bibliothèque Royale of Paris, there is an Apollo remarkable for its fine colour and great size. When the stone forms a part of the agate-onyx, it is called sardonyx.

SARDINE (*Atherina;* Gr. ἀθήρ, 'a spine'). A genus of fishes, belonging to the order *Acanthopterygii.* They form a very extensive fishery in the Mediterraenan. They are salted and preserved in oil, and are sent in large quantities to this country. Recently (1874) an establishment has been founded at Mevagissey in Cornwall for preserving the small pilchards in the same way as the sardines of the Mediterranean are prepared. It is thought by some that the sardine and the young pilchard are identical, but the sardine is of the genus *Atherina*, whereas the pilchard belongs to the *Clupeidæ.*

SARDONYX. A variety of onyx, composed of alternate layers of sard and white chalcedony. It much resembles agate, but the colours, usually a light clear brown and an opaque white, are arranged in flat horizontal planes. Amidst the chalcedonic series are various stones having the same general character, of mixtures of true quartz, with opal disseminated.—H. W. B.

SATIN (Eng., Fr. and Ger.) is the name of a silk stuff, first imported from China, which is distinguishable by its very smooth, polished, and glossy surface. It is woven upon a loom with at least five-leaved healds or heddles, and as many corresponding treddles. These are so mounted as to rise and fall four at a time, raising and depressing alternately four yarns of the warp, across the whole of which the weft is thrown by the shuttle, so as to produce a uniform smooth texture, instead of the chequered work resulting from intermediate decussations, as in common webs. Satins are woven with the glossy or right side undermost, because the four-fifths of the warp, which are always left there during the action of the healds, serve to support the shuttle in its race. Were they woven in the reverse way, the scanty fifth part of the warp-threads could either not support, or would be too much worn by the shuttle. See Textile Fabrics.

SATINET. A mixed fabric, woven to imitate satin.

SATIN SPAR. A fibrous variety of gypsum (sulphate of lime); when polished, used for ornamental purposes. It is sometimes a fibrous carbonate of lime.

SATIN-WOOD. A veneering wood of great beauty, the product of the *Chloroxylon Swietenia* of India. The light colour and lustrous polish of the wood, combined with the pleasing 'figure' it exhibits, renders it a favourite wood for drawing-room furniture. It is a native of Ceylon, and is found in the northern and southern —but chiefly in the eastern—districts. Above all things, it requires the most careful seasoning, for it is liable to warp and split; and once let such a misfortune happen to boards destined—say for wardrobe-panels—and the pecuniary loss is very great. Care being taken to exclude the rays of the sun, or violent alterations of heat and cold, there is little doubt of well-selected wood being seasoned successfully.

Flower satin-wood is generally obtained from the roots, and has been found of a size to yield planks 15 inches broad. Unfortunately, this is an exceptional dimension; it is not often seen in this country, for the cultivator's axe is destroying the finest satin-wood to be met with, that near the foot of the Anamallai Hills. In the Bombay Presidency it seldom reaches beyond the size of a small tree, which, when straight, would afford a log 3 by 3 inches square. The wood is very close-grained, hard, and durable, and of a light-orange colour, so light in fact, that the word 'orange' can hardly fairly be applied. Indeed, it is sometimes erroneously called 'yellow-wood,' which is another timber altogether, larger and straighter than box-wood, but not so close grained.

Satin-wood takes a fine polish, and is suited for all kinds of ornamental purposes; but it is rather apt to split. For picture-frames it is nearly equal to American maple. The timber bears submersion well, and in some instances it is beautifully feathered, and the flowered or feathered satin-wood, when first polished is one of the most beautiful woods.

SATURATION is the term employed to express the condition of a body which has taken its full dose or chemical proportion of any other substance with which it can combine; as water with a salt, or an acid with an alkali.

SATURN, EXTRACT OF. The old name of the acetate of lead.

SAW. Saws are formed from plates of sheet-steel, and are toothed, not by hand, but by means of a press and tools. Circular saws have the advantage of being divided in their teeth very accurately by means of a division-plate; this prevents irregularity of size, and imparts smoothness and uniformity of action. The larger sizes of circular saws are made in segments and connected together by means of dove-tails. All saws are hardened and tempered in oil; their irregularities are removed by hammering on blocks, and they are equalised by grinding. The several forms of teeth do not, as the casual observer may imagine, depend upon taste, but are those best fitted for cutting through the particular section, quality, or hardness of the material to be cut. The 'set' of the saw consists in inclining the teeth at the particular angle known to be the best to facilitate the exit of the saw-dust, and thereby allow the saw to operate more freely. Iron bars, shaftings, &c., are cut to length by a steel circular saw, in its soft state, the iron to be cut being presented to the saw red-hot; the saw rotates at a prodigious rate, and is kept in cutting condition, or cool, by its lower edge being immersed in water.

SAXIFRAGINE. See Explosive Agents.

SAXON BLUE. A solution of indigo in oil of vitriol. See Blue Pigments.

SCAGLIA. The red limestone of the Alps. See Limestone.

SCAGLIOLA is merely ornamental plaster-work, produced by applying a pap made of finely-ground calcined gypsum, mixed with a weak solution of Flanders glue, upon any figure formed of laths nailed together, or occasionally upon brickwork, and bestudding its surface, while soft, with splinters (*scagliole*) of spar, marble, granite, bits of concrete-coloured gypsum, or veins of clay, in a semi-fluid state. The substances employed to colour the spots and patches are the several ochres, boles, *terra di Sienna*, chrome-yellow, &c. The surface, if it be that of a column, is turned smooth upon a lathe, polished with stones of different fineness, and finished with some plaster-pap, to give it lustre. Pilasters and other flat surfaces are smoothed by a carpenter's plane, with the chisel finely serrated, and afterwards polished with plaster by friction. The glue is the cause of the gloss, but makes the surface apt to be injured by moisture, or even damp air. See Stone, Artificial.

SCARLET DYE. (*Teinture en écarlate*, Fr.; *Scharlachfärberei*, Ger.) Scarlet is usually given at two successive operations. The boilers (see Dyeing) are made of block tin, but their bottoms are formed occasionally of copper.

1. *The bouillon- or the colouring-bath.*—For 100 pounds of cloth, put into the water, when it is little more than lukewarm, 6 pounds of argal, and stir it well. When the water becomes too hot for the hand, throw into it with agitation, 1 pound of cochineal in fine powder. An instant afterwards, pour in 5 pounds of the clear mordant (see Mordant), stir the whole thoroughly as soon as the bath begins to boil, introduce the cloth, and wince it briskly for two or three rotations, and then more slowly. At the end of a two-hours' boil, the cloth is to be taken out, allowed to become perfectly cool, and well washed at the river, or winced in a current of pure water.

2. *The rougie, or finishing dye.*—The bouillon-bath is emptied and replaced with water for the *rougie*. When it is on the point of boiling, 5½ pounds of cochineal in fine powder are to be thrown in, and mixed with care; when the crust, which forms upon the surface, opens of itself in several places, 14 pounds of solution of tin (muriate of tin) are to be added. Should the liquor be likely to boil over the edges of

the kettle, a little cold water is to be added. When the bath has become uniform, the cloth is to be put in, taking care to wince it briskly for two or three turns; then to boil it bodily for an hour, thrusting it under the liquor with a rod whenever it rises to the surface. It is lastly taken out, aired, washed at the river, and dried.

Below will be found the tables of the composition of the *bouillon* and the *rougie*.

M. Lenormand stated that he had made experiments of verification upon all the formulæ of the following tables, and declared his conviction that the finest tint might be obtained by taking the *bouillon* of Scheffer and the *rougie* No. 4 of Poërner.

Tables of the Composition of the Bouillon and Rougie for 100 *pounds of Cloth or Wool.*

Composition of the Bouillon.

Names of the authors	Starch		Cream of tartar		Cochineal		Solution of tin		Common salt	
	lbs.	ozs.	lbs.	ozs.	lbs.	ozs.	lbs.	ozs.	lbs.	ozs.
Berthollet . . .	0	0	6	0	8	0	5	0	0	0
Hellot . . .	0	0	12	8	18	6	12	8	0	0
Scheffer . . .	9	0	9	6	12	4	9	6	0	0
Poërner . . .	0	0	10	15	0	0	10	15	0	0

Composition of the Rougie.

M. Robiquet has given the following prescription for making a *printing scarlet*, for well-whitened woollen cloth:—Boil a pound of pulverised cochineal in 4 pints of water down to 2 pints, and pass the decoction through a sieve. Repeat the boiling three times upon the residuum, mix the 8 pints of decoction, thicken them properly with 2 pounds of starch, and boil into a paste. Let it cool down to 104° Fahr., then add 4 ounces of the solution of tin and 2 ounces of ordinary muriate of tin. When a ponceau red is wanted, 2 ounces of pounded tumeric should be added.

A solution of chlorate of potash is said to beautify scarlet cloth in a remarkable manner. For several fine scarlet dyes, see 'Practical Handbook of Dyeing,' by Wm. Crookes, F.R.S. See Lac Dye; Aniline; Murexide.

SCHEELE'S GREEN is a pulverulent arsenite of copper, which may be prepared as follows:—Form, first, an arsenite of potash, by adding gradually 11 ounces of arsenious acid to 2 pounds of carbonate of potash, dissolved in 10 pounds of boiling water; next, dissolve 2 pounds of crystallised sulphate of copper in 30 pounds of water; filter each solution, then pour the first progressively into the second, as long as it produces a rich grass-green precipitate. This being thrown upon a filter-cloth, and edulcorated with warm water, will afford 1 pound 6 ounces of this beautiful pigment. It consists of, oxide of copper, 28·51, and of arsenious acid, 71·46. This green is applied by an analogous double decomposition to cloth. See Calico-Printing. Much discussion has arisen relative to the use of this salt in paper-hangings, it having been supposed by many persons to have produced ill effects on those exposed to the atmosphere of such rooms.

SCHMELZE. A kind of glass prepared in Bohemia, chiefly for the purpose of receiving the red colour imparted by the oxide of gold. See Glass.

SCHWEINFURTH GREEN is a more beautiful and velvety pigment than the Scheele's green. It was discovered in 1814, by MM. Rusz and Sattler, at Schweinfurth, and remained for many years a profitable secret in their hands. M. Liebig having made its composition known in 1822, it has since been prepared in a great many colour-works. Braconnot published, about the same time, another process for manufacturing the same pigment. Its preparation is very simple, but its formation is accompanied with some interesting circumstances. On mixing equal parts of acetate of copper and arsenious acid, each in a boiling concentrated solution, a bulky olive-green precipitate is immediately produced; while much acetic acid is set free. The powder thus obtained appears to be a compound of arsenious acid and oxide of copper, in a peculiar state; since when decomposed by sulphuric acid, no acetic odour is exhaled. Its colour is not changed by drying, by exposure to air, or by being heated in water. But, if it be boiled in the acidulous liquor from which it was precipitated, it soon changes its colour, as well as its state of aggregation, and forms a new deposit in the form of a dense granular beautiful green powder. As fine a colour is produced by ebullition during five or six minutes as is obtained at the end of several hours by mixing the two boiling solutions, and allowing the whole to cool together. In the latter case, the precipitate, which is slight and flocky at first, becomes denser by degrees; it next betrays green spots, which progressively increase, till the mass grows altogether of a crystalline constitution, and of a still more beautiful tint than if formed by ebullition.

When cold water is added to the mixed solutions immediately after the precipitate takes place, the development of the colour is retarded, with the effect of making it much finer. The best mode of procedure is to add to the blended solutions their own bulk of cold water, and to fill a globe up to the neck with the mixture, in order to prevent the formation on any such pellicle on the surface as might, by falling to the bottom, excite premature crystallisation. Thus the reaction continues during two or three days with the happiest effect.

SCOURING. This art is that which is employed for removing grease spots, &c., from cloths and furniture, which require skill beyond that of the laundry. It is divided into two distinct branches, viz. French and English cleaning. We will first give an outline of English cleaning.

Gentlemen's clothes, such as trowsers, coats, &c., are treated in the following manner. They are stretched on a board, and the spots of grease, &c., first taken out by rubbing the spots well with a brush and cold strong soap-liquor; they are then done all over with the same, but the grease spots are done first, because they require more rubbing, of course, than the other parts, and when all the substance is wet the spots will not be so easily distinguished. After treatment with the strong soap-liquor, the soap is worked by a weaker soap-liquor; the articles are then well washed off with warm water, and treated with ammonia (*if black*), solution of common salt, or dilute acid, according to circumstances. They are then drained, beaten out with a little size, pressed and dried.

Ladies' articles of dress, as shawls and woollen dresses.—The spots are first removed by rubbing them on the board with very strong soap-liquor; they are then put into a strong soap-liquor, and well worked about in it; then taken out and treated with a weaker soap-liquor, to work out the soap, &c.; rinsed with warm and cold water alternately; treated with solution of common salt or very weak acid, to maintain the colours. They are starched, if necessary, and ironed. Woollen dresses that are taken to pieces are calendered instead of ironing.

Silk dresses, &c., are always taken to pieces, and each piece done separately, and as quickly as possible. If there are any spots of grease, they are taken out first, as above mentioned. Each piece, after the spots are removed, is immediately placed in a strong soap-liquor, and well worked about in it, and then into a thinner soap-liquor; well washed out with cold water, and treated with solution of common salt, or very weak acid, or both, as required; each piece is then neatly folded and wrung separately, again folded smoothly and placed in dry sheets, and pressed, so as to remove all dampness from them; they are then put into a frame, a little size or sugar-and-water being used to stiffen and glaze; lastly, they are dried while on the frame by a charcoal fire.

Furniture, as curtains, &c.—These things are put into a tub, with a strong cold soap-liquor, and well punched about with a large wooden punch made on purpose; and a great deal depends upon this being properly done. They are then treated in the same manner in a weaker soap-liquor, well rinsed with water, treated with common salt or weak acid, as required, wrung out, and dried. Woollen furniture will generally require to be treated several times with the first strong soap-liquor, to remove the dirt, but for cotton furniture once will be generally sufficient.

Carpets.—These are well beaten, then laid down on the floor of the dye-house, and *well* scrubbed with strong cold soap-liquor, by means of a long-handled brush or broom; then treated with a weaker soap-liquor; well rinsed with water, by throwing pails of water over them, and still rubbing with the brush; treated with water, to which a *very small quantity* of sulphuric acid has been added, to retain the colours· rinsed again, hung up to drain, and then hung up in a warm room to dry.

A great point in this kind of cleaning is to use *strong cold soap-liquors*; and this cannot be done with ordinary soaps, as they congeal when cold, and on this account Field's soap is the principal soap which is used, because it is made from oil, and does not congeal. It is probaby made from the *olein* obtained in the manufacture of composite candles.

French cleaning is what is called *dry cleaning*. In this process the articles are put into camphine and worked about in it, drained, sheeted, and dried. The camphine dissolves the grease, &c., and does not injure the colours; but when things are very dirty, it does not clean so effectually as the English method. It is, however, the only process that can be employed in some cases, as in cleaning kid gloves.

SCREWS. The elementary idea of the form of the screw is obtained by regarding it as a continuous circular wedge; and it is readily modelled by wrapping a wedge-formed piece of paper around a cylinder; the edge of the paper then represents the line of the screw. The use of the screw is well known to all; and the system of cutting a rod of iron or steel into a screw scarcely requires any description. The manipulatory details and the tools used in their manufacture are admirably and most fully described in Holtzapffel's 'Turning and Mechanical Manipulation.'

SEA-HOLLY. *Eryngium maritimum.* The sea-holly—sea eryngo or sea hulver—is found on the sea-shores of Britain, and on the European and African shores of the Mediterranean Sea. The root was at one time much used medicinally. It is now prepared as a sweetmeat, and is especially candied at Colchester in Essex.

The *E. fœtidum* is used in Jamaica as a remedy for hysterical fits; and the *E. aquaticum*, sometimes called 'rattlesnake-weed,' from the circumstance of the North American Indians using it as an application to the bite of that serpent.

SEA-KALE. The *Crambe maritima* is a native of the English coast, and is found as far north as the Polar circle. The plant is blanched in spring, and the etiolated leaves are used as a delicate vegetable.

SEAL, THE. A marine animal, belonging to the class *Mammalia*, order *Carnivora*, and sub-order *Pinnipedia*. Although there are many species, only two genera, properly speaking, belong to this group, the seal (*Phoca*) and the walrus or morse (*Trichecus*). The seal is an amphibious creature; it sleeps, basks, and feeds its young on land, but has never been seen to take its food excepting when in the water. Its limbs are very short and covered with a skin, so as to resemble fins more than legs; the feet are webbed, and have the power of considerable expansion, and serve as excellent oars when the animal is in the water, but are of little service when on land, its terrestrial progression being effected by a sort of shuffling, jumping, or creeping motion; it uses these fin-like legs in climbing on to rocks or ice out of the water. It is an excellent swimmer, and, when in deep water, dives with remarkable rapidity, in an instant reappearing at perhaps a distance of fifty yards; this rapidity of motion gives it great power over its prey, which can seldom escape, except by swimming into shoal water. It feeds on almost any kind of fish, even shell-fish; but the salmon of the northern seas seems to be its favourite food. It is a native of the northern seas generally, and is found on the coasts of England and France, but is most plentiful around Greenland and Newfoundland. It is everything to the Greenlander; it supplies his food, light, and clothing, its flesh is his food, the liver being considered a dainty, and even by English sailors an agreeable dish; the fat (of which there is a large quantity, especially in the young about six weeks old) is consumed in his lamp; and the skin, being dressed in a peculiar way that renders it waterproof, furnishes him with almost all the other necessaries of life. When the skin is dressed without the hair, the Esquimaux and Greenlanders use it instead of planks for their boats, and as an outer covering for themselves, so that they are enabled to invert their canoes and themselves in the water without getting their bodies wet. The skin of the young is used as raiment for the women; and the skin of old animals to cover the houses; the stomach is filled with air and used as a fishing buoy; while the teeth furnish the heads of the hunting-spears. The skins of the *Stemmatopus cristatus* and the *Calocephalus hispidus* are sent in great quantities to Great Britain, where they are much used for hats, waistcoats, jackets, &c. The walrus or morse (*Trichecus Rosmarius*) has two large canine teeth or tusks in the upper jaw, which measure from 15 to 30 inches in length. Great numbers of these animals are annually destroyed for the sake of their tusks, the ivory of which is highly esteemed. These animals do not produce much fat, but the oil is of good quality; the skin is used for carriage-traces, wheel-ropes, &c.

Mr. Frank Buckland writes as follows on the seal-fishery:—

'When engaged two years ago in examining the salmon-fisheries of Scotland, I had the pleasure of meeting at Peterhead Captain David Gray, commanding officer of the screw-steamer 'Eclipse,' one of the principal vessels which sail annually from Scotland in pursuit of whales and seals. These vessels leave Dundee and Peterhead about

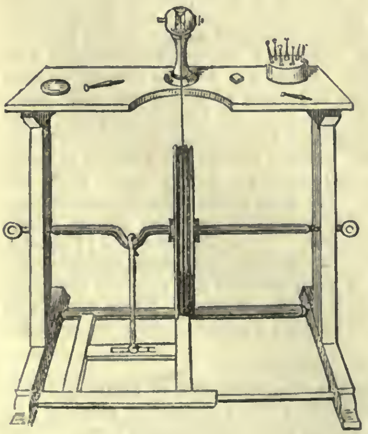
March 1; they make the ice about 72° or 73° north, in the neighbourhood of the island of Jan Mayan, a volcanic mountain rising 2,000 feet above the level of the sea. The young seals and mothers are found on the pack-ice near this island. There are four species of seals—the harp or saddle-back, the bladder-nose or hooded, the ground or bearded, and the floe or rat seal. The seals lie like flocks of sheep upon the ice, but every year they are observedly getting less and less in number.

'Captain Gray writes to me as follows in explanation of this:—

"On the seals being reached, the men are sent over the ice, the harpooners armed with rifles, the other men with seal-clubs, knife, and steel, also a rope to drag the skins to the ship. And now a work of brutal murder and cruelty goes on enough to make the hardest-hearted turn away with loathing and disgust. The harpooner chooses a place where a number of young seals are lying, knowing well that the mothers will soon make their appearance to see if the young are safe, and are then shot without mercy. This sort of work goes on for a few days, until tens of thousands of young seals are left motherless to die of starvation, not so much from the number of old ones killed (although too many of them are slain at this season, 40,000 being killed last year in March) as from those wounded and scared away. In a short time the old ones become shy and will not come near where the men are standing, but keep at a respectful distance. It is horrible to see the young ones trying to suck the carcases of their mothers, their eyes starting out of their sockets, looking the very picture of famine. They crawl over and over them until quite red with blood, poking them with their noses, no doubt wondering why they are not getting their usual food, uttering painful cries the while. The noise they make is something dreadful. If one could imagine himself surrounded by four or five hundred thousand human babies all crying at the pitch of their voices, he would have some idea of it. Their cry is very like an infant's. These motherless seals collect into lots of five or six, and crawl about the ice, their heads fast becoming the biggest part of their bodies, searching to find the nourishment they stand so much in want of. The females are very affectionate toward their young."

'The young seals are born about March 20, and are immediately slaughtered in thousands. At this time they are worth about 1*s.* per skin, and contain little or no oil. If they were not allowed to be killed before April 6, they would have time to suck and grow, and they grow very fast; this terrible "massacre of the innocents" would be prevented, the intelligent and affectionate mother-seals would be spared the agony of seeing their crying cubs slaughtered and skinned before their eyes—sometimes, as I hear, before they are quite dead—while each skin would then be worth 3*s.* or 4*s.*, and 100 seals would yield oil to the value of from 35*l.* to 40*l.* All that is required is an international agreement or treaty among the sealing-vessels, which are about 36 in number—20 from Scotland, 15 to 20 from Norway, and 2 from Germany —that an annual close-time should be given to the seals, and that they should not be killed before April 6, instead of March 20, in each year, as these seventeen days would make all the difference between their future multiplication and the present extermination which now threatens.'

1756



SEAL ENGRAVING. The art of *engraving gems* is one of extreme nicety. The stone having received its desired form from the lapidary, the engraver fixes it by cement to the end of a wooden handle, and then draws the outline of his subject with a brass needle or a diamond, upon its smooth surface.

Fig. 1756 represents the whole of the seal-engraver's lathe. It consists of a table on which is fixed the mill, a small horizontal cylinder of steel, into one of whose extremities the tool is inserted, and which is made to revolve by the usual fly-wheel, driven by a treddle. The tools that may be fitted to the mill-cylinder are the following:—*Fig.* 1757 a hollow cylinder, for describing circles, and for boring; *fig.* 1758 a knobbed tool, or rod terminated by a small ball; *fig.* 1759 a stem terminated with a cutting-disc whose edge may be either rounded, square, or sharp, being in the last case called a saw.

Having fixed the tool best adapted to his style of work in the mill, the artist applies to its cutting-point, or edge, some diamond-powder, mixed up with olive oil; and turning the wheel, he holds the stone against the tool, so as to produce the wished-for delineation and erosion. A similar apparatus is used for engraving on glass.

1757 1758 1759

In order to give the highest degree of polish to the engraving, tools of box-wood, pewter, or copper, bedaubed with moistened tripoli or rotten-stone, and lastly a brush, are fastened to the mill. These are worked like the above steel instruments. Modern engravings on precious stones have not in general the same fine polish as the ancient.

Several varieties of machine have been of late years introduced to facilitate the processes of engraving gems. Many of them involve the pentagraph, so that a seal may be engraved by the machine at once, either larger or smaller than the original from which it is copied. Most of these engraving machines are upon the principles described under CARVING BY MACHINERY.

SEAL-OIL. See OILS.

SEAL-SKIN. See FURS.

SEALING-WAX. (*Cire à cacheter*, Fr.; *Siegellack*, Ger.) The Hindoos from time immemorial have possessed the resin lac, and were long accustomed to use it for sealing manuscripts before it was known in Europe. It was first imported from the East into Venice, and then into Spain; in which country sealing-wax became the object of a considerable commerce, under the name of Spanish-wax.

If shellac be compounded into sealing-wax, immediately after it has been separated by fusion from the palest qualities of stick or seed lac, it then forms a better and less brittle article than when the shellac is fused a second time. Hence sealing-wax, rightly prepared in the East Indies, deserves a preference over what can be made in other countries, where the lac is not indigenous. Shellac can be restored in some degree, however, to a plastic and tenacious state by melting it with a very small portion of turpentine. The palest shellac is to be selected for bright-coloured sealing-wax, the dark kind being reserved for black.

The following proportions may be followed for making red sealing-wax:—Take 4 ounces of shellac, 1 ounce of Venice turpentine, and 3 ounces of vermilion. Melt the lac in a copper pan suspended over a clear charcoal fire, then pour the turpentine slowly into it, and soon afterwards add the vermilion, stirring briskly all the time of the mixture with a rod in either hand. In forming the round sticks of sealing-wax, a certain portion of the mass should be weighed while it is ductile, divided into the desired number of pieces, and then rolled out upon a warm marble slab, by means of a smooth wooden block, like that used by apothecaries for rolling a mass of pills. The oval sticks of sealing-wax are cast in moulds, with the above compound in a state of fusion. The marks of the lines of junction of the mould-box may be afterwards removed by holding the sticks over a clear fire, or passing them over a blue gas-flame. Marbled sealing-wax is made by mixing two, three, or more coloured kinds of it while they are in a semi-fluid state. From the viscidity of the several masses, their incorporation is left incomplete, so as to produce the appearance of marbling. Gold sealing-wax is made simply by stirring gold-coloured mica spangles into the melted resins. Wax may be scented by introducing a little essential oil, essence of musk, or other perfume. If 1 part of balsam of Peru be melted along with 99 parts of the sealing-wax composition, an agreeable fragrance will be exhaled in the act of sealing with it. Either lamp-black or ivory-black serves for the colouring-matter of black wax. Sealing-wax is often adulterated with rosin; in which case it runs into thin drops at the flame of a candle.

The following proportions are stated to form good sealing-wax:—

Red No. 1.—4 oz. Venetian turpentine, 6 oz. shellac, $\frac{3}{4}$ oz. colophony, $1\frac{3}{4}$ oz. cinnabar, &c.

Red No. 2.—4 oz. turpentine, $5\frac{1}{2}$ oz. shellac, $1\frac{1}{2}$ oz. colophony, $1\frac{1}{4}$ oz. cinnabar, magnesia to colour.

Fine Black.—$4\frac{1}{2}$ oz. Venetian turpentine, 9 oz. shellac, $\frac{1}{2}$ oz. colophony, lamp-black mixed with oil of turpentine as much as is required.

Black.—4 oz. Venetian turpentine, 8 oz. shellac, 3 oz. colophony, lamp-black, and oil of turpentine.

Yellow.—2 oz. Venetian turpentine, 4 oz. shellac, $1\frac{1}{4}$ oz. colophony, $\frac{3}{4}$ oz. king's yellow.

Dark Brown.—4 oz. Venetian turpentine, $7\frac{1}{2}$ oz. shellac, $1\frac{1}{2}$ oz. brown English earth (ochre).

Light Brown.—4 oz. Venetian turpentine, $7\frac{1}{2}$ oz. shellac, 1 oz. brown earth, $\frac{1}{2}$ oz. cinnabar.

Dark Blue.—3 oz. Venetian turpentine, 7 oz. fine shellac, 1 oz. colophony, 1 oz. mineral blue.

Green.—2 oz. Venetian turpentine, 4 oz. shellac, $1\frac{1}{4}$ oz. colophony, $\frac{1}{2}$ oz. king's yellow, $\frac{1}{4}$ oz. mountain blue.

Gold.—4 oz. Venetian turpentine, 8 oz. shellac, 14 sheets of genuine leaf-gold, $\frac{1}{2}$ oz. bronze, $\frac{1}{2}$ oz. magnesia with oil of turpentine.

SEA-WATER. The following has been given as the average composition of sea-water in 100 parts:—Chloride of sodium, 2·50; chloride of magnesium, 0·35; sulphate of magnesia, 0·58; carbonates of lime and of magnesia, 0·02; sulphate of lime, 0·01.

Dr. John Davy informs us that carbonate of lime is chiefly found in sea-water near the coast. Dr. George Wilson proved the existence of fluorine in the waters of the German Ocean, and Foret Lammr obtained it from sea-water collected near Copenhagen; Malaguti and Durocher have detected silver in sea-salt, and Mr. Field has shown that the copper sheathing of ships separates silver, in the process of time, from the waters of the ocean.

Lead and copper and some other metals have also been detected in sea-water, and in the ashes of some marine plants. These metals are said to exist in the sea-water in the form of chlorides, and to have been probably derived from the native sulphides of the metals by the action of the chlorine in the water.

SECRETAGE. A process in which mercury, or some of its salts, is employed to impart to the fur of animals the property of felting, which they did not previously possess. See FUR; MERCURY.

SEEDS *imported* in 1874:—

SELENITE. Hydrated sulphate of lime. See ALABASTER; GYPSUM.

SELENIUM, from σελήνη, *selēnē*, 'the moon,' is a chemical element, discovered by Berzelius in 1817. It occurs sparingly in combination with several metals, as lead, cobalt, copper, and quicksilver, in the Hartz, at Tilkerode; with copper and silver (*Eukairite*) in Sweden, with tellurium and bismuth in Norway, with tellurium and gold in Transylvania, in several copper and iron pyrites, and with sulphur in the volcanic products of the Lipari Islands. Selenium has been found likewise in a red sediment which forms upon the bottoms of the lead-chambers in which oil of vitriol has been made from a peculiar pyrites, or pyritous sulphur. The extraction of selenium from that deposit is a very complex process.

Selenium, after being fused and slowly cooled, appears of a bluish-grey colour, with a glistening surface; but it is a reddish-brown, and of metallic lustre when quickly cooled. It is brittle, not very hard, and has little tendency to assume the crystalline state. Selenium is dark red in powder, and transparent, with a ruby cast, in thin scales. Its specific gravity is 4·39. It softens at the temperature of 176° Fahr., is of a pasty consistency at 212°, becomes liquid at a somewhat higher heat, forming in close vessels dark yellow vapours, which condense into black drops; but in the air the fumes have a cinnabar-red colour. The atomic weight of selenium is 39·7, and its symbol Se. See Watts's 'Dictionary of Chemistry.'

SELTZER-WATER. See SODA-WATER, and WATERS, MINERAL.

SEMOULE. The name given in France to denote the large hard grains of wheat-flour retained in the bolting machine after the fine flour has been passed through its meshes. The best semoule is obtained from the wheat of the southern parts of Europe. With the semoule the fine white Parisian bread called *gruau* is baked. Skilful millers contrive to produce a great proportion of semoule from the large-grained wheat of Naples and Odessa.

Granular preparations of wheat deprived of bran are known in this country as *Semolina*, *Soujee*, and *Manna-croup*.

SENEGAL GUM. This gum is produced from the *Acacia Senegal*, a tree or shrub found in Arabia and the interior of Africa. See GUM.

SEPIA is a pigment prepared from a black juice secreted by certain glands of the cuttle-fish, which the animal ejects to darken the water when it is pursued. One part of it is capable of making 1,000 parts of water nearly opaque. All the species of this mollusc secrete the same juice; but the *Sepia officinalis*, the *S. loligo*, and the *S. tunicata*, are chiefly sought after for making the pigment. The first, which occurs abundantly in the Mediterranean, affords most colour; the sac containing it being extracted, the juice is to be dried as quickly as possible, because it runs rapidly into putrefaction. Though insoluble in water, it is extremely diffusible through it, and is very slowly deposited. Caustic alkalis dissolve the sepia, and turn it brown; but in proportion as the alkali becomes carbonated by exposure to air, the sepia falls to the bottom of the vessel. Chlorine blanches it slowly. It consists of carbon in an extremely-divided state, along with albumin, gelatine, and phosphate of lime.

The dried native sepia is prepared for the painter by first triturating it with a little caustic lye, then adding more lye, boiling the liquid for half an hour, filtering, next saturating the alkali with an acid, separating the precipitate, washing it with water, and finally drying it with a gentle heat. The pigment is of a brown colour, and a fine grain.

SEPTARIA (from *septum*, 'a division'), called anciently *ludus Helmontii* (the *quoits* of Van Helmont, from their form), are argillo-calcareous concretions intersected by veins of calc-spar, which, when calcined and ground to powder, form an excellent hydraulic cement.

From the regular arrangement of cracks in septaria which generally assume pentagonal forms resembling in appearance the divisions in the shell of a tortoise, they have received the common name of 'turtle-stones' or 'fossil tortoises.' The turtle-stones found in the Oxford clay at Weymouth, when cut into slabs and polished, form very handsome tables. The number of veins of calc-spar, upon which their beauty depends, renders these turtle-stones unfit for forming an hydraulic cement, in consequence of their furnishing too great a quantity of lime when calcined. Septaria fit for furnishing cement are dredged in large quantities in Chichester harbour, and off the coast of Hampshire, and are also procured from Harwich, Sheppy, and several other places. A stratum of septarian stone, forming the Broad Bench on the coast of Dorsetshire, affords an excellent cement, and is largely quarried.—H. W. B.

SERPENTINE is a mineral of the magnesian family, being a hydrated silicate of magnesia, composed of silica 43·64, magnesia 43·35, water 13·01 = 100. Its colour is either green or a mixture of red and green, seldom of a uniform tint, but generally of several shades, arranged in dotted, striped, and clouded forms. For this reason it has received the name of serpentine (or *ophiolite*, from Gr. ὄφις, *ophis*, 'a serpent,' and λίθος, *lithos*, 'stone'), from the fancied resemblance which it bears to the skin of a serpent, both in colour and in its spotted or mottled arrangement. Specific gravity, 2·5 to 2·6. It is slightly unctuous to the touch, sectile, and tough, and therefore easily cut into ornamental forms. It has been divided into *precious or noble serpentine*, comprising the purer translucent and massive varieties, with a rich olive-green colour; and *common serpentine*, or the opaque varieties, forming extensive rock masses, like those of the Lizard in Cornwall, of Anglesea, Portsoy in Banffshire, Unst and Fetlar in Shetland, and Zöblitz in Saxony.

Serpentine, though so soft as to be scratched by calcareous spar, and to be turned in the lathe, takes a good polish, and forms a very beautiful ornamental stone. At Zöblitz it has long been manufactured into a variety of articles, which find their way all over Germany; and works have been established in Cornwall, where, by means of powerful machinery, it is made into columns, vases, chimney-pieces, and other ornamental articles which have been rather extensively used. The serpentine of Portsoy is also a very beautiful stone, and was formerly exported for manufacturing into similar objects. The Cornish serpentine and steatite were at one time sent to Bristol in considerable quantities, where they were used in the manufacture of carbonate of magnesia.—H. W. B.

SESAMUM OIL, or *Teel Oil*. An oil produced from the *Sesamum orientale*, which yields the seeds known as teel seeds. It is of a peculiarly bland nature.

SEWING MACHINES. The history of these ingenions inventions has been so well told by Professor Willis, in his Report on the machinery for woven fabrics of the Paris Exhibition, that we do not hesitate to borrow from it.

At the Paris Exhibition in 1854, fourteen exhibitors came provided with sewing machines. They were of different characters, and have been divided by Mr. Willis into four classes.

Under the first class came the machines in which the needle is passed completely through the stuff, as in hand-working: 'It is so natural, in the first attempts to make an automatic imitation of handiwork, that the imitation shall be a slavish one, that we need not be surprised to find the earlier machines contrived to grasp a common needle, push it through the stuff, and pull it out on the other side.'

Thomas Stone and James Henderson, and some others, patented machines of this kind, which proved abortive. M. Heilmann exhibited an embroidering machine in 1834, in which '150, more or less, of needles are made to work simultaneously, and embroider each the same flower or device upon a piece of stuff or silk stretched in a frame and guided by a pentagraph.' Several embroidering machines have been from time to time introduced. See EMBROIDERING MACHINE.

The second class of sewing machine was that known as the chain-stitch, or 'crotchet.' This is wrought by a so-called crotchet-needle, which terminates with a hook; the needle is grasped by the opposite end, and the hook pushed through the stuff, so as to catch hold of a thread below, and, being then withdrawn, brings with it a small loop of the thread; the hook of the needle retaining this loop is then repassed through the stuff at a short distance in advance of the former passage, catches a new loop, and is again withdrawn, bringing with it the second loop, which thus passes through the first. Such a series is called chain-stitch, and may be used either to connect two pieces together, or as an embroidery stitch, for which it is well adapted by its ornamental and braid-like appearance. M. Thimonnier patented in 1830 the first machine of this character. M. Magnin was associated with Thimonnier in 1848 in a patent for improvements, and in 1851 it was exhibited in London.

In 1849 Morey and Johnson patented a sewing machine in this country, in which a needle with an eye near the point, perpendicular to the cloth, was combined with a hooked instrument parallel to the cloth, for effecting the same purpose as the crochet-needle. Mr. Singer improved on this, and he introduced a contrivance by which his machine forms a kind of knot at every eighth stitch.

The third class of sewing machines is wrought by two threads, and, as the stitch produced by them is known in America as the *mail-bag stitch*, it may be presumed it was employed by the makers of that article before the introduction of the machine. In the usual mechanical arrangement for its production, a vertical needle, having the eye very near the point, is constantly supplied with thread from a bobbin, and is carried by a bar, which is capable of an up-and-down motion. The cloth being placed below the needle, the latter descends, pierces it, and forms below it a small loop, with the thread carried down by its eye. A small shuttle, which has a horizontal motion beneath the cloth, is now caused to pass through this loop, carrying with it its own thread. The needle rises, but the loop is retained by the shuttle-thread. The cloth being next advanced through the space of a stitch, the needle descends again, and a fresh loop is made. This process being repeated along the line of the seam, it results that the upper thread sends down a loop through such needle-hole, and that the lower thread passes through all these loops, and thus secures the work. The first machine for producing this stitch was invented by Walter Hind, of New York, in 1834. Several patents for producing this stitch have been obtained. Howe's patent was one of the most practical. Mr. Thomas of London became the possessor of Howe's patent. This was improved, and a new patent obtained in June 1846, which was modified in December of that year. This machine has been extensively used. This invention, says the patentee, consists in certain novel arrangements of machinery, whereby fabrics of various textures may be sewn together in such a manner as to produce a firm and lasting seam. By this invention a shuttle, when the point of the needle has entered the cloth or other fabric under operation and formed a loop of thread, passes through that loop and leaves a thread on the face of the cloth, by which means the needle, when it is withdrawn from the cloth, instead of drawing back the thread with it, leaves a tightened loop on the opposite side of the cloth to that at which it entered. The fabric then passing forward to the distance of the length of the stitch required, is again pierced with the needle, and a stitch is in like manner produced. A figure of this machine is shown (*fig.* 1760), which will be understood from the following description:—

1. *The needle.* Place the needle in the slide A, with its flat side towards the shuttle, and the grooved side in front. Turn the wheel of the machine round till the line *g*, on the gun-metal slide, is level with the line *g* on the iron check. Place the *eye* of the needle level with the top of the shuttle-box, and screw the needle fast.

2. If the eye is above the box when the marks correspond, the needle is too high; if the eye cannot be seen, the needle is too low.

3. The needle should pass down the centre of the hole in the shuttle-box; but if it does not, it can be made to do so by bending.

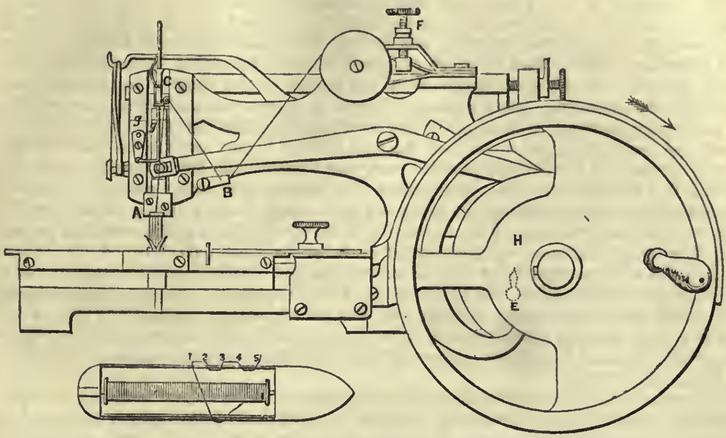
4. *The needle-thread* runs from the top of the reel, through the rings B, C, and through the eye of the needle.

5. *The shuttle.* It is necessary that the first coil of cotton be wound closely on the bobbin, or it will be difficult to make it lie side by side like that on ordinary reels. The reels should not be filled above the brass, and the cotton or silk should be free from knots, which sometimes pull the wire out of the shuttle.

6. The thread must run from the under side of the bobbin, round the wire and out through holes, Nos. 1, 2, and 3. If the thread is not tight enough, miss No. 3 and let it come out through Nos. 4 or 5, or it may be drawn through five holes. Put the shuttle in the box, turn the wheel round once, then pull the end of the needle-

thread and draw up the shuttle-thread through the hole in the plate. Place the cloth under the mover, and the machine is ready for work. The proper time for turning the work to sew a corner, &c., is when the spring at the top is lifted off.

1760



7. The length of stitch is regulated by the screw E at back of machine.

8. The tightness of the needle-thread is regulated by the screw F.

9. The tightness of the shuttle-thread is regulated by passing the thread through more or less holes.

11. The quantity of thread pulled off the reel for each stitch is regulated by the position of the piece of brass B. The lower the hole at its end, the greater the quantity pulled off: when the cloth is thick, more thread is used, and the end of the brass B should be lowered; when thin, raised. It should be in such a position that the trumpet C is drawn nearly down to the pin on the slide when the shuttle passes through the loop.

A patent was obtained by John Thomas Jones, of Glasgow, in February 1859, for a sewing machine presenting many novelties and improvements. Mr. Jones's patent well explains his machine; we therefore transfer his description to our pages.

The machine consists, under one modification, of an open frame, having a platform top upon which the sewing or stitching operations are carried on. Beneath this platform, and near one end of it, is a short transverse horizontal first-motion shaft running in bearings in the framing, and carrying a long crank, a connecting rod from which is jointed at its opposite end, directly the shuttle-driver or slide-piece, working in a horizontal guide recess beneath the opposite or front end of the platform or table. The first-motion shaft has also another and shorter crank upon it, the stud-pin of which is connected to the pin of the longer crank by an overhanging link piece, provision being made for the adjustment of the relative positions of the two cranks as regards their sequence of revolution. It is this shorter crank which actuates the needle movement, the pin being entered into a differentially slotted or operated cam piece, forming the pendent lower end of a bent lever, working on a stud-centre, in the interior of the overhead bracket or pillar arm of the framing. The centre on which this lever works is in the horizontal part of the overhead bracket arm, and its opposite or free-working end has a rectangular slot in it to embrace a rectangular block of metal working freely upon a lateral centre-stud upon the vertical needle-carrying bar. In this way the needle has imparted to it a differential reciprocatory vertical movement, the peculiar connection of the needle bar with the actuating lever having the effect of marking the needle in the most accurate manner, and preventing jarring and wear. These are the whole of the primary movements for working the stitches, which may be of various kinds, as made up from the combined action of the needle and shuttle, or thread-carrier; the form of the slotted piece or operated cam in the end of the needle lever, being variable to suit any required peculiarity of needle movement, the main elements of which are a direct up-and-down motion without a stop or rest, until at the termination of the down stroke, when a short rise takes place, succeeded by a rest to allow of the due looping and stitching of the thread. The feed of the fabric to be sewed is effected by the operation of a short vertical lever piece with a cranked and slotted lower end, where it is set on a fixed stud in the framing. This feed-lever has a roughened or toothed upper end, the teeth or asperities being set or inclined in the direction of the fabric's traverse. After each stitching action, the feed-lever being lowered just beneath the operating level, is raised up so as to press firmly against the under side of the fabric, and nip it between the stationary spring pressed above. This elevation of the roughened face is effected by the traverse of the shuttle-carrier, which at its back stroke comes against the inclined tail of a short horizontal lever set on a stud in the framing, and having its opposite bent end bearing against the lower end of the feed lever, at the part where it is carried by its slot upon the holding stud. At the commencement of the return of the shuttle, an inclined piece upon the shuttle-carrier bears against a lateral stud upon one end of a short rocking or oscillatory shaft set in bearings in the framing, the other end of the shaft having a lever arm bearing against the side of the feed-lever. In this way the feed-lever is traversed forward in its elevated position, carrying forward the fabric for the succeeding stitch. The adjustment of the spring presser is effected by an upper screw in the end of the bracket arm of the framing, the lower end of the screw bearing upon a lateral pressing piece which rests or abuts on the top end of a flattened helical spring upon the presser bar. The latter can be set up clear out of work by means of a small cam lever set on a stud in the stationary guide of the presser bar, the cam bearing against a lateral stud in the bar, so that by setting the lever up or down, the cam is correspondingly turned, and the lever set up or down, as required. The actual pressing or resisting foot of the bar is a bent piece of metal screwed on to the bar, and being thus removable to allow of various forms of feet guides, or presser surface pieces, being put on to suit varieties of forms of stitching.

This machine, or a modification of it, is available for working a duplex, or other stitching action without involving further modification of the prime movers. In working a duplex arrangement, two needles and two shuttles are used, each needle and shuttle working independently, so as to allow of sewing in two different and independent lines with one set of actuating parts. To aid the shuttle action there is attached to its side a flat curved blade spring, one end of which is free, but hooked into a hole in the body of the shuttle. Thus, as the shuttle traverses forward, the sewing thread is drawn beneath the hooked end portion of the spring, so as to be nipped against the shuttle. The thread is thus held, and the proper loop is secured at the part immediately outside the nipped portion. With this arrangement the needle can never work on the wrong side of the shuttle-thread. Provision is also made for securing an independent shuttle-thread controller. This is a nipper or retainer worked from any convenient part of the mechanism, but entirely independent of the shuttle movement. This may be arranged in various ways, the object being the variable and efficient control or retention of the thread, without interfering in any way with the fixed and determined action of the shuttle. Instead of fixing a horizontal shuttle race ,or guide track, in the framing, the shuttle-driver is itself made the race or carrier, so as to secure both offices in one detail or arrangement. A hook or finger, actuated by any convenient part of the movement, is also used for retaining the needle thread for any desired time after being passed through the fabric; this facilitates the movement or action of the needle bar. The shuttle race, when one is used, is made quite independent of the machine, so that it can be changed at any time to suit various-sized shuttles by merely slipping in or taking out the part. The portion of the framing carrying the shuttle race is cast in one piece with the main body of the platform, but the table or plate on which the stitching takes place is a loose piece slotted down the middle for the working movements, and fitted into its position by pins cast upon it, and entered into corresponding recesses in the main base.

There exists a fourth class of sewing machines, which produce more complex stitches than the preceding. These are formed by sewing two threads, which mutually interlace each other in chain-stitch, so as to avoid the unravelling to which the simple chain-stitch is subject, and also are intended to meet an objection which is urged against the shuttle-stitch machines, on the ground that, as the shuttle must be small to enable it to pass through the loop formed by the needle thread, so the bobbin carried by the shuttle can only obtain a moderate length of thread. Thus the operation is stopped at short intervals to supply fresh bobbins to the shuttle. Several patents have been obtained for compound chain-stitch machines: two in America, in 1851 and 1852, by Grover and Baker; another in 1852 by Avery; and another by M. Journaux Le Blond.

In England, as in France, all the most promising American patents have been repatented, and the use of the machine is rapidly extending itself. The sewing machine has acquired so prominent a position, and shown itself to be so useful, as to deserve the time and attention of able mechanists. It is now made in a considerable variety of forms to suit it to the various purposes to which it is now applied. We find it in almost every large manufactory; and in nearly every family, the hand-sewing machine has its place.

SHADDOCK. The fruit of the *Citrus decumana*, which is much cultivated in the West Indies. It is sold in this country as the 'Forbidden Fruit.'

SHAFT, in *mining*, signifies a perpendicular or slightly-inclined pit. See MINING.

SHAGREEN. (*Chagrin*, Fr.; *Schagrin*, Ger.) The true oriental shagreen is essentially different from all modifications of leather and parchment. It approaches the latter somewhat, indeed, in its nature, since it consists of a dried skin, not combined with any tanning or foreign matter whatever. Its distinguishing characteristic is having the grain or hair side covered over with small rough round specks or granulations.

It is prepared from the skins of horses, wild asses, and camels; of strips cut along the chine, from the neck towards the tail, apparently because this stronger and thicker portion of the skin is best adapted to the operations about to be described. These fillets are to be steeped in water till the epidermis becomes loose, and the hairs easily come away by the roots; after which they are to be stretched upon a board, and dressed with the currier's fleshing-knife. They must be kept continually moist, and extended by cords attached to their edges, with the flesh-side uppermost upon the board. Each strip now resembles a wet bladder, and is to be stretched in an open square wooden frame by means of strings tied to its edges, till it be as smooth and tense as a drum-head. For this purpose it must be moistened and extended from time to time in the frame.

The grain or hair-side of the moist strip of skin must next be sprinkled over with a kind of seed called *Allabuta*, which are to be forced into its surface either by tramping with the feet, or with a simple press, a piece of felt or other thick stuff being laid upon the seeds. The seeds belong probably to the *Chenopodium album*. They are lenticular, hard, of a shining black colour, farinaceous within, about the size of a poppy-seed, and are sometimes used to represent the eyes in wax figures.

The skin is exposed to dry in the shade, with the seeds indented into its surface; after which it is freed from them by shaking it, and beating upon its other side with a stick. The outside will be then horny, and pitted with small hollows corresponding to the shape and number of the seeds.

In order to make the next process intelligible, we must advert to another analogous and well-known operation. When we make impressions in fine-grained dry wood with steel punches or letters of any kind, then plane away the wood till we come to the level of the bottom of these impressions, and afterwards steep the wood in water, the condensed or punched points will swell above the surface, and place the letters in relief. Snuff-boxes have been sometimes marked with prominent figures in this way. Now shagreen is treated in a similar manner.

The strip of skin is stretched in an inclined plane, with its upper edge attached to hooks and its under one loaded with weights, in which position it is thinned off with a proper semi-lunar knife, but not so much as to touch the bottom of the seed-pits or depressions. By maceration in water, the skin is then made to swell, and the pits become prominent over the surface which had been shaved. The swelling is completed by steeping the strips in a warm solution of soda, after which they are cleansed by the action of salt-brine, and then dyed.

In the East the following processes are pursued. Entirely white shagreen is obtained by imbuing the skin with a solution of alum, covering it with the dough made with Turkey wheat, and after a time washing this away with a solution of alum. The strips are now rubbed with grease or suet, to diminish their rigidity, then worked carefully in hot water, curried with a blunt knife, and afterwards dried. They are dyed red with decoction of cochineal or kermes, and green with fine copper-filings and sal-ammoniac, the solution of this salt being first applied, then the filings being strewed upon the skin, which must be rolled up and loaded with weights for some time; blue is given with indigo, quicklime, soda, and honey; and black, with galls and copperas.

Shagreen is also prepared from the skin of the shark.

SHALES AND MINERAL OILS. *Shale*, according to old writers on petrology, signifies any rock, no matter of what mineral composition, splitting into thin laminæ, and found in what they termed the secondary and tertiary formations. *Schist* was the distinguishing appellative of such rocks splitting up in thin layers, found in the primitive formations of the same authors. The characteristic features of the individual rock were usually prefixed. Thus such terms as mica-schist, talc-schist, alum-shale, argillo-bituminous shale, &c., originated. But though they are still retained, a wider stratigraphical knowledge has made the two terms synonymous. Macculloch, in his 'Classification of Rocks,' has shown that a shale may leave the fissile state to pass in the same geological section into the botryoïdal, mammillary, and even earthy conditions. There are arenaceous, argillaceous, calcareous, or ferruginous shales, according to the nature of the parent-rock; thus, red hæmatite and the organically-derived Tripoli slate may be both included under the generic term. Use in manufactures has given names to alum-shales, argillo- or calcareo-bituminous, or, better still, oil-shales.

Like petroleum, oil-shales are found in all geological formations, and they appear to accompany both it and limestone geognostically. Wherever fossils indicate conditions of quiet subsidence, and estuary or lake formation, the observer has come on a locality, *primâ facie*, good for the occurrence of either oil-shales or petroleum. Such conditions in geography appear to have alternated with those of a sudden change to deep-sea life throughout all geological time. The Scottish carboniferous system appears to have been formed under very favourable circumstances for the production of oil-producing materials. The Mountain Limestone, instead of attaining the magnificent proportions of Derbyshire or Northumberland, is represented usually by six thin beds of a few feet thick. The reader, casting his eye on a geological map of midland Scotland, will mark how comparatively small a space is occupied by the coal-fields proper; that they are, in fact, surrounded by a large area of beds marked off in the books as the subcarboniferous or estuarine Burdiehouse-limestone formation. This, the area proper of the shales, extends through the counties of Fife, Edinburgh, Linlithgow, Lanark, Renfrew, and Ayr. But the true coal-formation also abounds in oil-producing material. Very intimately associated with each individual coal-bed, the occurrence of shale above it, and blackband ironstone below it, also an oil-yielder, may possibly indicate a different mode of formation from that of the Newcastle field. The rich cannels found throughout the Scotch coal-fields proper belong to the category of shales rather than coals.

During the years immediately succeeding the expiry of James Young's patent, oil-works were erected over the area of the Scottish coal-field. But since the continued depression of this new industry caused by the large importation of American petroleum, many small works have been dismantled; and the trade is now principally in the hands of a few large companies, who carry on their operations near West Calder and Broxburn, in the immediate neighbourhood of Edinburgh, and in the vicinity of Paisley. The amount of material used is still very great. The Addiewell works are alone capable of utilising 1,000 tons of shale weekly. So much as 782,000 tons of shale have been consumed annually; resulting in the manufacture of about 10,000,000 gallons of burning-oil, 5,000 tons of paraffin, and about 600 tons of sulphate of ammonia.

The Torbanehill mineral, the substance on which Young worked his patent, is now exhausted. But the high price given for it by foreign gas-companies, as well as the demand from the same quarters for the ordinary cannels, and for the bastard cannel, technically termed 'rums,' which abound throughout the Scotch coal-fields, have placed all these substances out of the reach of the oil-maker. The shales of the lower fresh-water series were waste products before the advent of this new industry; but from their special chemical nature, they yield an oil more easily brought to the white standard in colour of American petroleum than the substances first employed in the manufacture of crude oil.

The probable organic origin of a shale or cannel.—The Kimmeridge shale yielded an oil which could not be deodorised. So though a newly-discovered Brora shale yields as much as 57 gallons to the ton, it may probably be used only for the purposes of patent fuel, owing to the phosphorus it contains, derived from the animals whose remains are in part chemically represented by its oleaginous contents. So also of abundant flagstone bituminous beds of the Old Red Sandstone of Orkney and the North of Scotland. The same difficulty has been experienced with the Canadian petroleum; though it is said that in this special material the art of the refiner has overcome the disagreeable odour.

The close proximity of coal and shale, often found in one section, is of great importance in diminishing the working expenses of a shale oil-work. In Scotland, oil-makers generally also mine their raw products.

What is a Coal?—A strict chemical definition of coal or its allies has as yet been attempted in vain. Use has hitherto ruled the distinguishing nomenclature of coals. From the anthracite to the cannel, a clear gradation may be traced. But here we reach a once much contested border-land, where the true cannel graduates into the shale. The advocates of separation of the celebrated Torbanehill mineral from the class of cannel coals mainly contested that, unlike these bodies, after the oil or gas had been taken from them, it left no useful coke containing an appreciable percentage of fixed carbon; its sole residuum is a useless mass of clay. The superior character of the American petroleum, as well as the high prices ruling for gas material, have caused cannels, lignite, peat, as well as many caking coals, to be disregarded as oil-producing materials. At the same time, the technologist should note the physical and chemical capabilities of such bodies for producing oils for other than domestic uses. Dr. Eveleigh has proposed to manufacture gas from oil distilled first from ordinary coal by a special apparatus. Messrs. Odling and Keats, in reporting on this process for the Patent Gas Company, state that in their experiments, silkstone coal gave 16·4 gallons of tar and oil per ton; Clay cross main, 11·9 gallons; and Pelaw main, 13·9 gallons: or a mean of 14 gallons. They obtained from one ton of coal 9,500 cubic feet of 23-candle gas, and from 14 gallons of oil the produce of this 600 cubic feet of 25-candle gas. Though the American oil-wells may be said to have shut up the peat-works of the Continent, lignite is distilled there often specially for the extraction of paraffin.

A natural transition from petroleum to shale is exhibited, for instance, in the extensive gum-beds near Hamilton, Canada West. The viscous asphaltum may be only the fluid native naphtha changed by atmospheric oxidation; and, at least, some beds of anthracite may be only farther steps in the same series of changes. Attempts to extract their proximate constituents from these bodies by solvents have been as fruitless as those made on coals. Indeed, the recent experiments of Berthollet appear to show that the various hydrocarbons of coal-tar, and probably those also in crude shale oil, do not exist individually in the materials whence those bodies are extracted, but depend on different temperatures applied in distillation. By synthesis, Berthollet obtained benzine from acetylene; ethylene from acetylene and hydrogen; styrolene from ethylene and benzine; and naphthaline from ethylene and styrolene. Inversely, by the application of a red heat on toluene, xylene, and cumene, they were decomposed into hydrogen, formene, acetylene, ethylene, benzine, toluene, xylene, cumene, styrolene, naphthaline, anthracene, and chrysene. The gas-maker notes a strange individuality in the yield of special materials. The Newcastle coal-tar abounds in naphthaline; the Wigan cannel is specially rich in benzine and carbolic acid. So the oil-maker prefers crude tar from the lower carboniferous shales; specially, because they give a white odourless burning-oil; though other crude oils are cheaper, yield more paraffin, or may better suit applications to patent fuel, metallurgy, or gas-making. Probably more accurate knowledge of the different effects of heating in this manufacture may enable the oil-maker to extract equally good tar from any oil-yielding material; and likewise to obtain in gas-making from shales all the peculiar products of cannel coals.

Oil-shales, like cannel coals, have a yellow-brownish streak; are easily cut with a knife; and often exhibit a subconchoïdal fracture. The 'curley' bands have a black glossy external appearance; and are curiously bent into a series of corrugated foldings. They yield most oil; and are usually mixed with thick seams of poorly oleaginous shales. In some parts of Linlithgowshire, these shales are changed into a kind of black chalk; apparently in consequence of the trap rocks.

What are Mineral Oils?—To understand mineral oil-making, it is necessary to consult some good table of temperatures, such as Pouillet's.

The black heat or low-red heat of oil-making ranges betwixt 500° and 900° F., while the full cherry-red or dark-yellow red heats, so necessary in coal-gas manufacture, exceed 1000°. Shale-tar floats on the surface of water; whereas, coal-tar being of a higher density, sinks in it. Crude mineral-oil may be as high as 940° in sp. gr; but the shale-tar preferred for oil-making usually ranges from 840° sp. gr. to 890° sp. gr.

Crude-oil is really a series of oils held together by links destroyed in distillation. But the separate oils may be variously utilised, in accordance with their several physical and chemical properties. Yet, as they all are hydrocarbons, they cannot take the place of oxygenated oils of animal or vegetable origin used by painters or soap-makers. Mineral turpentine, the only apparent exception, is used by varnish-makers, not from its drying properties, but from its speedily evaporating altogether out of the paint-solution in which it was mixed.

Mineral oils in lamps.—They were first introduced as illuminants along with the now familiar German lamp; and they have largely displaced lamps using other vegetable or animal oils from their greater convenience, and from the superior brilliancy and cheapness of the light given. Olefiant gas mainly is thus given in the remotest hamlet, under circumstances of the easiest management. From the vaporisable nature of the oil, a lamp is supplied surpassing most previous similar contrivances in photogenic power. Continued application of ingenious minds has reduced the glass nuisance to a minimum, whilst it is now the fault of the purchaser should he employ a dangerous oil. Dr. Frankland gives the following results of experiments of the quantities of different bodies necessary to give the same amount of light, disregarding luminosity:—

Young's paraffin oil	4·53 litres.
American petroleum, No. 1	5·70 ,,
,, ,, No. 2	5·88 ,,
Paraffin candles	8·42 kilos.
Spermaceti candles	10·37 ,,
Wax ,,	11·95 ,,
Stearine ,,	12·50 ,,
Tallow ,,	16·30 ,,

Dr. Macadam ['Royal Scottish Society of Arts,' vol. viii. 1871] compared the photogenic power of mineral oil with its animal and vegetable rivals with the following results:—

	Time of burning	Candle-power	Cost
	hours		d.
Halfpenny dip or tallow candle	3	1¼	½
Three-farthing ,, ,,	4½	1¼	¾
Penny ,, ,,	6	1¼	1
Composite candle (average)	5½	1·1	1
Paraffin candle (average)	4·27	1·49	1
Common flat-wick lamps:			
Sperm oil	3·59	1·306	1
Rape ,,	6·84	1·05	1
Whale ,,	9·5	·9	1
Argand lamps:			
Sperm oil	·69	13	1
Rape ,,	1·25	11·33	1
Whale ,,	1·57	9·8	1

In a cottage-lamp, paraffin-oil at 2*s.* per gallon burned for 9 hours with a luminosity of 6-candle power for a 1*d.*, and in a parlour-lamp this oil burned for 6 hours, giving 9-candle power for the same price; while it burned the same money value in the dining-room lamp in 4½ hours giving 12-candle power.

In setting it against coal-gas, Dr. Macadam assumes the high candle-power given by Scotch gas companies, and he takes a moderate price which is not now likely to prevail. Assuming gas to sell at 5*s.* per 1,000 cubic feet, and to have a luminosity of 28 candles, he finds gas cheaper than paraffin oil, if consumed at No. 3 jet; but should gas cost 5*s.* 8*d.* per 1,000 cubic feet, the two illuminating agents are equal. When this high candle-power of gas is withdrawn they are also equivalent in price and luminosity. Paraffin oil is as cheap as gas when the latter is consumed at No. 3 jet, and its cost is 5*s.* per 1,000 cubic feet; while its luminosity is 24·70-candle power; or at No. 4 jet when the same-priced gas is of 21·53-candle power; or at No. 5 jet when it is only 20-candle power.

Silber proposes to burn oils in rooms from permanent pendants, just as we do gas; and with special contrivances for the purpose has attained very marked results. ['Journal of the Society of Arts,' vol. xix. p. 88.] Using petroleum of sp. gr. 795 he obtained an illuminating power perhaps 20 per cent. greater than the London coal-gas, which is given to the consumer at from 12 to 15 candles; though with gas at 3*s.* 9*d.* per 1,000 cubic feet the cost of petroleum was 10 to 20 per cent. greater than the gas. But by an alteration in the argand the illuminating power was increased from 40 to 50 per cent. more than at first. So though colza lamp costs five times as much as the gas; Valentin's experiments gave with Silber's lamp a light equivalent to a saving of 500 per cent. Mr. Silber is now adapting his lamp to use the heavier and safer mineral oils. See Silber Light.

Use of mineral oils in gas-making.—It has been proposed to use mineral oils in gas-making either by naphthalising the poor gas made from ordinary coal, or by the conversion of the rich, oily hydrocarbons into permanent gas.

1. Beautiful results have been obtained by passing the gas through oils, whether of heavier or lighter specific gravity. The objections of smell, and the tendency of oil to return to its original state, have militated against the extensive use of this method in domestic circles. It appears generally necessary that the carburetter be as close as

possible to the gas-jet. A modified carburetter has been successfully employed close to the burner on the Edinburgh street lamps.

2. The conversion of oil into a permanent gas long baffled inventors. The fact, too, that when oil was so decomposed it usually deposited much of its carbon as coke on the sides of the retort, was a standing difficulty. Many modifications of water-gas, to be introduced so as again to take up this carbon, and also to supply cheaply an additional volume of gas, were usually proposed. The patent records contain many fruitless schemes; but Messrs. Keats and Odling report that by Dr. Eveleigh's process, worked out by the Patent Gas Company, a permanent gas has been formed singularly free from impurities, and of 25-candle lighting power. The present position of gaswork economics do not, according to these gentlemen, warrant the hope that the process will be extensively used in large cities, but it may be available in the country and abroad.

The rising value of cannel coals has induced gas-makers to inquire whether mineral oils might be used as sources of auxiliary supply in ordinary gas retorts, whether admitted *per se*, or made into a patent-fuel composition. Mr. Cussiter, of Dalkeith, when introducing oil alone into a retort, obtained in one experiment 15,904 cubic feet, and in another 18,600 cubic feet, with respective illuminating powers of 38·5 and 23·55 candles. The illuminating power in another experiment was only 12 candles, but the yield increased to 28,300 cubic feet. When 30 gallons—or 284 lbs.—of oil were mixed with splint coal in a clay retort, the yield was increased from 10,000 to 12,500 cubic feet, and the illuminating power from 14 candles to 25·89 candles. When 42 gallons of oil were used with 1 ton of coal, 13,140 cubic feet of 28·59-candle gas were obtained.

As we have already seen, shale is very widely distributed throughout the geological formations; and shale, which is useless for oil-making from poorness of yield and probable organic origin, may be used for gas-making. Specially should the gaswork be planted where the shale is mined, and the manufacture led in by pipes to the town where it is to be used. During the winter of 1872 many Scotch gas companies used ordinary oil-shale brought into their works from a distance.

Paraffin and petroleum residues have been utilised in small gasworks supplying railway-stations or private residences in Germany. The stuff is pumped up by clock-work into a retort capable of making 200 cubic feet of gas in an hour, which contains only 0·69 per cent. of impurities in the hundred parts. The gas consists chiefly of acetylene; and it is burned from jets consuming per hour from a ¼ of a cubic foot to 2 cubic feet; but 200 cubic feet of this gas equal 1,000 cubic feet of coal-gas. Convenience rather than cost of material instigates the erection of such works.

Petroleum has been successfully employed in small towns and villages of Canada and the United States for gas-making. The method usually adopted is to mix its vapours with that of water passing over red-hot charcoal or iron. Youle, Hind, and Thomson found 10 cubic meters of the gas equal in intensity and cheapness to 40 cubic meters of coal-gas. Besides, the manufacture consumes much less time. See NAPHTHA.

Mineral oils as liquid fuel.—The proposal to use such oils for raising steam excited great interest when first proposed. Many contrivances were patented and experiments undertaken, though without the happy issue anticipated. The following *résumé* of our knowledge on this subject is mainly derived from the evidence of Dr. B. Paul given before the Royal Commission on Coal Supply.

The materials which have been suggested as fuel are: Petroleum in a crude state, with a specific gravity from 800° to 860°; crude paraffin oil of sp. gr. 860° to 900°; heavy oils, the waste products from the distillery known as 'bottoms,' 'foots,' &c.; dead oil, or creasote of coal-tar distiller, sp. gr. 1050°. All these substances are much more highly inflammable than coal. Crude petroleum and paraffin-oil stand at the top of the list in this respect; dead oil at the foot.

	Weight of 1 cubic foot	Volume of 1 ton
	lbs.	cubic feet
Crude petroleum	from 49·8 to 53·5	44·97 to 41·86
Crude paraffin-oil	53·5	41·86
Heavy oil from either	56·0	40·00
Coal	from 52·0 to 60·0	43·07 37·33

The next table shows the calorific power and evaporative efficacy of liquid fuel as compared with coal.

For 1 pound of	Total quantity of heat generated	Quantity of heat available for producing steam	Quantity of water heated from 60° to 212° F., and converted into steam at 212° F.	Temperature of flue or flame
	heat units	heat units	lbs.	°
Crude petroleum . .	20,000	16,847[1]	15	4646
Crude mineral oil .	20,000	16,847[1]	15	4646
Heavy oil from either .	20,000	16,847[1]	15	4646
Dead oil or creasote .	16,628	14,567[1]	13	4495
Coal . . .	from 13,890 to 14,833	10,000[2] 10,817	8·95 9·67[3]	2500

Thus oils may effect a saving of from 35 to 40 per cent. of the space occupied by a coal of equal steam-producing power. Not only would more space be available for cargo, but also fewer hands would be required. And in war-ships, steam would be more quickly raised; they could sail without smoke, and could keep to sea for a longer time. But against this, most of the oils proposed to be employed give off vapours even in the cold; and these, when mixed in certain proportions with the atmosphere are violently explosive. Then relative price must always be a great stumbling-block in the introduction of this new agency; when coal rises to 5*l.* or 6*l.* per ton the average prices of crude mineral oil or petroleum, the question will be a practicable one. Improvements in retorts, cheapening the cost of crude mineral oil, will also obviate this difficulty. [See PARAFFIN.] Creasote, estimated as worth 22*s.* per ton, has been advantageously used as a liquid fuel.

To use liquid fuel effectively, perfect combustion immediately under the steam-boiler must be obtained, so that smoke is prevented and the full heat or evaporative capacity of the fuel realised. The best coal-oils rarely contain more than 30 per cent. of volatile matter; but in those most suitable for steam fuel the quantity is very much less.

Richardson's method of applying liquid fuel was tested at the Woolwich Dockyard on July 6, 1866, under the supervision of Mr. Lloyd, engineer-in-chief of the Navy. The *rationale* of this plan is to employ steam-jets with the application of liquid fuel below the steam-boiler. In these trials much smoke was produced, and the tubes of the boiler rendered very foul by deposition of soot in them. The average results gave an evaporation of 13·2 lbs. of water per 1 lb. of oil consumed; the variations ranged from 7·14 lbs. to 18·38 lbs. of water; treated from 100° to 212° F.; and converted into steam at 212° F. In the most successful trials the evaporation was very low. Now average results have been obtained with coal of an evaporation of 8 lbs. of water to 1 lb. of the fuel, and much higher figures are not exceptional.

In Field's improved method, the oil flowing from a reservoir is projected into the heating furnace below the boiler along with a jet of high-pressure steam, introduced in the form of spray. As many as 19 lbs. of evaporative power have been quoted as the fruit of this patent, but 13 to 16 lbs. of water evaporated per lb. of oil consumed, are likelier figures.

By Dorsett's patent the oil is first vaporised before entering the heating furnace;

[1] It is assumed that these oils are burned with only just enough of air for the purposes of combustion, and that the furnace-gas is discharged at 600° F.

[2] The coal is burnt as usual, with twice the air necessary for combustion.

[3] The evaporative duty given in the above and subsequent table is probably higher than that actually obtained on an average in steam-vessels to the extent of 20 per cent.; the actual duty obtained being usually seven pounds of water converted into steam per lb. of coal.

The following table exhibits the relative efficacy of liquid fuel and coal as steam fuel, in relation to the space they occupy respectively:—

1 cubic foot of	Quantity of water heated from 60° to 212° F., and converted into steam at 212° F.	Relative steam producing capability of a given bulk of fuel	
	cubic feet		
Crude petroleum evaporated . .	from 11·95 to 12·85	1·53	·91
Crude mineral oil	„ 12·84 „ 13·44	1·63	·96
Heavy oil from either	„ 12·84 „ 13·44	1·63	·96
Dead oil from creasote . . .	about 13·60	1·68	1·00
Coal as stowed in bunkers . . .	from 7·48 to 8·64	1·00	·59

and while it is being burned under the boiler, the elastic force of heated vapour is made to produce a blast of air so as to ensure perfect combustion. This was first applied in a coal-tar distillery. The time for running a charge of tar through the stills was thus reduced from 24 to 12 hours. And the stills so fired do not require so frequent repairs as those worked with coal. Indeed, such applications of heavy oil appear to be very economical. In Mr. Miller's Works, Rumford Street, Glasgow, a ton of dead oil, valued at 1*d.* or 2*d.* per gallon, appears to do the work of $1\frac{1}{2}$ ton of coal at least.

In certain metallurgic operations at Woolwich, about 8 cwts. of liquid fuel were found equal in value to a ton of coal. One-fourth or one-fifth of the time occupied in heating with coal was saved, and a smaller number of furnaces were required. In heating a half-inch plate, 4 or 5 minutes served with liquid fuel in opposition to 15 or 20 minutes with coal. While a four-inch armour-plate took 3 hours in heating with coal, a very much better article was completed in 38 minutes with liquid fuel.

The different Mineral Oils.—The nomenclature of mineral oils is very obscure. It has partly originated from scientific discoverers; partly from tar-distillers who have been struck by the similarity of the educts from retorts or stills to those with which they have been familiar; and partly from the trade-marks of merchants. Eupion, photogen, kerosene, Cambrian oil, shale oil, Boghead naphtha, shale-naphtha or oil, paraffin oil, coal oil, are all synonymous for the article used in the German lamp. Then, again, all oils too high in sp. gr. to be used in such lamps were ranked as lubricating. But recent improvements in lamps for burning these heavy oils have caused the intermediate oils, betwixt 830° and 880°, to be sub-classed as lamp oils, lighthouse oils, railway-carriage oils, according to their several specific gravities. Blue oils or green oils are the refiner's terms for certain of his intermediate products which used to be in demand by grease-makers or printing-ink manufacturers. He describes other bye-products, as soda-tar and acid-tar; but we are in ignorance as to the true chemical nature of these bodies. Hard and soft paraffin correctly enough describe the solids sold respectively to the candle- or the lucifer-match-maker. 'Foots,' 'bottoms,' or such like names, have been borrowed from the tar-distiller to signify the refuse products of the stills. 'Scales' expressively denotes the paraffin pressed from the blue oil, to be subsequently refined. 'Naphtha' incorrectly designates the first product of the distillation of coal- or shale-tar, as the aniline-maker cannot find in the latter benzol, the foundation of his specialty. 'Coke,' however, truly describes a valuable bye-product obtainable at several stages of mineral-oil refining.

The prefix 'paraffin,' either to the lamp-oil or to mineral machinery-oil, is a misnomer, as there is none of that substance in either of these bodies. The proximate constituents of petroleum are the paraffin series; but mineral oils only contain $\frac{1}{6}$th or $\frac{1}{5}$th of these, their chief constituents being the olefiant-gas series.

Shale-tar, a local designation for crude oil, is correct enough when limited to the products of destructive distillation by a low red-heat, of sp. gr. 840° upwards. But a tar sinking in water might be obtained by the application of a bright cherry-red heat in distilling shale; and the converse is true of coal. The following scheme expresses to the eye the order of production of the various products:—

Yield from distillation of Crude Oil obtained from Coal or Shale, or from Petroleum got from natural Springs.

1. Light Oils or Spirits. 2. Burning Oils. 3. Heavy Oils.	Treated with acids and alkalis yield	Rectified Spirits or Benzine. 1. Burning Oil. 2. Acid Tar Residues. 3. Soda Tar Residues.
Heavy Oils rectified, besides yielding 2 and 3 residues.	1. Crude Paraffin. 2. Blue Oil.	1. Refined Paraffin. 2. Machinery Oil.

Residues may be used for greases, gas-making, patent fuels, &c. Gases may be used for heating.

Except in the case of the crude oil, which is of a dark greenish, viscous nature, analogous to tar, of the intermediate blue and green oils, which are sufficiently designated by their appellations, all the liquid products are now made as near water-white as possible. A burning oil is reckoned perfect in colour not only when it attains such purity, but when it also has the bluish opalescence so characteristic of refined petroleum. No doubt refiners here pander to a popular prejudice; for in striving after this standard of colour they diminish the burning qualities of their oils.

The merit of the common German lamp, whose introduction rendered these oils capable of domestic use, is in the introduction of so much air as thoroughly to consume the very great amount of carbon disengaged in their combustion. The sp. gr. 830° appears to indicate the highest number, in weight of the oil, capable of being consumed with comfort in such lamps. But inventors, such as Doty and Silber, have striven with some success to utilise the intermediate oils up to 888°, the recognised standard of superior mineral machinery-oil. All such oils possess higher luminosity and safety. The varied lamps for these purposes differ from the one used for common burning oil in admitting more air, so as to counteract the soot caused by the greater amount of carbon disengaged; and in adapting the shape of the lamp and the wicks, so as to cause those heavier oils easily to ascend them. The refiner is content to give all such higher oils a lemon-straw colour. So, in a very general way, it may be said that specific gravity and flash-point are the distinguishing features of the different products of destructive distillation at a low red heat. The relative figures of the hydrometer only may be taken as distinctive approximations of these different oils.

	Specific gravity	Flash-point
	°	° Fahr.
Crude oil	860 to 890	75
Mineral spirit . . .	740 „ 800	68 to 75

Lubricating	888 to 890	320

Lubricating Oils.—Dr. Wallace reports that in nine experiments on lubricating oils there was a varying specific gravity from 881° to 900°; and the flash-points ran from 293° to 388° Fahr. In seven experiments the flash-point was over 300° Fahr. As with the lighter oils, specific gravity is no *à priori* test of safety. The highest specific gravity amongst the samples 900° had the comparatively low flash-point 309°: another sample 20° in sp. gr. below this was only minus 1° Fahr. in flash-point; whilst another sample, 10° in sp. gr., below the first was 19° Fahr. in flash-point above it. The following are the specific gravities and flash-points of some well-known fatty oils:—

	S. G.	F.-P.
	°	° Fahr.
Whale oil (best)	923	492
Cloth oil (wool oil)	917	320
Olive oil	917	420
„ (genuine)	920	500
Rapeseed oil	913	440
Lard oil	914	560
Tallow oil	915	490

Mr. Gellatley's experiments on cotton-waste steeped in various oils ('British Association Report, 1872') appear to show that where a liability to high heats exists in using machines, mineral oils are safer than the older ones. Manufacturers are painfully aware of the liability to spontaneous ignition of cotton-waste which has been soaked with such a rapid oxidiser as linseed oil. Again, at a particular stage of calico-printing with Turkey-red, the batch is saturated with olive oil; and it cannot be allowed to lie for more than an hour without danger of spontaneous ignition.

For a discussion of the firing-points of burning oils, and their relative dangers, see Naphtha.

Preparation of Crude Oil.—When beginning the manufacture near Bathgate, Mr. Young used Torbanehill mineral as his raw material, though he was previously aware that any cannel would equally have served his purpose. But by the competition of gas-makers they have withdrawn all such bituminous substances from the oil-maker's market (see Paraffin); and even shale is now subject to a similar rival element. Shale is distilled in either horizontal or vertical retorts of cast iron. The charge of the horizontal retort is made in either the twelve or twenty-four hours, and varies from 6 to 12 cwts. Vertical retorts hold about a ton of shale, but are continuous; the charge is fed through a hopper at the top, and drawn out at the foot when exhausted, above a tray filled with water. Machinery has been introduced in some Scotch works for filling and discharging the retorts. With horizontal retorts it is not requisite to break the shale into small pieces the size of a hen's egg as specified by Young. A Carr's stone-breaker usually effects this for the vertical retorts. Scotch makers reckon steam as an indispensable adjunct in the distillation of crude oils. Experience has proved Torbanehill mineral to give 120 gallons per ton with steam; and only 90 gallons without it. Shale yields 40 gallons with steam, and 30 gallons without it. The difference in yield of finished products is 75 to 76 per cent. of the two crude oils respectively manufactured. In vertical crude the proportion of mineral spirits and burning oil is less than in horizontal, but 3 per cent. more paraffin is obtained.

Purification of the Crude Oil.—The crude oil issues as vapour into the condensers; it pours out at their extremity, as a mixed liquid of oil and water, into the separator. This is a wooden cylinder, 4 feet high and 3 feet broad. Through this barrel an iron syphon passes; this emerges at the side, a few inches from the top, and terminates about 8 inches from the bottom. The ammonia-water soon sinks under the crude oil, with which it is mixed on entering, by its higher specific gravity; whence it is drawn off by the above syphon. Almost at the top of the separator is another aperture, to serve as an educt for the crude oil.

The ammonia-water is next converted by the usual manufacturing methods of stills and evaporating-pans, into sulphate of ammonia. Some shales yield 8 to 10 lbs. of the sulphate per ton, whilst others give as much as 16 lbs. to the ton.

The crude oil is now transferred to the refinery by one of the series of underground pipes, in connection with the centrifugal pump worked by steam which now forms so integral a part in the economy of the establishment. The oil refinery, with tanks in which centrifugal revolving-stirrers, often only 2 feet in diameter, move by steam in iron vessels 10 feet in diameter, and agitate the oil with either sulphuric acid or soda. About 200 revolutions are made in a minute, and so a quarter-of-an-hour's agitation of the oil serves, instead of the night's work of early refining. There are also settling tanks, and a series of iron-pipes, which connects the oil with the stills outside, introduces the vitriol and soda used in purifying, or removes the vitriol and soda tars from the treated oils; all are subordinated to the main steam-pump. Indeed, throughout the varied processes the steam-engine as much as possible supplants mere manual toil; intelligent superintendence being only required from the few artizans on the establishment. The paraffin-house is usually distinct from the oil-refinery; it may contain only presses for making 'scales,' or the varied apparatus for the manufacture of refined paraffin. In either case, if the establishment is large it is associated with cooling-drums and an ice-machine, all of which, along with the presses, are worked by steam-power. In many large refineries the mineral spirits are refined in a separate building in connection with the paraffin-house. This is for greater safety from fire, which is sedulously guarded against by the adoption of iron doors, roofing, prohibition of smoking, use of covered lights, and such like appliances, throughout the entire establishment.

The following is a diagrammatic sketch of the various distillations of crude oil in its manufacture into burning oil:—

CRUDE OIL FROM SEPARATOR.

FIRST DISTILLATION.

Once-run oil.	*Coke in Bottom of Still.*
20° lower in sp. gr. than crude.	7 per cent. of oil converted into this, used as fuel, or drawn off as tar for patent fuel.
First Washing.	*Second Washing.*
5 per cent. brown vitriol, sp. gr. 1·745. May stand over a night in tank.	4 per cent. caustic soda, sp. gr. 1·300. Stirred for an hour.

SECOND DISTILLATION.

Third Washing.	*Fourth Washing.*
1 per cent. ordinary commercial vitriol.	2 per cent. caustic soda, sp. gr. 1·300.

THIRD DISTILLATION.

Fifth Washing.	*Sixth Washing.*
½ per cent. ordinary commercial vitriol.	½ per cent. caustic soda, sp. gr. 1·300.

Product.—Ordinary burning oil.

FOURTH DISTILLATION.

Seventh Washing.	*Eighth Washing.*
2 to 3 per cent. commercial vitriol.	With very dilute caustic soda.

This last product, termed *white horse oil*, is sold in competition with the American petroleum.

Cast-iron stills are still preferred by some for the first distillation; but the subsequent ones are usually performed in large malleable iron boilers of about 4,000 gallons capacity.

Refining Mineral Spirits.—Much care is requisite in separating oils which issue from the stills of such varied specific gravities. Were the light mineral spirit, or 'naphtha' of the works, to enter largely into either the burning, or at all into the lubricating oil, then would perish their reputation for safety.

The naphtha is first sent over by steam from the boiler, containing oil in the second stage of distillation. After being treated with ¾ per cent. of sulphuric acid, and neutralised with alkali, it is distilled again, by steam this time, at 13 lbs. to the square inch, and conducted by pipes down the sides of the still filled with naphtha, but playing freely into it through punctures in the pipes covering the bottom. The liquid is now ready for use in the paraffin-house, or for the special purposes to which it has been applied in various arts.

The Separating-house and Pressure-stills.—At Addiewell the contents of all the stills are conducted into a separating-house, containing 15 separators, leading to as many tanks outside. Here a man, by the aid of hydrometers, sends the oils into these varied receptacles, according to their specific gravities. Until lately burning and lubricating oils were the two marketable products, and the question rose, How to utilise the great quantity of intermediates? As a result of elaborate laboratory experiments, the application of pressure to oils was found to diminish their gravity; so pressure-stills have been introduced. A pressure of 15 lbs. on the square inch diminishes the specific gravity 30°. Thus intermediate oils can readily be converted into burning oil. Large malleable iron stills, with pressure-gauges and loaded safety-valves, with likewise a valve at the neck of the still, are employed for this purpose. The pressure on the oil-vapours themselves answers; hence when the still is put in action the valve is turned on at the neck, and the fires beneath well stoked till the pressure required is indicated on the gauge, when the oil-vapours are allowed to flow into the condenser.

Messrs. Henderson and Cooke have been able to dispense, at Oakbank, with the tedious process of settling and its multitudinous tanks, by simply agitating the oil, after it has come from the soda stirring-tank, with ground-glass or fuller's earth. This process is patented.

Preparation of Lubricating Oil and Paraffin.—The blue oils with paraffin scales are separated from the burning oil in the refinery after its treatment succeeding the second distillation, and pumped up into a tank on the roof of the paraffin-refinery. It is then sent through Henderson's cooling-drum, where the scale-paraffin crystallises out from the slobbery liquid. It is now subjected in canvas bags to two hydraulic pressures, whence commercial 'scales' are obtained, and heavy oil containing soft paraffin; this again is separated by ingress into another cooling-drum, where it meets a brine-solution of 22° or 24° Fahr., from Kirk's ice-machine. The soft paraffin is thus thoroughly taken out of its containing-liquid, which is now to be made into lubricating oil. It is subjected to a—

First Washing.	*Second Washing.*
2 per cent. of vitriol. Strength as before.	1 per cent. caustic soda.

DISTILLATION.

Third Washing.	*Fourth Washing.*
3 per cent. of vitriol.	1 per cent caustic soda.

It is then finished, though it is sometimes again distilled.

PREPARATION OF REFINED PARAFFIN FROM SCALE.

First Washing.	*First Cooling in Drum.*
⅓rd per cent. of its volume of hot naphtha.	

FIRST DRESSING.

Second Washing.	*Second Cooling in Drum.*
As before.	

SECOND PRESSING.

Third Washing.	*Third Cooling in Drum.*

THIRD PRESSING.

Tenth. Boiled with bone-black in jacketted steam-bath.

Twelfth. Filtered through Swedish blotting-paper in a steam-jacketted filter, and run into trays.

Thirteenth. It may again be boiled in a jacketted steam-still, so as to expel all odour of mineral spirits.

According to the price of candle wanted, the tenth process may succeed either the first, second, or third pressing.

From the washings which flow from the paraffin when under hydraulic pressure, soft paraffin, much used in lucifer-match-making, and burning oil, or spirits, for re-use in the process, are recovered. The spirits used must not be too light; those having a specific gravity of 745° were once used at Addiewell, but strong electric sparks were emitted from the cooling-drums; and hence there was constant liability to fires. A specific gravity of 765° may be safely used. For a new way of manufacturing this beautiful material, see the article PARAFFIN.

Kirk's Refrigerator, invented to meet Mr. Young's necessities in this manufacture, works on the principle that just as force is exerted air loses heat. By a series of pistons and plungers air is expanded, and then rarefied. During this rarefaction so much heat is extracted that a cold current, sufficient to form ice, is produced. Such machines are made to make 1 to 4 tons in the 24 hours. In the paraffin-refinery a solution of common salt in water receives the cold current; this is more easily manipulated than ice.

Henderson's Cooling-drum (Spec., A.D. 1870, No. 3310) is now preferred to that of Kirk. It is the instrument by which the cold current is applied to the paraffin, either in separating it from the lubricating oil or before bagging.

Most refineries recover the caustic soda from the soda-tar by the usual methods pursued in that manufacture. At Oakbank Works Mr. Henderson has an ingenious plan by which he first separates the vitriol used in washing the oils from the tars, to re-transfer it for use in manufacturing sulphate of ammonia. The now neutral tar is conducted by a pipe, within which is another containing steam, to the still-furnaces, and burned as fuel. It is first projected on a hearth above the ordinary furnaces where it is coked, and then allowed to fall down into the ordinary furnace. Half of the fine oil-stills are thus fired, and all the available tar is thus used up. The stills stand much longer than if they had been heated by ordinary coals. There is thus no just cause why oil-refiners should subject themselves to vexatious actions for river pollution.—A. T.

SHAMOY, or **SCHAMOIS LEATHER.** See LEATHER.

SHANGHAI OIL. A good oil obtained in China from the *Brassica chinensis*. See COLZA.

SHAWL MANUFACTURE. Shawls were originally, and still continue to be woven in the centre of India, from the fine silky wool of the Thibet goat; and the most precious of them still come from Cashmere. The wool is beautifully rich and soft to the touch, and is superior to the finest Continental lamb's-wool. It is also divisible into qualities. The source from which this article of apparel has sprung is well known to be the ancient and beautiful fabric of the valley of Cashmere, where the excellence of the raw material stands unrivalled, although its manufacture has been, and still is, carefully prosecuted in many other parts of the world. The great beauty of the eastern tissue, considering the rudeness of the machinery employed, as compared with that which is now available to the European manufacturer, is a marvel in the eyes of the most experienced.

The following information, which has been communicated (1874) by a well-known London firm, will prove of interest:—

'The importance of the London public sales of India shawls has greatly diminished of late years, owing to the establishment in Umritzir of agencies of the principal Paris shawl-dealers. Shawls are in consequence bought on the spot by these representatives of the Paris firms, and forwarded direct to their principals in Paris, thus escaping the London market. We continue to hold public sales twice a year, as usual; in June and December; but unfortunately, they are now for the reason explained above, shorn of much of their former interest and importance by the direct trading between Paris and the India shawl-districts; these French buyers naturally secure all the more desirable shawls, and those which are left, or passed over, are sent to the London sales. Some few years ago, say during the 15 or 20 years preceding 1862–3, the sales were of considerable magnitude and importance, and used to range in value from 100,000*l.* to 140,000*l.*, every sale: but after 1863, they rapidly declined, and ceased to be held during the Franco-German war; after that epoch we revived the sales, and they continue, but their value now is reduced to from 30,000*l.* to 40,000*l.* a sale, and contain *very few rich shawls*.

'The highest value of *Cashmere* shawls is from 100*l.* to 140*l.* each, *maximum cost*, and of the good ordinary Cashmere 40*l.* to 80*l.* There are no such prices as 10,000 francs for a shawl; such a price may have existed in bygone days, but not of late years. We have in exceptional times (in past years) obtained from 160*l.* to 220*l.*, per shawl for a few long shawls in public sale, but they were shawls of the grandest kind, and such as it would be impossible to obtain now. Furthermore, the competition among the shawl-dealers in Paris, Lyons, Bordeaux, &c., is so great that they work for close profits, and first-class shawls may be bought in Paris or in London for 2,500 to 5,000 francs in Paris; or from 100*l.* to 200*l.* here.

'Fashion is against shawls for the moment, since the introduction of the "costume" dresses, and they are hardly worn; this necessitates severe holding by the wealthy Paris dealers; we estimate the money value of shawls in the hands of the half-dozen leading Paris shawl firms, at the present moment at little, if at all, short, of half a million *sterling*.

'During the Franco-German war, shawls were hurried over to our care by the Paris dealers, for safety, and we received between 300,000*l.* and 400,000*l.* worth in this way. These were safely lodged at the Dock warehouses, and upon the return of peace, were sent back by us to the various owners in Paris; there was no pressure to sell them during all that time, the shawl-dealers being all wealthy men, and among the first merchants in Paris.'

The manufacture of shawls was first begun in this country, at Norwich, by Mr. Barrow and Alderman Watson, in 1784. They copied the Indian style, but the process was very slow, and the result consequently costly. Mr. John Harvey, of Norwich, followed up the enterprise with Piedmont silk warp and fine worsted shoot; but the designs were darned by hand. It was not until 1805 that a shawl was produced entirely by the loom at Norwich. In Paisley and Edinburgh the manufacture was introduced about the same time. At Paisley the manufacture is still continued, especially the manufacture of shawls of the Indian pattern, from real Cashmere wool. In 1802, a manufacture of shawls was commenced in Paris, and this led Jacquard to the invention of his loom (see JACQUARD LOOM), with which now all kinds of shawls are woven. For the mode of manufacture, the respective articles, SILK, TEXTILE FABRICS, and WEAVING will be sufficiently descriptive.

The varieties of shawls produced may be grouped as follow:—

Woven shawls of India, or of Indian style, made in Europe.

Barège shawls, made of wool: an imitation of shawls made in the Pyrenees, by the peasantry of a place so called.

Crape shawls, made of silk, in imitation of the Chinese fabrics.

Grenadines, made of silk of a peculiar twist.

Levantines and Albanians, made of silk and spun silk, to resemble the scarves worn in the Levant and Albania.

Chenille shawls; a novel application of silk, frequently combined with cotton.

Chiné shawls; a printed warp before weaving.

Woollen shawls; ordinary kinds.

Tartan plaids. The manufacture of these appears to be very ancient. In 1570, an ancient Scottish manuscript gives a list of the colours of the plaids worn by the different clans. In 1747, the weaving of this distinctive dress was prohibited by Act of Parliament, and the grey shepherd's mauds were made instead. In 1782, this Act was repealed; but tartans did not become fashionable until the visit of George IV. to Scotland, in 1822; after which, the Stirling fancy plaids began to be made. In 1828, clan-tartan shawls became fashionable, and the Galashiels weavers took up the trade. Paisley commenced to weave these shawls about twenty or thirty years ago, and it has since then extended to many other parts, both at home and in other countries.

SHEARING. See BLEACHING.

SHEATHING OF SHIPS. The process of coppering vessels has been generally adopted in order to protect their bottoms from the injurious effects of insects in hot countries, and to prevent the adherence of barnacles, &c., which greatly impede the progress of the vessels. It has, however, been open to objections, for not only is the prime cost of the material great, but the expense of rolling it into sheets, and the frequent renewal of parts which had been injured during the voyage, make this copper covering a serious item in the expenses attendant upon fitting-out ships.

In order to make the application of copper still more general, Sir Humphry Davy turned his attention to the subject, and endeavoured to devise some method of counteracting the rapid oxidation which takes place on its exposure to the sea-water, as it is rare for the copper-bottom of a ship to last longer than five or six years. Experiment proved to Sir H. Davy that if a portion of zinc were applied to the copper it would by its electrical relations prevent the process of oxidation in the copper. A vessel sheathed with copper and zinc plates was accordingly sent a voyage to a distant part of the world, from whence it returned with its copper perfectly uninjured by the salt water, but in as foul a state as if there had been no sheathing upon the bottom of the vessel. The presence of the zinc had prevented the oxidation of the copper which was necessary to resist the marine deposit. The problem, therefore, still remained to be solved, whether any metallic composition could be found for the sheathing of ships capable of preventing the bottom from fouling, and at the same time resisting the process of oxidation. To the solution of this problem Mr. Muntz, who was a metal-roller at Birmingham, directed his attention, and commenced a series of experiments, which resulted in his taking out a patent in 1832. This invention, slowly, but steadily, attracted the notice of the shipping interest of the country, and it appeared that in 1834, in the port of London, twenty ships were sheathed with metal prepared by Muntz's patent process. The number gradually increased, until in 1843 there were in the same port 257 vessels sheathed with the new composition, and now it is very generally used. The improved metal sheathing is a mixture of copper and zinc, which is cheaper than copper, more easily worked, and lasts longer than the pure metal. In the specification of Mr. Muntz's patent, the nature of his invention is thus described: 'I take that quality of copper known to the trade by the appellation of "best selected copper," and that quality of zinc known in England as "foreign zinc," and melt them together in the usual manner, in any proportions between 50 per cent. of copper to 50 per cent. of zinc, and 63 per cent. of copper to 37 per cent. of zinc, both of which extremes, and all intermediate proportions, will roll at a red heat; but, as too large a proportion of copper increases the difficulty of working the metal, and too large a proportion of zinc renders the metal too hard when cold, and not sufficiently liable to oxidation, I prefer the alloy to consist of about 60 per cent. of copper to 40 per cent. of zinc.' See MUNTZ METAL.

Various unctuous preparations and paints have been introduced for the purpose of coating the sheathing on the bottoms of ships. The secret of all of them is the presence of a metallic oxide which is offensive to both the vegetable and animal organisms.

SHELLS. Hollow projectiles filled with combustible materials. See ARTILLERY.

SHELLS OF MOLLUSCA. Many of these are used for ornamental manufacture. They will be found described under CAMEO.

SHERRY WINE. See WINE.

SHIFT. *A miner's term.* As used in Alston Moor and the Northern mines, a *shift* is the quantity of lead ore contained in six or eight waggons, and amounts to about 240 kibbles of 14 quarts each; each waggon in a six-waggon 'shift' contains 40 such kibbles; while in an eight-waggon 'shift' each waggon contains only 30 kibbles. In collieries a *shift* is the time during which the men work in the pit.

SHINGLING. Condensing the iron bloom by heavy hammers. See IRON.

SHODDY, properly so-called, is the refuse of the willowing and scribbling process in the preparation of mungo and wool, and is sold in large quantities for manure.

SHODEING. *Shodes* (related to the German *schutten*, 'to pour forth') are loose stones; applied to such as are of a mineral character. Shodeing, is tracing those loose stones from the valley in which they may be found up to the mineral lode from which they have possibly at some remote time been removed. In this manner many mineral lodes are discovered.

SIENNA. Clay coloured by the peroxide of iron and manganese. It is known as raw and burnt Sienna, according to the treatment it has received. It is a good artists' colour.

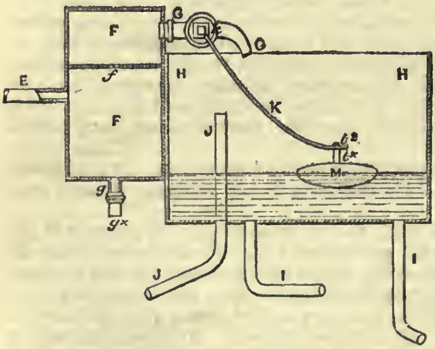
SILBER LIGHT. There is so much that is interesting in the progress of the inquiry, which resulted eventually in the production of the Silber light lamps that, we are pleased, at finding ourselves in a position to give a succinct record of that progress.

The first invention of interest dated from December 20, 1869, and is a method of indicating time at night. The figures of the hours are marked upon a glass globe, which revolves, by means of clockwork, around a stationary index. At night, any ordinary night-light is placed in a little glass tumbler which fits upon a platform, and is enclosed by a chimney, around which the globe revolves, the figures then being illuminated from within.

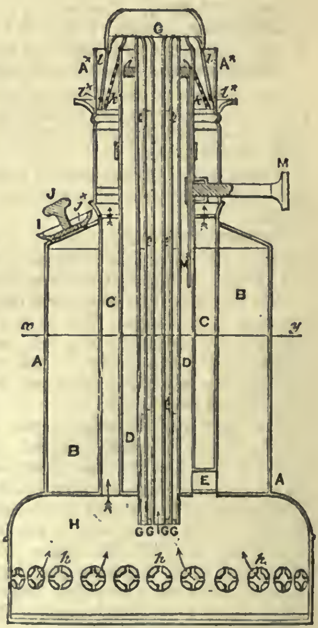
The lamp used for this purpose is constructed upon the moderator principle, but with a burner in which mineral oil may be used with safety. The moderator lamp could be used, but the disadvantages arising from the liability of its pumps and springs to get out of repair, and from the inconvenience of having to wind it up every four or five hours, led to a search for the means of maintaining the oil-supply at a constant level, not only in one burner, but in any number that might be required. In a patent dated May 20, 1870, Mr. Silber devised the following plan:—A ball-cock similar to those used in all water-cisterns, but with a china float, and a new joint which connects it with the elbow, and which, when properly constructed and adjusted, will work as correctly as a clock movement. The china float is not affected by either mineral, vegetable, or animal oil; and it overcomes the difficulty of producing a float which will act as readily on petroleum as on water, notwithstanding the lightness of the former, which is to water as 790 to 1,000. The china float is a circular double convex disc, pierced with a hole in the centre. Into this hole is fixed a piece of hard wood to which the arm or lever is attached by means of a metal pin.

By the means adopted, it is proposed to use any combustible oil, in a manner similar to that of gas, the oil flowing from a reservoir placed at some elevated point, and from it supplying any number of lamps. In the case of using petroleum or any easily inflammable oil, certain precautions particularised in the patent, are adopted. Sufficient for our present purpose to say that from the reservoir the combustible liquid is conducted (*fig.* 1761) to the receiving box H, through a branch pipe E, widened out into a box at F, and terminating in a tap G, that is to say, E, is a branch pipe, which leads from the cistern through the filtering box F and tap G, into the receiving box or chamber H. The box F and tap G form, in effect, portions of the service or supply-pipe leading from the main service; or, in other words, the branch E, box F, and tap G form a service or supply pipe. The filtering box F, which is connected with the branch E, is also attached to the back of the chamber H, and it contains a partition or diaphragm *f*, made of wire-gauze or perforated metal; *g* is an opening at the bottom of the box F (closed by a joint, nut, or screw cap $g^{\times}$) for removal of subsidence or deposit from time to time. G is a tap connected with and leading from the box F, and forming the termination of the service or supply pipe. This tap G leads from the box F into the chamber H. The pipe E opens into the box F below the partition *f*, and the tap G opens out of that box at a point above the partition *f*, so that the oil or liquid in passing from E to G is filtered by its passage through *f*. H is a vessel or chamber which contains a float-valve for opening and closing the pipe G. I is or are (one, two, or more) pipes, which lead from the vessel H, and communicate with burners *i*. J is an overflow pipe leading from the interior of the chamber H into the waste pipe. The oil or liquid in the tank will, by the law of equilibrium of fluids, flow through the branch pipe E into the filtering box F, and passing through the diaphragm *f* therein, it will rise into and flow through the tap G into the chamber H, the tap of pipe G being open, because the float hereinafter described will be depressed while the chamber H is empty, and it will rise when the chamber H is filled with oil or liquid to a certain level or height. From this chamber H the oil or liquid will flow through the pipes I and through the conduits communicating therewith (arms, brackets, pendants, as the case may be), to the burners where such oil or liquid is to be burnt and used for illuminating purposes.

1761



1762



In a communication made to the Society of Arts on December 21, 1870, Mr. Silber proposed by arrangements of this kind to light private houses, towns, or factories.

In the course of experiments upon combustion of petroleum, it was found that, by permitting the oil to remain below a certain level in the burner, a greatly-increased illumination was obtained with a diminished consumption of the oil, which is then vapourised in the upper part of the burner, before it reaches the flame, and is consumed at the top of the wick. By this method no residue is ever left in the burner itself.

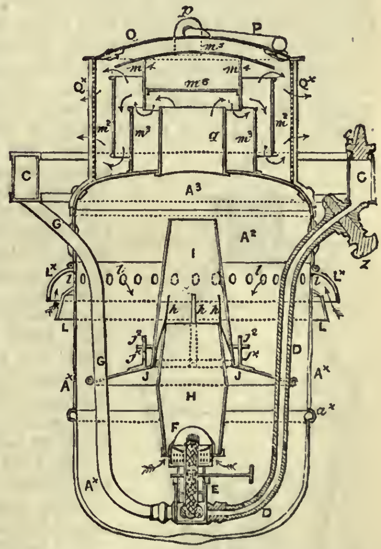
The arrangement of this burner will be seen in *fig.* 1762. A is the case or body of the lamp. The lamp contains a number of concentric chambers. The outermost chamber B contains the oil or combustible liquid to be supplied to the burner. C is a tubular or annular space into which air is fed and through which it circulates; it forms an air-jacket. D is the wick-case, that is to say, an inner concentric, annular, or tubular chamber, which holds the wick and which receives oil or combustible material from the chamber B, through the pipe E, which traverses the air-jacket C, and forms the communication between the chamber B and the wick-case D. The lower portion of the wick dips into the oil-supply through the pipe E from the chamber B. G are air-tubes inserted concentrically within the chambers B, C, D. They consist of tubes held by struts *t*. These tubes are preferably bell-mouthed at top.

It will be observed that the air-jacket C is interposed between the oil-chamber B and the wick-case D, so as to keep the oil and wick sufficiently cool and prevent the undue or immature evaporation of the oil.

Air is supplied to the air-jacket C and to the internal air-tubes G from a chamber H, which is in a space within the case A, at the foot of the lamp, which is supplied with air through orifices of plain or ornamental shape *h*, *h*, *h*. I is the feed-hole for supplying the chamber B with oil or combustible liquid; J is a screw-cap which closes the feed hole; $j^{\times}$ is an air-hole through the plug of the screw-cap J, forming a vent to the chamber B; *k* is a perforated conical cap surrounding the wick; *l* is a conical annular cap perforated only near the lower part, $l^{\times}$ also surrounding the wick. There are intervals for the passage of currents of air between the wick-case D, the cones *k*, *l*, and the outer shell or case $A^{\times}$ of the burner. M, $M^{\times}$, are the ordinary key and rack for raising and lowering the wick.

The next difficulty to be overcome was to produce a steady light, of a colour pleasing to the eye, and, at the same time, to secure the complete combustion of the oil employed. In the ordinary circular or Argand burner, the current of air produced by the flame passes so rapidly over the exposed part and surface of the wick, that it carries off with it much partially-consumed oil; and such a burner, if lighted for any length of time in a close room, very perceptibly contaminates the atmosphere. In the burners described, it will be observed that a tube or tubes are placed within the wick-case; and these tubes divide the current of air in the interior of the flame, and permit the atmospheric oxygen to mix freely with the carbon, not only at the top of the wick, but also higher up, about and above the centre of the flame. By this means a light of uniform white colour is obtained, and 3 inches high. Moreover, the insertion of tubes admits of an increase of the diameter of the burner. In this invention, the patentee claims two things: first, the conversion of the oil into vapour before it reaches the top of the wick; secondly, the admission of air by the inner tube, specially to the upper part of the flame, where it gives a fresh impulse to, and completes the combustion of volatilised matter that might otherwise be carried off unconsumed. The conversion into vapour is effected by separating the bulk of the oil from the wick-case, and by admitting to the latter only a few drops at a time. The heat generated by the flame is imparted to the metal at the top of the burner, and is thus communicated to the wick-case, where it at least partially volatilises the small quantity of oil contained therein.

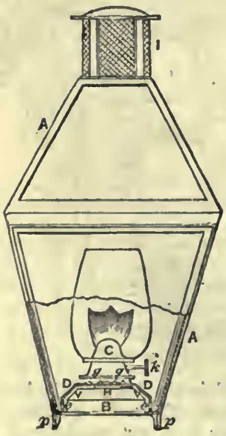
1763



Another patent, dated December 19, 1870, refers to a roof-lamp for railway carriages, in which the bulk of the oil is kept not only outside the lamp, but also outside the carriage, and thus nearly at the temperature of the air. In all previous roof-lamps the oil is contained within the lamp, and soon becomes greatly heated. $A^{\times}$, A^2, is the body of the lamp, which consists of two main portions, one fitting on the other. The lower portion $A^{\times}$ is the glass, or as it is technically called 'globe,' though it is not precisely of a globular form as ordinarily used. It is made of glass held in a metal frame $a^{\times}$. The upper portion A^2 is of metal. Brackets are fixed to the body of the lamp, and project outward from the same. On these brackets rests an annular receiver or receptacle or oil-holder C, intended to receive the oil for supplying the burner of the lamp. This receiver C is therefore on the outside of the lamp, and its outer surface is thus bathed with the circumambient air, so that the oil in the receiver is kept at the temperature of such circumambient air, and is thus prevented from being unduly heated, whereby the danger hitherto apprehended from burning mineral oils in such lamps is prevented. *c* is a screw-cap, which closes the feed hole by which oil is admitted into the receiver C; D is a pipe by which the oil flows from the receiver C to a chamber or socket E, which holds the burner F. The pipe D passes from the outside receiver C into the body of the lamp. G is an arm connected at one end with the socket E, and at the other with the body of the lamp. It (as well as the pipe D,) supports the socket E. The burner F holds a wick, which at its lower end dips into the oil in the socket E, and thus receives its supply. The apparatus E, F, is shown as constructed in *fig.* 1763. H is a glass chimney held in a gallery or groove; I is a metal chimney which surrounds the chimney H to a certain height, and at a little distance from it. The chimney I protects the chimney H, and the flame, from sudden draught or currents of air. J is a reflector of silvered-copper, which throws the rays downward; it is connected with the pipe D by a bracket, and it carries little uprights $j^{\times}$, through which pass rods j^2 for holding the chimney I in place; *h*, *h*, are springs which hold the chimney H firmly, and prevent it from oscillating or being shifted out of place; Z, tap for regulating the flow of oil towards the burner; *l*, *l*, are air-holes in the part $A^{\times}$ of the body of the lamp; they receive air through a channel formed by flanges L, $L^{\times}$, which are in a piece with the body of the lamp; A^3 is a dome or cap, which surmounts the lamp, and has over it a cap Q, fixed on a perforated cylinder $Q^{\times}$, formed of perforated metal or wire-cloth, and having an interior space as shown; *q*, short air-pipe or chimney fixed in the cap A^3; m^2, m^3, m^4, concentric wind-guards or cowls for protecting the light from gusts of air, and for allowing the aëriform or fuliginous products of combustion to escape into the external atmosphere; m^6 is a diaphragm attached to the cap m^4, and acting as a deflector to guide the said products into the open air; m^5 is a cap attached to the cowl m^4, for guiding the smoke outwards; *p*, *p*, are lugs, through which pass the ends of a handle P, which are hooked. On the lugs are tails, which pass through the cap Q, and support the parts Q, m^2, m^3, *q*.

Another arrangement, patented July 31, 1871, relates to street, signal, and carriage lamps, and affords a means of keeping the oil-supply contained in them at the temperature of the atmosphere, by surrounding the receptacle with an air-jacket. By this means the flame is prevented from rising, and the lamps may be left burning, without any attention for 24 hours or more. The reason for not separating the bulk of the oil, as in railway roof-lamps, and inserting a small cup for present supply in the centre, is that the available space, in those now under consideration, is too limited for this purpose; and also that, in street lamps, the oil receptacle would cast an objectionable shadow. In all other closed lamps, in which mineral oils are used, the oil becomes heated, and upon this the flame rises and becomes smoky, diminishing the light, fouling the chimney, and increasing the consumption of oil very considerably.

1764



Another important point in all lamps intended for use in the open air, is to establish such an equilibrium within the lantern that no more air will find admittance than is necessary for the support of the flame, and that there shall be no disturbing down-draught from the top or sides. This is effected by the use of a top or cowl, which entirely excludes down-draught. Lamps fitted with these cowls, and with no other protection, have been in use in the carriages of the Metropolitan Railway, and on lines on which a very high speed has been maintained, and they have burnt quite steadily, the flame being absolutely unaffected by the motion.

Fig. 1764 is an elevation, partly in section, of a street lamp constructed according to Silber's invention. A is the case of the lamp, consisting, as is usual, of a glazed frame, one side of which forms a door, but the case is formed open at bottom instead of being closed as usual, the bottom of the oil-holder closing the case when the lamp is in its place within it. The lamp, which is detachable from the case, so as to be readily placed in it and taken out of it, consists of an oil-holder B, and a burner or wick-holder C, which is inserted in, and communicates with the interior of the oil-holder B. D is a jacket or casing, which is connected with the oil-holder B, by ties or struts at intervals, and which surrounds the oil-holder on all sides except at the bottom, and also except at a small portion of the top. The contour of the jacket or casing D follows or corresponds with that of the oil-holder which it surrounds. V is the space between the jacket and the oil-holder: it forms a space or passage for the circulation of air, which enters at the bottom this space or passage, and also through air-holes *e*, *e*, formed in the lower part of the casing D. H is a short tube, socket, or ferrule, fitted in the space V, and attached to the oil-holder B and casing D to receive the burner or wick-holder C, the wick passing at bottom into the oil-holder B. The burner or wick-holder C, with its key *k* and chimney, are of ordinary construction; *g*, *g*, are ordinary air-holes at the lower part of the shell of the burner. The lamp rests by the bottom edge of the jacket or casing D, on a ledge *p*, fixed on the inside of the frame of the case A; this ledge thus supports the whole lamp in the case, and the case is closed at bottom by the bottom of the oil-holder B, except at the space V left open between the casing D and the sides of the oil-holder B, for the circulation of air, which bathes the oil-holder as described, keeps it cool, and allows of the light being maintained equal and steady for a number of hours in the case or frame. Air-holes *e* may be sometimes formed in the sides, and sometimes in the top of the casing or jacket D, as well as in the lower edge thereof.

Improvements in gas-burners have been founded upon combinations already described for supplying the flame in the proper place with the precise quantity of atmospheric air required for complete combustion. The inventor of this light directs attention to the curious influence exerted by the height of the chimney upon the illumination afforded by a given quantity of gas. If the height of the chimney be increased from 5 to 10 inches, the light produced appears to the unassisted eye to be whiter and better for the change. But when accurately measured by the photometer, we find that the light is actually diminished by one half, and, at the same time, the consumption of gas is considerably increased. A similar influence is exerted by the shape of the chimney; for if we place the chimney of a common moderator lamp over a gas-burner the same result is obtained.

Experiment has also shown that there is no gain, as compared with an Argand in the employment of a double flat-wicked or 'duplex' burner. If we take a duplex-burner, each wick of a given width, and a circular burner of such dimensions that its wick, if cut in two, would be precisely equal to the two wicks of the duplex, and if we test both burners under the same conditions, their illuminating power and consumption will be found to be precisely equal. This simple experiment could not have been tried before the modern duplex-burner was perfected; for two separate flat burners, each with a single wick, show a totally different result. The bodies of the burners prevent the flames from being brought into sufficiently close approximation.

Many attempts have been made, all more or less unsuccessful, to burn oils or gas without a chimney, and to convey air to the burner through apertures somewhere in the lantern, and from thence through tubes or chambers to the flames. These attempts are thought by Mr. Silber to have been wrong in principle, because the air-tracks in all of them, however circuitous, have been continuous and unbroken. If we take a rigid tube of whatever form, and twist it into any number of turns or coils, and then blow into it, we shall find that the forcible exit of air at one end will be simultaneous with its forcible entrance at the other. In the same way, a lamp with a continuous air-track, if moving with a train or vessel, is exposed to sudden rushes of air upon the flame; and, even if standing still, similar rushes will be produced by alterations in the force or direction of the wind, or by any other atmospheric disturbance. The Silber lamp, in the first place, receives its air supply from above, and neither movement nor atmospheric disturbance exerts much influence on the rate at which air descends through an aperture. This rate is mainly governed by that of the escape of the hot air, which has its outlet within the circle of ingress of the fresh supply. The entering cold air is met, a few inches below the aperture which gives it admission, by a solid metal top or inner roof, which becomes heated when the lamp has been burning for a few minutes. A slit at one end of this inner roof allows the slightly-warmed and rarefied air to proceed onwards whenever it can find opportunity; that is to say, just as rapidly as the exit of the exhausted or consumed air makes room for it. On its course it passes over the receptacle in which the supply of oil is stored, and keeps this at a moderate and regulated temperature; then between this receptacle and the inner side of the outer part of the lamp; and, lastly, beneath the chamber to which the burner is fixed, from whence it finds admission to the flame. The height of the wick is regulated without opening the lantern; and these lanterns having no opening at their lower part, are especially valuable for use on board ship. You will observe that there is no possibility under this arrangement of a continuous current of air driven in any one direction, but that the air can only diffuse itself gradually, and in proportion to the room made for it, through a succession of chambers which effectually break up its continuity. Moreover, the capacity of the chamber is so calculated that no more air can enter the lantern than is required for the maintenance of proper combustion.

With reference to the cost of artificial light from oil, obtained by the Silber system, and compared with the cost of gas, we have the evidence of Mr. William Valentine, who says:—

'The principle involved in the construction allows of the burning either of mineral, vegetable, or animal oils, and of oils which hitherto have never been burnt to advantage, such as the so-called heavy mineral oils.

'The same principle is equally applicable to ordinary moderator lamps, with the additional advantage that largely-increased lights can now be constructed on the principle of the moderator lamp burning colza or mineral oils.

'The light produced by the burners constructed on these new principles is whiter and steadier than any light I am acquainted with; and the increase in the illuminating power, as compared with that from ordinary burners hitherto in use, is fully equal to from 40 to 50 per cent. without any increased consumption of oil.

'My experiments show that a light can be produced from mineral oils 40 to 50 per cent. cheaper than the same light from coal-gas, costing 3*s.* 9*d.* per 1,000 cubic feet.

'Experience has shown that the burning of properly-purified mineral oil has no detrimental effect upon animal and vegetable life.'

It is known that the volatilisation of colza or other vegetable oil cannot be properly effected if the oil is allowed to ascend in excessive quantity to the top of the wick. On this account, instead of allowing the oil to overflow the top of the wick-case, as it does in ordinary moderators, Mr. Silber drills holes through the case about a quarter of an inch below the top. The overflow in the Silber lamps takes place by means of these holes, and combustion is carried on with only a small portion of the wick raised above the case. By this arrangement also, the wick is preserved for a much longer time than when it is exposed to the atmosphere as in ordinary moderators.

Signal-lamps for railway and other purposes are constructed of two parts: the outer casing, or lantern; and the inner part, or lamp proper. Generally speaking, the lantern is a fixture, from which the lamp is withdrawn to be trimmed and lighted. In the Silber signal-lamp, the lamp proper is so portable that a man can carry three or four in his hands at once, either lighted or unlighted, in any weather. Whilst thus carried the lamp remains effectually closed; but as soon as it is in its place within the lantern, it is opened at the top by the falling of a self-acting handle, so as to allow the escape of the products of combustion. This self-acting handle is a very important matter, because it prevents mistakes, which frequently happen with other lamps, from the man forgetting to open the top. Such negligence causes the lamp to go out as soon as it has consumed the limited supply of air enclosed in it, and then of course, although the lamp is supposed to be in action, no signal is displayed, and serious mischief may result.

Another advantage is, that the oil-reservoir of these lamps drops through the inner shell of the lamp, and is kept cool by being exposed to wind and weather, while the flame is perfectly protected.

SILESIAN LINENS. See FLAX and LINEN.

SILEX. Quartz, or pure flint. See SILICA.

SILICA or **SILICIC ACID.** SiO^2. This substance exists nearly pure in rock-crystal, chalcedony, opal, agate, and many other minerals; and it is an important constituent of a very large class of minerals. See AGATE; OPAL; QUARTZ.

It may be obtained perfectly pure by precipitation from any of its combinations. Silicic acid forms a class of salts termed silicates, which are generally formed by fusing silicic acid with the bases. Those silicates in which the acid predominates are insoluble in water, and constitute the different varieties of glass. See GLASS.

Recent researches have shown that crystallised silica exists in nature under three distinct forms: (1) *Quartz*, crystallising in the hexagonal system, with sp. gr. 2·6; (2) *Tridymite*, crystallising in the same system, but with different parameters, and with sp. gr. 2·3; (3) *Asmanite*, belonging to the rhombic system, and having a sp. gr. of 2·24.

Some curious natural deposits of silica are found in nature. Way discovered at Farnham large deposits of silica, in the condition in which it is readily soluble in hot solutions of caustic potash, or soda. These beds are situated at the base of the chalk formations, between the Upper Greensand and the Gault Clay. Mr. Way proposed to employ those beds as a convenient source of silicate of lime for agricultural purposes. He found that a mixture of slaked lime with the powdered rock, when made into a thin paste and left for some weeks, is entirely converted into silicate of lime. The action is promoted by the presence of 2 or 3 per cent. of carbonate of soda; the latter appearing to act as the carrier between the silica and the lime. Similar deposits had been previously found by Sauvage in the Département des Ardennes.

Siliceous deposits are often formed from warm springs. In the Island of Terceira a deposit of this kind contains 77·05 of silicic acid. The hot springs of New Zealand deposit a crust containing 75 of silica; and some springs in the Azores leave precipitated a stratum containing 67·6 of silica. In the Steamboat Springs in California remarkable deposits of silica, associated with metallic sulphides, are in course of formation.

The Dinas sand, Glamorganshire, is remarkable. Some samples are actually pure silica, and most of it gives 91·95 of silicic acid: the sand of Penderyn, in the same county, giving 94·05 silica. A similar deposit is found near Llandudno, in North Wales. See STONE, ARTIFICIAL.

SILICATE PAINTS. Curious local deposits of almost pure silica have been discovered near Llandudno, in North Wales. The deposit lies in a basin, at a considerable level above the sea, and appears to form the bed of a small lake. The silica bed has a thickness of several feet, and overlies a deposit of greater thickness, but less purity. The following analysis has been made thereof:—Silica, 79 parts; water, 13; oxide of iron, 3; alumina, 4; magnesia, 1.

This material is unique, and possesses a wide range of usefulness in the arts and manufactures. It would be especially suited for producing crystal glass, and in the manufacture of porcelain, if the small percentage of oxide of iron were removed from it. Again, chemists report that this earth is a peculiar and interesting material, and is almost pure silica thoroughly calcined, reduced to such an impalpable powder as to be, without further treatment, fit to be employed in various ways.

The material, when excavated, is freely washed in water, which holds it in partial suspension, and is then allowed to dry, when it becomes brilliantly white, and is more finely divided than could be done by mechanical means. At present the use made thereof is in the production of paint. Before being so used the water is dried out, so that the base of the paint contains 92 per cent. of pure silica. For this purpose it is especially suitable, as it mixes freely with the pigments and oils, and is worked with the greatest ease. Moreover, it entirely resists the action of acid, and the effect of heat, and, when laid on, becomes extremely hard and polished on the surface; no small advantages.

The Silicate Paint Company (Fenwick Street, Liverpool), supply this useful paint. Its preservative influence, in shielding sensitive materials from the destructive action of heat and flame in conflagrations is insisted on, but surely a mere coating of silica cannot possess any extraordinary power in this respect.

The Silicate Paint Company also manufacture a water-proofing solution from this peculiar silica, which, when applied to the interior or exterior of houses, entirely excludes damp. The silica is conveyed into the pores of the brick, plaster, stone, or other material, and the action of the air causes it to petrify and return to its original condition. See STONE, ARTIFICIAL.

SILICATISATION. The process of impregnating bodies with silica.

SILICATES. Compounds of silicic acid (*silica, oxide of silicon* or *silicium*), with earthy, alkaline, or metallic bases. In mineralogical arrangements these have been divided into *anhydrous silicates*, which include, as Dana classifies them, the *augite* section, the *garnet* section, the *mica* section, the *felspar* section, and some others; and the *hydrous silicates*, which include the *talc* section, the *serpentine* section, the *chlorite* section, the *calamine* section, the *datholite*, and others.

SILICEOUS CEMENTS. An interesting paper on hydraulic cements was submitted to the Academy of Sciences by M. F. Kuhlmann, showing the advantage that may be derived from the combination of silicates with mortars and cements in general, and especially with those that are intended to resist the action of sea-water. It is well known that the first effect of water on cements is that of forming hydrates; after which a gradual contraction takes place, producing a degree of hardness, which increases in proportion as the contraction is slower, and there is more silex or alumina in the cement. Now, M. Kuhlmann has observed that if alumina or its silicate, or else magnesia, whether caustic or carbonated, be kneaded into a paste with a solution of silicate of potash or soda, the compounds resulting therefrom will bear a perfect resemblance to the natural silicates, such as felspar, talcose slate, magnesite, &c., and will, by repose and slow contraction, become hard and semi-transparent, resisting in a high degree the erosive effects of water. If slaked lime be added to the said compounds they acquire the properties of hydraulic cements. M. Vicat, junr., having shown that calcined magnesia added to a cement would resist the action of sulphate of magnesia, M. Kuhlmann endeavoured to turn this observation to account, by mixing calcined dolomites (which contain magnesia) with mortar, containing the alkaline silicates. This composition he found very advantageous, since most of the salts contained in sea-water must contribute towards the preservation of such cements. In fact, the chloride of magnesium, as well as the sulphate of magnesia, will be decomposed and form a layer of silicate of magnesia on the surface of the cement; in the same manner, the sulphate of lime must, being in contact with the silicate of potash or soda, form a silicate of lime; and all these silicates strongly resist the action of sea-water. As for sea-salt, which is a chloride of sodium, M. Kuhlmann proved that, in the proportion in which it exists in sea-water, it will slowly decompose the silicate of potash contained in the cement, and leave the silex free. The compositions proposed have therefore the singular property, not only of resisting the action of sea-water, but of actually becoming more insoluble the longer they are in contact with it. A cement composed of 30 parts of rich lime, 50 of sand, 15 of uncalcined clay, and 5 of powdered silicate of potash, is recommended by M. Kuhlmann as having all the requisite hydraulic properties, especially for cisterns intended for spring-water. In marine constructions care should be taken to add an excess of silicate to those portions of cement which are exposed to the immediate contact of the sea. See HYDRAULIC CEMENTS.

Ransome's artificial stone is prepared by cementing sand with soluble silica, or silicate of potash, and decomposing this salt with muriate of lime. See STONE, ARTIFICIAL.

SILICON, or SILICIUM. The base of silica or flint. It was first obtained by Berzelius in 1823. Silicon is obtained by heating the double fluoride of potassium and silicon with sufficient potassium to combine with the whole of the fluorine, and afterwards washing the mass with cold water, until no alkaline reaction is observable, then boiling with water to decompose any of the double fluoride which may not have been acted upon, and finally washing the silicon perfectly with hot water.

Silicon is a dark-brown powder, heavier than water, infusible before the blowpipe, non-volatile, increasing in density when considerably heated. Silicon exists in three distinct forms: amorphous, graphitoïdal, and diamond-like. Silicon, boron, and carbon, indeed, exhibit great similarity.

SILK MANUFACTURE. (*Fabrique de soie*, Fr.; *Seidenfabrik*, Ger.) This may be divided into two branches: 1. the production of raw silk; 2. its filature and preparation in the mill, for the purposes of the weaver. The threads, as spun by the silkworm, and wound up in its cocoon, are all twins, in consequence of the twin orifice in the lip of the insect through which they are projected. These two threads are laid parallel to each other, and are glued more or less evenly together by a kind of glossy varnish, which also envelopes them, constituting nearly 25 per cent. of their weight. Each ultimate filament measures about $\frac{1}{2000}$ of an inch in average fine silk, and the pair measures of course fully $\frac{1}{1000}$ of an inch. In the raw silk, as imported from Italy, France, China, &c., several of these twin filaments are slightly twisted and agglutinated to form one thread, called single.

The specific gravity of silk is 1·300, water being 1·000. It is by far the most tenacious or the strongest of all textile fibres, a thread of it of a certain diameter being nearly three times stronger than a thread of flax, and twice stronger than hemp. Some varieties of silk are perfectly white, but the general colour is a golden yellow.

The production of silk was unknown in Europe till the sixth century, when two monks, who brought some eggs of the silkworm from China or India to Constantinople, were encouraged to breed the insect, and cultivate its cocoons, by the Emperor Justinian. Several silk manufactures were in consequence established in Athens, Thebes, and Corinth, not only for rearing the worm upon mulberry-leaves, but for unwinding its cocoons, for twisting their filaments into stronger threads, and weaving these into robes. The Venetians having then and long afterwards intimate commercial relations with the Greek Empire, supplied the whole of western Europe with silk goods, and derived great riches from the trade.

About 1130, Roger II., king of Sicily, set up a silk manufacture at Palermo, and another in Calabria, conducted by artisans whom he had seized and carried off as prisoners of war in his expedition to the Holy Land. From these countries, the silk industry soon spread throughout Italy. It seems to have been introduced into Spain at a very early period, by the Moors, particularly in Murcia, Cordova, and Granada. The last town, indeed, possessed a flourishing silk trade when it was taken by Ferdinand in the 15th century. The French having been supplied with workmen from Milan, commenced, in 1521, the silk manufacture; but it was not till 1564 that they began successfully to produce the silk itself, when Traucat, a working gardener at Nismes, formed the first nursery of white mulberry-trees, and with such success, that in a few years he was enabled to propagate them over many of the southern provinces of France. Prior to this time, some French noblemen on their return from the conquest of Naples, had introduced a few silkworms with the mulberry into Dauphiny; but the business had not prospered in their hands. The mulberry-plantations were greatly encouraged by Henry IV.; and since then they have been the source of most beneficial employment to the French people. James I. was most solicitous to introduce the breeding of silkworms into England, and in a speech from the throne he earnestly recommended his subjects to plant mulberry-trees; but he totally failed in the project. This country does not seem well adapted for this species of husbandry, on account of the great prevalence of blighting east winds during the months of April and May, when the worms require a plentiful supply of mulberry-leaves. The manufacture of silk goods, however, made great progress during that king's peaceful and pompous reign. In 1629 it had become so considerable in London that the silk-throwsters of the city and suburbs were formed into a public corporation. So early as 1661 they employed 40,000 persons. The revocation of the Edict of Nantes, in 1685, contributed in a remarkable manner to the increase of the English silk trade, by the influx of a large colony of skilful French weavers, who settled in Spitalfields. The great silk-throwing mill mounted at Derby, in 1719, also served to promote the extension of this branch of manufacture; for soon afterwards, in the year 1730, the English silk goods bore a higher price in Italy than those made by the Italians, according to the testimony of Keysler.

The ordinary silkworm, called by entomologists *Bombyx mori*, is, like its kindred species, subject to four metamorphoses. The egg, fostered by the genial warmth of spring, sends forth a caterpillar, which, in its progressive enlargement, casts its skin either three or four times, according to the variety of the insect. Having acquired its full size in the course of 25 or 30 days, and ceasing to eat during the remainder of its life, it begins to discharge a viscid secretion, in the form of twin filaments, from tubes opening on the under lip, which harden in the air. These threads are coiled into an ovoïd nest round itself, called a cocoon, which serves as a defence against living enemies and changes of temperature. Here it soon changes into the chrysalis or nymph state, in which it lies swaddled, as it were, for about 15 or 20 days. Then it bursts its cerements, and comes forth furnished with appropriate wings, antennæ, and feet, for living in its new element, the atmosphere. The male and the female moths couple together at this time, and terminate their union by a speedy death, their whole existence being limited to two months. The cocoons are completely formed in the course of three or four days; the finest being reserved as seed-worms. From these cocoons, after an interval of 18 or 20 days, the moth makes its appearance, perforating its tomb by knocking with its head against one end of the cocoon, after softening it with saliva, and thus rendering the filaments more easily torn asunder by its claws. Such moths or aurelias are collected and placed upon a piece of soft cloth, where they couple and lay their eggs.

The eggs, or grains as they are usually termed, are enveloped in a liquid which causes them to adhere to the piece of cloth or paper on which the female lays them. From this glue they are readily freed, by dipping them in cold water, and wiping them dry. They are best preserved in the *ovum* state at a temperature of about 55° F. If the heat of spring advances rapidly in April, it must not be suffered to act on the eggs, otherwise it might hatch the caterpillars long before the mulberry has sent forth its leaves to nourish them. Another reason for keeping back their incubation is, that they may be hatched together in large broods, and not by small numbers in succession. The eggs are made up into small packets, of an ounce, or somewhat more, which in the south of France are generally attached to the girdles of the women during the day, and placed under their pillows at night. They are, of course, carefully examined from time to time. In large establishments, they are placed in an appropriate stove-room, where they are exposed to a temperature gradually increased till it reaches the 86th degree of Fahrenheit's scale, which temperature it must not exceed. Aided by this heat, nature completes her mysterious work of incubation in eight or ten days. The teeming eggs are now covered with a sheet of paper pierced with numerous holes, about $\frac{1}{12}$th of an inch in diameter. Through these apertures the new-hatched worms creep upwards instinctively, to get at the tender mulberry-leaves strewed over the paper.

The nursery where the worms are reared is called by the French a *magnanière;* it ought to be a well-aired chamber, free from damp, excess of cold or heat, rats and other vermin. It should be ventilated occasionally, to purify the atmosphere from the noisome emanations produced by the excrements of the caterpillars and the decayed leaves. The scaffolding of the wicker-work shelves should be substantial; and they should be from 15 to 18 inches apart. A separate small apartment should be allotted to the sickly worms. Immediately before each moulting, the appetite of the worms begins to flag; it ceases altogether at that period of cutaneous metamorphosis, but revives speedily after the skin is fairly cast, because the internal parts of the animal are thereby allowed freely to develope themselves. At the end of the second age, the worms are half an inch long; and should then be transferred from the small room in which they were first hatched, into the proper apartment where they are to be brought to maturity and set to spin their balls. On occasion of changing their abode, they must be well cleansed from the litter, laid upon beds of fresh leaves, and supplied with an abundance of food every six hours in succession. In shifting their bed, a piece of network being laid over the wicker-plates, and covered with leaves, the worms will creep up over them; when they may be transferred in a body upon the net. The litter, as well as the sickly worms, may thus be readily removed, without handling a single healthy one. After the third age, they may be fed with entire leaves; because they are now exceedingly voracious, and must not be subsequently stinted in their diet. The exposure of chloride of lime, spread thin upon plates, to the air of the *magnanière*, has been found useful in counteracting the tendency which sometimes appears of an epidemic disease among the silkworms, from the fœtid exhalations of the dead and dying,

When they have ceased to eat, either in the fourth or fifth age, according to the variety of the *bombyx*, and when they display the spinning instinct by crawling up among the twigs of heath, &c., they are not long in beginning to construct their cocoons, by throwing the thread in different directions, so as to form the floss, *filoselle*, or outer open network, which constitutes the *bourre* or silk for carding and spinning.

The cocoons destined for filature, must not be allowed to remain for many days with the worms alive with them; for should the chrysalis have leisure to grow mature or come out, the filaments at one end would be cut through, and thus lose almost all their value. It is therefore necessary to extinguish the life of the animal by heat, which is done either by exposing the cocoons for a few days to sunshine, by placing them in a hot oven, or in the steam of boiling water. A heat of 202° Fahr. is sufficient for effecting this purpose, and it may be best administered by plunging tin cases filled with the cocoons into water heated to that pitch.

80 pounds French (= 88 Engl.) of cocoons, are the average produce from one ounce of eggs, or 100 from an ounce and a quarter; but M. Folzer of Alsace obtained no less than 165 pounds. The silk obtained from a cocoon is from 750 to 1,150 feet long. The varnish by which the coils are glued slightly together, is soluble in warm water.

The silk husbandry, as it may be called, is completed in France within six weeks from the end of April, and thus affords the most rapid of agricultural returns, requiring merely the advance of a little capital for the purchase of the leaf. In buying up cocoons, and in the filature, indeed, capital may be often laid out to great advantage. The most hazardous period in the process of breeding the worms, is at the third and fourth moulting; for upon the sixth day of the third age, and the seventh day of the fourth, they in general eat nothing at all. On the first day of the fourth age, the worms proceeding from one ounce of eggs will, according to Bonafons, consume upon an average twenty-three pounds and a quarter of mulberry-leaves; on the first of the fifth age, they will consume forty-two pounds; on the sixth day of the same age, they acquire their maximum voracity, devouring no less than 223 pounds. From this date their appetite continually decreases, till on the tenth day of this age they consume only fifty-six pounds. The space which they occupy upon the wicker-tables, being at their birth only nine feet square, becomes eventually 239 feet. In general, the more food they consume the more silk will they produce.

A mulberry-tree is valued, in Provence, at from 6*d.* to 10*d.*; it is planted out of the nursery at four years of age; it is begun to be stripped in the fifth year, and affords an increasing crop of leaves till the twentieth. It yields from 1 cwt. to 30 cwts. of leaves, according to its magnitude and mode of cultivation. One ounce of silkworm eggs is worth in France about 2½ francs; it requires for its due development into cocoons about 15 cwts. of mulberry-leaves, which cost upon an average 3 francs per cwt. in a favourable season. One ounce of eggs is calculated, as I have said, to produce from 80 to 100 pounds of cocoons, of the value of 1 fr. 25 centimes per pound, or 125 francs in the whole. About 8 pounds of reeled raw silk, worth 18 francs a pound, are obtained from these 100 pounds of cocoons.

There are three denominations of raw silk: viz., organzine, *trame* (shute or tram), and floss. Organzine serves for the warp of the best silk stuffs, and is considerably twisted; tram is made usually from inferior silk, and is very slightly twisted, in order that it may spread more, and cover better in the weft; floss, or *bourre*, consists of the shorter broken silk, which is carded and spun like cotton. Organzine and trame may contain from 3 to 30 twin filaments of the worm; the former possesses a double twist, the component filaments being first twisted in one direction, and the compound thread in the opposite; the latter receives merely a slender single twist. Each twin filament gradually diminishes in thickness and strength, from the surface of the cocoon, where the animal begins its work in a state of vigour, to the centre, where it finishes it, in a state of debility and exhaustion; because it can receive no food from the moment of its beginning to spin by spouting forth its silky substance. The winder is attentive to this progressive attenuation, and introduces the commencement of some cocoons to compensate for the termination of others. The quality of raw silk depends, therefore, very much upon the skill and care bestowed upon its filature.

The quality of the raw silk is determined by first winding off 400 ells of it, equal to 475 meters, round a drum one ell in circumference, and then weighing that length. The weight is expressed in grains, 24 of which constitute one denier; 24 deniers constitute one ounce; and 16 ounces make one pound, *poids de marc*. This is the Lyons rule for valuing silk. The weight of a thread of raw silk 400 ells long, is two grains and a half, when five twin filaments have been reeled and associated together.

Raw silk is so absorbent of moisture, that it may be increased ten per cent. in weight by this means. This property has led to falsifications; which are detected by enclosing weighed portions of the suspected silk in a wire-cloth cage, and exposing it to a stove heat of about 78° Fahr. for twenty-four hours, with a current of air. The loss of weight which it thereby undergoes, demonstrates the amount of the fraud. There is an office in Lyons called the *Condition*, where this assay is made, and by the report of which the silk is bought and sold. The law of France requires, that all the silk tried by the *Condition* must be worked up into fabrics in that country. It has been lately noticed that a still more serious falsification of silks has been made in France. The silks are treated with astringent vegetable decoctions, and then with salts of iron—the cyanides and, in some cases, iodides being also used. It is stated that the weight of the silk can be, by this process, more than doubled. At the same time it is considerably deteriorated in quality; and if a flame is applied to it, it burns like tinder. It is found also, in some cases, to be spontaneously combustible.

Switzerland.—There are silk-stuff factories in the canton of Bâle: but the trade of this town lies in the manufacture of silk-ribbons. In this and the neighbouring canton of Bâle-Champagne there are about 4,000 looms, which give employment to 16,000 workmen, as weavers, dyers, &c. Manual labour is extremely cheap, enabling the manufacturer to sell at a very low rate. The greater number of the manufacturers of this canton employ their own capital, and have not to surmount those difficulties and disadvantages inseparable from the employment of borrowed principal. The chief articles of manufacture are plain taffeta, ribbons, plain satin, and figured ribbons: in all these articles, Bâle maintains an incontestable superiority.

The silk trade in Switzerland has grown and prospered without the aid of protective duties, and it is a remarkable fact that the difficulties occasioned by the high prohibitive customs, instead of being prejudicial, have been of advantage, by increasing the active genius and emulation of the manufacturers, and inducing them to seek more distant and more favourable outlets for their goods. The morality, activity, and commercial knowledge of the Swiss may be considered the basis of their success.

The production of silk is conducted on the most important scale in the Lombardo-Venetian States; next in order of importance comes the Tyrol: the same business is also carried on in the military frontier, Görz and Gradiska, and also in Istria and Trieste, in Dalmatia and south of Hungary. Trials have likewise been made in Lower Austria, Bohemia, and Carniola.

The cocoons are prepared at the reeling establishment into raw silk. From the result of inquiries, it would appear that Lombardy comprises 3,060 reeling establishments. The entire production amounts to 2,512,000 Vienna lbs.; and since 12 lbs. of cocoons yield 1 lb. of raw silk, there are required for this aggregate of raw silk 300,400 cwts. of cocoons. The quantity of cocoons required in excess of the quantity produced, an excess of nearly 50,000 cwts., is covered by the production of the Venetian provinces, chiefly by that of Verona.

Within the province of Venice, the reeling establishments are also numerous. The nearest approximation in reference to this matter is obtained by taking the extent of the production at one-half of that in Lombardy. The remainder of the cocoons produced in the province undergo further preparation in Lombardy, and partly in the Tyrol also; whilst a portion of those obtained in Görz and Gradiska, as well as in Istria, are prepared in Venetian reeling establishments.

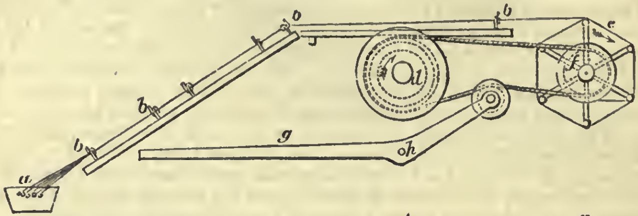
The whole production of raw silk obtained in the Austrian monarchy is about 4,108,700 lbs. The number of working hands employed in the reeling establishments is not less than 160,000. Besides the products already enumerated, about 900 cwts. of cocoons are annually imported into Lombardy, principally from Switzerland and the neighbouring Italian States, and are prepared in the Lombardy reeling establishments.

The raw silk undergoes further preparation in the throwing mills; but the whole mass of the production is not thus worked up within the monarchy, for the exports of raw silk are found considerably to exceed the imports.

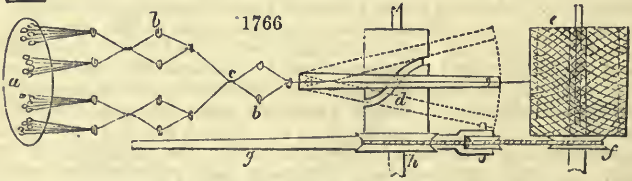
There are in the Tyrol above 55 throwing mills, with 125,047 spindles; 85,583 of which latter are for spinning, and 39,464 for twisting. In these mills 500 men and 1,200 women and children are employed. The production there, including that of the smaller throwing mills, which give occupation to 500 workmen, amounts to 220,400 Vienna lbs. of thrown silk, for which 231,400 Vienna lbs. of raw silk have to be worked up.

The mechanism of the silk filature, as improved in France, is very ingenious. *Figs.* 1765 and 1766 exhibit it in plan and longitudinal view. *a* is an oblong copper basin containing water heated by a stove or by steam. It is usually divided by transverse partitions into several compartments, containing 20 cocoons, of which there are five in one group, as shown in the figure. *b*, *b*, are wires with hooks or

1765



1766



eylets at their ends, through which the filaments run, apart, and are kept from ravelling. *c*, *c*, the points where the filaments cross and rub each other, on purpose to clean their surfaces. *d* is a spiral groove, working upon a pin-point, to give the traverse motion alternately to right and left, whereby the thread is spread evenly over the surface of the reel *e*. *f*, *f*, are the pulleys, which by means of cords transmit the rotatory movement of the cylinder *d* to the reel *e*. *g* is a friction lever or tumbler, for lightening or slackening the endless cord, in the act of starting or stopping the winding operation. Every apartment of a large filature contains usually a series of such reels as the above, all driven by one prime mover; each of which, however, may, by means of the tumbler-lever, be stopped at pleasure. The reeler is careful to remove any slight adhesions by the application of a brush in the progress of her work.

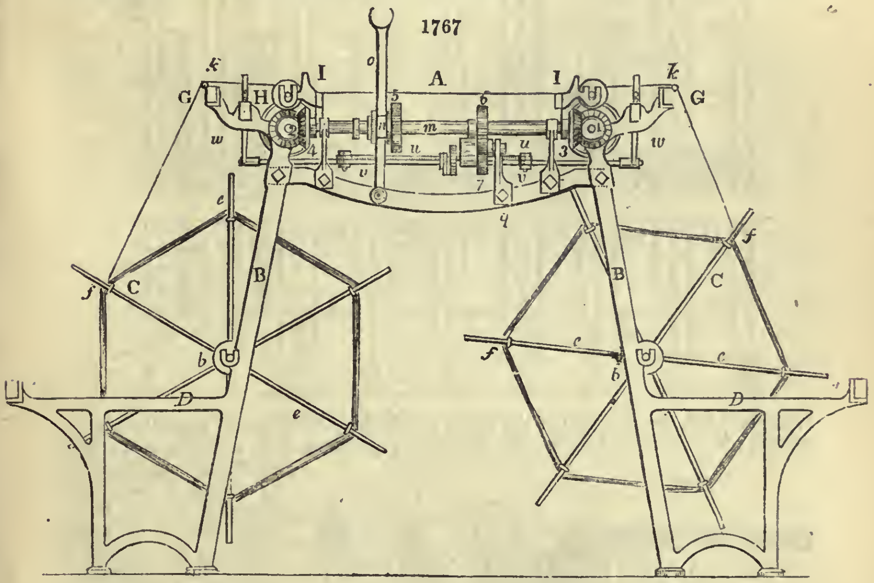
The expense of reeling the excellent Cevennes silk is only 3 francs and 50 centimes per Alais pound; from 4 to 5 cocoons going to one thread. That pound is 92 hundredths of our avoirdupois pound. In Italy, the cost of reeling silk is much higher, being 7 Italian livres per pound, when 3 to 4 cocoons go to the formation of one thread; and 6 livres when there are from 4 to 5 cocoons. The first of these raw silks will have a *titre* of 20 to 24 deniers; the last, of 24 to 28. If 5 to 6 cocoons go to one thread, the titre will be from 26 to 32 deniers, according to the quality of the cocoons. The Italian livre is worth 7½*d.* English. The woman employed at the kettle receives one livre and five sous per day; and the girl who turns the reel gets thirteen sous a day; both receiving board and lodging in addition. In June, July, and August, they work 16 hours a day, and then they wind a *rubo* or ten pounds weight of cocoons, which yield from 1-5th to 1-6th of silk, when the quality is good. The whole expenses amount to from 6 or 7 livres upon every ten pounds of cocoons; which is about 2*s.* 8*d.* per English pound of raw silk.

The raw silk, as imported into this country in hanks from the filatures, requires to be regularly wound upon bobbins, doubled, twisted, and reeled in our silk-mills. These processes are called *throwing* silk, and their proprietors are called silk *throwsters;* terms probably derived from the appearance of swinging or tossing which the silk-threads exhibit during their rapid movements among the machinery of the mills.

It was in Manchester that throwing-mills received the greatest improvement upon the ancient Italian plan, which had been originally introduced into this country by Sir Thomas Lombe, and erected at Derby. That improvement is chiefly due to the eminent factory engineers, Messrs. Fairbairn and Lillie, who transferred to silk the elegant mechanism of the throstle, so well known in the cotton trade. Still, throughout the silk districts of France the throwing-mills are generally small, not many of them turning off more than 1,000 pounds of organzine per annum, and not involving 5,000*l.* of capital. The average price of throwing organzine in that country, where the throwster is not answerable for loss, is 7 francs; of throwing trame, from 4 fr. to 5 fr. (per kilogramme?) Where the throwster is accountable for loss, the price is from 10 fr. to 11 fr. for organzine, and from 6 to 7 for trame. In Italy, throwing adds 3*s.* 9*d.* to the price of raw silk, upon an average. It seems probable, from the perfection and speed of the silk-throwing machinery in this country, as about to be described, that the cost of converting a pound of raw silk either into organzine or trame must be considerably under any of the above sums.

The first process to which the silk is subjected, is winding the skeins, as imported, off upon bobbins. The mechanism which effects this winding off and on, is technically called the *engine*, or swift. The bobbins to which the silk is transferred, are wooden cylinders, of such thickness as may not injure the silk by sudden flexure, and which may also receive a great length of thread without having their diameter materially increased, or their surface velocity changed. *Fig.* 1767 is an end view of

1767



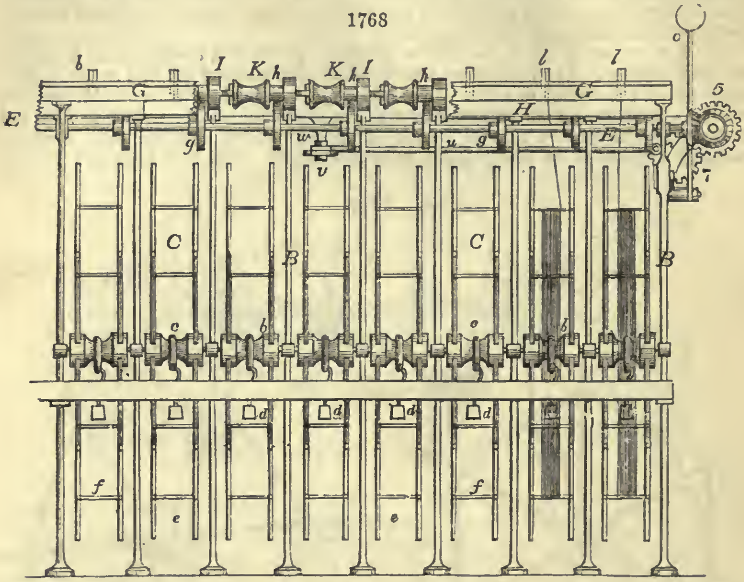
the silk-throwing machine, or *engine*, in which the two large hexagonal reels, called swifts, are seen in section, as well as the table between them, to which the bobbins and impelling mechanism are attached. The skeins are put upon these reels, from which the silk is gradually unwound by the traction of the revolving bobbins. One principal object of attention, is to distribute the thread over the length of the bobbin-cylinder in a spiral or oblique direction, so that the end of the slender semi-transparent thread may be readily found when it breaks. As the bobbins revolve with uniform velocity, they would soon wind on too fast, were their diameters so small at first as to become greatly thicker when they are filled. They are therefore made large, are not covered thick, but are frequently changed. The motion is communicated to that end of the engine shown in the figure.

The wooden table A, shown here in cross section, is sometimes of great length, extending 20 feet, or more, according to the size of the apartment. Upon this the skeins are laid out. It is supported by the two strong slanting legs B, B, to which the bearings of the light reels C are made fast. These reels are called *swifts*, apparently by the same etymological casuistry as *lucus a non lucendo*, for they turn with reluctant and irregular slowness; yet they do their work much quicker than any of the old apparatus, and in this respect may deserve their name. At every eighth or tenth leg there is a projecting horizontal piece D, which carries at its end another horizontal bar *a*, called the knee-rail, at right angles to the former. This protects the slender reels or swifts from the knees of the operatives.

These swifts have a strong wooden shaft *b*, with an iron axis passing longitudinally through it, round which they revolve, in brass bearings fixed near to the middle of the legs B. Upon the middle of the shaft *b*, a loose ring is hung, shown under *c*, in *fig.* 1768, to which a light weight *d*, is suspended, for imparting friction to the reel, and thus preventing it from turning round, unless it be drawn with a gentle force, such as the traction of the thread in the act of winding upon the bobbin.

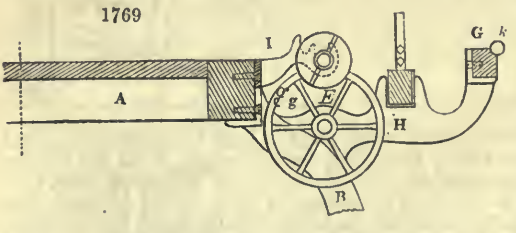
Fig. 1768 is a front view of the engine. B, B, are the legs, placed at their appropriate distances (scale 1½ inch to the foot); C, C, are the swifts. By comparing *figs.*

1768



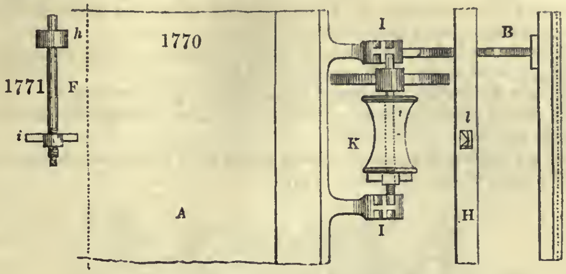
1768 and 1769, the structure of the swifts will be fully understood. From the wooden shaft *b*, six slender wooden (or iron) spokes *c*, *e*, proceed, at equal angles to each other; which are bound together by a cord *f*, near their free ends, upon the transverse line *f*, of which cord, the silk thread is wound in a hexagonal form; due tension being given to the circumferential cords, by sliding them out from the centre. Slender wooden rods are set between each pair of spokes, to stay them, and to keep the cord tight. E is one of the two horizontal shafts, placed upon each side of the *engine*, to which are affixed a number of light iron pulleys *g*, *g* (shown on a double scale in *fig.* 1769). These serve, by friction, to drive the bobbins which rest upon their peripheries.

1769



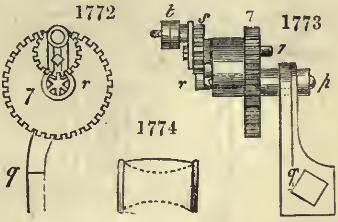
To the table A, *fig.* 1767, are screwed the light cast-iron slot bearings, I, I, wherein the horizontal spindles or skewers rest, upon which the bobbins revolve. The spindles (see F, *fig.* 1771,) carry upon one end a little wooden pulley *h*, whereby they press and revolve upon the larger driving pulleys *g*, of the shaft E. These pulleys are called *stars* by our workmen. The other ends of the spindles, or skewers, are cut into screws, for attaching the swivel-nuts *i* (*fig.* 1771), by which the bobbins K, K (*fig.* 1768), are made fast to their respective spindles. Besides the slots, above described, in which the spindles rest when their friction pulleys *h*, are in contact with the moving stars *g*, there is another set of slots in the bearings, into which the ends of the spindles may be occasionally laid, so as to be above the line of contact of the rubbing periphery of the star *g*, in case the thread of any bobbin breaks. Whenever the girl has mended the thread, she replaces the bobbin-spindle in its deeper slot-bearings, thereby bringing its pulley once more into contact with the star, and causing it to revolve.

G (*fig.* 1768) is a long ruler or bar of wood, which is supported upon every eighth or twelfth leg B, B. (The figure being, for convenience of the page, contracted in length, shows it at every sixth leg.) To the edge of that bar the smooth glass-rods *k*, are



made fast, over which the threads glide from the swifts, in their way to the bobbins. H (*fig.* 1770) is the guide-bar, which has a slow traverse or seesaw motion, sliding in slots at the top of the legs B, where they support the bars G. Upon the guide-bar H, the guide-pieces *l*, *l*, are made fast. These consist of two narrow, thin, upright plates of iron, placed endwise together, their contiguous edges being smooth, parallel, and capable of approximation to any degree by a screw, so as to increase or diminish at pleasure the ordinary width of the vertical slit that separates them. Through this slit the silk thread must pass, and, if rough or knotty, will be either cleaned or broken; in the latter case, it is neatly mended by the attendant girl.

The motions of the various parts of the *engine* are given as follows:—Upon the end of the machine, represented in *fig.* 1767, there are attached to the shafts E (*fig.* 1768), the bevel-wheels 1 and 2, which are set in motion by the bevel-wheels 3 and 4, respectively. These latter wheels are fixed upon the shaft *m*, *fig.* 1767; *m* is moved by the main steam-shaft which runs parallel to it, and at the same height through the length of the *engine* apartment, so as to drive the whole range of the machines. 5 is a loose wheel or pulley upon the shaft *m*, working in gear with a wheel upon the steam-shaft, and which may be connected by the clutch *n*, through the hand-lever or gearing-rod *o* (*figs.* 1767 and 1768), when the engine is to be set at work. 6 is a spur-wheel upon the shaft *m*, by which the stud-wheel 7, is driven, in order to give the traverse motion to the guide-bar H. This wheel is represented, with its appendages, in double size, *figs.* 1772 and 1773, with its boss upon a stud *p*, secured to the bracket *q*. In an eccentric hole of the same boss, another stud *r*, revolves, upon which the little wheel *s*, is fixed. This wheel *s* is in gear with a pinion cut upon the end of the fixed stud *p*; and upon it is screwed the little crank *t*, whose collar is connected by two rods *u* (*figs.* 1767 and 1768), to a cross-piece *v*, which unites the two arms *w*, that are fixed upon the guide-bar H, on both sides of the machine. By the revolution of wheel 7, the wheel *s* will cause the pinion of the fixed stud *p* to turn round. If that wheel bear to the pinion the proportion of 4 to 1, then the wheel *s* will make, at each revolution of the wheel 7, one-fourth of a revolution; whereby the crank *t* will also rotate through one-fourth of a turn, so as to be brought nearer to the centre of the



stud, and to draw the guide-bar so much less to one side of its mean position. At the next revolution of wheel 7, the crank *t* will move through another quadrant, and come still nearer to the central position, drawing the guide-bars still less aside, and therefore causing the bobbins to wind on more thread in their middle than towards their ends. The contrary effect would ensue, were the guide-bars moved by a single or simple crank. After four revolutions of the wheel 7, the crank *t* will stand once more as shown in *fig.* 1774, having moved the bar H through the whole extent of its traverse. The bobbins, when filled, have the appearance represented in *fig.* 1774; the thread having been laid on them all the time in diagonal lines, so as never to coincide with each other.

Doubling is the next operation of the silk-throwster. In this process, the threads of two or three of the bobbins, filled as above, are wound together in contact upon a single bobbin. An ingenious device is here employed to stop the winding-on the moment that one of these parallel threads happens to break. Instead of the swifts or reels, a creel is here mounted for receiving the bobbins from the former machine, two or three being placed in one line over each other, according as the threads are to be doubled or trebled. Though this machine is in many respects like the *engine*, it has some additional parts, whereby the bobbins are set at rest, as above mentioned, when one of the doubling-threads gets broken.

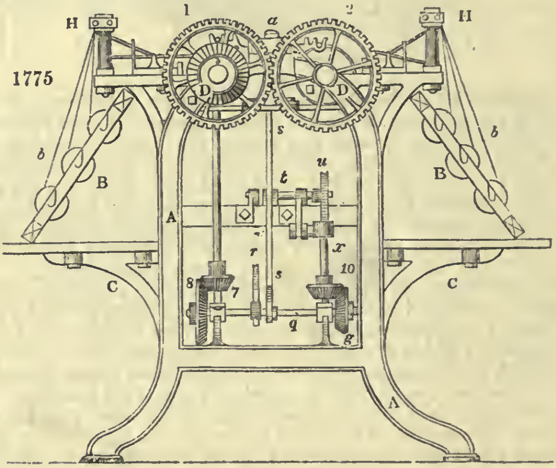
Fig. 1775 is an end view, from which it will be perceived that the machine is, like the preceding, a double one, with two working sides.

Fig. 1776 is a front view of a considerable portion of the machine.

Fig. 1777 shows part of a cross section, to explain minutely the mode of winding upon a single bobbin.

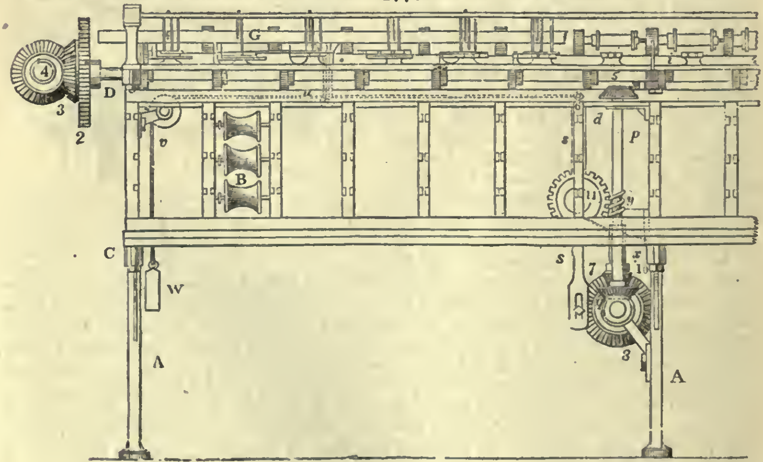
Fig. 1779 is the plan of the parts shown in *fig.* 1777; these two figures being drawn to double the scale of *figs.* 1775 and 1776.

1775



A, A, *figs.* 1775 and 1776, are the end frames, connected at their tops by a wooden stretcher, or *bar-beam*, *a*, which extends through the whole length of the machine; this bar is shown also in *figs.* 1777 and 1779.

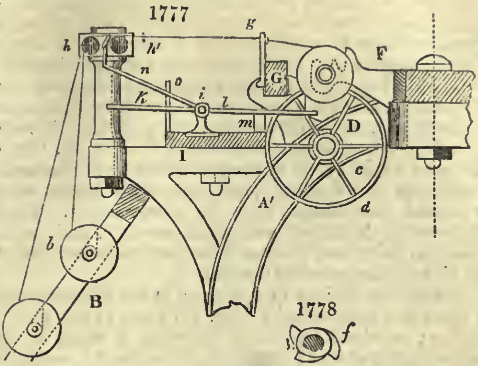
1776



B, B, are the creels upon each side of the machine, or bobbin-bearers, resting upon wooden beams or boards, made fast to the arms or brackets C, about the middle of the frames A.

D, D, are two horizontal iron shafts, which pervade the whole machine, and carry a series of light moveable pulleys, called *stars*, *c*, *c* (*figs.* 1777, 1779), which serve to drive the bobbins E, whose fixed pulleys rest upon their peripheries, and are therefore turned simply by friction. These bobbins are screwed by swivel-nuts, *e*, *e*, upon spindles, as in the silk-engine. Besides the small friction-pulley, or boss, *d*, seen best in *fig.* 1779, by which they rest upon the star-pulleys *c*, *c*, a little ratchet-wheel, *f*, is attached to the other end of each bobbin. This is also shown by itself at *f*, in *fig.* 1778.

1777

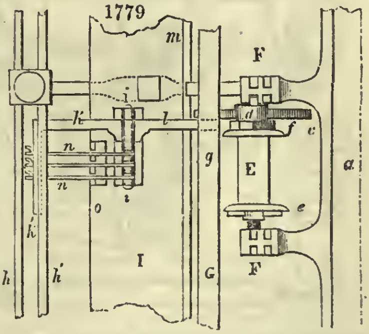


1778

The spindles, with their bobbins, revolve in two slot-bearings, F, F, *fig.* 1779, screwed to the bar-beam *a*, which is supported by two or three intermediate upright frames, such as A′. The slot-bearings F have also a second slot, in which the spindle with the bobbin is laid at rest, out of contact of the *star*-wheel, while its broken thread is being mended. G is the guide-bar (to which the cleaner slit-pieces, *g*, *g*, are attached), for making the thread traverse to the right and the left, for its proper distribution over the surface of the bobbin. The guide-bar of the doubling-machine is moved with a slower traverse than in the engine; otherwise, in consequence of the different obliquities of the paths, the single threads would be readily broken. *h*, *h*, is a pair of smooth rods of iron or brass, placed parallel to each of the two sides of the machine, and made fast to the standards H, H, which are screwed to brackets projecting from the frames A, A′. Over these rods the silk threads glide, in their passage to the guide-wires *g*, *g*, and the bobbins E.

I, I, is the *lever-board* upon each side of the machine, upon which the slight brass bearings or fulcrums *i*, *i*, one for each bobbin in the creel, are made fast. This board bears the *balance-lever* *k*, *l*, with the *fallers* *n*, *n*, *n*, which act as dexterous fingers, and stop the bobbin from winding-on the instant a thread may chance to break. The levers *k*, *l*, swing upon a fine wire axis, which passes through their props *i*, *i*, their arms being shaped rectangularly, as shown at *k*, *k′* (*fig.* 1779). The arm *l* being heavier than the arm *k*, naturally rests upon the ridge-bar *m*, of the lever-board I. *n*, *n*, *n*, are three wires, resting at one of their ends upon the axis of the fulcrum *i*, *i*, and having each of their other hooked ends suspended by one of the silk threads, as it passes over the front steel rod *h*, and under *h′*. These faller-wires, or stop-fingers, are guided truly in their up-and-down motions with the thread, by a cleaner-plat *o*, having a vertical slit in its middle. Hence, whenever any thread happens to break, in its way to a winding-on bobbin E, the wire *n*, which hung by its eyelet end to that thread, as it passed through between the steel rods in the line of *h*, *h′*, falls upon the lighter arm of the balance-lever *k*, *l*, weighs down that arm *k*, consequently jerks up the arm *l*, which pitches its tip or end into one of the three notches of the racket or catch-wheel *f* (*figs.* 1778 and 1779), fixed to the end of the bobbin. Thus its motion is instantaneously arrested, till the girl has had leisure to mend the thread, when she again hangs up the faller-wire *n*, and restores the lever *k*, *l*, to its horizontal position. If, meanwhile, she took occasion to remove the winding-bobbin out of the sunk slot-bearing, where pulley *d* touches the *star*-wheel *c*, into the right-hand upper slot of repose, she must now shift it into its slot of rotation.

1779



The motions are given to the doubling-machine in a very simple way. Upon the end of the frame, represented in *fig.* 1775, the shafts bear two spur-wheels, 1 and 2, which work into each other. To the wheel 1 is attached the bevel-wheel 3, driven by another bevel-weeel 4 (*fig.* 1776), fixed to a shaft that extends the whole length of the apartment, and serves, therefore, to drive a whole range of machines. The wheel 4 may be put in gear with the shaft, by a clutch- and gear-handle, as in the silk-*engine*, and thereby it drives two shafts, by the one transmitting its movement to the other.

The traverse-motion of the guide-bar G is effected as follows:—Upon one of the shafts D, there is a bevel-wheel 5, driving the bevel-wheel 6, upon the top of the upright shaft *p* (*fig.* 1776, to the right of the middle); whence the motion is transmitted to the horizontal shaft *q* below, by means of the bevel-wheels 7 and 8. Upon this shaft *q*, there is a heart-wheel *r*, working against a roller which is fixed to the end of the lever *s*, whose fulcrum is at *t*, *fig.* 1775. The other end of the lever *s*, is connected by two rods (shown by dotted lines in *fig.* 1776) to a brass piece which joins the arms *u* (*fig.* 1776), of the guide-bars G. To the same cross-piece a cord is attached, which goes over a roller *v*, and suspends a weight W, by means of which the lever *s*, is pressed into contact with the heart-wheel *r*. The fulcrum *t*, of the lever *s*, is a shaft which is turned somewhat excentric, and has a very slow rotatory motion. Thus the guide-bar, after each traverse, necessarily winds the silk in variable lines to the side of the preceding threads.

The motion is given to this shaft in the following way:—Upon the horizontal shaft *q*, there is a bevel-wheel *g* (*figs.* 1775 and 1776), which drives the wheel 10 upon the shaft *x*; on whose upper end, the worm *y* works on the wheel 11, made fast to the said excentric shaft *t*; round which the lever *s*, swings or oscillates, causing the guide-bars to traverse.

The Spinning Silk-mill.—The machine which twists the silk threads, either in their single or doubled state, is called the spinning-mill. When the raw singles are first twisted in one direction. next doubled, and then twisted together in the opposite direction, an exceedingly wiry, compact thread, is produced, called *organzine*. In the spinning-mill, either the singles or the doubled silk, while being unwound from one set of bobbins, and wound upon another set, is subjected to a regular twisting operation; in which process the thread is conducted as usual through guides, and coiled diagonally upon the bobbins by a proper mechanism.

1780

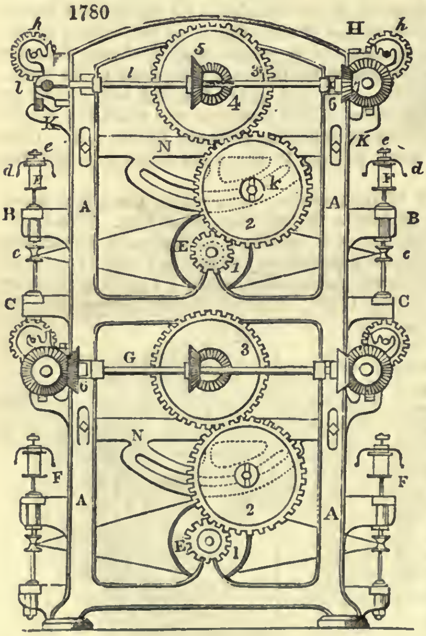


Fig. 1780 exhibits an end-view of the spinning-mill; in which four working lines are shown; two tiers upon each side, one above the other. Some spinning-mills have three working tiers upon each side; but as the highest tier must be reached by a ladder or platform, this construction is considered by many to be injudicious.

Fig. 1781 is a front view, where, as in the former figure, the two working lines are shown.

Fig. 1782, is a cross section of a part of the machine, to illustrate the construction and play of the working parts; *figs.* 1788, 1789, are other views of *fig.* 1782.

Fig. 1784, shows a single part of the machine, by which the bobbins are made to revolve.

Figs. 1783 and 1785, show a different mode of giving the traverse to the guide-bars, than that represented in *fig.* 1782.

Figs. 1786 and 1787, show the shape of the full bobbins, produced by the action of these two different traverse motions.

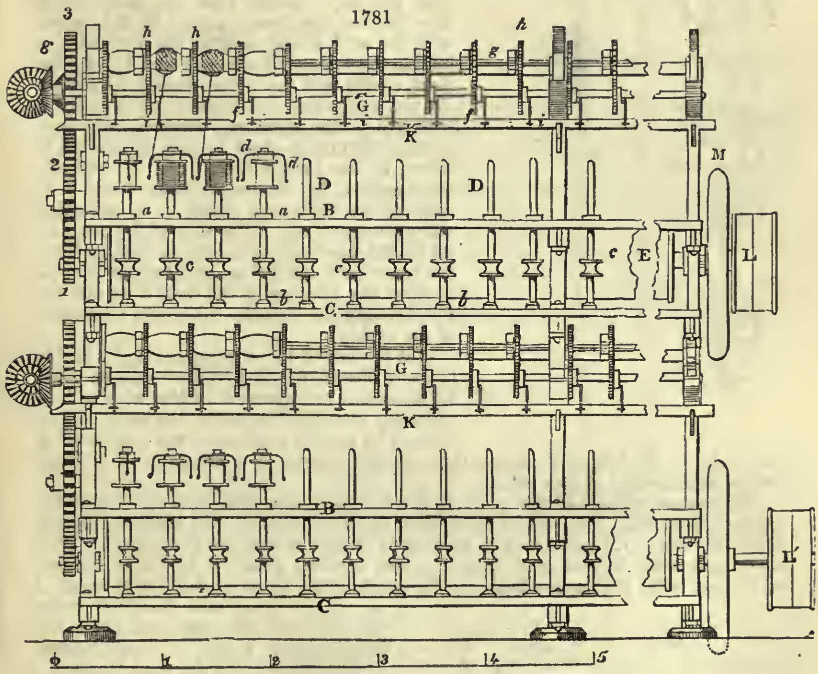
The upper part of the machine being exactly the same as the under part, it will be sufficient to explain the construction and operation of one of them.

A, A, are the end upright frames or standards, between which are two or three intermediate standards, according to the length of the machine. They are all connected at their sides by beams B and C, which extend the whole length of the machines.

D, D, are the spindles, whose top bearings *a*, *a*, are made fast to the beams B, and their bottoms turn in hard brass steps, fixed to the bar C. These two bars together are called by the workmen the spindle-box. The standards A, A, are bound with cross-bars N, N.

c, *c*, are the wharves or whorls, turned by a band from the horizontal tin cylinder in the lines of E, *fig.* 1781, lying in the middle lines between the two parallel rows of spindles D, D. F, F, are the bobbins containing the untwisted double silk, which are simply pressed down upon the taper end of the spindles. *d*, *d*, are little flyers, or forked wings of wire, attached to washers of wood, which revolve loose upon the tops of the said bobbins F, and round the spindles. One of the wings is sometimes bent upwards, to serve as a guide to the silk, as shown by dotted lines in *fig.* 1782. *e*, *e*, are pieces of wood pressed upon the tops of the spindles, to prevent the flyers from starting off by the centrifugal force. G are horizontal shafts bearing a number of little spur-wheels *f*, *f*. H are slot-bearings, similar to those of the doubling-machine, which are fixed to the end and middle frames. In these slots, the light square cast-iron shafts or spindles *g*, *fig.* 1784, are laid, on whose end the spur-wheel *h* is cast; and when the shaft *g* lies in the front slot of its bearing, it is in gear with the wheel *f*, upon the shaft G; but when it is laid in the back slot, it is out of gear, and at rest. See F, F, *fig.* 1780.

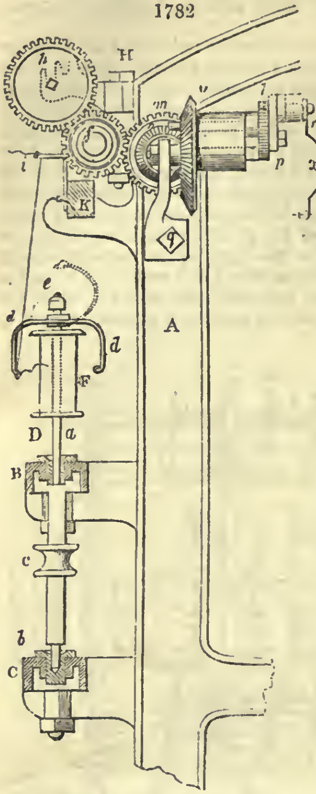
1781



Upon these little cast-iron shafts or spindles *g*, *fig.* 1784, the bobbins or blocks I, are thrust, for receiving by winding-on the twisted or spun silk. These blocks are made of a large diameter, in order that the silk fibres may not be too much bent; and they are but slightly filled at each successive charge, lest, by increasing their diameter too much, they should produce too rapid an increase in the rate of winding, with proportional diminution in the twist, and risk of stretching or tearing the silk. They are therefore the more frequently changed. K, K, are the guide-bars, with the guides *i*, *i*, through which the silk passes, being drawn by the revolving bobbins I, and delivered or laid on by the flyers *d*, *d*, from the rotatory twisting-bobbins F. The operation of the machine is therefore simple, and the motions are given to the parts in a manner equally so.

Upon the shaft of the tin cylinder or drum, exterior to the frame, the usual fast and loose pulleys or riggers, L, L′, are mounted, for driving the whole machine. These riggers are often called steam-pulleys by the workmen, from their being connected by bands with the steam-driven shaft of the factory. In order to allow the riggers upon the shafts of the upper and the under drums to be driven from the same pulley upon the main shaft, the axis of the under drum is prolonged at L, L′, and supported at its end, directly from the floor, by an upright bearing. Upon the shafts of the tin cylinders there is also a fly-wheel, M, to equalise the motion. Upon the other ends of these shafts, namely, at the end of the spinning mill, represented in *fig.* 1782, the pinions 1, are fixed, which drive the wheels 3, by means of the intermediate or carrier-wheel, 2, called also the plate-wheel, from its being hollowed somewhat like a trencher. 1 is called the change pinion, because it is changed for another of a different size and different number of teeth, when a change in the velocity of wheels 2 and 3 is to be made. To allow a greater or smaller pinion to be applied at 1, the wheel 2 is mounted upon a stud *k*, which is moveable in a slot concentric with the axis of the wheel 3. This slot is a branch from the cross-bar N. The smaller the change-pinion is, the nearer will the stud *k* approach to the vertical line joining the centres of wheels 1 and 3; and the more slowly will the plate-wheel 2 be driven. To the spur-wheel 3, a bevel-wheel 4, is fixed, with which the other also revolves loose upon a stud. The bevel-wheel 5, upon the shaft *l*, is driven by the bevel-wheel 4; and it communicates motion, by the bevel-wheels 6 and 7, to each of the horizontal shafts G, G, extending along the upper and under tiers of the machine. At the left-hand side of the top part of *fig.* 1781, the two wheels 6 and 7 are omitted, on purpose to show the bearings of the shaft G, as also the slot-bearings for carrying the shafts or skewers of the bobbins.

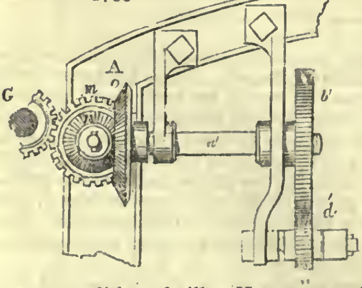
1782



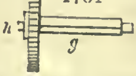
If it be desired to communicate twist in the opposite direction to that which would be given by the actual arrangement of the wheels, it is necessary merely to transpose the carrier-wheel 2, from its present position on the right hand of pinion 1, to the left of it, and to drive the tin cylinder by a crossed or close strap, instead of a straight or open one.

The traverse motion of the guide is given here in a similar way to that of the engine (*fig.* 1766). Near one of the middle or cross-frames of the machine (see *fig.* 1782), the wheel *f*, in gear with a spur-wheel *h*, upon one of the block-shafts, drives also a spur-wheel *m*, that revolves upon a stud, to which wheel is fixed a bevel-wheel *n*, in gear with the bevel-wheel *o*. To wheel *o*, the same mechanism is attached as was described under *figs.* 1780 and 1781, and which is here marked with the same letters.

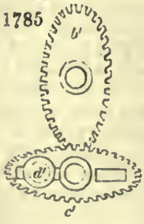
1783



1784



1785

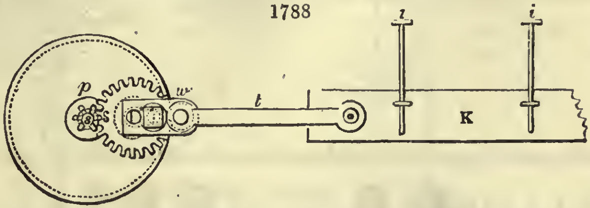


To the crank-knob *r*, *fig.* 1782, a rod, *x*, is attached, which moves or traverses the guide-bar belonging to that part of the machine: to each machine one such apparatus is fitted. In *figs.* 1783 and 1785, another mode of traversing the guide-bar is shown, which is generally used for the coarser qualities of silk. Near to one of the middle frames, one of the wheels *f*, in gear with the spur-wheel *m*, and the bevel-wheel *n*, both revolving on one stud, gives motion also to the wheel *o*, fixed upon a shaft *a*′, at whose other end the elliptical wheel b' is fixed, which drives a second elliptical wheel c', in such a way that the larger diameter of the one plays in gear with the smaller diameter of the other; the teeth being so cut as to take into each other in all positions. The crank-piece d' is screwed upon the face of the wheel c', at such a distance from its centre as may be necessary to give the desired length of traverse motion to the guide-bar, for laying the silk spirally upon the blocks. The purpose of the elliptical wheel is to modify the simple crank-motion, which would wind on more silk at the ends of the bobbins than in their middle, and to effect an equality of winding-on over the whole surface

1786

1787

1788

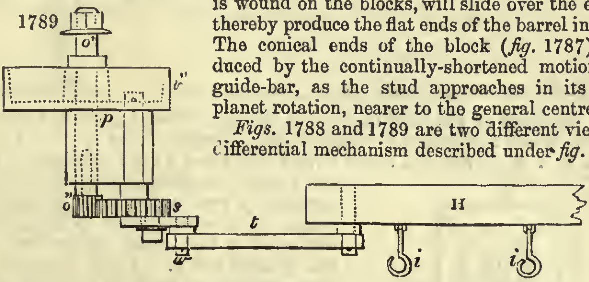


of the blocks. In *fig.* 1785, the elliptical wheels are shown in front, to illustrate their mode of operating upon each other.

Fig. 1786, is a block filled by the motion of the excentric, *fig.* 1782; and *fig.* 1787, is a block filled by the elliptical mechanism. As the length of the motions of the bar in the latter construction remains the same during the whole operation, the silk, as it is wound on the blocks, will slide over the edges, and thereby produce the flat ends of the barrel in *fig.* 1786. The conical ends of the block (*fig.* 1787) are produced by the continually-shortened motions of the guide-bar, as the stud approaches in its sun-and-planet rotation, nearer to the general centre.

Figs. 1788 and 1789 are two different views of the differential mechanism described under *fig.* 1782.

1789



The bent wire x, *fig.* 1782, is called the guide-iron. It is attached at one end to the pivot of the sun-and-planet wheel-work t, s, o, and at the other to the guide-bar f, f, *fig.* 1781. The silk threads pass through the guides, as already explained. By the motion communicated to the guide-bar (*guider*), the diamond-pattern is produced, as shown in *fig.* 1786.

The Silk Automatic Reel.

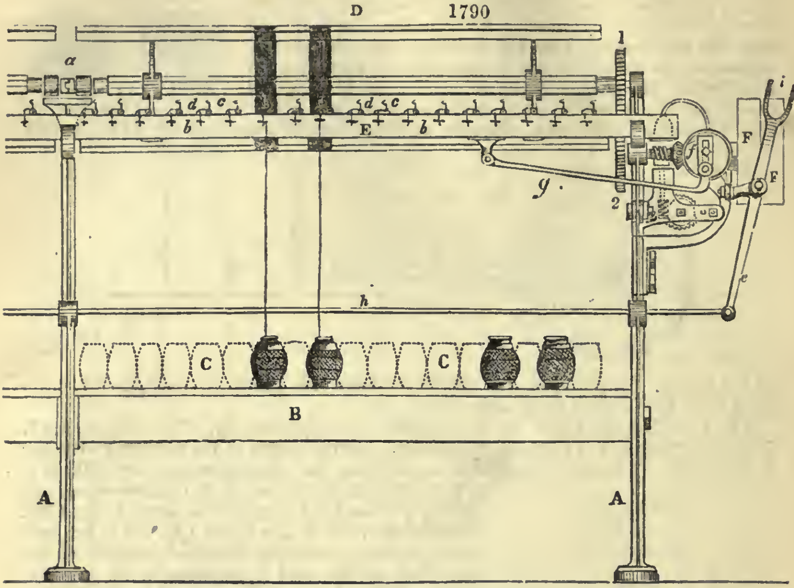
In this machine, the silk is unwound from the blocks of the throwing-mill, and formed into hanks for the market. The blocks being of a large size, would be productive of much friction, if made to revolve upon skewers thrust through them, and would cause frequent breakage of the silk. They are, therefore, set with their axes upright upon a board, and the silk is drawn from their surface, just as the weft is from a cop in the shuttle. On this account the previous winding-on must be executed in a very regular manner, and preferably as represented in *fig.* 1786.

Fig. 1790, is a front view of the reel; little more than one-half of it being shown.

Fig. 1791, is an end view. Here the steam-pulleys are omitted, for fear of obstructing the view of the more essential parts. A, A, are the two end framings, connected by mahogany stretchers, which form the table B, for receiving the bobbins C, C, which are sometimes weighted at top with a lump of lead to prevent their tumbling. D is the reel, consisting of four long laths of wood, which are fixed upon iron frames, attached to an octagonal wooden shaft. The arm which sustains one of these laths is capable of being bent inwards by loosening a tightening hook, so as to permit the hanks, when finished, to be taken off, as in every common reel.

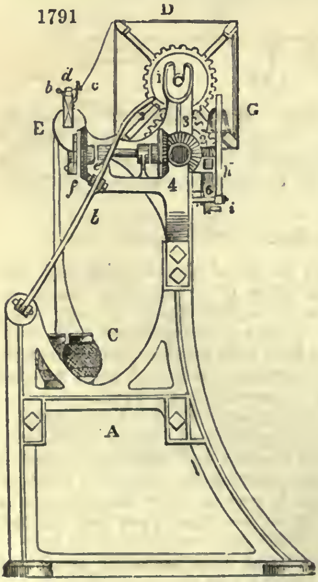
The machine consists of two equal parts coupled together at a, to facilitate the removal of the silk from either half of the reel; the attendant first lifting the one part and then the other. E, is the guide-bar, which by a traverse motion causes the silk to be wound on in a cross direction. *b* and *c* are the wire-guides, and *d* are little levers lying upon the cloth-covered guide-bar E. The silk in its way from the block to the reel, passes under these levers, by which it is cleaned from loose fibres.

1790



On the other end of the shaft of the reel, the spur-wheel 1 is fixed, which derives motion from wheel 2, attached to the shaft of the steam-pulley F. Upon the same shaft there is a bevel-wheel 3, which impels the wheel 4 upon the shaft *e*; to whose end a plate is attached, to which the crank *f* is screwed, in such a way as to give the proper length of traverse motion to the guide-bar E, connected to that crank or excentric stud by the jointed rod *g*. Upon the shaft of the steam-pulleys F, there is a worm or endless screw, to the left of *f*, *fig.* 1790, which works in a wheel 5, attached to the short upright shaft *h* (*fig.* 1791). At the end of *h* there is another worm, which works in a wheel, 6; on whose circumference there is a stud, *i*, which strikes once at every revolution against an arm attached to a bell, seen to the left, G; thus announcing to the reel-tenter that a measured length of silk has been wound upon her reel. *e*, is a rod or handle, by which the fork *l*, with the strap, may be moved upon the fast or loose pulley, so as to set on or arrest the motion at pleasure.

1791



Throwsters submit their silk to scouring and steaming processes. They soak the hanks, as imported, in lukewarm soap-water in a tub; but the bobbins of the twisted single silk from the spinning mill are enclosed within a wooden chest and exposed to the opening action of steam for about ten minutes. They are then immersed in a cistern of warm water, from which they are transferred to the doubling-frame.

The wages of the work-people in the silk-throwing mills of Italy are about one-half of their wages in Manchester; but this difference is much more than counterbalanced by the superior machinery of our mills.

There is a peculiar kind of silk called *marabout*, containing generally three threads, made from the white Novi raw silk. From its whiteness, it takes the most lively and delicate colours without the discharge of its gum. After being made into tram by the single twist upon the spinning mill, it is reeled into hanks, and sent to the dyer without further preparation. After being dyed, the throwster re-winds and re-twists it upon the spinning mill, in order to give it the whip-cord hardness which constitutes the peculiar feature of marabout. The cost of the raw Novi silk is 19*s.* 6*d.* a pound; of throwing it into tram, 2*s.* 6*d.*; of dyeing, 2*s.*; of re-winding and re-twisting, after it has been dyed, about 5*s.*; of waste, 2*s.*, or 10 per cent.: the total of which sum is 31*s.*; being the price of one pound of marabout in 1832.

As nearly as can be ascertained, the following is a correct statement of the present condition of our silk-manufacture (1874):—

The number of silk factories in England and Wales are: Spinning, 227; weaving, 390; spinning and weaving, 39; others, 36: total, 692. Scotland: spinning and weaving, 4. Total in the United Kingdom, 696 factories.

The number of spindles in the United Kingdom being: Spinning, 940,143; doubling, 190,298.

The number of power-looms, 12,378.

The motive horse-power of the machinery employed being: Steam, 7,604; water, 985.

Total number of persons employed, 48,124.

At present the United Kingdom draws its supply of the raw material for manufacture principally from the East Indies; and France, Italy, Turkey, and China, also supply a considerable amount. About 20 years since, the annual imports for home consumption amounted to 4,734,755 lbs.

In 1857, the quantity of 12,077,931 lbs. of silk in its several conditions of raw, waste, and thrown, was imported into this country.

The following represents our *Import* trade in silk for the year 1873:—

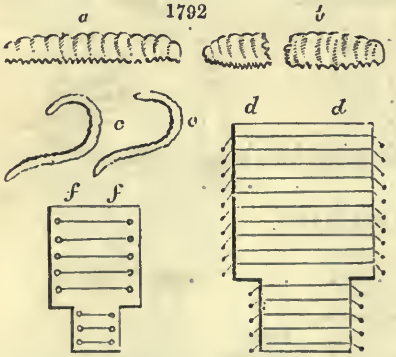
SILKWORM GUT, for angling, is made as follows:—Select a number of the best and largest silkworms, just when they are beginning to spin; which is known by their refusing to eat, and having a fine silk thread hanging from their mouths. Immerse them in strong vinegar, and cover them closely for twelve hours, if the weather be warm, but two or three hours longer, if it be cool. When taken out, and pulled asunder, two transparent guts will be observed, of a yellow-green colour, as thick as a small straw, bent double. The rest of the entrails resembles boiled spinage, and therefore can occasion no mistake as to the silk-gut. If this be soft, or break upon stretching it, it is a proof that the worm has not been long enough under the influence of the vinegar. When the gut is fit to draw out, the one end of it is to be dipped into the vinegar, and the other end is to be stretched gently to the proper length. When thus drawn out, it must be kept extended on a thin piece of board, by putting its extremities into slits in the end of the wood, or fastening them to pins, and then exposed in the sun to dry. Thus genuine silk-gut is made in Spain. From the manner in which it is dried, the ends are always more or less compressed or attenuated. In *fig.* 1792, *a* is the silkworm; *b*, the worm torn asunder; *c, c*, the guts; *d, d*, a board slit at the ends, with the gut to dry; *f, f*, boards with wooden pegs, for the same purpose.

1792



SILVER (*Argent*, Fr.; *Silber*, Ger.) was formerly called a *perfect* metal, because heat alone revived its oxide, and because it could pass unchanged through trials by fire, which apparently destroyed most other metals. The distinctions, perfect, imperfect, and noble, are now rejected.

When pure and polished, silver is the brightest of the metals. Its specific gravity in the ingot is 10·47; but, when condensed under the hammer or in the coining-press, it becomes 10·6. It melts at a bright red heat, at a temperature estimated by some as equal to 1873° Fahr. It is exceedingly malleable and ductile, affording leaves not more than $\frac{1}{100000}$ of an inch thick, and wire far finer than a human hair.

By Sickingen's experiments, its tenacity is, to that of gold and platinum, as the number 19, 15, and $26\frac{1}{4}$; so that it has an intermediate strength between these two metals. Pure atmospheric air does not affect silver, but that of houses impregnated with sulphuretted hydrogen soon tarnishes it with a film of brown sulphide. It is distinguished chemically from gold and platinum by its ready solubility in nitric acid, and from almost all other metals, by its saline solutions affording a curdy precipitate with a most minute quantity of sea-salt or any soluble chloride.

The atomic weight of silver is 108; its chemical symbol is Ag (*argentum*).

Silver occurs in nature under many forms:—

1. *Native silver* possesses most of the above properties; yet, on account of its being more or less alloyed with other metals, it differs a little in malleability, lustre, density, &c. It sometimes occurs crystallised in octahedrons, in cubes, and cubo-octahedrons. At other times it is found in dendritic shapes, or arborescences, resulting from minute crystals implanted upon each other. But more usually it presents itself in small grains without determinable form, or in amorphous masses of various magnitude.

The *gangues* (mineral matrices) of native silver are so numerous, that it may be said to occur in all kinds of rock. At one time it appears as if filtered into their fissures, at another as having vegetated on their surface, and at a third, as if impasted in their substance. Such varieties are met with principally in the mines of Peru.

The native metal is found in almost all the silver mines now worked; but especially in those of Kongsberg in Norway, in carbonate and fluoride of calcium, &c.; at Schlangenberg in Siberia, in sulphate of baryta; at Allémont, in a ferruginous clay, &c. The mines of Chili and Peru have yielded large quantities of native silver.

The metals most usually associated with silver in the native alloy, are gold, copper, arsenic, and iron. At Andreasberg and Guadalcanal it has been found alloyed with about five per cent. of arsenic. The auriferous native silver is the rarest.

2. *Antimonial silver, or Dyscrasite.*—This rare ore is destitute of malleability, and very brittle; spec. grav. 9·5. It melts before the blowpipe, and affords white fumes of oxide of antimony: being readily distinguished from arsenical iron and arsenical cobalt by its lamellar fracture. It consists of from 76 to 84 per cent. of silver, and from 24 to 16 of antimony.

3. *Argentite, Sulphide of silver or Silver glance.*—This is an opaque substance, of a dark-grey or leaden hue; slightly malleable, and easily cut with a knife, when it betrays a metallic lustre. The silver is easily separated by the blowpipe. It consists of 13 of sulphur to 89 of silver, by experiment; 13 to 87 are the theoretic proportions. Its specific gravity is 6·9. It occurs crystallised in cubes, and is found in the mines of Freiberg in Saxony, Joachimsthal in Bohemia, Schemnitz in Hungary, and Mexico.

4. *Pyrargyrite, Red Silver ore, Ruby Blende, or Antimoniated sulphide of silver,* is an ore remarkable for its lustre, colour, and the variety of its forms. It is friable, easily scraped by the knife, and affords a powder of a lively crimson-red. Its colour in mass is brilliant red, dark red, or even metallic reddish-black. It crystallises in a variety of hexagonal forms. Its constituents are: silver from 56 to 62; antimony from 20 to 24; sulphur from 16 to 18. It is found in almost all silver mines; but principally in those of Freiberg, Andreasberg, and Guadalcanal.

5. *Proustite, Light Red Silver ore, or Arsenical sulphide of silver,* is a similar but rarer mineral, in which arsenic takes the place of antimony.

6. *Stephanite, or Black sulphide of silver,* is a blackish, brittle mineral, affording globules of silver at the blowpipe. It is found at Allémont and at Freiberg; but more abundantly in the silver mines of Peru and Mexico. The Spaniards call it *negrillo.*

7. *Polybasite* is a sulphide of silver and copper, generally with antimony and arsenic. It occurs in Mexico, Chili, Nevada, and Idaho.

8. *Sternbergite* is a rare sulphide of silver and iron.

9. *Chloride of silver, or Horn silver.*—In consequence of its semi-transparent aspect, its yellowish or greenish colour, and such softness that it may be cut with the nail, this ore has been compared to horn, and may be easily recognised. It melts at the flame of a candle, and may be reduced when heated along with iron or black-flux. It is occasionally crystallised in forms belonging to the cubic system; but occurs chiefly in irregular forms, sometimes covering the native silver with a thick crust, as in Peru and Mexico. Its density is only 4·74. It is found in considerable quantities at North Dolcoath in Cornwall.

Chloride of silver sometimes contains 60 or 70 per cent. of clay; and is then called 'butter-milk ore' by the German miners.

10. *Bromide of silver* or *Bromyrite,* and *Iodide of silver* or *Iodyrite,* occur in the mines of Chili and Mexico; whilst a mineral called *Embolite,* which is a chloro-bromide of silver, is found rather abundantly in some of the mines of Chili.

11. *Carbonate of silver, or Selbite,* is a mineral of doubtful occurrence.

Large quantities of silver are annually obtained in this country, and in the lead-producing districts of Europe, by the treatment of argentiferous galena; but the New

Continent, which produces for the most part ores containing but a small proportion of lead, is estimated to furnish twelve times more silver than the Old. See Lead.

Silver has been produced in the following countries:—

Norway.—The mines of Kongsberg were discovered in 1623, and they have been worked, almost continuously, up to the present time, their average annual produce being about 18,000 lbs. troy.

Hungary, *Transylvania*, and the *Banat*, are stated to produce about 92,000 lbs. of silver annually.

Saxony and Bohemia.—The mines near Freiberg are the most important.

The *Mines of the Hartz* produce about 28,000 lbs. troy of silver annually; while those of the *Alps* produce small quantities.

France has no silver mines of importance.

In *Spain*, the mines of Guadalcanal and Cazalla have been highly productive. The total produce of the Spanish silver mines, in 20 years, was 8,200,000 Spanish ounces.

In *North America*, the mines of *Mexico* are the most ancient, and the silver lodes the most remarkable. The vein called the Veta Madre, of Guanaxuato, was often 200 feet in width, and that of Zacatecas is sometimes 75 feet wide. Humboldt stated the production of silver in Mexico, in 1789, to have been 7,314,344 lbs. troy. There are about sixteen silver mines producing silver ore at the present time in Mexico; the ores varying from 55 ounces to 81 ounces of silver to the ton. The Real del Monte Company produced annually silver to the value of three millions and a half of dollars.

Nevada.—The discovery of silver in this region dates only from 1859; but the production of silver and gold has been immense, often rising to nearly 300,000 tons of ore per annum; sometimes yielding silver to the value of 150 dollars per ton, and seldom of less value than 28 dollars. There are numerous other districts, which space will not allow us to mention. See 'The Mining and Metallurgy of Gold and Silver,' by J. Arthur Phillips, for full accounts of the North American silver mines.

South America.—The silver mines are confined to the Republics of Peru, Bolivia, and Chili. The mines of Cerro de Pasco are the most celebrated in Peru, the principal ores being known as *pacos*; these are ferruginous earths, containing varying amounts of silver. These mines were discovered in 1630, and are still being worked, upon a small scale. The production of silver, in Peru, has been estimated at 299,000 lbs. troy.

Bolivia.—The mines of Potosi, which once formed a portion of the viceroyalty of Buenos Ayres, are now included in this republic. Thirty-two veins have been worked in this historical mine, which was discovered in 1545, with great profit, and numerous smaller ones, with more or less advantage. In the province of Potosi, according to Whitney, the United States Geologist, there were, when he visited the district, 1,800 abandoned mines, and only 26 at work; in other parts, there were 2,365 mines abandoned, and only 40 at work.

Chili.—The most important silver mines of Chili are those in the neighbourhood of Copiapo. Chlorides of silver are the most abundant ores, but there are also arsenides and sulphides, the ore containing from 100 to 250 ounces of silver to the ton. Chili appears to have produced in seven years 1,750,000 lbs. of silver.

New Granada.—The Santa Anna mines, in the province of Mariquita, have been long celebrated. They produced 1,266,455 ounces of silver between 1852 and 1864. Since that time, the production has been limited.

Mexican Amalgamation Process.—The following description of the extraction and treatment of silver ores in Mexico is derived from a paper published by Mr. J. A. Phillips, who for some years acted as manager for the firm of John Taylor and Sons. His excellent description may be applied to the amalgamation process, as carried out in other places.

We may previously state some of the peculiar features observable in the working of the mines of Mexico, confining our attention to the mines of Guanaxuato, Zacatecas (including Fresnillo), and Real del Monte. The mines of Guanaxuato are situated upon one vein of great length and width. It should be understood that this vein, like all mineral veins, is not productive of silver ore throughout its whole extent, but the ore occurs in branches and bunches, leaving intermediate spaces of dead or unproductive ground; and, as an ordinary mine-level seldom exceeds 6 feet in width, it is clear that a level like this would not explore a vein of such dimensions as that of Guanaxuato, while the expense of cross-cutting, as miners term it, would require more capital than the owners of the mine were willing to risk, or able, in many instances, to spare. Hence, there sprang up in Guanaxuato a system of working well adapted to the circumstances noticed, and being based upon the principle that the hope of reward acts as a stimulus to exertion, was attended with the best effects, and led to the discovery of some of the richest deposits of ore.

This system is called that of the *buscones* or 'seekers,' who are the working miners. These men, at their own risk, work in the mines under certain restrictions; and following up such indications as may appear to them favourable, oftentimes meet with a valuable course of ore, but frequently work for months, earning scarcely enough for bare subsistence. While thus employed the *buscon* receives half the produce of the ore he breaks; and it may be readily conceived that if he should fall in with a rich deposit, his gains should be very large: thus, instances have been known where a man has obtained, in this way, 1,000 or 1,500 dollars in a month.

The owners of the mine, however, have the option of taking away such a discovery from the hands of the miner, after a short notice, and working it on their own account, or, as it is termed, *hacienda account*, when they pay the miners a dollar per day each, without any share of the ore. To do this, however, the mine must be rich, and as it is, a very large portion of the ore in Guanaxuato is raised by the *buscones*, who divide the produce equally with the owners.

The ore, being broken and separated as much as possible from the rocky parts underground, is tied up in the *botas* of bullocks' hides, which are drawn to the surface by the *malacates*, in the same manner as the water. In some of the Guanaxuato mines, labourers are employed to take the ore to the surface, and these will carry on their backs from 2 to 3 cwts., and perform several journeys in a day from the bottom of a mine 400 or 500 yards in depth. At the mine of Mellado there is a very excellent double tramroad, on an inclined plane of timber, upon which the ore is drawn up in waggons to a height of 200 varas from the bottom of the mine, where the diagonal joins the perpendicular shaft at about the same depth from the surface: each carriage will contain 160 arrobas of 25 lbs. each. The power applied is that of a malacate working underground; and here at 200 yards from the surface, and shut out from the light of day, one is surprised to behold a storehouse and stabling, with all the necessary appurtenances for thirty-six horses, employed in moving the machine above mentioned, nine horses working at a time.

Having brought the ore to the surface, it is conveyed to the mine-yard, and placed in separate heaps, under the eye of the *buscon* or miner, who prepares it for sale. At a stated time the auctioneer appears, accompanied by a clerk; he walks round to the heaps of ore in succession, and sells them in the following manner:—

Standing before the heap of ore to which he invites attention, those who come to purchase step forward and whisper into his ear the price they severally offer. When all have done, he declares aloud the name of the highest bidder, and the price, which are entered in a book by the clerk; and the same process is followed throughout until all the ore is sold.

The practice in the Real del Monte differs from both the others, but assimilates a little towards the Guanaxuato system, inasmuch as the miner has a share of the ore, called *partido*. This partido system has prevailed from a very early period, and has led to many broils and disturbances with the miners.

The method of extracting the silver from the ore, at the establishments maintained for that purpose, called '*haciendas de beneficio*,' or '*haciendas de Plata*,' of which there are many of great extent in the country, is thus carried forward. The Haciendas Nueva in Fresnillo, of Sauceda in Zacatecas, of Barrera in Guanaxuato, and of Regla at Real del Monte, are the principal establishments of this kind at present in use. That in Fresnillo is the largest used for amalgamation only, the outer walls being 492 varas in length by 412 varas in width. It was erected at a cost of 300,000 dollars, and is very complete in all its arrangements.

The Hacienda de Regla combines very extensive smelting works with those for amalgamation.

The ore being placed in heaps in the yard is broken by hammers into pieces of moderate size, and carefully picked; the richer parts being set aside for smelting, and the poorer for amalgamation.

In the smelting process, the ore after being crushed, is mixed with slag or remains from former smeltings, litharge or oxide of lead, and a little iron ore and lime. These are put into the furnace with charcoal, and the silver is brought down with the lead; the two metals being afterwards separated in refining furnaces. The German high furnace is usually employed, although the Castilian furnace described in the article on Lead, would probably be found preferable.

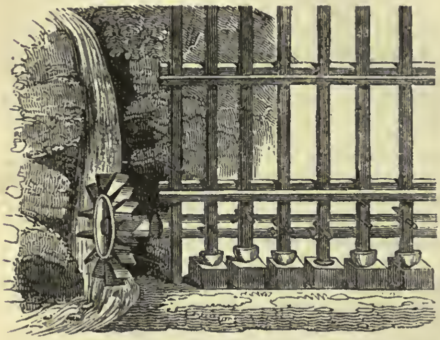
It is estimated that about an eighth part of the silver produced in Mexico is obtained by smelting; but as only the richest ores are subjected to this process, on account of the expense, which is from 15*l.* to 20*l.* per ton, except in a district like Zimapan, where lead ore is abundant, the proportion which the quantity of ore smelted bears when compared with that reduced by amalgamation must be very small indeed.

The process of amalgamation, to which attention is now more particularly directed, depends upon the great affinity of quicksilver for silver. In order, however, to make this known property available, certain operations are requisite, to reduce the silver contained in the ore to such a state that the quicksilver will readily combine with it.

After the breaking and dressing by hand, the ore is crushed, either by crushing-rollers or more generally by stamps, called in Mexico, *molinos*. The stamps are similar in principle to those used in the tin mines of Cornwall, but not so powerful, and are worked either by water-power or by mules. As the ore is crushed, it falls through small holes of about the size of a pea, perforated in strong hides stretched in a slope on either side of the machine placed over a pit which receives the fine ore, from whence it is conveyed to the *arrastres* or grinding mills.

These stamping mills are sometimes driven by a small breast water-wheel, of five feet diameter and one foot broad. *Fig.* 1793 will give a sufficient idea of their construction. The long horizontal shaft, fixed on the axis of the wheel, is furnished with 5 or 6 rams placed at different situations round the shaft, so as to act in succession on the projecting teeth of the upright rods or pestles. Each of these weighs 200 lbs., and works in a corresponding oblong mortar of stone or wood.

1793



The arrastre, or '*tahona*,' as it is called in the northern districts, is exceedingly simple, but for so rude a machine is very effective. Baron Humboldt, in alluding to it, says that he never saw ore so finely pulverised as he saw it in Mexico. In Guanaxuato, where there is much gold in the ore, this is particularly observable.

The arrastre consists, in the first place, of a strong wooden post moving on a spindle in a beam above it, and resting on an iron pivot beneath, turning in an iron socket on the top of a small post of hard wood which rises about a foot above the ground in the centre of the arrastre. See ORE DRESSING.

These arrastres are usually arranged in rows in a large gallery or shed, as will be seen by reference to *fig.* 1794, which represents the gallery of the Hacienda of Salgado.

A machine has been introduced at Real del Monte which has superseded the old Mexican arrastres. This machine is similar in principle to some of the grinding mills of this country, and to the *trapiche* of Peru. It consists of two large circular edge stones faced with iron, and moving over iron bottoms, the ore being crushed and ground with water between the two metal-surfaces. The machine is turned by twelve mules in the twenty-four hours, four mules working at a time, and the quantity ground to a fine slime is sixty quintals, or about ten times the quantity ground by a common arrastre; and there is reason to believe that the quantity might be doubled by the use of water- or steam-power, as the number of revolutions would be increased.

The ore being brought into a finely-divided state, is allowed to run out of the arrastre into shallow tanks or reservoirs, where it remains exposed to the sun until a larger portion of the water has evaporated, when it has the appearance of thick mud; and in this state the process is proceeded with.

The *lama* as it is called, or slime, is now laid out on the *patio*, or amalgamation-floor (which is in some places boarded, and in others paved with flat stones), in large masses called *tortas*, 40 to 50 feet in diameter and about a foot thick, consisting frequently of 60 or 70 tons of ore; and so extensive are the floors that a large number of these tortas are seen in progress at the same time. Thus, at the Hacienda de Regla, the patio, which is boarded and carefully caulked, to render it water-tight, is capable of containing ten of these tortas, of about 60 tons each and 50 feet in diameter. The Hacienda de Barrera in Guanaxuato will hold eighteen tortas of 70 to 75 tons each. The Hacienda Sauceda at Zacatecas will contain twenty-four tortas of 60 tons each; and the patio floor of the Hacienda Nueva at Fresnillo is still larger, being 180 varas in length by as many in width, and capable of containing sixty-four tortas of 70 tons each!

Having laid out the masses of ore in the patio, the operations necessary to produce the chemical changes commence. The first ingredient introduced is salt, which is put into the torta in the proportion of 50 lbs. to every ton of ore (but varying in different districts), and a number of mules are made to tread it, so that it may become dissolved in the water, and intimately blended with the mass. On the following day another ingredient is introduced, called in Mexico *magistral*. It is common copper pyrites, or sulphide of copper and iron, pulverised and calcined, which converts it into a sulphate. About 25 lbs. of this magistral are added for every ton of ore in the torta, and the mules are again put in, and tread the mass for several hours. Chemical action now commences: the salt, magistral and metallic sulphurets are decomposed, and new combinations are in progress. Quicksilver is then introduced, being spread over the torta in very small particles, which is effected by passing it through a coarse cloth. The quantity required is six times the estimated weight of the silver contained in the ore, or 3 lbs. for every marc of 8 ozs.

The quicksilver being spread over the surface, the mules are once more put in, and tread the whole until it is well mixed. This treading is called the *repaso*, and is repeated every other day, or less often, according to the judgment of the *azoguero* or superintendent, until the operation is completed.

But it is in the progress of the operation that the skill of the azoguero is most required, because he must attend to certain signs or appearances which present themselves to him, and upon which depends the success of his work, whether as it regards the produce of silver or the economy of quicksilver and other materials and time. For this purpose he has a small quantity of the torta put on one side, upon which he operates before adding materials to the torta itself; this is called a *guia*, or guide.

1794

In order to ascertain how the chemical action in the torta proceeds, he collects a small quantity of the slime and washes it in a small bowl, and by the signs presented by the quicksilver and amalgam he, from his practical knowledge of the subject, is able to judge as to the state of the torta; whether it requires more magistral or quicksilver; or whether it has had too much magistral, in which case it is hot, and a little lime must be put in to decompose the excess of chloride of copper. This simple plan is termed the *tentadura*, by which in fact the azoguero is guided throughout the amalgamation process.

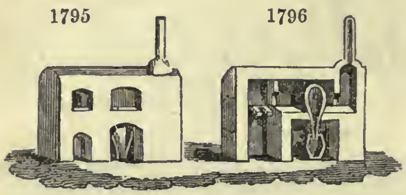
When at length he finds the quicksilver is no longer absorbed, the operation is considered complete, and the torta *rendida*, or ready to be washed, and sometimes lime is added to stop further action. A large quantity of quicksilver is then thrown in, and is called *el baño*, or bath, which combining with the amalgam, causes it to separate the more readily from the slime in the washing. The time required to complete the process varies from ten to thirty days; but in some places is often considerably more, according to climate and the nature of the ore.

The amalgam has now to be separated from the mass, which is done at Real del Monte by washing it in a large square vat, in which several men keep constantly stirring it with their feet, while at the same time a stream of water is made to pass through. By this means the lighter particles of the mud flow out into canals furnished with basins, called *apuros*, to catch all stray amalgam and quicksilver, and the great body of the amalgam remains at the bottom of the vat.

In Guanaxuato, the process of washing is more perfect. They have three circular vats called *tinas*, in which the ore is stirred by means of long wooden teeth fixed in cross bars attached to a vertical shaft, the whole turned by a simple machine, worked by mules. The slime has to pass through the third vat before being carried entirely away, so that a very small portion indeed of the amalgam escapes. The process of washing is somewhat similar in Zacatecas, but there they use but one tina or vat.

The amalgam is carried in bowls into the *azogueria*, where it is subjected to straining through the strong canvas bottom of a leathern bag. The hard mass left in the bag is moulded into wedge-shaped masses of 30 lbs., which are arranged in the burning house (*fig.* 1795), to the number of 11, upon a solid copper stand, called *baso*, having a round hole in its centre. Over this row of wedges several others are built; and the whole pile is called *piña*. Each circular range is firmly bound round with a rope. The base is placed over a pipe which leads to a small tank of water for condensing the quicksilver; a cylindrical space being left in the middle of the piña, to give free egress to the mercurial vapours.

1795 1796



A large bell-shaped cover, called *capellina*, is now hoisted up, and carefully lowered over the piña, by means of pulleys. A strong lute of ashes, saltierra, and lama is applied to its lower edge, and made to fit very closely to the plate on which the base stands. A wall of fire-bricks is then built loosely round the capellina, and this space is filled with burning charcoal, which is thrice replenished, to keep it burning all night. After the heat has been applied 20 hours, the bricks and ashes are removed, the luting broken, and the capellina hoisted up. The burned silver is then found in a hard mass, which is broken up, weighed, and carried to the casting-house, to be formed into bars.

It will be observed that quicksilver performs a very important part in the process of amalgamation, the silver being through its agency collected from the ore: but this is only done by an enormous loss of its own bulk, occasioned in part mechanically from its minute subdivision through such an immense mass of matter, but principally from the chemical action upon it during the reducing process. The consumption of quicksilver varies in different districts, according to the nature of the ores, the climate, and the practical skill attained by the operator.

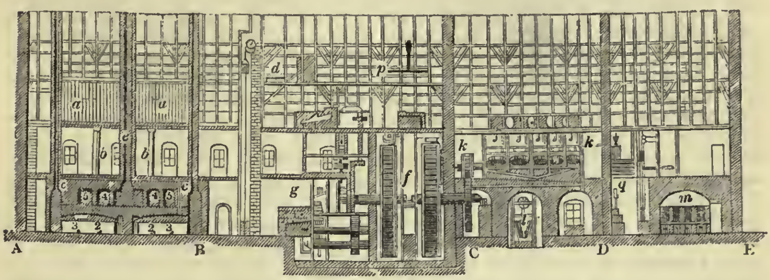
In some places and on some ore the loss of quicksilver is as low as ten ounces for every marc of silver produced, while in others it exceeds 20 ounces; the average loss may, however, be taken to be a pound of quicksilver for every half-pound of silver extracted.

Gay-Lussac, Boussingault, Karsten, and several other chemists of note have offered solutions of the amalgamation enigma of Mexico and Peru. The following seems to be the most probable *rationale* of the successive steps of the process:—

The addition of the *magistral* (powder of the roasted copper pyrites), is not for the purpose of disengaging hydrochloric acid from the sea-salt (*saltierra*), as has been supposed, since nothing of the kind actually takes place; but, by reciprocal or compound affinity, it serves to form chloride of copper and chloride of iron, upon the one hand, and sulphate of soda, upon the other. Were sulphuric acid to be used instead of the magistral, as certain novices have prescribed, it would certainly prove injurious, by causing muriatic acid to exhale. Since the ores contain only at times oxide of silver, but always a great abundance of oxide of iron, the acid would partly carry off both, but leave the chloride of silver in a freer state. A magistral, such as sulphate of iron, which is not in a condition to generate the chlorides, will not suit the present purpose; only such metallic sulphates are useful as are ready to be transformed into chlorides by the saltierra. This is peculiarly the case with sulphate of copper. Its proto-chloride gives up chlorine to the silver, becomes in consequence a subchloride, while the chloride of silver, thus formed, is revived, and amalgamated with the quicksilver present, by electro-chemical agency which is excited by the saline menstruum; just as the voltaic pile of copper and silver is rendered active by a solution of sea-salt. A portion of chloride of mercury will be simultaneously formed, to be decomposed in its turn by the sulphate of silver resulting from the mutual action of the acidified pyrites, and the silver or its oxide in the ore. An addition of quicklime counteracts the injurious effect of too much magistral, by decomposing the resulting sulphate of copper. Quicksilver, when introduced in too great quantities, is apt to cool the mass too much, and thereby enfeebles the operation of the proto-chloride of copper upon the silver.

Washoe Amalgamation Process.—The system of amalgamation largely carried out in the silver-works at Nevada, was originally introduced in the Washoe district, whence it derives its name. The ores having been broken by Blake's stone-breaker, or by hammers, are fed into a stamping-mill, where they are crushed wet. The stuff discharged from the stamps passes to the settling-tanks, in which the finely-suspended ore is allowed to subside. It is then transferred to the amalgamators, which are usually cast-iron pans, of which various forms have been constructed by Varney and Wheeler, Hepburn and Peterson, and other makers. In these pans the ore is ground with hot water and mercury, often with addition of certain 'chemicals,' such as common salt and sulphate of copper. The impure amalgam is discharged from the pan into the separators or settlers, where it is cleansed, and whence it is generally transferred to the agitators. The superfluous mercury having been strained away, the clean amalgam is retorted, the mercury being thus distilled off, whilst the silver remains behind, and after melting is cast into ingots.

1797



Barrel Amalgamation.—The old amalgamation-works at Halsbrücke, near Freiberg, for the treatment of silver ores by mercury, were much admired, and we will therefore give a sketch of their former arrangement. It should be mentioned, however, that the barrel-amalgamation process has not been worked there since 1856.

Fig. 1797 presents a vertical section of this great *Usine* or *Hüttenwerk*, subdivided into four main departments. The first, A, B, is devoted to the preparation and roasting of the matters intended for amalgamation. The second, B, C, is occupied with two successive siftings and the milling. The third, C, D, includes the amalgamation apartment above, and the wash-house of the residuums below. And in the fourth, D, E, is placed the distilling apparatus, where the amalgam is finally delivered.

1. In division A, B; *a*, *a*, is the magazine of salt; *b*, *b*, is the hall of preparation of the ores; on the floor of which they are sorted, interstratified, and mixed with salt; *c*, *c*, are the roasting furnaces; in each of which we see, 1, the fireplace; 2, 3, the reverberatory hearth, divided into two portions, one a little higher than the other, and more distant from the fireplace, called the *drier*; the materials to be calcined fall into it through a chimney, 6. The other part, 2, of the hearth is the calcining area. Above the furnace are chambers of sublimation, 4, 5, for condensing any volatile matters which may escape by the opening 7. *e* is the main chimney.

2. In the division B, C, we have *d*, the floor for the coarse sifting; beneath, that for the fine sieves; from which the matters fall into the hopper, whence they pass down to *g*, the mill-house, in which they are ground to flour, exactly as in a corn-mill, and are afterwards bolted through sieves. *p*, *f*, is the wheel-machinery.

3. The compartment C, D, is the amalgamation-house, properly speaking, where the casks are seen in their places. The washing of the residuums is effected in the shop *l*, below. *k*, *k*, is the compartment of revolving casks.

4. In the division D, E, the distillation process is carried on. There are four similar furnaces, represented in different states, for the sake of illustration. The wooden drawer is seen below, supporting the cast-iron basin, in which the tripod, with its candelabra for bearing the amalgam-saucers, is placed. *q* is a store chamber.

At B, are placed the pulleys and windlass for raising the roasted ore, to be sifted and ground; as also for raising the milled flour, to be transported to the amalgamation-casks. At D, the crane stands for raising the iron bells that cover the amalgamation candelabra.

Details of the Amalgamation Process, as formerly practised at Halsbrücke.—All ores containing more than 7 lbs. of lead, or 1 lb. of copper, per cent., are excluded from this reviving operation (*Anquickverfahren*); because the lead would render the amalgam very impure, and the copper would be wasted. They are sorted for the amalgamation in such a way that the mixture of the poorer and richer ores may contain 7½, or, at most, 8 loths (of ½ oz. each) of silver per 100 lbs. The most usual constituents of the ores are, sulphur, silver, antimonial silver (*Speissglanzsilber*), bismuth, sulphides of arsenic, of copper, iron, lead, nickel, cobalt, zinc, with several earthy minerals. It is essential that the ores to be amalgamated shall contain a certain proportion of sulphur, in order that they may decompose enough sea-salt in the roasting to disengage as much chlorine as to convert all the silver present into chloride. With this view, ores poor in sulphur are mixed with those that are richer, to make up a determinate average. The ore-post is laid upon the *bed-floor*, in a rectangular heap, about 17 ells long and 4½ ells broad (13 yards and 3½); and upon that layer the requisite quantity of salt is let down from the floor above, through a wooden funnel; 40 cwts. of salt being allotted to 400 cwts. of ore. The heap being made up with alternate strata to the desired magnitude, must be then well mixed, and formed into small bings, called *roast-posts*, weighing each from 3½ to 4½ cwts. The annual consumption of salt at Halsbrücke was 6,000 cwts., supplied by the Prussian salt-works.

Roasting of the Amalgamation Ores.—The furnaces appropriated to the roasting of the ore-posts are of a reverberatory class, provided with soot-chambers. They are built alongside the *bed-floor*, and connected with it by a brick tunnel. The prepared ground-ore (*Erzmehl*) is spread out upon the hearth, and dried with incessant turnings over; then the fire is raised so as to kindle the sulphur, and keep the ore red hot for one or two hours; during which time, dense white-grey vapours of arsenic, antimony, and water, are exhaled. The desulphuration next begins, with the appearance of a blue flame. This continues for three hours, during which the ignition is kept up; and the mass is diligently turned over, in order to present new surfaces, and prevent caking. Whenever sulphurous acid ceases to be formed, the finishing calcination is to be commenced with increased firing; the object being now to decompose the sea-salt by means of the metallic sulphates that have been generated, and to convert them into chlorides, with the simultaneous production of sulphate of soda. The stirring is to be continued till the proofs taken from the hearth no longer betray the smell of sulphurous, but of hydrochloric acid gas. This roasting stage commonly lasts three quarters of an hour; 13 or 14 furnaces are worked at the same time at Halsbrücke, and each turns out in a week upon an average 5 tons. Out of the *Nicht* chambers or soot-vaults of the furnaces, from 96 to 100 cwts. of ore-dust are obtained, containing 32 marcs (16 lbs.) of silver. This dust is to be treated like unroasted ore. The fuel of the first fire is pitcoal; of the finishing one fir-wood. Of the former 115½ cubic feet, and of the latter 294½, are, upon an average, consumed for every 100 cwts. of ore.

During the last roasting, the ore increases in bulk by one-fourth, becoming in consequence a lighter powder, and of a brown colour. When this process is completed, the ore is raked out upon the stone pavement, allowed to cool, then screened in close sieve-boxes, in order to separate the finer powder from the lumps. These are to be bruised, mixed with sea-salt, and subjected to another calcination. The finer powder alone is taken to the millstones, of which there are 14 pairs in the establishment. The stones are of granite, and make from 100 to 120 revolutions per minute. The roasted ore, after it has passed through the bolter of the mill, must be as impalpable as the finest flour.

The Amalgamation.—This (the *Verquicken*) is performed in 20 horizontal casks, arranged in 4 rows, each turning upon a shaft which passes through its axis; and all driven by the water-wheel shown in the middle of *fig.* 1797. The casks are 2 feet 10 inches long, 2 feet 8 inches wide, inside measure, and are provided with iron ends. The staves are 3½ inches thick, and are bound together with iron hoops. They have a double bung-hole, one formed within the other, secured by an iron plug fastened with screws. They are filled by means of a wooden spout terminated by a canvas hose; through which 10 cwts. of the boiled ore-flour (*Erzmehl*) are introduced after 3 cwts. of water have been poured in. To this mixture, from ¾ to ⅞ of a cwt. of pieces of iron, 1½ inch square, and ⅜ thick, are added. When these pieces get dissolved, they are replaced by others. The casks being two-thirds full, are set to revolve for 1½ or 2 hours, till the ore-powder and water become a uniform pap; when 5 cwts. of quicksilver are poured into each of them. The casks being again made tight, are put in gear with the driving machinery, and kept constantly revolving for 14 or 16 hours, at the rate of 20 or 22 turns per minute. During this time they are twice stopped and opened, in order to see whether the pap be of the proper consistence; for if too thick, the globules of quicksilver do not readily combine with the particles of ore; and if too thin, they fall and rest at the bottom. In the first case some water must be added; in the second, ore. During the rotation, the temperature rises, so that even in winter it sometimes stands so high as 104° Fahr.

The chemical changes which occur in the casks are the following:—The metallic chlorides present in the roasted ore are decomposed by the iron, whence results chloride of iron, whilst the protochloride of copper is reduced partly to subchloride, and partly to metallic copper, which throw down metallic silver. The mercury dissolves the silver, copper, lead, antimony, in a complex amalgam. If the iron is not present in sufficient quantity, or if it has not been worked with the ore long enough to convert the cupric chloride into a cuprous chloride, previously to the addition of the mercury, more or less of the last metal will be wasted by its conversion into protochloride (calomel). The water holds in solution sulphate of soda, undecomposed sea-salt, with chlorides of iron, manganese, &c.

As soon as the revivification is complete, the casks must be filled with water, set to revolve slowly (about 6 or 8 times in the minute), by which in the course of an hour, or an hour and a half at most, a great part of the amalgam will have collected at the bottom; and in consequence of the dilution, the portion of horn-silver held in solution by the sea-salt will fall down and be decomposed. Into the small plug in the centre of the bung, a tube with a stopcock is now to be inserted, to discharge the amalgam into its appropriate chamber. The cock must be stopped whenever the brown muddy residuum begins to flow. The main bung being then opened, the remaining contents of the casks are emptied into the *wash-tun*, while the pieces of iron are kept back. The residuary ore is found to be deprived of its silver to within $\frac{5}{32}$ or $\frac{7}{40}$ of an ounce per cwt. The emptying of all the casks, and charging them again, takes 2 hours; and the whole process is finished within 18 or 20 hours; namely, 1 hour for charging; 14 to 16 hours for amalgamating; $1\frac{1}{2}$ hour for diluting; 1 hour for emptying. In 14 days 3,200 cwts. of ore are amalgamated. For working 100 cwts. of ore, $14\frac{1}{2}$ lbs. of iron are required; and for every pound of silver obtained, 3 ozs. of mercury are consumed.

Trials have been made to conduct the amalgamation-process in iron casks, heated to 150° or 160° Fahrenheit, over a fire; but although the desilvering was more complete, the loss of mercury was so much greater as to more than counterbalance that advantage.

Treatment of the Amalgam.—It is first received in a moist canvas bag, through which the thin uncombined quicksilver spontaneously passes. The bag is then tied up and subjected to pressure. Out of 20 casks, from 3 to $3\frac{1}{2}$ cwts. of solid amalgam are thus procured, which usually consist of 1 part of an alloy, containing silver of 12 or 13 *loths* (in 16), and 6 parts of quicksilver. The foreign metals in that alloy are copper, lead, gold, antimony, cobalt, nickel, bismuth, zinc, arsenic, and iron. The filtered quicksilver contains moreover 2 to 3 loths of silver in the cwt.

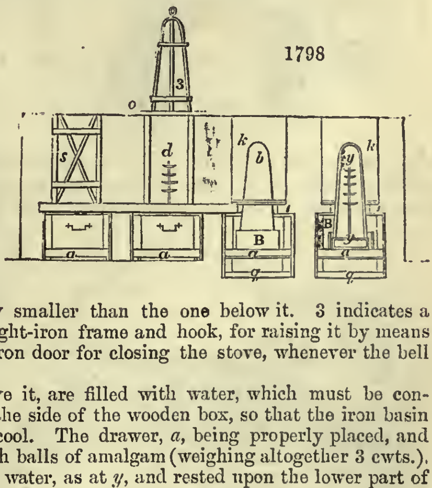


Fig. 1798 represents the apparatus formerly used for distilling the amalgam in the Halsbrücke works. *a* is the wooden drawer, sliding in grooves upon the basis, *q*; B is an open basin or box of cast iron, laid in the wooden drawer; *y* is a kind of iron candelabrum, supported upon four feet, and set in the basin, B; under *d* are five dishes or plates, of wrought iron, with a hole in the centre of each, by which they are fitted upon the stem of the candelabrum, 3 inches apart, each plate being successively smaller than the one below it. 3 indicates a cast-iron bell, furnished with a wrought-iron frame and hook, for raising it by means of a pulley and cord. *s* is a sheet-iron door for closing the stove, whenever the bell has been set in its place.

The box, *a*, and the basin, B, above it, are filled with water, which must be continually renewed, through a pipe in the side of the wooden box, so that the iron basin may be kept always submersed and cool. The drawer, *a*, being properly placed, and the plates under *d* being charged with balls of amalgam (weighing altogether 3 cwts.), the bell, 3, is to be let down into the water, as at *y*, and rested upon the lower part of the candelabrum. Upon the ledge, 1, which defines the bottom of the fireplace, a circular plate of iron is laid, having a hole in its middle for the bell to pass through.

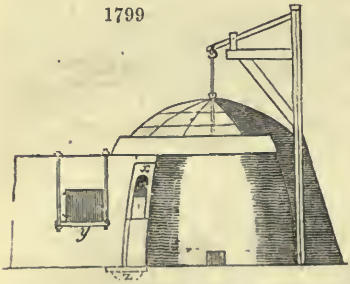
Upon this plate chips of fir-wood are kindled, then the door, *s*, which is lined with clay, is closed and luted tight. The fuel is now placed in the vacant space, *k*, round the upper part of the bell. The fire must be fed-in most gradually, first, with turf, then with charcoal; whenever the bell gets red, the mercury volatilises, and condenses in globules into the bottom of the basin, B. At the end of 8 hours, should no more drops of mercury be heard to fall into the water, the fire is stopped. When the bell has become cool, it is lifted off; the plates are removed from the candelabrum, *d*; and this being taken out, the drawer, *a*, is slid away from the furnace. The mercury is drained, dried, and sent again into the amalgamation-works. The silver is fused and refined by cupellation.

From 3 cwts. of amalgam, distilled under the bell, from 95 to 100 marcs ($\frac{1}{2}$ lbs.) of *Tellersilber* (dish-silver) are procured, containing from 10 to 13$\frac{1}{2}$ parts of fine silver out of 16; one fifth part of the metal being copper. The teller silver is refined in quantities of 160 or 170 marcs, in black-lead crucibles filled within two inches of their brims, and submitted to brisk ignition. The molten mass exhales some vapours, and throws up a liquid slag, which being skimmed off, the surface is to be strewed over with charcoal-powder, and covered with a lid. The heat having been briskly urged for a short time, the charcoal is then removed along with any fresh slag that may have risen, in order to observe whether the vapours have ceased. If not, fresh charcoal must be again applied, the crucible must be covered, and the heat increased, till fumes are no longer produced, and the surface of the silver becomes tranquil. Finally, the alloy, which contains a little gold, and much copper, being now from 11 to 13 *löthig* (that is, holding from 11 to 13 parts of fine silver in 16 parts), is cast into iron moulds, in ingots of 60 marcs. The loss of weight by evaporation and skimming of the slag amounts to 2 per cent.; the loss in silver is inconsiderable.

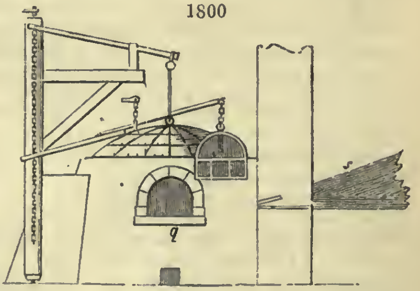
The dust from the furnace (*Tiegelofen*) is collected in a large condensation chamber of the chimney, and affords from 40 to 50 marcs of silver per cwt. The slags and old crucibles are ground and sent to the small amalgamation mill.

The earthy residuum of the amalgamation casks being submitted to a second amalgamation, affords out of 100 cwts. about 2 lbs. of coarse silver. This is first fused along with three or four per cent. of a mixture of potash and calcined *Quicksalz* (impure sulphate of soda), and then refined. The supernatant liquor that is drawn

1799

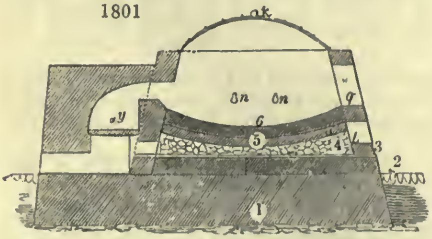


1800

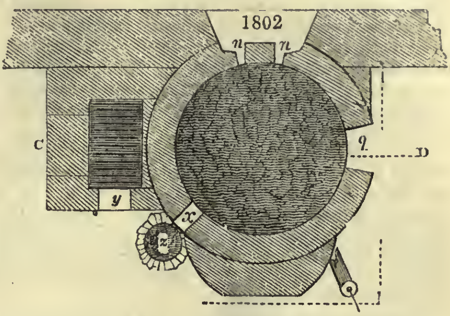


out of the tanks in which the contents of the casks are allowed to settle, consists chiefly of sulphate of soda, along with some common salt, sulphates of iron and manganese, and a little phosphate, arsenate, and fluoride of sodium. The earthy deposit contains from $\frac{1}{4}$ to $\frac{2}{32}$nds of a loth of silver per cwt., but no economical method of extracting this small quantity was used.

1801



Argentiferous or *rich lead* is treated in Germany by the cupellation furnace represented in *figs.* 1799, 1800, 1801, and 1802. These figures exhibit the cupellation furnace of the principal smelting work in the Hartz, where the following parts must be distinguished: (*fig.* 1801) 1, masonry of the foundation; 2, flues for the escape of moisture; 3, stone covers of the flues; 4, bed of hard-rammed scoriæ; 5, bricks set on edge, to form the permanent area of the furnace; 6, the sole, formed of wood-ashes, washed, dried, and beaten down; *k*, dome of iron plate, moveable by a crane, and susceptible of being lined two inches thick with loam; *n*, *n*, tuyères for two bellows, *s*, having valves suspended before their orifices to break and spread the blast; *q*, door for introducing into the furnace the charge of lead, equal to 84 quintals at a time; *s*, *fig.* 1800, two bellows, like those of a smith's forge; *y*, door of the fireplace, through which billets of wood are thrown on the grate; *x*, small aperture or door, for giving issue to the frothy scum of the cupellation, and the litharge; *z*, basin of safety, usually covered with a stone slab, over which the litharge falls: in case of accident the basin is laid open to admit the *rich lead*.



The following is the mode of conducting the cupellation:—Before putting the lead into the furnace, a floor is made in it of ashes beaten carefully down (see *fig.* 1801); and there is left in the centre of this floor a circular space, somewhat lower than the rest of the hearth, where the silver ought to gather at the end of the operation. The cupel is fully 6 feet in diameter.

In forming the floor of a cupel, 35 cubic feet of washed wood-ashes, usually got from the soap-works, are employed. The preparation of the floor requires two and a half hours' work; and when it is completed, and the moveable dome of iron plate has been lined with loam, 84 quintals (cwts.) of lead are laid on the floor, 42 quintals being placed in the part of the furnace farthest from the bellows, and 42 near to the fire-bridge; to these, scoriæ containing lead and silver are added, in order to lose nothing. The moveable lid is now luted on the furnace, and heat is slowly applied in the fire-place by burning fagots of fir-wood; this is gradually raised. Section *fig.* 1801, is in the line C, D, of *fig.* 1802.

At the end of three hours, the whole lead being melted, the instant is watched for when no more ebullition can be perceived on the surface of the bath or melted metal; then, but not sooner, the bellows are set a-playing on the surface at the rate of four or five strokes per minute, to favour the oxidation.

In five hours, reckoned from the commencement of the process, the fire is smartly raised; when a greyish froth (*Abstrich*) is made to issue from the small aperture *x*, of the furnace. This is found to be a brittle mixture of oxidised metals and impurities. The workman now glides the rake over the surface of the bath, so as to draw the froth out of the furnace; and as it issues, powdered charcoal is strewed upon it at the aperture *x*, to cause its coagulation. The froth-skimming lasts for about an hour and a half.

After this time the litharge begins to form, and it is also led off by a small opening *x*, its issue being aided by a hook. In proportion as the floor of the furnace gets impregnated with litharge, the workman digs in it a gutter for the escape of the liquid litharge; it falls in front of the small aperture, and concretes in stalactitic forms.

By means of the two moveable valves suspended before the tuyères *n*, *n* (*fig.* 1802), the workman can direct the blast as he wishes over the surface of the metal. The wind should be made to cause a slight curl on the liquid, so as to produce circular undulations, and gradually propel a portion of the litharge generated towards the edges of the cupel, and allow this to retain its shape till the end of the operation. The stream of air should drive the greater part of the litharge towards the small opening *x*, where the workman deepens the outlet for it, in proportion as the level of the metallic bath descends. Litharge is thus obtained during about twelve hours; after which period the cake of silver begins to take shape in the centre of the cupel.

Towards the end of the operation, when no more than four additional quintals of litharge can be looked for, and when it forms solely in the neighbourhood of the silver cake in the middle of the floor, great care must be taken to set apart the latter portions, because they contain silver. About this period the fire is increased, and the workman places before the little opening *x*, a brick, to serve as a mound against the efflux of litharge. The use of this brick is,—1, to hinder the escape of the silver in case of any accident; for example, should an explosion take place in the furnace; 2, to reserve a magazine of litharge, should that still circulating round the silver cake be suddenly absorbed by the cupel, for in this dilemma the litharge must be raked back on the silver; 3, to prevent the escape of the water that must be thrown on the silver at the end of the process.

When the argentiferous litharge, collected in the above small magazine, is to be removed, it is let out in the form of a jet, by the dexterous use of the iron hook.

Lastly, after twenty hours, the silver cake is seen to be well formed, and nearly circular. The moment for stopping the fire and the bellows is indicated by the sudden disappearance of the coloured particles of oxide of lead, which, in the latter moments of oxidation, undulate with extreme rapidity over the slightly convex surface of the silver-bath, moving from the centre to the circumference. The phenomenon of their total disappearance is called the *lightning*, or *brightening* (*Blick*). Whenever this occurs, the plate of silver being perfectly clean, there is introduced into the furnace by the door *q*, a wooden spout, along which water, previously heated, is carefully poured on the silver.

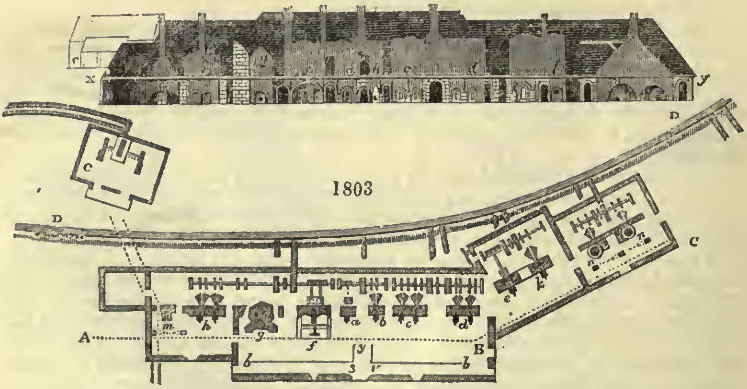
The cupellation of 84 quintals of argentiferous lead takes in general eighteen or twenty hours. The promptitude of the operation depends on the degree of purity of the leads employed, and on the address of the operator, with whom also lies the economy of fuel. A good workman completes the cupellation of 84 quintals with 300 billets, each equivalent to a cubic foot and $\frac{8}{10}$ths of wood (Hartz measure); others consume 400 billets, or more. In general, the cupellation of 100 quintals of lead, executed at the rate of 84 quintal charges, occasions a consumption of 790 cubic feet of resinous wood-billets.

The products of the charge are as follow:—

1. Silver, holding in 100 marcs, 7 marcs and 3 loths of alloy .	24 to 30 marcs.
2. Pure litharge, containing from 88 to 90 per cent. of lead .	50 ,, 60 quintals.
3. Impure litharge, holding a little silver	2 ,, 6
4. Skimmings of the cupellation	4 ,, 8
5. Floor of the furnace impregnated with litharge . . .	22 ,, 30

The marc is 7 oz. 2 dwts. 4 grs. English troy; and the loth is half an ounce. 16 loths make a marc. 100 lbs. Cologne are equal to 103 lbs. avoirdupois; and the above quintal contains 116 Cologne lbs.

The loss of lead inevitable by this operation is estimated at 4 parts in 100. It has been diminished as much as possible in the Frankenscharn works of the Hartz, by leading the smoke into long flues, where the lead-fumes are condensed into a metallic soot.



1803

Reduction of the litharge.—This is sometimes executed in a slag-hearth, with the aid of wood-charcoal.

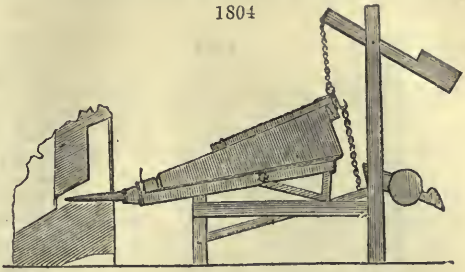
The following is the series of operations:—

1. The fusion of the schlich; 2, the roasting of the matts under a shed, and their treatment by four successive smeltings; 3, the treatment of the resulting black copper; 4, the liquation; 5, the reliquation (*ressuage*); 6, the refining of the copper; 7, the cupellation of the silver; 8, the reduction of the litharge into lead. The fifth and sixth processes are carried on at the smelting-works of Altenau.

The buildings are shown at A, B, C, and the impelling stream of water at D (*fig.* 1803): the upper figure being the elevation; the lower, the plan of the works.

a, is a melting furnace, with a cylinder bellows behind it; *b*, *c*, *d*, furnaces similar to the preceding, with wooden bellows, such as *fig.* 1804; *e*, is a furnace for the same purpose, with three tuyères, and a cylinder bellows; *f*, the large furnace of fusion, also with three tuyères; *g*, a furnace with seven tuyères, now seldom used; *h*, low furnaces, like the English slag-hearths (*Krummöfen*), employed for working the last *mattes*; *k*, slag-hearths for reducing the litharge; *m*, the area of the liquation; *n*, *n*, cupellation furnaces.

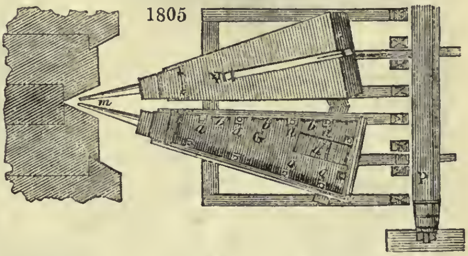
1804



x, *y*, a floor which separates the principal smelting-houses into two stories; the materials destined for charging the furnaces being deposited in beds upon the upper floor, to which they are carried by means of two inclined planes, terraced in front of the range of buildings.

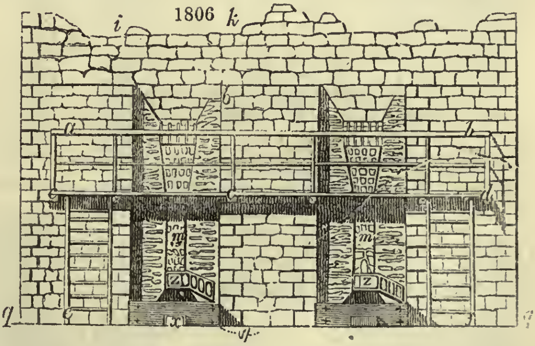
Fig. 1805 represents such wooden bellows, consisting of two chests or boxes, fitted into each other; the upper or moving one being called the *fly*, the lower or fixed one the *seat* (*gîte*). In the bottom of the gîte there is an orifice furnished with a clack-valve, *d*, opening inwards when the fly is raised, and shutting when it falls. In order that the air included in the capacity of the two chests may have no other outlet than the nose-pipe *m*, the upper portion of the gîte is provided at its four sides with small square slips of wood, *c*, *c*, *c*, which are pressed against the sides of the fly by strong springs of iron wire, *b*, *b*, *b*, while they are retained upon the gîte by means of small square pieces of wood, *a*, *a*, *a*, *a*.

1805



The latter *a*, *a*, are perforated in the centre, and adjusted upon rectangular stems, called *buchettes*; they are attached, at their lower ends, to the upright sides of the gîte G. P is the driving-shaft of a water-wheel, which, by means of cams or tappets, depresses the fly, while the counterweight Q, raises it again.

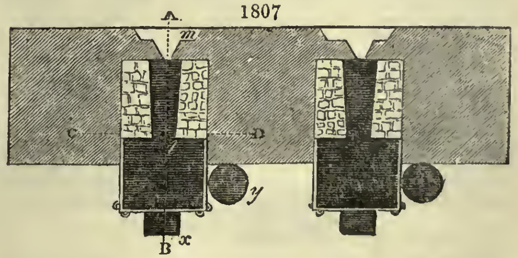
1806



Figs. 1806 to 1809 represent the moderately high (*demi-hauts*, or *half-blast*) furnaces employed in the works of the Lower Hartz, near Goslar, for smelting the silvery lead ore extracted from the mine of Rammelsberg.

Fig. 1806 is the front elevation of the twin furnaces, built in one body of masonry; *fig.* 1807 is a plan taken at the level of the tuyères.

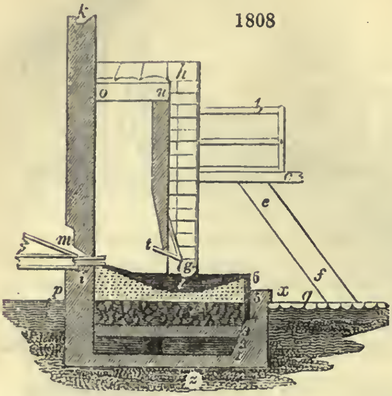
1807



Figs. 1808 and 1809 exhibit two vertical sections; the former in the line A, B, the latter in the line C, D, of *fig.* 1807. In these four figures the following objects may be distinguished:—

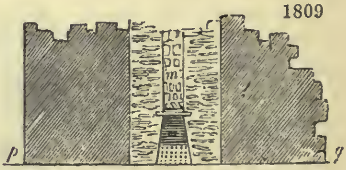
a, b, c, d, a balcony or platform, which leads to the place of charging, *n*; *e, f*, wooden stairs, by which the workmen charging mount from the ground, *p, q*, of the works, to the platform; *g, h*, brickwork of the furnaces; *i, k*, wall of the smelting-works, against which they are supported; *l*, upper basin of reception, hollowed out of the *brasque* (or bed of ground charcoal and clay) 6; *m*, arch of the tuyère v, by which each furnace receives the blast of two bellows; *n*, place of charging, which takes place through the upper orifice *n, o*, of the basin *n, o*, v, *t*, of the furnace; *t*, a sloping gutter, seen in *fig.* 1808, formed of slates cemented together with clay.

1808

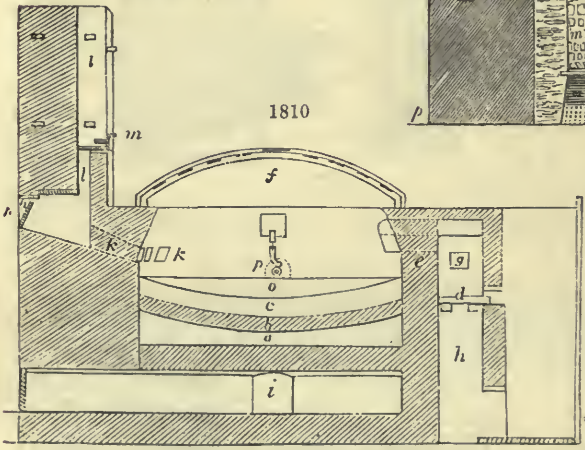


In *figs.* 1808 and 1809, *z* is the brickwork of the foundations; *m*, conduits for the exhalation of moisture; 4, a layer of slags, rammed above; 5, a bed of clay, rammed above the slags; 6, a brasque, composed of one part of clay and two parts of ground charcoal, which forms the sole of the furnace.

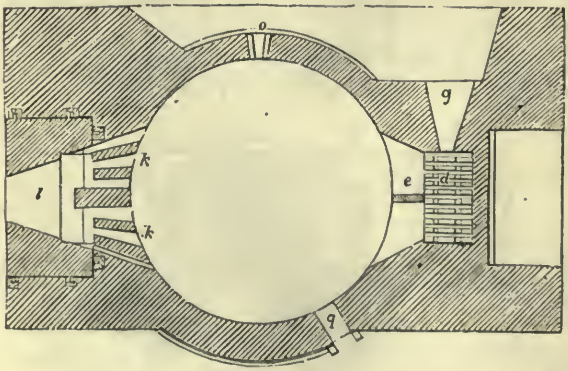
1809



1810



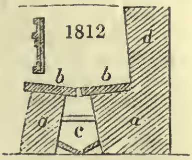
1811



The refinery furnace, or *Treibheerd*, of Friedrichshütte, near Tarnowitz, in Upper Silesia, is represented in *figs.* 1810 and 1811. *a*, is the bottom, made of slag or cinders; *b*, the foundation, of fire-bricks; *c*, the body of the hearth proper, composed of a mixture of 7 parts of dolomite and 1 of fire-clay, in bulk; *d*, the grate of the air-furnace; *e*, the fire-bridge; *f*, the dome or cap, made of iron-plate strengthened with bars, and lined with clay-lute, to protect the metal from burning; *g*, the door of the fireplace; *h*, the ash-pit; *i*, the tap-hole; *k*, *k*, the flue, which is divided by partitions into several channels; *l*, the chimney; *m*, a damper-plate for regulating the draught; *n*, a back valve, for admitting air to cool the furnace, and brushes to sweep the flues; *o*, tuyère of copper, which by means of an iron wedge may be sloped more or less towards the hearth; *p*, the *Schnepper*, a round piece of sheet iron, hung before the *eye* of the tuyère, to break and spread the blast; *q*, outlet for the glassy litharge.

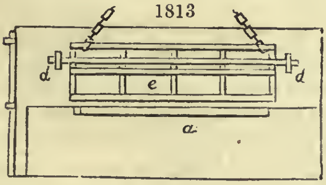
Lime-marl has been found to answer well for making the body of the hearth-sole as it absorbs litharge freely, without combining with it. A basin-shaped hollow is formed in the centre, for receiving the silver at the end of the process; and a gutter is made across the hearth for running off the *Glätte* or fluid litharge.

1812

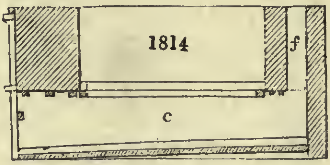


Figs. 1812 to 1814 represent the eliquation hearth of Neustadt. *Fig.* 1812 is a cross-section; *fig.* 1813 is a front view; and *fig.* 1814 a longitudinal section. It is formed by two walls, *a*, *a*, 3½ feet high, placed from ½ to 1 foot apart, sloped off at top with iron-plates, 3 inches

1813



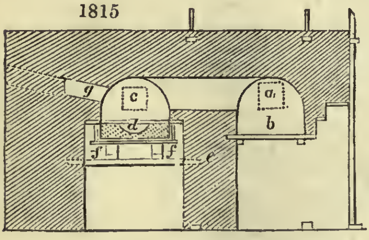
1814



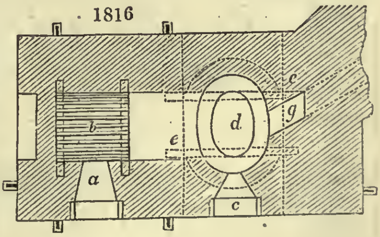
thick and 18 inches broad, called *Saigerscharten*, or refining plates, *b*, *b*, inclined 3 inches towards each other in the middle, so as to leave at the lowest point a slit 2½ inches wide between them, through which the lead, as it sweats out by the heat, is allowed to fall into the space between the two walls c, called the *Saigergasse* (sweating-gutter). The sole of this channel slopes down towards the front, so that the liquefied metal may run off into a crucible or pot. Upon one of the long sides, and each of the shorter ones, of the hearth the walls *d*, *d*, are raised 2 feet high, and upon these the liquidation lumps rest; upon the other long side, where there is no wall, there is an opening for admitting these lumps into the hearth. The openings are then shut with a sheet- or cast-iron plate *e*, which, by means of a chain, pulley, and counter-weight, may be easily raised and lowered. *f* is a passage for increasing the draught of air.

Figs. 1815 and 1816 represent the refining furnaces of Friedhricshütte, near Tarnowitz: *a*, is the fire-door; *b*, the grate; *c*, the door for introducing the silver; *d*, the moveable test, resting upon a couple of iron rods, *e*, *e*, which are let at their ends into the brickwork. They lie lower than would seem to be necessary; but this is

1815



1816



done in order to be able to place the surface of the test at any desired level, by placing tiles, *f*, *f*, under it; *g*, the flue, leading to a chimney 18 feet high. For the refining of 100 marks of *Blicksilber*, of the fineness of 15½ loths (half-ounces) per cwt., 3 cubic feet of pit-coal are required. The test or cupel must be heated before the impure silver and soft lead are put into it.

At these smelting-houses from 150 to 160 cwts. of *Werkblei* or *work-lead* (lead containing silver), are operated on at a time.

Extraction of Silver by Wet Processes.—Of late years several wet methods of extracting silver from its ores and from metallurgical products have been so successfully employed as to supplant, in many cases, the old processes of amalgamation and liquation previously described. The principal wet processes which have been largely used, are those of Augustin, Ziervogel, and Von Patera.

Augustin's Process.—The argentiferous ore, or the matt or regulus, is first roasted with common salt, whereby the silver passes into the state of chloride, which is then dissolved out by a hot concentrated solution of salt; chloride of silver being soluble in hot brine. From this solution, the silver is precipitated by means of metallic copper. This process was introduced at the Mansfeld Kupferschiefer works, in Prussian Saxony, by Augustin, in 1849, but was abandoned in 1857. It was used at Freiberg, in Saxony, between the years 1849 and 1862.

Ziervogel's Process.—By roasting the argentiferous copper-matts, from the smelting of the Kupferschiefer, in a reverberatory furnace, the iron is converted into sulphate, which is then decomposed and yields peroxide of iron; the copper also forms sulphate, which is afterwards reduced to black oxide; and in like manner, the silver present as sulphide is oxidised to the state of sulphate. When, therefore, the roasted product is lixiviated with hot water, the sulphate of silver is freely dissolved out, whilst the oxides of copper and iron remain insoluble. The silver is precipitated in the metallic form by means of copper. This is the process still employed at the Gottesbelohnungs-hütte Silver-extraction works, near Mansfeld.

Von Patera's Process.—This method is based on a suggestion made by Dr. Percy in 1848. The ore is first roasted with common salt, whereby chloride of silver is directly formed, and this chloride is then dissolved out by a cold dilute solution of hyposulphite of soda. The silver is precipitated from this solution as sulphide, by addition of sulphide of sodium; and the silver sulphide is afterwards reduced to metallic silver by heating in a muffle-furnace. This process was introduced by Von Patera at Joachimstahl, in Bohemia, in 1858, and is believed to be still working.

Sulphuric Acid Method.—Argentiferous copper-matts are treated with hot dilute sulphuric acid, whereby sulphate of copper is formed, and passes into solution, whilst most of the silver and gold present is left in the residues. These are then smelted with lead-ores, and the silver extracted from the argentiferous lead. This process is now employed at Oker, in the Lower Hartz.

Pattinson's process for extracting silver from argentiferous lead is fully described under SILVER; and Claudet's recent process for recovering silver from the liquors obtained in the wet treatment of coppery pyrites, is duly noticed under PYRITES.

The following statement of the production of silver in all parts of the world is given by Mr. J. Arthur Phillips, chiefly on the authority of Duport and Chevalier. See Phillips's 'Gold and Silver':—

Places	1865 lbs. troy	Ratio per cent.
Russian Empire	58,000	1·5
Scandinavia	15,000	0·4

SILVER ASSAYING. This may be conveniently divided into: 1. The assaying of silver ores; 2. The assaying of silver and its alloys.

1. *The assaying of silver ores.*—The ores are reduced to fine powder, and passed through a sieve of 80 holes to the linear inch, and any residual metalliferous particles carefully collected and submitted to a separate assay. The total weight of the sample is ascertained, in order that the proportion of silver obtained from the residue may be calculated. The sifted portion is well mixed, and submitted to assay by one of the following methods:—

a. Fusion Method.—This process is conducted in crucibles, in an air-furnace similar to that described in *fig.* 533, p. 941, vol. i. (See COPPER.)

In the assay of silver ores not containing lead, it is usual to obtain the silver they afford in the form of an alloy with lead; and this is subsequently passed to the cupel in the ordinary way. For the assaying of lead ores containing silver, see LEAD.

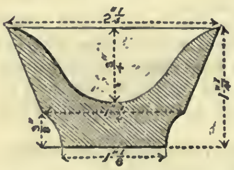
Ores of silver in which the associated metals exist in the form of oxides are commonly fused with a mixture of litharge or red lead, and powdered charcoal, by which an alloy of lead is obtained, which is afterwards treated by cupellation. The amount of litharge employed must be varied according to circumstances, as the resulting button should not be too small, since in that case a portion of the silver might be lost in the slag; nor too large, as the cupellation would then occupy a longer time.

In most cases, if from 100 to 400 grains of ore be operated on, a button of 200 grains will be a convenient weight for cupellation; this may be obtained by the addition of 400 grains of litharge, and from 7 to 8 grains of pulverised charcoal. This is to be well mixed with 200 grains of carbonate of soda, and introduced into an earthen crucible, of which it should not fill more than one-half the capacity. This is covered by a layer of borax, and fused in the assay-furnace, taking care to remove it from the fire as soon as a perfectly liquid slag has been obtained, since the unreduced litharge might otherwise cut through the crucible and spoil the assay. When cold, the pot is broken, and the button of lead cupelled in the ordinary way, or the liquid-products are poured out into a mould (*fig.* 534, see COPPER), and when cold, the slag is detached from the lead.

In this, and all other similar experiments, it is necessary to ascertain the proportion of silver contained in the lead obtained from the litharge used, in order to make the requisite deduction from the results obtained. When other minerals than oxides are to be examined, the addition of charcoal becomes in many cases unnecessary, since litharge readily attacks all the sulphides, arsenio-sulphides, &c., and oxidises many of their constituents, whilst a proportionate quantity of metallic lead is set free. The slags thus formed contain the excess of litharge, and the button of alloy obtained is cupelled. The proportion of oxide of lead to be added to ores of this description varies in accordance with the amounts of oxidisable substances present; but it must always be added in excess in order to prevent any chance of loss of silver from the action of sulphides in the slags. The only objection to this method of assay is the large quantity of lead produced for cupellation, since iron pyrites afford by the reduction of the litharge 8½ parts of lead, whilst sulphide of antimony and grey copper ore yield from 6 to 7 parts. This inconvenience may be obviated by the previous oxidation of the mineral, either by roasting, or by the aid of nitre, by the judicious employment of which, buttons of almost any required weight may be obtained. Should this reagent be employed in excess, it would cause the oxidation of all the metallic and combustible substances present, not even excepting the silver. When, however, the mixture contains at the same time a large excess of litharge, and the quantity of nitre added is not sufficient to decompose the whole of the sulphides, a reaction takes place between the undecomposed sulphide and the oxide of lead added, which gives rise to the formation of metallic lead, and this combining with the silver, affords a button of alloy, which may be treated by cupellation. The quantity of nitre to be used for this purpose will depend on the nature and richness of the ores under examination; but it must be remembered that 2½ parts of nitre will decompose and completely oxidise pure iron pyrites, whilst 1½ and ⅔rds of its weight are in the case of sulphide of antimony and galena respectively sufficient. In cases where the excess of sulphur present is very great, a partial roasting of the ore is preferable to the addition of a large quantity of nitre. Instead of operating according to any of the processes above described, it is sometimes found advantageous to expel the whole of the arsenic and sulphur, by a careful roasting, and then to fuse the residue with a mixture of litharge, carbonate of soda, and borax, taking care to add a sufficient amount of some reducing flux to obtain a button of convenient size. When, in addition to silver, the mineral operated on contains gold, the button obtained by cupellation will consist of a mixture of these metals, which may be separated by the aid of nitric acid. See GOLD ASSAYING.

b. Scorification Method.—This process is conducted in a muffle-furnace. A cup-shaped vessel or scorifier of fire-clay is employed, which varies in size according to the quantity of ore operated on. The scorifier represented in *fig.* 1816 *a* is 2¼ inches in diameter at the top, and the internal cavity is ¾ of an inch in depth. Tongs of peculiar construction, and varying from 2 feet 3 inches to 3 feet in length, are used for lifting the scorifiers, the lower leg being divided near the end into a two-pronged fork, in order to grasp the lower part of the vessel, while the upper leg is made straight, and holds it firmly on the upper surface. Scorification is a roasting-fusion process. The sulphur and other oxidisable substances present are roasted or decomposed by the oxide of lead produced, and atmospheric air. When these are decomposed, the oxide of lead produces a fusible slag with the silica and other matters present in the ore. The silver alloys with the lead retained in the lower part of the scorifier. The process may be conducted as follows:—50 or 100 grs. of the finely-divided ore are weighed out and transferred to the scorifier. The ore is now mixed with about half of the finely-granulated lead required for the assay, and the other portion is afterwards placed upon the top. From 10 to 20 times its weight of lead is used, according to the nature of the vein-stuff, and minerals present; a small quantity of borax is also added. The scorifier is now placed in a muffle, and the heat increased until fusion occurs. The door of the muffle is now partly removed, in order to admit more air, and allow the oxidation of the lead and other substances to proceed. When the surface of the lead is covered with slag, the scorifier is removed, and its contents poured into an iron mould, see *fig.* 534 (COPPER). When cold, the slag is detached, the lead submitted to cupellation, and the button of silver weighed. The button of lead should be

1816 *a*



soft and malleable, and from 200 to 300 grs. in weight; larger buttons should be reduced in weight by rescorifying. The slag should be free from small lumps, and perfectly fused before pouring. All silver ores may be assayed by this method, and several assays made at one time, but a fusion-method is preferable for ores poor in silver. Where a number of assays are made by the scorification process, a muffle-furnace of somewhat larger dimensions is constructed than that described under the Assaying of Silver Alloys. With poor ores, four or more scorifiers are charged with weighed portions of ore and lead, and the resulting buttons of lead reduced to one button by repeated scorification, and then finally cupelled. Correction must be made for the silver contained in the amount of granulated lead employed.

In England the results obtained from the assays are reported to ounces, pennyweights, and grains troy, upon the statute ton of 2,240 lbs. The calculations may be made by the following Table:—

Table showing the weight of silver to the ton of ore or alloy corresponding to the weight in grains obtained from 400 *grains of the substance operated on.*

If 400 grains give fine metal,	One ton will yield			If 400 grains give fine metal,	One ton will yield

2. *The Assaying of Silver and its Alloys.*—This is conducted by the dry and wet methods.

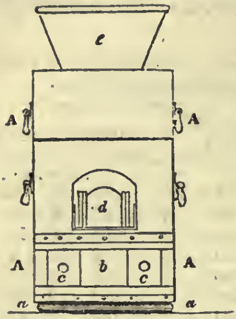
a. Dry Method—by Cupellation (*Coupellation*, Fr.; *Abtreiben auf der Cupelle*, Ger.). The assay by this method is made upon a cupel, and the process is conducted in a cupellation-furnace, or a muffle-furnace. The art of assaying silver by the cupel is founded upon the feeble affinity which this metal has for oxygen, in comparison with lead and copper, and other metals; and on the tendency which the latter metal has to oxidise rapidly in contact with lead at a high temperature, and sink with it into any porous earthy vessel in a thin glassy or vitriform state. The porous vessel may be made either of wood-ashes, freed from their soluble matter by washing with water; or, preferably, of burned bones, or bone-ash, reduced to a fine powder. The cupels allow the fused oxides to be absorbed into them like a sponge, but are impermeable to the particles of metals; and thus the former pass readily down into their substance, while the latter remain upon their surface: a phenomenon owing to the circumstance of the oxides moistening, as it were, the bone-ash powder, whereas the metals can contract no adherence with it. Hence also the liquid metals preserve a hemispherical shape in the cupels, as quicksilver does in a cup of glass, while the fused oxide spreads over, and penetrates their substance, like water.

If we put into a cupel, therefore, two metals, of which the one is unalterable in the air, the other susceptible of oxidisement, and of producing a very fusible oxide, it is obvious that, by exposing both to a proper degree of heat, we shall succeed in separating them. We should also succeed, though the oxide were infusible, by placing it in contact with another one, which may render it fusible. In both cases, however, the metal from which we wish to part the oxides must not be volatile: it should also melt, and form a button at the heat of cupellation; for, otherwise, it would continue disseminated, attached to the portion of oxide spread over the cupel, and incapable of being collected.

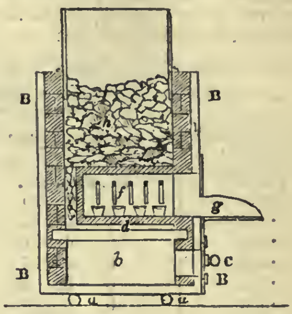
Furnace and Implements.—The cupellation-furnace and implements used for assaying in the Royal Mint and Goldsmiths' Hall, in the City of London, are the following:—

A A A A (*fig.* 1817) is a front elevation of an assay-furnace: *a a*, a view of one of the two iron rollers on which the furnace rests, and by means of which it is moved for-

1817



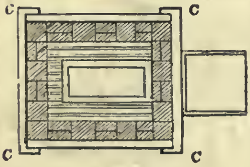
1818



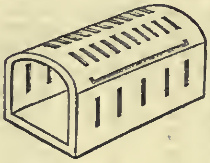
ward or backward; *b*, the ash-pit; *c c* are the ash-pit dampers, which are moved in a horizontal direction towards each other for regulating the draught of the furnace; *d*, the door, or opening, by which the cupels and assays are introduced into the muffle; *e*, a moveable funnel or chimney by which the draught of the furnace is increased.

B B B B (*fig.* 1818) is a vertical section of *fig.* 1817: *a a*, end view of the rollers; *b*, the ash-pit; *c*, one of the ash-pit dampers; *d*, the grate, over which is the plate upon which the muffle rests, and which is covered with loam nearly one inch thick; *f*, the muffle in section, representing the situation of the cupels; *g*, the mouth-plate, and upon it are laid pieces of charcoal, which, during the process, are ignited, and heat the air that is allowed to pass over the cupels, as will be more fully explained in the sequel; *h*, the interior of the furnace, exhibiting the fuel.

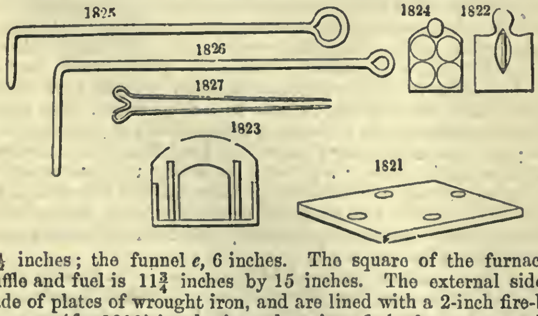
1819



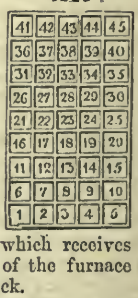
1820



The total height of the furnace is 2 feet 6½ inches; from the bottom to the grate, 6 inches; the grate, muffle, plate, and bed of loam, with which it is covered, 3 inches; from the upper surface of the grate to the commencement of the funnel, *e*, *fig.* 1817,



1828



21½ inches; the funnel *e*, 6 inches. The square of the furnace which receives the muffle and fuel is 11¾ inches by 15 inches. The external sides of the furnace are made of plates of wrought iron, and are lined with a 2-inch fire-brick.

C C C C (*fig.* 1819) is a horizontal section of the furnace over the grate, showing the width of the mouth-piece, or plate of wrought iron, which is 6 inches, and the opening which receives the muffle-plate.

Fig. 1820 represents the muffle or pot, which is 12 inches long, 6 inches broad inside; in the clear $6\frac{3}{4}$; in height $4\frac{1}{2}$ inside measure, and nearly $5\frac{1}{2}$ in the clear.

Fig. 1821, the muffle-plate, which is of the same size as the bottom of the muffle.

Fig. 1822 is a representation of the sliding-door of the mouth-plate, as shown at *d*, in *fig.* 1817.

Fig. 1823, a front view of the mouth-plate or piece, *d*, *fig.* 1817.

Fig. 1824, a representation of the mode of the making, or shutting-up, with pieces of charcoal, the mouth of the furnace.

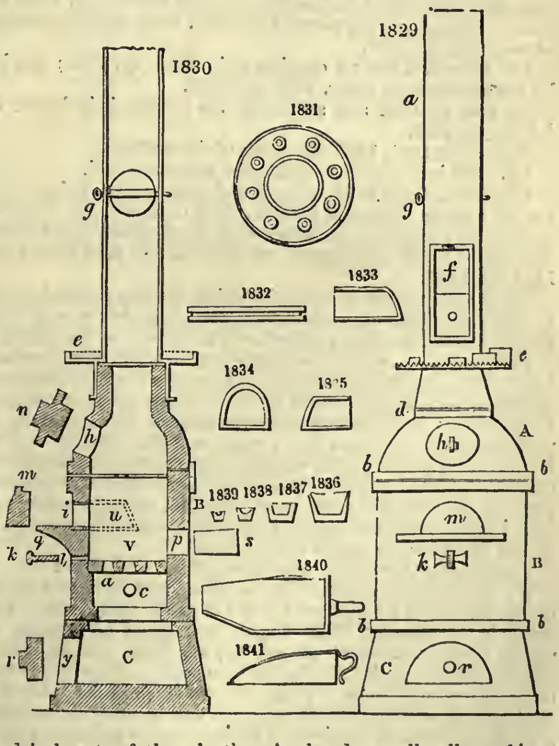
Fig. 1825, the teaser, for cleaning the grate.

Fig. 1826, a larger teaser, which is introduced at the top of the furnace, for keeping a complete supply of charcoal around the muffle.

Fig. 1827, the tongs used for charging the assays into the cups.

Fig. 1828 represents a board of wood used as a register, and is divided into 45 equal compartments, upon which the assays are placed previously to their being introduced into the furnace. When the operation is performed, the cupels are placed in the furnace in situations corresponding to these assays on the board. By this means all confusion is avoided, and without this regularity it would be impossible to preserve the accuracy which the delicate operations of the assayer require. In the furnace above described 45 assays can be made at one time. Of late years some modifications and improvements have been introduced in the above furnaces in the Royal Mint and other assay offices. The fuel employed is charcoal, coke, or anthracite. (See MINT.)

We now proceed to a description of a small assay-furnace invented by Messrs. Anfrye and D'Arcet, of Paris. They termed it, *le petit Fourneau à Coupelle*. *Fig.* 1829 represents this furnace, which is composed of a chimney or pipe of wrought iron, *a*, and of the furnace, B. It is $17\frac{1}{2}$ inches high and $7\frac{1}{4}$ inches wide. The furnace is formed of three pieces: of a dome, A; the body of the furnace, B; and the ash-pit, C, which is used as the base of the furnace, *figs.* 1829 and 1830. The principal piece, or body of the furnace, B, has the form of a hollow tower, or of a hollow cylinder, flattened equally at the two opposite sides parallel to the axis, in such a manner that the horizontal section is elliptical. The foot which supports it is a hollow truncated cone, flattened in like manner upon the two opposite sides, and having consequently for its basis two ellipses of different diameters: the smallest ought to be equal to that of the furnace, so that the bottom of the latter may exactly fit it. The dome, which forms an arch above the furnace, has also its base elliptical; whilst that of the superior orifice, by which the smoke goes out, preserves the cylindrical form. The tube of wrought iron is 18 inches long, and $2\frac{1}{2}$ inches in diameter; having one of its ends a little enlarged, and slightly conical, that it may be exactly fitted or jointed upon the upper part of the furnace-dome, *d* (*fig.* 1829). At the union of the conical and cylindrical parts of the tube there is placed a small gallery of iron, *e*, *figs.* 1829, 1830. (See also a plan of it, *fig.* 1831). This gallery is both ingenious



and useful. Upon it are placed the cupels, which are thus annealed during the ordinary work of the furnace, that they may be introduced into the muffle when it is brought into its proper degree of heat. A little above this gallery is a door, *f*, by which, if thought proper, the charcoal could be introduced into the furnace; above that there is placed, at *g*, a throttle-valve, which is used for regulating the draught of the furnace at pleasure. Messrs. Anfrye and D'Arcet say, that, to give the furnace the necessary degree of heat so as to work assays of gold, the tube must be about 18 inches above the gallery for annealing or heating the cupels. The circular opening in the dome, *h* (*fig.* 1829, and as seen in section *fig.* 1830), is used to introduce the charcoal into the furnace: it is also used to inspect the interior of the furnace, and to arrange the charcoal round the muffle. This opening is kept shut during the working of the furnace, with the mouth-piece, of which the face is seen at *n*, *fig.* 1830.

The section of the furnace, *fig.* 1830, presents several openings, the principal of which is that of the muffle; it is placed at *i*; it is shut with the semicircular door *m*, *fig.* 1829, and seen in the section *m*, *fig.* 1830. In front of this opening, is the table or shelf upon which the door of the muffle is made to advance or recede. The letter *q*, *fig.* 1830, shows the face, side, and cross-section of the shelf, which makes part of the furnace. Immediately under the shelf is a horizontal slit, *l*, which is pierced at the level of the upper part of the grate, and used for the introduction of a slender rod of iron, that the grate may be easily kept clean. This opening is shut at pleasure, by the wedge represented at *k*, *figs.* 1829 and 1830.

Upon the back of the furnace is a horizontal slit, *p*, *fig.* 1830, which supports the fire-brick, *s*, and upon which the end of the muffle, if necessary, may rest; *u*, *fig.* 1830, is the opening in the furnace where the muffle is placed.

The plan of the grate of the furnace is an ellipse: *fig.* 1832 is a horizontal view of it. The dimensions of that ellipsis determine the general form of the furnace, and thickness of the grate. To give strength and solidity to the grate, it is encircled by a bar or hoop of iron. There is a groove in which the hoop of iron is fixed. The holes of the grate are truncated cones, having the greater base below, that the ashes may more easily fall into the ash-pit. The letter *v*, *fig.* 1830, shows the form of these holes. The grate is supported by a small bank or shelf, making part of the furnace, as seen at *a*, *fig.* 1830.

The ash-pit, c, has an opening, *y*, in front, *fig.* 1830; and is shut when necessary by the mouth-piece, *r*, *figs.* 1829 and 1830.

To give strength and solidity to the furnace, it is bound with hoops of iron, at *b b b b*, *fig.* 1829.

Figs. 1833, 1834, 1835, are views of the muffle.

Fig. 1836 is a view of a crucible for annealing gold.

Figs. 1837, 1838, 1839, are cupels of various sizes, to be used in the furnace. They are the same as those used by assayers in their ordinary furnaces.

Figs. 1840 and 1841 are views of the hand-shovels, used for filling the furnace with charcoal; they should be made of such size and form as to fit the opening *h*, in *figs.* 1829 and 1830.

The smaller pincers or tongs, by which the assays are charged into the cupels, and by which the latter are withdrawn from the furnace, as well as the teaser for cleansing the grate of the furnace, are similar to those used at the British Mint. (See MINT.)

Cupel-mould; Cupels.—The cupels used in the assay process are made of the ashes of burnt bones (phosphate of lime). The cupels are formed in a cupel-mould made of cast steel, very nicely turned, by which means they are easily freed from the mould when struck. The bone-ash is used moistened with a quantity of water, sufficient to make the particles adhere firmly together. The circular mould is filled, and pressed level with its surface; after which, a pestle or plug, having its end nicely turned, of a convex shape, and of a size equal to the degree of concavity wished to be made in the cupel for the reception of the assay, is placed upon the ashes in the mould, and struck with a mallet until the cupel is properly formed. These cupels are allowed to dry in the air for some time before they are used.

The assay by cupellation may be conducted as follows:—

We begin this assay process by weighing, in a delicate balance, a certain weight of the metallic alloy; a gramme (= 15·432 gr.) is usually taken in France, and 10 or 12 grains in this country. The weight is wrapped up in a slip of lead-foil or paper, should it consist of several fragments; and there is added to it the proportion of lead suitable to the quality of alloy to be assayed; there being less lead, the finer the silver is presumed to be. Those who are much in the habit of cupellation can make good guesses in this way. If too much lead be used for the proportion of baser metal present, a portion of the silver is wasted; but if too little, then the whole of the copper is not carried off, and the button of fine silver remains more or less impure. The lead must be, in all cases, as free as practicable from silver; otherwise errors of the most serious kind would be occasioned in the assays.

The assay is then placed upon a cupel which has been previously heated to the proper temperature in the muffle, and the door closed. Fusion immediately occurs, and the cupellation begins when the uncovering, or removal of the black skin of oxide of lead takes place. The oxidation of the lead proceeds rapidly, and the spots of oxide formed on the surface are rapidly absorbed by the cupel. Near the completion of the assay the oxide forms thin films or bands; and when the surface of the silver becomes bright and immoveable, as the brightening occurs, the cupellation is finished. The cupel is now allowed to remain in the muffle until the temperature is diminished and the silver is solid. It is now removed from the muffle, and when cold the button of silver is detached from the cupel by a pair of pliers squeezed or hammered on the side, the under surface cleaned by means of a hard brush, and finally weighed. An assay is thought to be good when the bead is of a round form, if its upper surface is brilliant and crystalline, its lower surface granular and dead white, and if it separates readily from the cupel. When copper is present the oxide of copper produced forms a fusible compound with the oxide of lead and passes into the cupel. The proportion of lead added varies with the amount of copper present in the alloy operated on.

Quantity of Lead to be employed for Cupellation of Alloys of Copper and Silver (M. D'Arcet).

Alloy		Lead for 1 of alloy	Ratio of the copper to the lead
Silver	Copper		
1000	0	$\frac{3}{10}$	0
950	50	3	1 : 70
900	100	7	1 : 60
800	200	10	1 : 50
700	300	12	1 : 40
600	400	14	1 : 35
500	500	16 or 17	1 : 32
400	600	16 — 17	1 : 26·7
300	700	16 — 17	1 : 22·9
200	800	16 — 17	1 : 20
100	900	16 — 17	1 : 17·8
0	1000	16 — 17	1 : 16

Bismuth may be used as a substitute for lead in cupellation; two parts of it being nearly equivalent to three of lead. But its higher price prevents its introduction among assayers.

During the process of cupellation, a portion of the silver is absorbed by the cupel, varying in amount according to the temperature and the quantity of lead employed. This loss is estimated and added on to the weight of the button of silver obtained. The results are returned on 1,000 parts or on the pound troy. It is also customary to report the assays in relation to standard. For example, English standard silver contains 925 parts of silver in 1,000 of alloy. If the result obtained was 920, it would be reported 5 W., or 5 parts in 1,000 worse than standard, and 930 would be reported 5 B., or 5 parts better than standard.

An assay may prove defective for several reasons. Sometimes the button or bead sends forth crystalline vegetations on its surface with such force as to make one suppose a portion of the silver may be thrown out of the cupel, technically called '*spitting*.' When the surface of the bead is dull and flat, the assay is considered to have been too hot, and it indicates a loss of silver in fumes. When the tint of the bead is not uniform, when its inferior surface is bubbly, when yellow scales of oxide of lead remain on the bottom of the cupel, and the bead adheres strongly to it,—by these signs it is judged that the assay has been too cold, and that the silver retains some lead. After the lead is put into the cupel, it gets immediately covered with a coat of oxide, which resists the admission of the silver to be assayed into the melted metal; so that the alloy cannot form. When a bit of silver is laid on a lead-bath in this predicament, we see it swim about a long time without dissolving. In order to avoid this result, the silver is wrapped up in a bit of paper; and the carburetted hydrogen generated by its combustion reduces the film of the lead oxide, gives the bath immediately a bright metallic lustre, and enables the two metals readily to combine. As the heat rises, the oxide of lead flows round about over the surface, till it is absorbed by the cupel. When the lead is wasted to a certain degree, a very thin film of it only remains on the silver, which causes the iridescent appearance like the colours of soap-bubbles: a phenomenon called, by the old chemists, fulguration.

When the cupel cools in the progress of the assay, the oxidation of the lead ceases; and, instead of a very liquid vitreous oxide, an imperfectly-melted oxide is formed, which the cupel cannot absorb. To correct a cold assay, the temperature of the furnace ought to be raised, and pieces of paper put into the cupel, till the oxide of lead which adheres to it be reduced. On keeping up the heat, the assay will resume its ordinary train. Pure silver is more liable to vegetate. Some traces of copper destroy this property, which is obviously due to the oxygen which the silver can absorb while it is in fusion, and which is disengaged the moment it solidifies. An excess of lead, by removing all the copper at an early stage, tends to cause the vegetation. The brightening is caused by the heat evolved when the button passes from the liquid to the solid state. Many other substances present the same phenomenon. In the above operation it is necessary to employ lead which is very pure, or at least free from silver. This is called *poor lead.* The lead reduced from Pattinson's 'oxychloride' is very free from silver; the lead reduced from the litharge of commerce usually contains 10 dwts. or more of silver per ton.

2. *Wet Methods.* (*a.*) *By means of a Standard Solution of Salt or Chloride of Sodium.*—The process by the humid way, recommended at the Royal Mint in 1829, and exhibited as to its principles before the Right Honourable John Herries, then Master, in 1830, has all the precision and certainty we could wish. It is founded on the well-known property which silver has, when dissolved in nitric acid, to be precipitated as an insoluble chloride of silver by a solution of salt or by muriatic acid; but, instead of determining the weight of the chloride of silver, we take the quantity of the solution of salt which has been necessary for the precipitation of the silver. To put the process in execution, a liquor is prepared composed of water and salt in such proportions that 1,000 measures of this liquor may precipitate completely 10 grains of silver, perfectly pure or of the standard 1,000, previously dissolved in nitric acid. The liquor thus prepared gives, immediately, the true standard of any alloy whatever, of silver and copper, by the quantity of which it may be necessary to precipitate the silver in a known weight of this alloy.

The process by the humid way is, so to speak, independent of the operator, the manipulations being very easy; and the term of the operation is very distinctly announced by the absence of any sensible turbidity on the addition of salt to the silver solution, while there remains in it one quarter of a thousandth of metal. The process is not tedious, and in experienced hands it may rival the cupel in rapidity; it has the advantage over the cupel of being more within the reach of ordinary operators, and of not requiring a long apprenticeship. It is particularly useful to such assayers as have only a few assays to make daily, as it will cost them very little time and expense.

By agitating briskly, during two minutes, the liquid rendered milky by the precipitation of the chloride of silver, it may be sufficiently clarified to enable us to appreciate, after a few moments of repose, the disturbance that can be produced in it by the addition of 1000th of a grain of silver. The presence of lead and copper, or any other metal, except mercury, has no perceptible influence on the quantity of salt necessary to precipitate the silver; that is to say, the same quantity of silver, pure or alloyed, requires for its precipitation a constant quantity of the solution of salt.

Supposing that we operate upon a gramme of pure silver, the solution of salt ought to be such that 100 cubic centimeters may precipitate exactly the whole of the silver. The standard of an alloy is given by the number of thousandths of solution of salt necessary to precipitate the silver contained in a gramme of alloy.

When any mercury is accidentally present, which is however, a rare occurrence, it is made obvious by the precipitated chloride remaining white when exposed to daylight; whereas, when there is no mercury present, it becomes speedily first grey and then purple. Silver so contaminated must be strongly ignited before being assayed, and the loss of weight noted; or a cupel assay may be had recourse to.

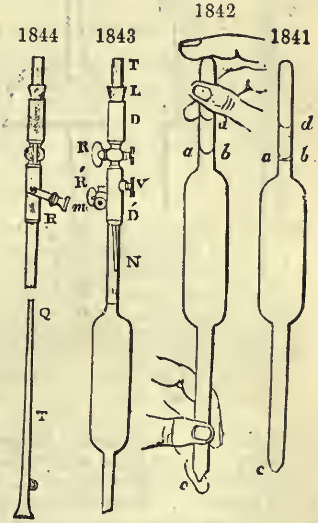
The following is a description of the process and apparatus as first introduced by Gay-Lussac:—

Preparation of the Normal Solution of Salt when it is measured by Weight.—Supposing the salt pure as well as the water, we have only to take these two bodies in the proportion of 0·5437 k. of salt to 99·4573 k. of water, to have 100 k. of solution, of which 100 grammes will precipitate exactly one gramme of silver. But instead of pure salt, which is to be procured with difficulty, and which besides may be altered readily by absorbing the humidity of the air, a concentrated solution of the salt of commerce is to be preferred, of which a large quantity may be prepared at a time to be kept in reserve for use, as it is wanted.

Preparation of the Normal Solution of Salt when measured by Volume.—The measure by weight has the advantage of being independent of temperature, of having the same degree of precision as the balance, and of not standing in need of correction. The measure by volume has not all these advantages; but, by giving it sufficient precision, it is more rapid. This normal solution is so made, that a volume equal to that of 100 grammes of water, or 100 cubic centimeters, at a determinate temperature, may precipitate exactly one gramme of silver. The solution may be kept at a constant temperature, and in this case the assay stands in no want of correction; or if its temperature be variable, the assay must be corrected according to its influence. These two circumstances make no change in the principle of the process, but they are sufficiently important to occasion some modifications in the apparatus.

We readily obtain a volume of 100 cubic centimeters by means of a *pipette, fig.* 1841, so gauged, that when filled with water up to the mark *a b*, and well dried at its point, it will run out, at a continuous efflux, 100 grammes of water at the temperature of 15° C. (59° F.) We say purposely at one efflux, because after the cessation of the jet, the pipette may still furnish two or three drops of liquid, which must not be counted or reckoned upon. The weight of the volume of the normal solution, taken in this manner with suitable precautions, will be uniform from one extreme to another, upon two centimeters and a half, at most, or to a quarter of a thousandth, and the difference from the mean will be obviously twice less, or one half. Let us indicate the most simple manner of taking a measure of the normal solution of salt.

After having immersed the beak, *c*, of the pipette in the solution, we apply suction, by the mouth, to the upper orifice, and thereby raise the liquid to *d*, above the circular line *a b*. We next apply neatly the forefinger of one hand to this orifice, remove the pipette from the liquid, and seize it as represented in *fig.* 1842. The mark *a b* being placed at the level of the eye, we make the surface of the solution become exactly a tangent to the plane *a b*. At the instant it becomes a tangent, we leave the beak, *c*, of the pipette open, by taking away the finger that had been applied to it, and without changing anything else in the position of the hands, we empty it into the bottle which should receive the solution, taking care to remove it whenever the efflux has run out.



If, after filling the pipette by suction, anyone should find a difficulty in applying the forefinger fast enough to the upper orifice without letting the liquid run down below the mark *a b*, he should remove the pipette from the solution with its top still closed with his tongue, then apply the middle finger of one of his hands to the lower orifice; after which he may withdraw his tongue, and apply the forefinger of the other hand to the orifice previously wiped. This method of obtaining a measure of normal solution of sea-salt is very simple, and requires no complex apparatus; but we shall indicate another manipulation still easier, and much more exact.

In this new process the pipette is filled from the top like a bottle, instead of being filled by suction, and it is moreover fixed. *Fig.* 1843 represents the apparatus. D and D′ are two sockets, separated by a stopcock R. The upper one, tapped interiorly, receives by means of a cork stopper, L, the tube T, which admits the solution of sea-salt. The lower socket is cemented on to the pipette; it bears a small air-cock R′, and a screw-plug V, which regulates a minute opening intended to let the air enter very slowly into the pipette. Below the stopcock R′, a silver tube, N, of narrow diameter, soldered to the socket, leads the solution into the pipette, by allowing the air, which it displaces, to escape by the stopcock, R′. The screw-plug, with the milled head, V, replaces the ordinary screw by which the key of the stopcock may be made to press, with more or less force, upon its conical seat.

Fig. 1844 represents a side view of the apparatus just described. We here remark an air-cock R, and an opening *m*. At the extremity Q, of the same figure, the conical pipe T enters with friction. It is by this pipe that the air is sucked into the pipette, when it is to be filled from its beak.

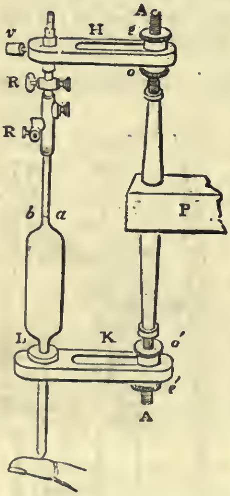
The pipette is supported by two horizontal arms H K (*fig.* 1845) moveable about a common axis, A A, and capable of being drawn out or shortened by the aid of two longitudinal slits. They are fixed steadily by two screw-nuts, *e e'*, and their distance may be varied by means of round bits of wood or cork interposed, or even by opposite screw-nuts, *o o'*. The upper arm H is pierced with a hole, in which is fixed, by the pressure of a wooden screw *v*, the socket of the pipette. The corresponding hole of the lower arm is larger; and the beak of the pipette is supported in it by a cork stopper, L. The apparatus is fixed by its tail-piece P, by means of a screw to the corner of a wall, or any other prop.

The manner of filling the pipette is very simple. We begin by applying the forefinger of the left hand to the lower aperture, *c*; we then open the two stopcocks R and R'. Whenever the liquor approaches the neck of the pipette, we must temper its influx, and when it has arrived at some millimeters above the mark *a b*, we close the two stopcocks, and remove our forefinger. We have now nothing more to do than to regulate the pipette; for which purpose the liquid must touch the line *a b*, and must simply adhere externally to the beak of the pipette.

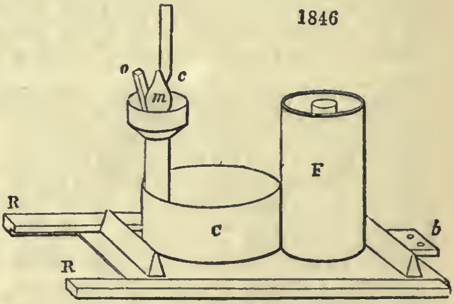
This last circumstance is easily adjusted. After taking away the finger which closed

1847

1845



1846



the aperture *c* of the pipette, we apply to this orifice a moist sponge, *m*, *fig.* 1846, to absorb the superfluous liquor as it drops out. This sponge is called the 'handkerchief' by M. Gay-Lussac (*mouchoir*). The pipette is said to be wiped, when there is no liquor adhering to its point exteriorly,

For the convenience of operating, the handkerchief is fixed by friction in a tube of tin-plate, terminated by a cup, open at bottom to let the droppings flow off into the cistern C, to which the tube is soldered. It may be easily removed for the purpose of washing it; and, if necessary, a little wedge of wood, *o*, can raise it towards the pipette.

To complete the adjustment of the pipette, the liquid must be made merely to descend to the mark *a*, *b*. With this view, and whilst the handkerchief is applied to the beak of the pipette, the air must be allowed to enter very slowly, by unscrewing the plug *v*, *fig.* 1843; and at the moment of the contact, the handkerchief must be removed, and the bottle F, destined to receive the solution, must be placed below the orifice of the pipette, *fig.* 1846. As the motion must be made rapidly, and without hesitation, the bottle is placed in a cylinder of tin-plate, of a diameter somewhat greater, and forming one body with the cistern and the handkerchief. The whole of this apparatus has for a basis a plate of tinned-iron, moveable between the wooden rollers R R, one of which bears a groove, under which the edge of the plate slips. Its traverses are fixed by two abutments, *b b*, placed so that when it is stopped by one of them, the beak of the pipette corresponds to the centre of the neck of the bottle, or is a tangent to the handkerchief. This arrangement, very convenient for wiping the pipette, and emptying it, gives the apparatus sufficient solidity, and allows of its being taken away, and replaced without deranging anything. It is obvious that it is of advantage, when once the entry of the air into the pipette has been regulated by the screw V, to leave it constantly open, because the motion from the handkerchief to the bottle is performed with sufficient rapidity to prevent a drop of the solution from collecting and falling down.

Temperature of the Solution.—After having described the manner of measuring by volume the normal solution of the salt, we shall indicate the most convenient means of taking the temperature. The thermometer is placed in a tube of glass, T, *fig.* 1847, which the solution traverses to arrive at the pipette. It is suspended in it by a piece of cork, grooved on the four sides to afford passage to the liquid. The scale is engraved upon the tube itself, and is repeated at the opposite side, to fix the eye by the coincidence of this double division at the level of the thermometric column. The tube is joined below to another narrower one, through which it is attached by means of a cork stopper B, in the socket of the stopcock of the pipette. At its upper part it is cemented into a brass socket, screw-tapped in the inside, which is connected in its turn by a cock, with the extremity, also tapped, of the tube above T, belonging to the reservoir of the normal solution. The corks employed here as connecting links between the parts of the apparatus, give them a certain flexibility, and allow of their being dismounted and remounted in a very short time; but it is indispensable to make them be traversed by a hollow tube of glass or metal, which will hinder them from being crushed by the pressure they are exposed to. If the precaution be taken to grease them with a little suet, and to fill their pores, they will suffer no leakage.

For the preservation of the normal solution of salt, M. Gay-Lussac uses a cylindrical vessel or drum of copper, of a capacity of about 110 litres, having its inside covered with a resin-and-wax cement. If the drum contains 110 litres, we should only put 105 into it, in order that sufficient space may be left for agitating the liquor without throwing it out. According to the principle that 100 cubic centimeters, or $\frac{1}{10}$th of a litre of the solution should contain enough of salt to precipitate a gramme of pure silver; and, admitting moreover, 13·516 for the equivalent of silver, and 7·335 for that of salt, we shall find the quantity of pure salt that should be dissolved in the 105 litres of water, and which corresponds to $105 \times 10 = 1050$ grammes of silver, to be, by the following proportion:—

$$13{\cdot}516 : 7{\cdot}335 :: 1050 \text{ grammes} : x = 569{\cdot}83 \text{ grammes.}$$

And as the solution of the salt of commerce, formerly mentioned, contains approximatively 250 grammes per kilogramme, we must make 2279·3 grammes of this solution to have 569·83 grammes of salt. The mixture being perfectly made, the tubes and the pipette must be several times washed by running the solution through them, and putting it into the drum. The standard of the solution must be determined after it has been well agitated, supposing the temperature to remain uniform.

To arrive more conveniently at this result, we begin by preparing two decimal solutions; one of silver, and another of salt.

The decimal solution of silver is obtained by dissolving 1 gramme of silver in nitric acid, and diluting the solution with water till its volume becomes a litre.

The decimal solution of salt may be obtained by dissolving 0·543 gramme of pure salt in water, so that the solution shall occupy a litre; but we shall prepare it even with the normal solution which we wish to test, by mixing a measure of it with 9 measures of water; it being understood that this solution is not rigorously equivalent to that of silver, and that it will become so only when the normal solution employed for its preparation shall be finally of the true standard. Lastly, we prepare beforehand several stoppered bottles, in each of which we dissolve 1 gramme of silver in 8 or 10 grammes of nitric acid. For brevity's sake, we shall call these 'tests.'

Now, to investigate the standard of the normal solution, we must transfer a pipette of it into one of these test-bottles; and we must agitate the liquors briskly to clarify them. After some instants of repose, we pour in 2 thousandths of the decimal solution of salt, which we suppose will produce a precipitate. The normal liquor is consequently too feeble; and we should expect this, since the salt employed was not perfectly pure. We agitate and add 2 fresh thousandths, which will also produce a precipitate. We continue thus, by successive additions of 2 thousandths till the last produces no precipitation. Suppose that we have added 16 thousandths: the last two should not be reckoned, as they produced no precipitate; the preceding two were necessary, but only in part; that is to say, the useful thousandths added are above 12 and below 14, or otherwise they are on an average equal to 13.

Thus, in the condition of the normal solution, we require 1,013 parts of it to precipitate 1 gramme of silver, while we should require only 1,000. We shall find the quantity of concentrated solution of salt that we should add, by noting that the quantity of solution of salt, at first employed, viz. 2279·3 grammes, produced a standard of only 987 thousandths $= 1000 - 13$; and by using the following proportion:

$$987 : 2279{\cdot}3 :: 13 : x = 30{\cdot}02 \text{ grammes.}$$

This quantity of the strong solution of salt, mixed with the normal solution in the drum, will correct its standard, and we shall see now by how much.

After having washed the tubes and the pipette with the new solution, we must repeat the experiment upon a fresh gramme of silver. We shall find, for example, in proceeding only by a thousandth at a time, that the first causes a precipitate, but not the second. The standard of the solution is still too weak, and is comprised between 1000 and 1001; that is to say, it may be equal to 1000½, but we must make a closer approximation.

We pour into the test-bottle 2 thousandths of the decimal solution of silver, which will destroy 2 thousandths of salt, and the operation will have retrograded by 2 thousandths; that is to say, it will be brought back to the point at which it was first of all. If, after having cleared up the liquor, we add half a thousandth of the decimal solution, there will necessarily be a precipitate, as we knew beforehand, but a second will cause no turbidity. The standard of the normal liquor will be consequently comprehended between 1000 and 1000½, or equal to 1000¼.

We should rest content with this standard; but if we wish to correct it, we may remark that the two quantities of solution of salt added, viz. 2279·3 gr. + 30·02 gr. = 2309·32 gr., have produced only 999·75 thousandths, and that we must add a new quantity of it corresponding to ¼ of a thousandth. We make, therefore, the proportion

$$999{\cdot}75 : 2309{\cdot}32 :: 0{\cdot}25 : x.$$

But since the first term differs very little from 1000, we may content ourselves to have x by taking the $\frac{0{\cdot}25}{1000}$ of 2309·32, and we shall find 0·577 gr. for the quantity of solution of salt to be added to the normal solution.

It is not convenient to take exactly so small a quantity of solution of salt by the balance, but we shall succeed easily by the following process. We weigh 50 grammes of this solution, and we dilute it with water, so that it occupies exactly half a litre, or 500 centimeters cube. A pipette of this solution, one centimeter cube in volume, will give a decigramme of the primitive solution, and as such a small pipette is divided into twenty drops, each drop, for example, will present 5 milligrammes of the solution. We should arrive at quantities smaller still by diluting the solution with a proper quantity of water; but greater precision would be entirely needless.

The testing of the normal liquor just described is, in reality, less tedious than might be supposed. It deserves also to be remarked, that liquor has been prepared for more than 1,000 assays; and that, in preparing a fresh quantity, we shall obtain directly its true standard, or nearly so, if we bear in mind the quantities of water and solution of salt which have been employed.

Correction of the Standard of the Normal Solution of Salt, when the Temperature changes.—We have supposed, in determining the standard of the normal solution of salt, that the temperature remained uniform. The assays made in such circumstances have no need of correction; but if the temperature should change, the same measure of the solution will not contain the same quantity of salt. Supposing that we have tested the solution of the salt at the temperature of 15° C.; if, at the time of making the experiment, the temperature is 18° C., for example, the solution will be too weak on account of its expansion, and the pipette will contain less of it by weight; if, on the contrary, the temperature has fallen to 12°, the solution will be thereby concentrated, and will prove too strong. It is therefore proper to determine the correction necessary to be made for any variation of temperature.

To ascertain this point, the temperature of the solution of salt was made successively, to be 0, 5°, 10°, 15°, 20°, 25°, and 30° C., and three pipettes of the solution were weighed exactly at each of these temperatures. The third of these weighings gave the mean weight of a pipette. The corresponding weights of a pipette of the solution were afterwards graphically interpolated from degree to degree. These weights form the second column of the following Table. They enable us to correct any temperature between 0° and 30° C. (32° and 86° F.) when the solution of salt has been prepared in the same limits.

Let us suppose, for example, that the solution has been made standard at 15°, and that at the time of using it, the temperature has become 18°. We see by the second column of the Table, that a weight of a measure of the solution is 100·099 gr. at 15°, and 100·065 at 18°; the difference, 0·034 gr., is the quantity of solution less which has been really taken; and of course we must add it to the normal measure, in order to make it equal to one thousand *millièmes*. If the temperature of the solution had fallen to 10° the difference of the weight of a measure from 10° to 15° would be 0·019 gr., which we must, on the contrary, deduct from the measure, since it had been taken too large. These differences of weight of a measure of solution at 15°, from that of a measure at any other temperature, form the column 15° of the table where they are expressed in thousandths; they are inscribed on the same horizontal lines as to the temperatures to which each of them relates with the sign + *plus*, when they must be added, and with the sign − *minus*, when they must be subtracted.

Table of Correction for the Variations in the Temperature of the Normal System of the Salt.

Temperature	Weight	5°	10°	15°	20°	25°	30°
degrees	gram.	mill.	mill.	mill.	mill.	mill.	mill.
4	100,109	0·0	−0·1	+0·1	+0·7	+1·7	+2·7

28	99,879	−2·3	−2·4	−2·2	−1·6	−1·6	+0·7
29	99,858	−2·6	−2·6	−2·4	−1·8	−0·9	+0·2
30	29,836	−2·8	−2·8	−2·6	−2·0	−1·1	0·0

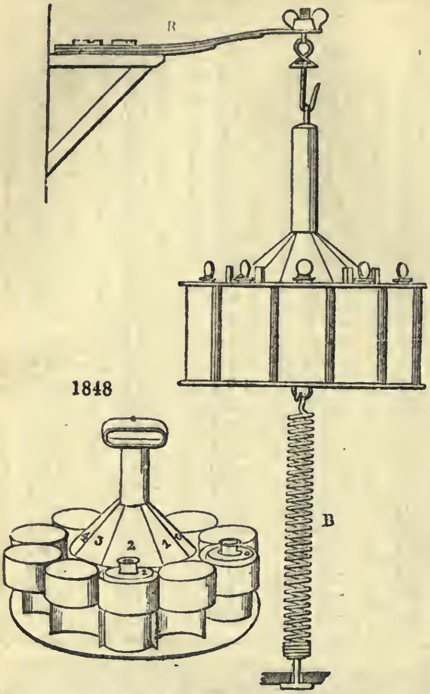
The columns 5°, 10°, 20°, 25°, 35°, have been calculated in the same manner for the cases in which the normal solution may have been graduated to each of these temperatures. Thus, to calculate the column 10°, the number 100·118 has been taken in the column of weights for a term of departure, and its difference from all the numbers of the same column has been sought.

Several expedients have been employed to facilitate and abridge the manipulations. In the first place, the bottles for testing or assaying the specimens of silver should all be of the same height and of the same diameter. They should be numbered at their top, as well as on their stoppers, in the order 1, 2, 3, &c. They may be ranged successively in tens; the stoppers of the same series being placed on a support in their proper order. Each two bottles should, in their turn, be placed in a japanned tin case (*fig.* 1848) with ten compartments, duly numbered. These compartments are cut out anteriorly to about half their height, to allow the bottoms of the bottles to be seen. When each bottle has received its portion of alloy, through a wide-beaked funnel, there must be poured into it about 10 grammes of nitric acid, of specific gravity 1·28, with a pipette, containing that quantity; it is then exposed to the heat of a water-bath, in order to facilitate the solution of the alloy. The water-bath is an oblong vessel made of tin-plate, intended to receive the bottles. It has a moveable double bottom, pierced with small holes for the purpose of preventing the bottles being broken, as it insulates them from the bottom, to which the heat is applied. The solution is rapid; and, since it emits nitrous vapours in abundance, it ought to be carried on under a chimney.

The Agitator.—Fig. 1849 gives a sufficiently exact idea of it, and may dispense with a lengthened description. It has ten cylindrical compartments, numbered from 1 to 10. The bottles, after the solution of the alloy, are arranged in it in the order of their numbers. The agitator is then placed within reach of the pipette intended to measure out the normal solution of salt, and a pipette full of this solution is put into each phial. Each is then closed with its glass-stopper, previously dipped in pure water. They are fixed in the cells of the agitator by springs. The agitator is then suspended to a spring R, and, seizing it with both hands, the operator gives an alternating rapid movement, which agitates the solution, and makes it, in less than a minute, as limpid as water. This movement is sometimes promoted by a spiral spring, B, fixed to the agitator and the ground; but this is seldom made use of, because it is convenient to be able to transport the agitator from one place to another. When the agitation is finished, the catches are released, and the bottles are placed in order upon a table furnished with round cells destined to receive them, and to screen them. When we place the bottles upon this table, we must give them a brisk circular motion to collect the chloride of silver scattered round their sides; we must lift out their stoppers, and suspend them in wire rings, or pincers. We next pour a thousandth of the decimal solution into each bottle; and before this operation is terminated, there is formed in the first bottle, when there *should be* a precipitate, a nebulous stratum, very well marked, of about a centimeter in thickness. At the back of the table there is a black board, divided into compartments, numbered from 1 to 10, upon each of which we mark, with chalk, the thousandths of the decimal liquor put into the corresponding bottle. The thousandths of salt, which indicate an augmentation of standard, are preceded by the sign +, and the thousandths of nitrate of silver by the sign −. When the assays are finished, the liquor of each bottle is to be poured into a large vessel in which a slight excess of salt is kept; and when it is full, the supernatant clear liquid must be run off with a syphon.

1849

1848



The chloride of silver may be reduced without any perceptible loss. After having washed it well, we immerse pieces of zinc in it, and add sulphuric acid in sufficient quantity to keep up a feeble disengagement of hydrogen gas. The mass must not be touched. In a few days the silver is completely reduced. This is easily recognised by the colour and nature of the product; or by treating a small quantity of it with water of ammonia, we shall see whether there be any chloride unreduced, for it will be dissolved by the ammonia, and will again appear upon saturating the ammonia with an acid. The chlorine remains associated with the zinc in a state of solution. The first washings of the reduced silver must be made with an acidulous water, to dissolve the oxides which may have been formed, and the other washings with common water. After decanting the water of the last washing, we dry the mass, and add to it a little powdered borax. It must now be fused. The silver being in a bulky powder is to be put in successive portions into a crucible as it sinks down. The heat should be at first moderate; but towards the end of the operation, it must be pretty strong, to bring into complete fusion the silver and the scoriæ, and to effect their complete separation. In case it should be supposed that the whole of the silver had not been reduced by the zinc, a little carbonate of potash should be added to the borax. The silver may also be reduced by exposing the chloride to a strong heat, in contact with chalk and charcoal.

The following remarks by M. Gay-Lussac, the author of the above method, upon the effect of a little mercury in the humid assay, are important:—

It is well known that chloride of silver blackens the more readily when it is exposed to an intense light, and that even in the diffused light of a room it becomes soon sensibly coloured. If it contains 4 to 5 thousandths of mercury, it does not blacken; it remains of a dead white; with 3 thousandths of mercury, there is no marked discolouring in diffused light; with 2 thousandths it is slight; with 1 it is much more marked, but still it is much less intense than with pure chloride. With half a thousandth of mercury the difference of colour is not remarkable, and is perceived only in a very moderate light. But when the quantity of mercury is so small that it cannot be detected by the difference of colour in the chloride of silver, it may be rendered quite evident by a very simple process of concentration. Dissolve one gramme of the silver supposed to contain a quarter of a thousandth of mercury, and let only a quarter of it be precipitated, by adding a quarter of the common salt necessary to precipitate it entirely. In thus operating, the quarter thousandth of mercury is concentrated in a quantity of chloride of silver four times smaller: it is as if the silver having been entirely precipitated, four times as much mercury, equal to 2 thousandths, have been precipitated with it. On taking two grammes of silver, and precipitating only a quarter by common salt, the precipitate would be, with respect to the chloride of silver, as if it amounted to 4 thousandths. By this process, which occupies only five minutes because exact weighing is not necessary, one tenth of a thousandth of mercury may be detected in silver. It is not useless to observe that, in making these experiments, the most exact manner of introducing small quantities of mercury into a solution of silver, is to weigh a minute globule of mercury, and to dissolve it in nitric acid, diluting the solution so that it may contain as many cubic centimeters as the globule weighs of centigrammes. Each cubic centimeter, taken by means of a pipette, will contain one milligramme of mercury. If the ingot of silver to be assayed be found to contain a greater quantity of mercury—1 thousandth, for example—the humid process ought, in this case, either to be given up or to be compared with cupellation. When the silver contains mercury, the solution from which the mixed chlorides are precipitated does not really become clear. Silver containing mercury, put into a small crucible, and mixed with lamp-black, to prevent the volatilisation of the silver, was heated for three-quarters of an hour in a muffle, but the silver increased sensibly in weight. This process for separating the mercury, therefore, failed. It is to be observed, that mercury is the only metal which has thus the power of disturbing analysis by the humid way. The error caused by the presence of mercury may be avoided by the addition of a small quantity of acetate of soda to the solution of the silver in nitric acid, previous to the addition of the chloride of sodium, as this salt prevents the precipitation of the mercury.

Since the above process was first introduced by Gay-Lussac, several modifications in the form of apparatus and other details have been introduced; but the principles upon which the method is worked are essentially the same. The normal solution of salt is preserved in a vessel of glass or stoneware, instead of metal. The use of metal tubes is dispensed with. Various modes of filling the pipettes from below or otherwise are in use. Instead of the thermometer placed within the tube to indicate the temperature of the salt-solution, the standard is verified once a day or oftener if necessary by check assays. The assay of silver, or silver alloys by a standard solution of salt may be conducted as follows:—Ten grs. or more of the metal according to circumstances, is weighed out, transferred to the bottle, dilute nitric acid added and solution effected by placing the bottle in a water-bath. The red fumes are expelled, and the solution diluted with water. The bottle is now placed under the lower end of the pipette, 1000 grs. of the normal solution of salt (equal to ten grs. of silver) run in, and the contents briskly shaken until clear. Ten grs. of the decimal solution of salt (1000 grs. of which are equal to 1 gr. of silver) is now added from a pipette and, as precipitate forms, the solution is again shaken until clear. This process is repeated until the last 10 grs. added, does not produce any precipitate. As the last 10 grs. of decimal solution added does not give any precipitate, it proves that it is in excess; it is therefore, deducted from the total quantity used, and also the half, say of the previous 10 grs. added, as it is obvious that the previous 10 grs. added were not sufficient to precipitate the whole of the silver. For example, 11 grs. of the alloy require 1000 grs. of the normal solution, and 50 grs. of the decimal solution of salt, for the working of the assay. The amount found necessary is, therefore, 35 grs. of the decimal solution, which is equal to 3·5 of the normal solution, which added on to the 1000 grs. makes the total quantity required for the precipitation of the silver 1003·5. Therefore—

	Salt-solution		Salt-solution		Silver		Silver
	1000	:	1003·5	:	10	:	10·035
Then as							
	Alloy		Alloy		Silver		Silver
	11 grs.	:	1000	:	10·035	:	912·2

The weight of alloy operated on should contain about 10 grs. of silver. The contents of silver should, therefore, be approximately determined by cupellation or otherwise before submitting it to assay by this method. It is also desirable to take a quantity of the metal for the assay, so as to require the decimal solution of salt to complete it; by this means the error noticed by Mulder and other assayers is obviated. However, if it is found in the working of an assay that the first 10 grs. of the decimal solution of salt does not yield any precipitate, excess of the decimal solution of silver (1000 grs.

of which contain 1 gr. of silver) is added, and the assay completed as before with the decimal salt-solution. The measure of decimal solution of salt corresponding to the measure of the decimal solution of silver added, is deducted, and the remainder equals the quantity of salt solution required to precipitate the silver in the metal operated on.

b. By weighing the chloride of silver.—This process is used for the Indian Mint assays, special apparatus being employed to carry on a number of assays at one time. The process may be conducted as follows:—A portion of the silver, or alloy, is accurately weighed, transferred to a stoppered bottle, dilute nitric acid added, and solution effected by heating the bottle in a water-bath or otherwise. When decomposed, the solution is diluted with water, hydrochloric acid added in excess, and the bottle well shaken till the precipitated chloride of silver collects, and the solution is clear. The bottle is now filled to the neck with water, allowed to settle, and the supernatant liquor carefully removed by means of a glass syphon. The bottle is again filled with water, the chloride of silver allowed to settle, and the solution syphoned off as before. Two or more washings are made, according to the purity of the silver or alloy operated on. The bottle is now inverted over a small Wedgwood crucible, and manipulated until the whole of the chloride of silver is collected therein. The chloride of silver is now broken up and gently stirred, by means of a glass rod, until it lies evenly at the bottom of the crucible. The water is carefully drained off, and the crucible heated at first at a low temperature, and afterwards for some time at a temperature of about 300° F. When the chloride of silver is thoroughly dried, it is allowed to cool, and then carefully transferred to the skiff of the assay balance, and weighed. The amount of chloride of silver obtained from a known weight of pure silver by working under similar conditions is ascertained, and the calculations made from this data. Special weights are used in India, to facilitate calculations. The assay weight indicating from the amount of chloride of silver the actual quantity of silver present in 1,000 parts.

SILVER, BROMIDE OF (AgBr), is occasionally found native. If a soluble bromide is added to a solution of nitrate of silver, a precipitate of bromide of silver is formed of a very pale yellow colour. This salt changes readily under the action of the solar rays, and for photographic purposes possesses many very important properties, of which photographers have not availed themselves. This is mainly owing to the neglect of scientific investigation amongst the body of photographic artists, which is exceedingly to be regretted.

SILVER, CHLORIDE OF, (AgCl) is obtained by adding hydrochloric acid, or any soluble chloride, to a solution of nitrate of silver. A curdy precipitate falls, quite insoluble in water, which being dried and heated to dull redness, fuses into a semi-transparent grey mass, called, from its appearance, *horn-silver.* Chloride of silver dissolves readily in water of ammonia, and crystallises in proportion as the ammonia evaporates. It is not decomposed by a red heat, even when mixed with calcined charcoal; but when hydrogen or steam is passed over the fused chloride, hydrochloric acid exhales, and silver remains. When fused along with potash (or its carbonate), the silver is also revived; while oxygen (or also carbonic acid) gas is liberated, and chloride of potassium is formed. Alkaline solutions do not decompose chloride of silver. When this compound is exposed to light, it suffers a partial decomposition, hydrochloric acid being disengaged.

The best way of reducing the chloride of silver, says Mohr, is to mix it with one-third of its weight of colophony (black resin), and to heat the mixture moderately in a crucible till the flame ceases to have a greenish-blue colour; then suddenly to increase the fire, so as to melt the metal into an ingot.

The subchloride may be directly formed by pouring a solution of proto-chloride of copper or iron upon silver-leaf.

SILVER, CYANIDE OF. See Cyanides.

SILVER FIR. *Abies picea.* This species yields the Burgundy pitch and Strasburg turpentine. See Abies.

SILVER, FULMINATING. See Fulminating Silver.

SILVER GLANCE. Sulphide of silver. See Silver.

SILVER, HYPOSULPHITE OF. $AgO.S^2O^2.HO$ ($\mathbf{Ag^2S^2H^2O^4}$). This salt is formed in the process of fixing photographic pictures with *hyposulphite of soda.* Solutions of the hyposulphite of soda, potash, or lime, which are bitter salts, dissolve chloride of silver into liquids possessing a remarkable sweetness. See Hyposulphite of Soda.

SILVER, IODIDE OF. (AgI.) This compound of iodine and silver, which is obtained when a solution of an iodide is added to nitrate of silver, is a pale yellow powder. It is also found native, but not in large quantities. This silver salt is remarkable, like some other metallic compounds, for changing its colour alternatively with heat and cold. If a sheet of white paper be washed over with a solution of nitrate of silver, and afterwards with a somewhat dilute solution of iodide of potassium, it will immediately assume the pale yellow tint of the cold silver iodide. On placing the paper before the fire, it will change colour from a pale primrose to a gaudy brilliant yellow, like the sunflower; and on being cooled, it will again resume the primrose hue. These alternations may be repeated indefinitely, like those with the salts of cobalt, provided too great a heat be not applied. The pressure of a finger upon the hot yellow paper makes a white spot, by cooling it quickly. Iodide of silver, when quite pure, is very slowly darkened when exposed to sunshine; but if in combination with an organic compound, or with an excess of nitrate of silver, it changes colour with much rapidity. From this property it furnishes one of the most valuable of our photographic agents. It is the active material in the calotype, the collodion, the Daguerreotype, and other processes, See Photography.

SILVER, NITRATE OF. $AgO.NO^5$ ($\mathbf{AgNO^3}$). This salt was known to Geber, and was chiefly used in medicine; but since the discovery of photography, it has been made on a very large scale. It is found in commerce in two different forms, viz. crystallised, and in sticks, the former being more general; in sticks it is called 'lunar caustic,' and is used by the surgeon. It is prepared by digesting metallic silver with moderately strong nitric acid; the silver speedily dissolves, especially if heat be applied. Some of the nitric acid is decomposed, yielding oxygen to the silver, and liberating binoxide of nitrogen, which, in contact with the air, abstracts oxygen and forms red vapours of hyponitric acid.

The clear solution is evaporated, either to the crystallising point or to dryness; if for *caustic*, it is fused and cast into sticks. If ordinary standard silver be used, the solution will contain some nitrate of copper; in this case it must be evaporated to dryness, and gradually heated till all the nitrate of copper is decomposed, which may be known by taking a little of the salt, dissolving in water, and adding excess of ammonia; when, if copper be still present, the solution will have a blue tint. When all the copper is thus rendered insoluble, the fused mass is dissolved in distilled water, evaporated and crystallised. When pure, nitrate of silver is white; the crystals are transparent, colourless, hexagonal tables, or right rhombic prisms, very soluble in water, requiring only their own weight of cold water and half that quantity of boiling water for solution; they are also readily soluble in hot alcohol, but the greater portion is again deposited on cooling. Nitrate of silver possesses a strongly metallic and bitter taste. It is not deliquescent, and when free from organic matter is not decomposed by light (*Scanlan*). The dark colour of the outside of the ordinary sticks of the shops is caused by the decomposition of the nitrate by the paper in which they are wrapped, as the presence of organic matter reduces the silver to the metallic state. Nitrate of silver is frequently adulterated to a considerable extent, principally with nitrate of potash, but sometimes with other nitrates. The price at which it is sometimes sold is proof enough that it is largely adulterated; for instance, it may sometimes be bought for 3*s.* an ounce; at that price it does not pay for the silver alone that *should be* in it: we will prove this. Every ounce (437·5 grains) of pure nitrate of silver contains 278 grains of pure silver, and this itself, without taking notice of nitric acid and time of preparation, is worth 3*s.* 2*d.* This clearly proves there must be considerable adulteration; but although the adulterating substances do not interfere generally with the photographic processes, it is certain that no advantage can be gained by buying it at so low a price. The way to detect the adulteration is to precipitate the silver by hydrochloric acid, and evaporate the filtered liquid to dryness, when, if the salt is pure, there will be no residue.

As many, who use much nitrate of silver in photography, &c., throw away the residues, and hence in course of time waste much silver, it will not be out of place here to show how it may be saved and converted again into nitrate of silver fit for use.

If the papers, on which there is silver, are preserved, the silver can be obtained by merely burning them, and may be fused in a porcelain crucible into one lump. In the case of the nitrate-of-silver baths, when too weak for further use, the silver may be precipitated in the form of chloride, by adding hydrochloric acid. The chloride of silver thus obtained may be easily reduced to the metallic state: 1st, by digesting the moist chloride with metallic zinc and dilute sulphuric acid; the hydrogen which is thus liberated reduces the silver to the metallic state, which remains in the form of a black powder, and when well washed with water may be dissolved in nitric acid, evaporated and crystallised. 2nd, by digesting it by the aid of heat with a caustic alkali and tartaric acid, when it will also be reduced to metallic silver, and will remain as a black powder, which may be treated as above. 3rd, by collecting the precipitated chloride of silver on a filter, washing well with water, and drying; the dry chloride is then mixed with four or five times its weight of a mixture of carbonate of potash and carbonate of soda, and subjected to a white heat in a porcelain crucible; the silver will be reduced to the metallic state. This salt is used not only in photography, but in making permanent ink, and as a dye for the hair.

SILVER, OXIDES OF. There are two oxides of silver: the *protoxide* AgO (**Ag^2O**) and the *peroxide* AgO^2 (**AgO**). The first is obtained by adding solution of caustic potash, or lime-water, to a solution of nitrate of silver. The precipitate has a brownish-grey colour, which darkens when dried, and contains no combined water. Its specific gravity is 7·143. On exposure to the sun it gives out a certain quantity of oxygen, and becomes a black powder. This oxide is an energetic base; being slightly soluble in pure water, reacting like the alkalis upon reddened litmus-paper, and displacing, from their combinations with the alkalis, a portion of the acids with which it forms insoluble compounds. It is insoluble in the caustic lyes of potash or soda. By combination with caustic ammonia, it forms *fulminating silver.* The second, or peroxide, is formed when a very dilute solution of nitrate of silver is decomposed by the voltaic current; dark grey lustrous needles of the peroxide of silver are formed around the positive pole. See Fulminating Silver.

SILVER, SULPHATE OF, $AgO.SO^3$ (**Ag^2SO^4**) may be prepared by boiling sulphuric acid upon the metal. It dissolves in 88 parts of boiling water, but the greater part of the salt crystallises in small needles as the solution cools. It consists of 118 parts of oxide, combined with 40 parts of dry acid.

SILVER, SULPHIDES OF, of which several exist native, may be readily prepared by fusing the constituents together. A sulphide forms spontaneously upon the surface of silver exposed to the air of inhabited places. The tarnish may be easily removed by rubbing the metal with a solution of *chameleon mineral*, prepared by calcining peroxide of manganese with nitre. Sulphide of silver is a powerful sulpho-base; since though it be heated to redness in close vessels, it retains the volatile sulphides, whose combinations with the alkalis are decomposed at that temperature. It consists of 87·04 of silver and 12·96 of sulphur.

SILVER-LEAF is made by beating silver out very thin, in precisely the same way as *gold-leaf* is manufactured. See Gold Beating.

SILVERING is the art of covering the surfaces of bodies with a thin film of silver. This is now effected either by applying thin films of silver mechanically to the article to be silvered, or by the electro-metallurgical process. When silver-leaf is to be applied, the methods prescribed for gold-leaf are suitable. Among the metals, copper or brass are those on which the silverer most commonly operates. Iron is seldom silvered; but the processes for both metals are essentially the same. The white alloy of nickel is now often plated.

The principal steps of this operation are the following:—

1. The *smoothing down* the sharp edges, and polishing the surface of the copper; called *emorfiler* by the French artists.

2. The *annealing;* or, making the piece to be silvered red hot, and then plunging it in a very dilute nitric acid, till it be bright and clean.

3. *Pumicing;* or, clearing up the surface with pumice-stone and water.

4. The *warming*, to such a degree merely as, when it touches water, it may make a slight hissing sound; in which state it is dipped in the very weak aquafortis, whereby it acquires minute insensible asperities, sufficient to retain the silver-leaves that are to be applied.

5. The *hatching.* When these small asperities are inadequate for giving due solidity to the silvering, the plane surfaces must be hatched all over with a graving tool; but the chased surfaces need not be touched.

6. The *blueing*, consists in heating the piece till its copper or brass colour changes to blue. In heating, they are placed in hot tools made of iron, called *mandrins* in France.

7. The *charging*, the workman's term for silvering. This operation consists in

placing the silver-leaves on the heated piece, and fixing them to its surface by burnishers of steel, of various forms. The workman begins by applying the leaves double. Should any part darken in the heating, it must be cleared up by the scratch-brush.

The silverer always works two pieces at once; so that he may heat the one, while burnishing the other. After applying two silver-leaves, he must heat up the piece to the same degree, as at first, and he then fixes on with the burnisher four additional leaves of silver; and he goes on *charging* in the same way, 4 or 6 leaves at a time, till he has applied, one over another, 30, 40, 50, or 60 leaves, according to the desired solidity of the silvering. He then burnishes down with great pressure and address, till he has given the surface a uniform silvery aspect.

Silvering by the precipitated chloride of silver.—The white curd obtained by adding a solution of common salt to one of nitrate of silver is to be well washed and dried. One part of this powder is to be mixed with 3 parts of good pearlash, 1 of washed whiting, and one and a half of sea-salt. After cleaning the surface of the brass, it is to be rubbed with a bit of soft leather, or cork moistened with water, and dipped in the above powder. After the silvering, it should be thoroughly washed with water, dried, and immediately varnished. Some use a mixture of 1 part of the silver precipitate, with 10 of cream of tartar, and this mixture also answers very well.

Others give a coating of silver by applying with friction, in the moistened state, a mixture of 1 part of silver-powder precipitated by copper, 2 parts of cream of tartar, and as much common salt. The piece must be immediately washed in tepid water very faintly alkalised, then in slightly warm pure water, and finally wiped dry before the fire.

The inferior kinds of plated buttons get their silver coating in the following way:—

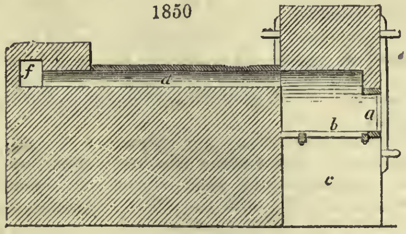
Two ounces of chloride of silver are mixed up with 1 ounce of corrosive sublimate, 3 pounds of common salt, and 3 pounds of sulphate of zinc, with water, into a paste. The buttons being cleaned, are smeared over with that mixture, and exposed to a moderate degree of heat, which is eventually raised nearly to redness, so as to expel the mercury from the amalgam formed by the reaction of the horn-silver and the corrosive sublimate. The copper button thus acquires a silvery surface, which is brightened by cleaning and burnishing. See ELECTRO-METALLURGY.

SILVERING OF GLASS. See MIRRORS.

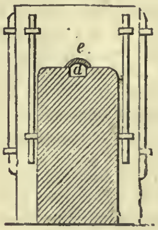
SIMILOR. A name given to a rich-coloured brass, composed of 3 oz. of zinc to 1 lb. of copper. See ALLOY and BRASS.

SINGEING. In the article BLEACHING, the modern and most approved singeing apparatus is described. The old furnace for singeing cotton goods is represented in longitudinal section, *fig.* 1850, and in a transverse one in *fig*, 1851. *a* is the fire-door; *b*, the grate; *c*, the ashpit; *d*, a flue, 6 inches broad and 2½ high, over which a hollow semi-cylindrical mass of cast iron *e*, is laid, 1 inch thick at the sides, and 2½ thick at the top curvature. The flame passes along the fire-flue *d*, into a side opening *f*, in the chimney. The goods are swept swiftly over this ignited piece of iron, with considerable friction, by means of a wooden roller, and a swing frame for raising them at any moment out of contact.

1850



1851



In some shops, semi-cylinders of copper, three-quarters of an inch thick, have been substituted for those of iron, in singeing goods prior to bleaching them. The former last three months, and do 1,500 pieces with one ton of coal; while the latter, which are an inch and a half thick, wear out in a week, and do no more than from 500 to 600 pieces with the same weight of fuel.

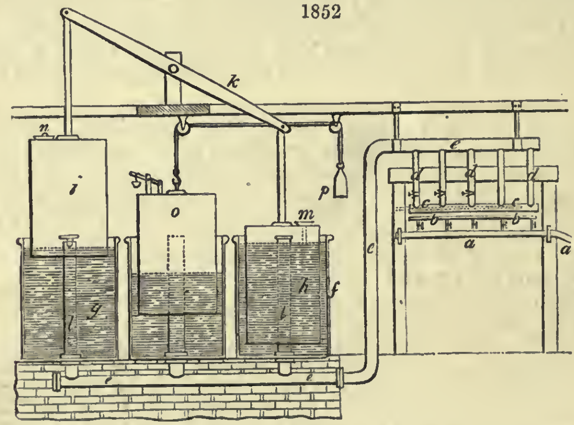
In the early part of the year 1818, Mr. Samuel Hall introduced the plan for removing the downy fibres of the cotton thread from the interstices of bobbinet lace, or muslins, by singeing the lace with the flame of a gas-burner. And in 1823 he modified this process by causing a strong current of air to draw the flame of the gas through the interstices of the lace, as it passes over the burner, by means of an aperture in a tube placed immediately above the row of gas-jets, which tube communicates with an air-pump or exhauster.

Fig, 1852 shows the construction of the apparatus complete, and manner in which it operates: *a*, *a*, is a gas-pipe, supplied by an ordinary gasometer; from this pipe, several small ones extend upwards to the long burner *b*, *b*. This burner is a horizontal tube, perforated with many small holes in the upper side, through which, as jets, the gas passes; and when it is ignited, the bobbinet lace, or other material intended to be singed, is extended and drawn rapidly over the flame, by means of rollers, which are not shown in the figure.

The simple burning of the gas, even with a draught chimney, is found not to be at all times efficacious. There is now introduced a hollow tube *c*, *c*, with a slit or opening, immediately over the row of burners; and this tube, by means of the pipes *d*, *d*, *d*, communicates with the pipe *e*, *e*, *c*, which leads to the exhausting apparatus.

This exhausting apparatus consists of two tanks, *f* and *g*, nearly filled with water, and two inverted boxes or vessels, *h* and *i*, which are suspended by rods to the vibrating beam *k*: each of the boxes is furnished with a valve opening upwards; *l*, *l*, are pipes extending from the horizontal part of the pipe *c*, up into the boxes or vessels *h* and *i*, which pipes have valves at their tops, also opening upward. When

1852

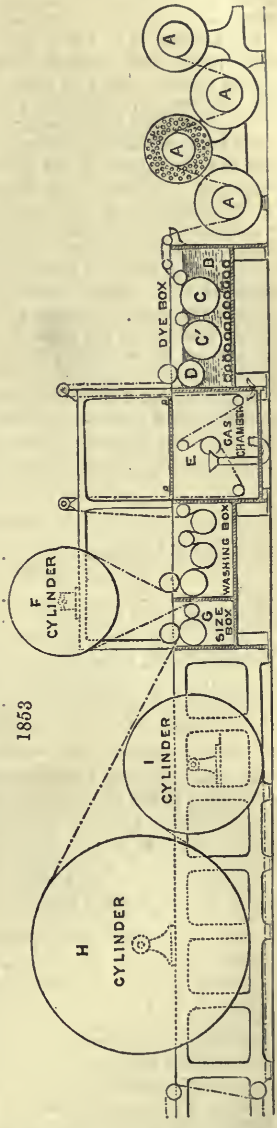


the vessel *h* descends, the water in the tank forces out the air contained within the vessel at the valve *m*; but when that vessel rises again, the valve *m* being closed, the air is drawn from the pipe *e*, through the pipe *l*. The same takes place in the vessel *i*, from which the air in its descent is expelled through the valve *n*, and in its ascent draws the air through the pipe *l*, from the pipe *c*. By these means, a partial exhaustion is effected in the pipe *e*, *e*, and the tube *c*, *c*; to supply which, the air rushes with considerable force through the long opening of the tube *c*, *c*, and carries with it the flame of the gas-burners. The bobbinet lace, or other goods, being now drawn over the flame between the burner *b*, *b*, and the exhausted tube *c*, *c*, by means of rollers, as above said, the flame of the gas is forced through the interstices of the fabric, and all the fine filaments and loose fibres of the thread are burnt off, without damaging the substance of the goods.

To adjust the draught from the gas-burners, there are stop-cocks introduced into several of the pipes *d*; and to regulate the action of the exhausting apparatus, an air vessel *o* is suspended by a cord or chain passing over pulleys, and balanced by a weight *p*. There is also a scraper introduced into the tube *c*, which is made, by any convenient contrivance, to revolve and slide backwards and forwards, for the purpose of removing any light matter that may arise from the goods singed, and which would otherwise obstruct the air-passage. Two of these draught tubes *c* may be adapted and united to the exhausting apparatus, when a double row of burners is employed, and the inclination of the flame may be directed upwards, downwards, or sideways, according to the position of the slit in the draught tube, by which means any description of goods may, if required, be singed on both sides at one operation.

SIZE. A solution of gelatinous matter, usually made from skin, employed for the purpose of giving adhesiveness to certain substances, which could not be otherwise secured to surfaces. See GELATINE and GLUE

SIZING AND DYEING MACHINE. The process of sizing and dyeing of yarns has usually been effected by two processes. The yarn was dyed in the bale warp, and in that state each thread was not equally exposed to the dye; and then the system of ball-warp sizing was adopted. Dawson and Slater have recently introduced a new process, by which the yarn is both dyed and sized at the same time. This is effected by passing the yarn first through a solution of the colouring-matter, and the mordant held in solution by some acid, then through ammoniacal vapour, and lastly through the size-box. The process is as follows:—Beginning with the four-warp roller A A (at the right hand of the machine) as seen in *fig.* 1853), the yarn passes thence into the dye-vessel B, over three guide-rollers to a copper cylinder C, thence over another guide-roller to a second copper cylinder, eventually coming up through the two squeezing rollers D, at the end of the dye-box. It may be observed, that the copper cylinders can be raised or lowered in the dye-box by means of a rack and pinion, and that the small circles at the bottom of the dye-vessel represent steam-pipes for boiling the dye-liquor. The yarn then passes from the squeezing rollers over other rollers into the ammoniacal or gas-chamber E, which, with the exception of two openings, the one for the passing in of the yarn, and the other for letting it out, is wholly closed by the lid here represented in the centre of the chamber. By following the dotted lines, it will be perceived that herein the yarn passes under and over four guide-rollers before its exit from the chamber, it being during the passage fully exposed to the vapour of the ammonia, which is introduced by means of the funnel represented in the centre. Thence the yarn passes into the next vessel termed the washing-box or chamber, over and under suitable rollers and through the two squeezing rollers at the end, there being a perforated pipe, not shown in the drawing, for discharging water on to the yarn. Coming out of the washing-box, the yarn continues its journey over a steam-drying cylinder F, down into the size-box G below, the smaller circle in the engraving representing a guide-roller, and the others two copper squeezing rollers. Then the yarn, after leaving the squeezing rollers, passes over and under a larger cylinder H, and a smaller drying cylinder I, whence it is conveyed by suitable rollers to the weaver's beam as marked.



1853

The advantages of this arrangement are that the yarn is less strained, less crossed, and in a better condition for weaving. It enters the size and the dye in the form of a sheet, in which state each thread is separated, and completely surrounded by the dye, and afterwards by the size; the result is uniformity of shade and an absence of streaky or uneven places. Not only so, but there is a great saving of time, for warps in the grey in the morning may be dyed, sized, and in the loom weaving by noon of the same day, and all done on the manufacturer's own premises and under his supervision, contrasting very favourably with the old plan of getting the work done out of doors. By that system the time that elapses from sending the warps to the dyer to receiving them back again is frequently ten days to a fortnight, which necessitates the keeping of a larger stock than is requisite by the new plan, when all is done in a few hours.

To illustrate the principle of these improvements, one example will suffice. Suppose that a black dye is required; a coloured solution is made by boiling about 100 parts of logwood of good quality in 600 parts of water; after which twelve parts of sulphate of iron and two parts of sulphuric acid are added. A sufficient quantity of this solution is introduced into the dye-trough, so as to cover the rollers therein. The solution is kept on the boil by means of the coil of steam-piping placed at the bottom, and the yarn is drawn through the solution, and, passing thence through the chamber containing the ammoniacal vapour on to the drying cylinders, it ends its course on the loom-beam, unless otherwise required. See CALICO-PRINTING.

SKATES. The fishes comprehended under the genus *Raia.* There are many species, the most common being the blue or grey skate, *Raia batis.* Some of this species weigh as much as 200 lbs. The thornback, or rough ray, is the *Raia clavata*; and the homelyn, or sand ray, *Raia miraletus.* All three are good eating; the last is the most common in our markets.

SKIN. (*Peau*, Fr.; *Haut*, Ger.) The external membrane of animal bodies consists of three layers: 1. the epidermis, or scarf-skin (*Oberhaut*, Ger.); 2, the vascular organ, or papillary body, which performs the secretions; and 3, the true skin (*Lederhaut*, Ger), of which leather is made. The skin proper, or dermoid substance, is a tissue of innumerable very delicate fibres, crossing each other in every possible direction, with small orifices between them, which are larger on its internal than on its external surface. The conical channels thus produced are not straight, but oblique, and filled with cellular membrane; they receive vessels and nerves which pass out through the skin (*cutis vera*), and are distributed upon the secretory organ. The fibrous texture of the skin is composed of the same animal-matter as the serous membranes, the cartilages, and the cellular tissue; the whole possessing the property of dissolving in boiling water, and being, thereby, converted into glue. The skins of animals are imported for the preparation of furs, for use, and ornament, and for the manufacture of leather. See GLUE, LEATHER, TAN, and FURS.

In 1873 our *Imports* of skins, furs, and pelts were as follow:—

	Number	Value
		£
Goat and kid, undressed	1,358,895	174,093
,, ,, tanned, tawed, or dressed	5,456,709	623,087
Seal	876,077	427,274
Sheep and lamb, undressed	8,363,736	1,322,848
,, ,, tanned, tawed, or dressed	3,760,619	313,369
Unenumerated, being furs	4,026,665	419,104
,, not being furs, dressed and undressed	3,768,970	458,998
Skins and furs manufactured	...	30,677
Specimens illustrative of natural history	...	36,021

SLAG. (*Laitier*, Fr.; *Schlacke*, Ger.) This is the vitreous mass which covers the fused metal in the smelting-hearths. In the iron-works it is commonly called *cinder.* Slags consist, in general, of bi-silicates of lime and magnesia, along with the oxides of iron and other metals; being analogous in composition, and having the same crystalline form in some cases as the mineral *pyroxene*; in others as that of *olivine.*

The following, selected from the analyses of Percy and Forbes, show the composition of the iron-furnace slags:—

Silica	28·32	42·06	39·52	29·60
Alumina	24·24	12·93	15·11	41·28
Lime	40·12	32·53	32·52	0·47
Magnesia	2·79	1·06	3·49	0·35
Protoxide of manganese	0·07	2·26	2·89	1·13
Protoxide of iron	0·27	4·94	2·02	48·43
Sesquioxide of iron	...	...	...	17·11
Potash, with traces of soda	0·64	2·69	1·06	...
Sulphate of lime	0·26	...	...	...
Sulphide of calcium	3·38	1·03	2·15	...
Phosphoric acid	...	0·31	...	1·34
Sulphide of iron	...	...	...	1·61
Loss	...	0·19	1·24	...
	100·09	100·00	100·00	101·32

Of the last of these, Dr. Percy remarks:—

'An immense quantity of iron slag, *far richer than many iron ores*, is annually thrown away, and it may be that the presence of phosphoric acid in sensible quantity is one of the causes which prevents the re-smelting of this slag to advantage. The fact has not yet sufficiently attracted the attention of those engaged in the manufacture of iron. The discovery of a method of extracting economically good iron from these rich slags would be of great advantage to the country, and could not fail amply to reward its author.'

Numerous attempts have been made to utilize the slags produced in great quantity from our blast furnaces, but hitherto no process appears to have been attended with success. One of the most recent attempts has been that of Mr. Charles Wood, of Middlesbro'. He employs a machine for caking the slag, which is simply a horizontal rotative table on which the slag flowing from the slag-spout of the blast-furnace is deposited and slowly borne round in a continuous layer of from half an inch to three-quarters of an inch in thickness. The table is composed of thick slabs of iron with water flowing freely through them to keep them cool. The thin layer of slag is solidified by the cool slabs, then water is allowed to flow freely on it, and scrapers placed athwart the table break the friable material into pieces and gather it right away into the waggons. Mr. Wood attempts to prove by comparative statements that great economy would be effected by the use of the caked slag and slag-sand as concrete, and of the slag-sand mixed with lime as a mortar. The slag-sand is prepared by allowing the molten slag to flow from the furnace into a rotating drum containing water; the slag falling into the water is disintegrated to a coarse powder.

Blast-furnace slags have been much used for road-mending, but they do not answer well on account of their extreme brittleness. This fault can, however, be to a great extent remedied by devitrifying them. This is done by allowing them to cool very slowly. The slag, by a process introduced by Mr. Egleston, is cast in huge blocks, which are then subjected to pressure; after the blocks are cold they are found to possess much toughness, and are said to furnish an excellent material for road-making.

For many years past the slags of copper furnaces have been used for building purposes, and to a less extent the slags from blast-furnaces. Processes are now being practised, which though somewhat complicated and troublesome, furnish blocks which are completely impervious to damp, possess the necessary toughness, and are admirably suited for the foundation of buildings.

In one plan, when the furnace is tapped, the slag is allowed to run into a semi-circular vessel, which being on wheels, is readily brought to and from the furnace. At the bottom of this vessel, is a layer of sand and coke dust three centimeters thick. A bent rake or paddle is then employed to mix thoroughly the slag with the sand and cinders, until the gases cease to be evolved, and the mass is nearly solid. The semi-solid mass is then ladled into moulds, provided with iron lids, which are fixed down as soon as no more bubbles of gas appear. When completely solid, but while still red hot, the block is placed in an annealing oven, and covered with coke-dust, so that the complete cooling shall not take place in less than three or four days.

When the slag contains 38 per cent. and upwards of silica, a serviceable building stone can be obtained from it by simply taking care that the annealing process is sufficiently long. This is in some works effected by allowing the whole of the slag to run down a shoot into a pit lined with sand and ashes, with which it is also covered up. If proper precautions have been taken to prevent premature chilling, it will be nearly ten days before the slag is sufficiently pasty to allow of its being filled into moulds. The blocks are, subsequently, as carefully cooled as in the former process.

In some parts of Belgium the slag is met, as it leaves the blast-furnace, by a stream of water, with the effect of breaking it up into a powder even finer than sand. This product the puddlers use for making the moulds for their pig-iron, and greatly prefer it to sand. A kind of glass is also made by running the slag on iron plates, which are afterwards cooled by the judicious application of water. The slag-powder is also used for mortar-making. Very rapid hardening is said to be thus secured, a point of great importance in the building of foundation-walls and all subsoil erections. Bricks are, in some parts of Europe, glazed by powdering them with slag before drying, and afterwards burning them out of contact with carbon. The glaze thus produced is very perfect, and as the slags are of different colours a variety of tints are obtained. Tiles, drain-pipes, and earthenware generally may be thus treated. It has been tried how far a mixture of clay and granulated slag may with advantage be used for fire-bricks. The results of its use in a brass furnace are said to have been exceedingly satisfactory.

SLATES. (*Ardoises*, Fr.; *Schiefer*, Ger.) The substances belonging to this class may be distributed into the following species:—1. Mica-schist, occasionally used for covering houses. 2. Roofing slate. 3. Whet slate. 4. Polishing slate. 5. Drawing slate, or black chalk. 6. Adhesive slate. 7. Bituminous shale. 8. Slate-clay.

1. *Mica-schist*, sometimes called *Mica-slate.*—This is a rock occupying a vast extent, in some mountain chains: it is of a schistose texture composed of the minerals mica and quartz, the mica being generally predominant.

2. *Roofing-slate.*—This substance is closely connected with mica-slate; so that uninterrupted transitions may be found between these rocks in many mountain chains. It is a simple schistose mass, of a bluish-grey or greyish-black colour, of various shades, and a shining, somewhat pearly internal lustre on the faces, but of a dead colour in the cross fracture.

This slate is extensively distributed in Great Britain. It skirts the Highlands of Scotland, from Loch Lomond by Callender, Comrie, and Dunkeld; resting on, and gradually passing into mica-slate throughout the whole of that territory. Roofing-slate occurs on the western side of England, in the counties of Cornwall and Devon; in various parts of North Wales and Anglesea; in the north-east parts of Yorkshire, near Ingleton, and in Swaledale; as also in the counties of Cumberland and Westmoreland. It is likewise met with in the counties of Wicklow and other mountainous districts of Ireland.

All the best beds of roofing-slate improve in quality as they lie deeper under the surface; near to which, indeed, they have little value. This variety of slate is found in the Cambrian, Silurian, and Devonian formations.

A good roofing-slate should split readily into thin even laminæ: it should not be absorbent of water either on its face or endwise, a property evinced by its not increasing perceptibly in weight after immersing in water; and it should be sound, compact, and not apt to disintegrate in the air. The slate raised at Eisdale, on the west coast of Argyleshire, is very durable. The slates of Penrhyn and other quarries in North Wales are very celebrated; those of Delabole in Cornwall are also well known and much esteemed.

Cleaving and Dressing of the Slates.—The splitter begins by dividing the blocks, cut lengthwise, to a proper size, which he rests on end, and steadies between his knees. He uses a mallet and a chisel, which he introduces into the stone in a direction parallel to the cleavage planes. By this means he reduces it into manageable pieces, he gives to each the requisite length, by cutting cross grooves on the flat face, and then striking the slab with the chisel. It is afterwards split into thinner sections, by finer chisels dexterously applied to the edges. The slab is then dressed to the proper shape, by being laid on a block of wood, and having its projecting parts at the ends and sides cut off with a species of hatchet or chopping-knife. It deserves to be noticed that blocks of slate may lose their property of divisibility into thin laminæ. This happens from long exposure to the air, after they have been quarried. The workmen say, then, that they have lost their waters. For this reason, the number of splitters ought to be always proportionate to the number of block-hewers. Frost renders the blocks more fissile; but a supervening thaw renders them quite refractory. A new frost restores the faculty of splitting, though not to the same degree; and the workmen therefore avail themselves of it without delay. A succession of frosts and thaws renders the quarried blocks quite intractable.

3. *Whet slate, or Turkey hone*, is a slaty rock, containing a great proportion of quartz, in which the component particles, the same as in clay-slate and mica-slate, but in different proportions, are so very small as to be indiscernible.

4. *Polishing slate.* Colour, cream-yellow, in alternate stripes; massive; composition impalpable; principal fracture, slaty, thin, and straight; cross fracture, fine earthy; feels fine, but meagre; adheres little, if at all, to the tongue; is very soft, passing into friable; specific gravity, in the dry state, 1·6; when imbued with moisture, 1·9. It is supposed to have been formed from the ashes of burnt coal. It is found at Planitz near Zwickau, and at Kutschlin near Bilin in Bohemia.

5. *Drawing slate, or Black chalk*, has a greyish-black colour; is very soft, sectile, easily broken, and adheres slightly to the tongue; spec. grav. 2·11. The streak is glistening. It occurs in beds in primitive and transition clay-slate; also in secondary formations, as in the coal-measures of most countries. It is used in crayon-drawing. Its trace upon paper is regular and black. The best kinds are found in Spain, Italy, and France. Some good black chalk occurs also in Caernarvonshire and in the island of Islay.

6. *Adhesive slate* has a light greenish-grey colour, is easily broken or exfoliated, has a shining streak, adheres strongly to the tongue, and absorbs water rapidly, with the emission of air-bubbles and a crackling sound.

7. *Bituminous shale* is a species of soft, sectile slate-clay, much impregnated with bitumen, which occurs in the coal-measures. See Kimmeridge Shale, and Shales.

8. *Slate-clay* has a grey or greyish-yellow colour; is massive, with a dull glimmering lustre from spangles of mica interspersed. Its slaty fracture approaches at times to earthy; fragments, tabular; soft, sectile, and very frangible; specific gravity,

2·6. It adheres to the tongue, and crumbles down when immersed for some time in water. It is the *Killas* of the Cornish miners.

In addition to the slates properly so called, many fissile rocks, which split along planes of bedding into sufficiently thin slabs to be used for roofing, are popularly called 'slates.' Thus the *Stonesfield slate* is a thin-bedded arenaceous limestone, at the base of the Great Oolite, largely quarried at Stonesfield, in Oxfordshire. The *Colley-weston slate* is a similar fissile limestone, belonging to the Lincolnshire (Inferior) Oolite, which is worked at Colleyweston, in Northamptonshire, and is much used by Sir Gilbert Scott for roofing churches built in the Gothic style. The *Duston slate* is a similar material occurring in the Northampton sands.

SLATY CLEAVAGE. See CLEAVAGE.

SLIDES. *A miner's term* for a dislocation of the strata, which is evidenced by the sliding of one portion of the rock over the other. These slides are often, but not always, filled with a softer matter than the rock, a clay in a greater or less state of induration.

SLIKENSIDES. The name given to smooth striated surfaces of rocks or of mineral lodes, indicating the grinding action of the movement of heavy masses. Many polished surfaces are called *slikensides* to which the term is evidently inapplicable.

SLIP. A fracture of strata, with the levels of the relative beds altered on the opposite sides of the fracture: the beds are thus slipped out of their original position.

SLOKE. The common name for *laver.* See ALGÆ.

SMALT. A beautiful blue glass made by melting cobalt ore with flint and potash. It is largely prepared in Saxony; for an account of its manufacture, see COBALT. The chemical composition of a specimen of German smalt was as follows:—Silica, 66·20; potash and soda, 16·31; oxide of cobalt, 6·49; alumina, 0·43; oxide of iron, 0·24; arsenic, a trace; water, &c., 0·57.

SMALTINE. See COBALT.

SMECTITE. A name given to a kind of fuller's earth, found in Lower Styria.

SMITHSONITE. See CALAMINE; ZINC.

SMELTING. The processes for obtaining the metals from the ores. These are described under their respective heads. See COPPER, IRON, LEAD, SILVER, TIN, ZINC, &c.

SMOKE. The more volatile portions of coal, passing off, charged with finely-divided carbon, at a comparatively low temperature.

If the black smoke, which escapes from a furnace when a quantity of cold coals is thrown in upon an incandescent mass, can be made to pass over another portion of coal in active combustion, this carbon is consumed, *i.e.* combined with atmospheric oxygen, and converted into carbonic oxide, which burns, producing carbonic acid; and it therefore eventually escapes as colourless vapour.

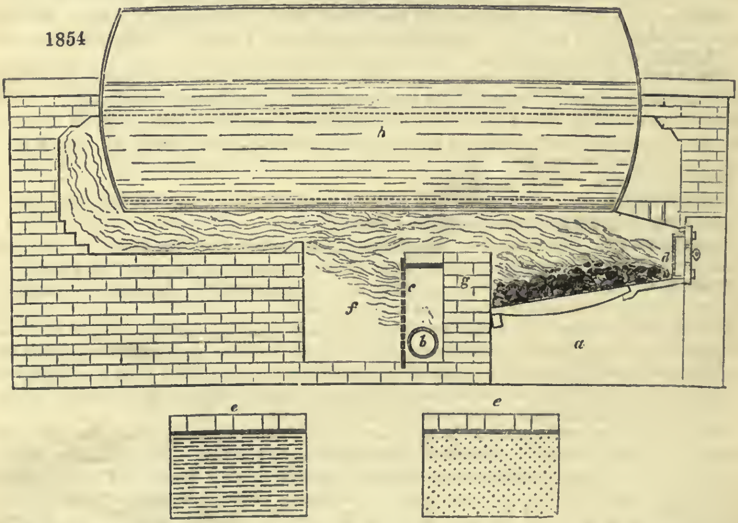
One great cause, and perhaps the greatest cause of the annoyance of smoke in large towns is the carelessness of the man supplying fuel to the fire. Where coal is abundant, the stoker usually piles an unnecessary quantity of fuel upon his fire, and this has the effect of reducing the heat, and of producing dense volumes of black smoke. Where coal is scarce and dear, as in Cornwall, careful stoking leads to an almost entire absence of smoke. A small quantity of coal is placed in front of the fire at a time; here it undergoes a coking process, the volatile carbon passing over the heated coal is burnt, and no visible smoke escapes. When the coal is thoroughly coked, it is shovelled in over the fire, and a fresh portion of coal is placed in front, to undergo the same process.

Prevention of Smoke.—The attention of the legislature has been directed to this nuisance, and sundry Acts have been passed to regulate and reduce the evil. The following extract from the 'Act to Amend the Smoke Nuisance Abatement (Metropolis) Act' (16 & 17 Vict. cap. cxviii.) August 20, 1853, should have every attention from manufacturers:—

'From and after the 1st day of August 1854, every furnace employed or to be employed in the metropolis in the working of engines by steam, and every furnace employed or to be employed in any mill, factory, printing-house, dye-house, iron-foundry, glass-house, distillery, brew-house, sugar-refinery, bake-house, gas-works, water-works, or other buildings used for the purpose of trade or manufacture within the metropolis (although a steam-engine be not used or employed therein), shall in all cases be constructed or altered so as to consume or burn the smoke arising from such furnace; and if any person shall, after the 1st day of August 1854, within the metropolis, use any such furnace which shall not be constructed so as to consume or burn its own smoke, *or shall so negligently use any such furnace*, as that the smoke arising therefrom shall not be effectually consumed or burnt, or shall carry on any trade or business which shall occasion any noxious or offensive effluvia, or otherwise annoy the neighbourhood or inhabitants, without using the best practical means for preventing or counteracting such smoke or other annoyance, every person so offending, being the *owner or occupier of the premises, or being a foreman or other* *person employed by such owner or occupier*, shall, upon a summary conviction for such offence before any justice or justices, forfeit and pay a sum not more than 5*l.* nor less than 40*s.*, and upon a second conviction for such offence, the sum of 10*l.*, and for each subsequent conviction, a sum double the amount of the penalty imposed for the last preceding conviction: provided always, that nothing in this Act shall extend or apply to any glass-works or pottery-works established and existing within the metropolis before the passing of this Act, with the exception, however, of all steam-engine furnaces and slip-kiln furnaces employed in and belonging to such works respectively, to which furnaces the provisions of this Act shall extend and apply.'

'An Act to Amend the Smoke Nuisance Abatement (Metropolis) Act, 1853.' (July 29, 1856.) 'From and after the 1st day of January 1858, the above-mentioned provision whereby certain furnaces in glass-works and pottery-works were exempted from the operation of the said Act shall be repealed; and all steam-vessels plying to and fro between London Bridge and any place on the river Thames to the westward of the Nore Light shall be subject to the provisions of the said recited Act relating to steam-vessels above London Bridge.

1854



'And whereas it is expedient that furnaces employed in public baths and wash-houses should be included within the provisions of the said recited Act: be it enacted, that from and after the said 1st day of January 1858, every furnace employed or to be employed in any such public baths and wash-houses in the metropolis, although the same shall not be used for the purposes of trade or manufacture, shall be, and the same is hereby included in and made liable to all the provisions of the said recited Act.'

Among the numerous inventions which have been patented for effecting this purpose, with regard to steam-boilers and other large furnaces, very few are sufficiently economical or effective. The first person who investigated this subject in a truly philosophical manner was Mr. Charles Wye Williams, managing director of the Dublin and Liverpool Steam Navigation Company, and he also has had the merit of constructing many furnaces, both for marine and land steam-engines, which thoroughly prevent the production of smoke, with increased energy of combustion, and a more or less considerable saving of fuel, according to the care of the stoker. The specific invention, for which he obtained a patent in 1840, consists in the introduction of a proper quantity of atmospheric air to the bridges and flame-beds of the furnaces, through a greater number of small orifices, connected with a common pipe or canal, whose area can be increased or diminished according as the circumstances of complete combustion may require, by means of an external valve. The operation of the air thus passed in small jets into the half-burned carburetted hydrogen gases over the fires, is their perfect combustion, the development of all the heat which they can produce, and the entire prevention of smoke. One of the many ingenious methods in which Mr. Williams has carried out the principles of what he justly calls his Argand furnace, is represented by *fig.* 1854, where *a* is the ash-pit of a steam-boiler furnace; *b* is the mouth of a tube which admits the external air into the chamber or iron box of distribution, *c*, placed immediately beyond the fire-bridge, *g*, and before the diffusion or mixing chamber, *f*. The front of the box is perforated either with round or oblong orifices, as shown in the two small figures *e*, *e*, beneath *fig.* 1854; *d*, is the fire-door, which may have its fire-brick lining also perforated. In some cases, the fire-door projects in front, and it, as well as the sides and arched top of the fire-place, are constructed of perforated fire-tiles, enclosed in common brickwork, with an intermediate space, into which the air may be admitted in regulated quantity through a moveable valve in the door. Fire-places of this latter construction perform admirably without smoke, with an economy of one-seventh of the coals usually consumed in producing a like amount of steam from an ordinary furnace; *h* is the steam-boiler.

Evidence was presented some years ago to the Smoke Prevention Committee of the House of Commons of the successful application of Mr. Williams's patent invention to many furnaces of the largest dimensions, more especially by Mr. Henry Houldsworth, of Manchester, who, mounting in the first flue a pyrometrical rod, which acted on an external dial-index, succeeded in observing every variation of temperature produced by varying the introduction of the air-jets into the mass of ignited gases passing out of the furnace. He thereby appeared to demonstrate, that 20 per cent. more heat could be obtained from the fuel, when Mr. Williams's plan was in operation than when the fire was left to burn in the usual way, and with the production of the usual volumes of smoke.

It should be borne in mind that *consumption* of smoke implies cleanliness, economy of health, and economy of labour. Are not these sufficient reasons to induce manufacturers to use the best means possible to do away with a great nuisance, and to avoid the waste of so precious a commodity as coal, for a time may come when we shall have cause to regret our extravagant consumption of that article? We have shown that the cause of smoke is incomplete combustion, caused either by the want of a sufficient quantity of air, or by such air being admitted under such circumstances that its admission is worse than useless. Experience has proved that there are but few difficulties in constructing arrangements which will effect the consumption of smoke; but desirable as the process is, it must be admitted that smoke-consuming is not found to be economical, although it is in every sense desirable.

By means of Wright's patent smoke-consumer, the air admitted into the furnace is regulated by a self-acting ventilating door, so as to furnish the necessary amount of oxygen requisite for perfect combustion. The air is also diffused over the entire surface of the fire. By this apparatus, a partially-decomposed and nearly red-hot jet of steam is projected from over the door down upon the incandescent fuel. By that means the fire becomes brighter, not damped, as it would be were wet steam used, and not only causes a vacuum in the furnace, thereby increasing the draught, but effectually prevents the cold air admitted through the door and the gases distilled from the coal from touching the boiler-plates, thus avoiding—

1. The cooling of the boiler-plates by the action of the cold air striking them, and causing the continual expansion and contraction of the metal, which is so injurious to boilers.

2. The gases formed by the first action of the hot furnace on the coal thrown in from coming in contact with the top of the furnace or boiler-plates, the temperature of which being no greater than that of the contents of the boiler, can only cool those gases to such an extent that their combination with oxygen cannot take place.

Not only are these two great evils avoided, but the jet of steam forces the gases distilled from the coal on to the incandescent fuel at the back of the furnace, together with the air admitted through the door, thus multiplying the points of contact *ad infinitum*, thereby causing instantaneous combination of their elements, making the combustion as perfect as it can be in a manufacturing point of view; and obtaining all the heat that the combination of oxygen with the hydrogen and carbon can give. The smoke is never allowed to pass the bridge of the furnace; in fact, its forming is prevented. The apparatus is simple and efficient in its action, not liable to get out of repair. It can be applied in two days at the utmost, and has been frequently fitted in one day, and it is adapted for every description of furnace. Under all circumstances, however, it has been proved that careful stoking is the best method for preventing the escape of smoke.

SMOKY QUARTZ. A variety of quartz having a smoke-coloured tint: it comprises the clove-brown variety of *cairngorms*.

SOAP is a chemical compound, manufactured on a very extensive scale, forming, accordingly, a considerable article of commerce. It is a compound resulting from the combination of certain constituents derived from fats, oils, grease of various kinds, both animal and vegetable, with certain salifiable bases, which, in detergent soaps, are potash or soda.

Oils and fats consist chiefly of oleine and stearine, as in tallow, suet, and several vegetable fats; of margarine, which occurs in animal fats, in butter, in olive and other vegetable oils; of palmitine, which is found in palm oil; and so on with various other immediate principles, according to the nature of the fats and oils employed by the soap-maker. Natural fatty substances, however, are never exclusively formed of one of these principles, but are, on the contrary, composed of several of them in various proportions, oleine alone being a constant constituent in all of them.

Natural or neutral fats and oils, chemically considered, are really salts, sometimes called 'glycerides;' that is to say, are combinations of acids, oleic, stearic, margaric, acid, &c., with the oxide of a hypothetical radical called *glyceryl*.

Stearine being, therefore, a combination of stearic acid with oxide of glyceryl, is a stearate of oxide of glyceryl.

Oleine is a combination of oleic acid with oxide of glyceryl, and is, therefore, an oleate of oxide of glyceryl.

Margarine is a combination of margaric acid and oxide of glyceryl, and is, therefore, a margarate of oxide of glyceryl, and so on with the other constituents of fats and oils.

Glycerine is a combination of oxide of glyceryl with water, which, in that case, plays the part of an acid to form a hydrate of oxide of glyceryl (glycerine).

Now, when neutral fats (namely, oleine, stearine, margarine, &c., or the fats or oils which they constitute) are treated by solutions of caustic alkalis, such as potash or soda, their constituents react upon each other, and combine with the potash or soda; and provided too great an excess of alkali has not been used, the fat or oil dissolves in the alkaline solution into a syrupy liquid, which on cooling forms a gelatinous mass which is nothing else than an aqueous solution of soap mixed with the glycerine, which the treatment has set free.

The following equation, in which, for the sake of simplicity, one of these principles only, *stearine*, and soda dissolved in water, are taken as examples, will clearly illustrate this interesting reaction:—

$$\overbrace{\text{Stearate of oxide of glyceryl}}^{\text{Stearine.}} + \text{soda} + \text{water}$$
$$= \underbrace{\text{stearate of soda}}_{\text{hard soap.}} + \underbrace{\text{hydrate of oxide of glyceryl}}_{\text{glycerine.}}$$

In the same way:—

$$\overbrace{\text{Oleate of oxide of glyceryl}}^{\text{Oleine.}} + \text{soda} + \text{water}$$
$$= \underbrace{\text{oleate of soda}}_{\text{hard soap.}} + \underbrace{\text{hydrate of oxide of glyceryl}}_{\text{glycerine.}}$$

According to the modern views of chemists, however, glycerine may be regarded as propenylic alcohol, one of the group of triatomic alcohols. The natural fats then become triatomic ethers of the fatty acids; thus stearine (tristearine) consists of propenyl tristearate. All soaps are metallic salts of the fatty acids, or mixtures of those salts.

Soaps made with soda are hard; those made with potash are soft; the degree of hardness being so much greater as the melting-point of the fats employed in their manufacture is higher, hence the more oleine a fatty matter contains, the softer the soap made with it will be, and *vice versâ*. The softest soap, therefore, would be that made altogether with oleine (oleic acid) and potash (oleate of potash); the hardest would be that made with stearine and soda (stearate of soda).

The fats or oils employed for the manufacture of soaps, are tallow, suet, palm oil, cocoa-nut oil, kitchen fat, bone-grease, horse oil or fat, lard, butter, train oil, seal oil, and other fish oils, rape oil, poppy oil, linseed and hempseed oil, olive oil, oil of almonds, sesame, and ground-nut oil, and *resin*. This last substance, though very soluble in alkaline menstrua, is not, however, susceptible, like fats, of being transformed into an acid, and will not, of course, saponify or form a proper soap by itself. The more caustic the alkali the less consistency has the resinous compound which is made with it. The employment of caustic alkalis, however, is not necessary with it, since it dissolves readily in aqueous solutions of carbonated alkalis, but even with carbonate of soda it forms only a viscid mass, owing to its great affinity for water, so that even after having been artificially dried in an oven, and thus rendered to a great extent hard, the mass deliquesces again spontaneously by exposure, and returns to the soft state. The drying oils, such as those of linseed and poppy, produce the softest soaps.

We said that by boiling fats or oils with an aqueous solution of potash or of soda a solution of soap was produced. The object of the soap-maker is to obtain the soap thus produced in a solid form, which is done by boiling the soapy mass so as to evaporate the excess of water to such a point that the soap may separate from the concentrated liquor and float on the surface thereof in a melted state, or by an admixture of common salt, soap being insoluble in lyes of a certain strength or degree of concentration, and in solutions of common salt of a certain strength, the glycerine remaining, of course, in solution in the liquor below the separated soap. Such is the theory of soap-making; but the *modus operandi* followed by practical soap-makers will be described presently.

On the Continent olive oil, mixed with about one-fifth of rape oil, is principally used in making hard soap. This addition of rape oil is always resorted to, because olive oil alone yields a soap so hard and so compact that it dissolves only with difficulty and slowly in water, which is not the case with rape oil and other oils of a similar nature, that is to say, with oils which become thick and viscid by exposure, and which on that account are called drying oils, experience having taught that the oils which dry the soonest by exposure, yield with soda a softer soap than that made with oils which, like olive oil, remain limpid for a long period under the influence of the air. The admixture of rape oil has, therefore, the effect of modifying the degree of hardness of the soap, and, consequently, of promoting its solubility. In England tallow is used instead of olive oil; the soap resulting from its treatment with soda is known under the name of *curd soap*, and is remarkable for the extreme difficulty with which it dissolves in water. The small, white, cubic, waxy, stubborn masses, which until a few years ago were generally met with on the washing-stand of bedrooms in hotels, and which for an indefinite period passed on from traveller to traveller, each in turn unsuccessfully attempting, by various devices and cunning immersions in water, to coax it into a lather, is *curd soap*. Rape or linseed oil, added in certain proportions to tallow, would modify this extreme hardness and difficult solubility, but it is now the general practice to qualify the tallow with cocoa-nut oil, an oil, which, converted into soap, has the property of absorbing incredible quantities of water, so that the soap into the manufacture of which it has entered lathers immediately. Cocoa-nut oil, however, acquires by saponification a most disagreeable odour (due to the formation of caprylic acid), which it imparts to all the soaps in the manufacture of which it enters, an odour which persists in spite of any perfume which may be added to mask it.

The admixture of one-fourth or one-fifth of resin with tallow, in the process of saponification, modifies also the hardness and considerably increases the solubility of curd soap, and this, in fact, constitutes the best *yellow soap*.

It has been said above that soap was more or less hard in proportion as the melting-point of the fats employed in its manufacture was higher or lower. There are certain fatty substances, technically called 'weak goods,' such as kitchen fat, bone-fat, horse oil, &c., which could hardly be used alone, still less with resin, the soap which they yield being too soft, and melting or dissolving away too rapidly in the washing-tub. This led the writer to think, that if a means could be devised of artificially hardening soap, a larger class of oleaginous and fatty substances could be rendered available, at any rate to a greater extent than they theretofore had been, and that, by thus extending the resources of the soap-boiler, he should be enabled to produce a good and useful soap from the cheapest materials, and thus convert soaps of little commercial value into useful and economical products.

In making experiments with this view, he found that the introduction of a small quantity of melted crystals of sulphate of soda into the soap answered the purpose admirably, and that the salt in recrystallising, imparted to the soap, which otherwise would have been soft, a desirable hardness, and prevented its being wasted in the tub. The use of sulphate of soda acts, therefore, *inversely*, like the addition of rape oil, or linseed oil, or of resin to tallow, in the manufacture of soap. This process, which was patented in 1841, has been, since the removal of the duties on soap, extensively employed by soap-makers, and continues to be highly approved of by the public. We shall describe further on the manner of practising this process, and the further improvements which were made to it in 1855.

Of the manufacture of hard soap.—The fat of this soap, in the northern countries of Europe, is usually tallow, and in the southern, coarse olive oil, Different species of grease are saponified by soda, with different degrees of facility; among oils, the olive, sweet almond, rapeseed, and castor oil; and among solid fats, tallow, bone-grease, and butter, are most easily saponified. According to the practice of the United Kingdom, six or seven days are required to complete the formation of a pan of hard soap, and a day or two more for settling the impurities, if it contains resin. From 12 to 13 cwts. of tallow are estimated to produce one ton of good soap. Several years ago, in many manufactories the tallow used to be saponified with potash-lyes, and the resulting soft soap was converted, in the course of the process, into hard soap, by the introduction of muriate of soda, or weak kelp-lyes, in sufficient quantity to furnish the proper quantity of soda by the reaction of the potash upon the neutral salts. But the high price of potash, and the diminished price, as well as improved quality of the crude sodas, have led to their general adoption in soap-works.

The first step in the production of soap consists in obtaining a solution of soda, or what is termed caustic lye. For this purpose a given quantity of the soda-ash above alluded to, is stratified with a quantity of recently-burnt quick-lime, in tanks of wrought-iron, or cylindrical cast-iron vats, from 6 to 7 feet wide and from 4 to 5 feet deep, the lowest layer being, of course, quick-lime. These vats have frequently a false bottom, perforated with holes, or else a coarse piece of matting is placed over the plug-hole, placed at the bottom of the said vats or tanks, which plug-hole is, of course, closed generally by a wooden plug. Water is then poured upon the whole mass until the tanks are full, and the whole is allowed to stand for twelve or eighteen hours. The plug being then withdrawn, the saturated solution of caustic soda flows down into a reservoir placed beneath, after which the plug is replaced, more water applied, and this operation is repeated five or six times, until, in fact, the soda is almost entirely extracted; the various liquors thus obtained, in a clear and caustic state, after infiltration through the beds of lime, being conveyed to separate and distinct reservoirs, distinguished from each other by the names of *first running*, *second running*, and so on; the last, being, of course, the weakest.

Having in this way produced a series of caustic lyes of different degrees of strength, about 200 gallons of the weakest, which has a specific gravity of about 1·040, is pumped into the soap-pan or boiler, or *copper*, as it is called, though generally made of cast iron, and about 1 ton of tallow is added; heat is applied, and after a gentle ebullition of about four hours, it will be found that the lye will have lost its causticity, or, in technical language, that it is *killed*, and that the fat is saponified, which is known by taking a portion of the mass on a trowel, when it will be observed that the liquid separates at once from the soapy mass, which it leaves in streaks on the towel. The lyes thus used at first, if composed of pure soda, would contain about 4 per cent. of alkali, but from the presence of neutro-saline matter they seldom contain as much as 2 per cent.; in fact, a gallon may be estimated to contain not more than 2 ounces, so that 200 gallons contain 25 lbs. of real soda. The fire being withdrawn, the whole is now allowed to cool and remain at rest for about one hour, until the lye, now deprived of its alkali, and therefore, called *spent lye*, settles to the bottom of the copper. This spent lye contains a portion of glycerine derived from the fat or tallow, together with the sulphate of soda and common salt of the soda-ash, and is pumped off by means of an iron pump, which is lowered down into the lower pan of the soap-copper, a practice which might be advantageously replaced by opening a cock which might be placed at the bottom of the copper, but which is retained as a remnant of that abominable system of excise, which did not permit the spent lyes to be otherwise withdrawn, as the excise laws forbade any cock or aperture being placed or made at the bottom of soap-coppers. This constitutes what is called an operation. A second similar charge of lye is now introduced into the pan along with a fresh quantity of tallow or of grease, and a similar boiling process is again repeated. Three or four such boilings may be practised in the course of a day by an active soap-boiler, with lyes of gradually-increasing strength. Next day the same routine is renewed with stronger lyes, and so progressively until towards the sixth day the lye may have the density of 1·160, when a period arrives at which it will be found that the whole of the tallow or fat is completely saponified, that is to say, has combined with its full equivalent of soda. This point is well known to the workmen by the consistency of the compound; in effect it is sufficient to take a portion of the mass on a trowel, and to squeeze a little of the mass between the forefinger and thumb; if not quite and thoroughly finished it will still have a greasy feel, but if done it will on cooling readily separate from the skin in hard scales; neither has it the taste peculiar to grease. A more certain mode, however, especially for those who have not acquired sufficient practice, is to decompose a portion of the saponified or partly-saponified mass with an acid, and to ascertain whether the grease is *wholly soluble* in boiling spirits of wine, for if it is not thus wholly soluble, the saponification is imperfect. The addition of common salt for the separation of the spent lyes is essential to the proper granulation and separation of the soap, for otherwise the tallow and the lye would unite into a uniform emulsion, from which it would be very difficult afterwards to separate the spent lye; but as soap is quite insoluble in a solution of common salt, the partly-saponified mass is thus brought to float on the surface, so that the spent lye precipitates to the botttom, whence as we said, it is pumped off.

Assuming, however, that a perfect result has been secured, the soap has now to be brought to a marketable condition, and for this purpose it is boiled with a quantity of weak lye or water. As soon as combination has taken place, a quantity of very strong lye is added, until an incipient separation begins to show itself. The heat is now increased, and the boiling continued for a considerable time, the mass being prevented from boiling over the vessel by workmen armed with shovels, who dash the soap to and fro, so as to break the froth upon the surface and favour evaporation. At first the soap is divided into an innumerable number of small globules, each separate and distinct from its fellow; but as the boiling goes on, those gradually run together into larger and larger globules, till at last the soap is seen to assume a pasty consistency, and to unite in one uniform mass, through which the steam from below slowly forces its way in a series of bursts of little explosions. The process is now finished, and all that remains to be done is to shut down the lid of the copper, having previously extinguished the fire. In from one to two or three days, according to the nature and quantity of the soap in question, the lid is again raised, and the semifluid soap ladled from the precipitated lye by means of ladles; the product being thrown into a wooden or iron frame of specific dimensions, where its weight is estimated by measurement. In making common yellow or resin soap, the resin is usually added after the saponification of the tallow, in the proportion of one-third or one-fourth of the tallow employed. The subsequent operations are much about the same as those above described; but in addition, just before closing the lid of the copper a quantity of water or weak lye is sprinkled over the melted soap, which carries down with it the mechanical impurities of the resin; and these constitute a dark layer of soap resting upon the lye, which is not poured into the frame with the rest, but is placed apart under the name of '*niger*,' and brings a less price. Good curd or white soap should contain of grease, 61·0 parts; soda, 6·2; water, 32·8; total 100; or consist of grease-acid, 1 atom = 315; soda, 1 atom = 32; water, 17 atoms = 153. Resin soap has a more variable composition, but when not adulterated with water should contain about as follows: grease and resin, 60; soda, 6; water 34; total 100.

Manufacture of mottled soap.—Soda which contains sulphides is preferred for making the mottled or marbled soap, whereas the desulphuretted soda makes the best white curd soap. Mottling is usually given in the London soap-works, by introducing into the nearly-finished soap in the pan a certain quantity of the strong lye of crude soda, through the rose spout of a watering-can. The dense sulphuretted liquor, in descending through the pasty mass, causes the marbled appearance. In France a small quantity of solution of sulphate of iron is added during the boiling of the soap, or rather with the first service of the lyes. The alkali seizes the acid of the sulphate, and sets the protoxide of iron free to mingle with the paste, to absorb more or less oxygen, and to produce thereby a variety of tints. A portion of oxide combines also with the stearine to form a metallic soap. When the oxide passes into the red state, it gives the tint called *manteau Isabelle.* As soon as the *mottler* has broken the paste, and made it pervious in all directions, he ceases to push his rake, from right to left, but only plunges it perpendicularly till he reaches the lye; then he raises it suddenly in a vertical line making it act like the stroke of a piston in a pump, whereby he lifts some of the lye, and spreads it over the surface of the paste. In its subsequent descent through the numerous fissures and channels on its way to the bottom of the pan, the coloured lye impregnates the soapy particles in various forms and degrees, whence a varied marbling results.

The best and most esteemed soap on the Continent is that known under the name of Marseilles soap, and it differs from the English mottled soap by a different disposition of the mottling, which in that soap is granitic instead of being streaky. It has also an agreeable odour, somewhat resembling that of the violet, whereas the English mottled soap, generally made of coarse kitchen and bone-fat, has an odour which reminds one of the fat employed. The best English mottled soap in which tallow is employed has no unpleasant smell, and if bleached palm oil has been used it acquires an agreeable odour, analogous to that of the Marseilles soap, which is made of olive oil alone, or mixed with rape or other grain or seed oil, which, however, seldom exceeds 10 per cent., for otherwise it would not have the due proportion of blue to the white which is characteristic of soap made of genuine olive oil, the mottling becoming more closely granular when an undue proportion of grain has been used, a sign of depreciation which the dealers are perfectly well acquainted with, and of which they at once avail themselves, to compel the maker to reduce his price.

Pelouze and Frémy, in their *Traité de Chimie générale*, give the following reliable observations:—

'The best olive oil for the use of the soap-maker is Provence oil; that of Aix comes next; it is cheaper, but the same weight of it yields less soap than the other, and the latter has then a slight lemon-yellow tinge. The oil from Calabre contains less margarine, and yields a softer soap.

'Two kinds of soda-ash are used in Marseilles—the soft soda (*soude douce*) and the salted soda (*soude salée*), which contains a large quantity of common salt.

'To prepare the lye, the soft soda previously reduced into small lumps is mixed with 12 per cent. of slaked lime, and shovelled up into tanks of masonry of about 2 cubic yards' capacity, called *barquieux*, and the exhaustion of the mass with water gives lyes of various degrees of strength.

'The lye marking 12° is used for the first treatment, or *empâtage* of the oil which is then submitted to a second and third treatment with a lye marking 15° or 20°, the object of which is to close the grains of the emulsive mass in process of saponification (*serrer l'empâtage*). The operation requires about twenty-four hours. During all the time of that operation a workman is constantly agitating the boiling mixture of the oil and lye by means of a long rake or crutch, called *râble*. The *empâtage* is generally practised in large conical tanks of masonry terminated at bottom by a copper-pan, and capable of containing 12 or 13 tons of made soap, and the operation proceeds so much the more rapidly, as the soda-lye employed contains less common salt, wherefore soft soda-lye (*soude douce*) must be used at the beginning, as we said.

'The next operation is that called *relargage*, the object of which is to separate the large quantity of water which has been used to facilitate the *empâtage*. This separation of the water, or *relargage*, is effected by means of salted soda (that is to say, of soda-ash, containing a good deal of common salt), of which as much is dissolved in water as will make a lye marking 20° or 25°. This salted lye is then gradually poured by a workman on the surface of the saponifying goods in the copper, while another workman is diffusing it in the mass by stirring the whole with a rake or crutch.

'The immediate effect of the salt thus added is to separate from the soapy mass the water in which it was dissolved, and which gave it a homogeneous and syrupy appearance, and to coagulate it, the soap being thereby cured or coagulated, and converted into a multitude of granules floating among the excess of water in which they were dissolved, and which the salt has separated. The whole being then left at rest for two or three hours, in order to give the grains of soap time to rise and agglomerate at the surface, a workman proceeds to the *épinage*, an operation which consists in withdrawing the liquid portion by removing a wooden plug placed at the lower part of the boiler.'

In this country the *épinage* is generally performed by means of an iron pump plunging through the soap down to the pan at the bottom of the copper.

This *spent lye*, in well-conducted factories, retains but little alkali, and is generally thrown away; but as it contains a rather large quantity of salt, which, in France, is an expensive article, it might be, and is sometimes, kept and used for preparing fresh lyes.

After the first *épinage*, the soap is treated twice again with salt-lye, followed of course by two *épinages*; but as the salt-lye used in these two operations is not exhausted, it is always kept for preparing fresh lyes.

The cleansing, that is to say, the removing of the soap into the frames, takes place on the third day, at which time the operation called *madrage* is performed. For that purpose a plank is thrown across the boiler or copper, and two or three men standing on it, and therefore over the soapy mass in the copper, proceed to stir it up for two or three hours, by means of long crutches, which they alternately move up and down through it, the object being to keep the grains of soap well diffused through the liquid, weak lyes marking only 8° or 10°, or ordinary water, as the case may be, being sprinkled from time to time into the mass, until the grains of soap have reabsorbed a sufficient quantity of water and have swollen to such a size as to have a specific gravity very little greater than that of the liquid in which they float about. A skilful workman knows by the appearance of the soap grains whether he should use alkaline lyes or simple water, and this is indeed a most important point in the manufacture of *Marseilles* soap, for upon it the success of the operation depends in a commercial point of view, that is to say, all things being equal in other respects, a profit or loss on the batch of soap made will ensue. In effect, if too much water has been added the soap will lose either the whole, or too great a portion of its *mottling*, that is to say, the result will be either a dingy white curd, or a soap in which the white portions will predominate to too great an extent over the blue streaks; a circumstance which so far deteriorates the market value, the buyer shrewdly suspecting then that he would pay for water the price of soap. If, on the contrary, a sufficient quantity of water has not been added, the soap grains remaining hard and dry, will form a more or less friable soap, thereby causing also a deterioration of price, the buyer knowing that such soap, by crumbling into small pieces every time he has to cut it with his knife in selling it to his customers, will considerably reduce his profit, or perhaps even entail a positive loss to him

In the best conditions, that is to say, by employing the best Gallipoli oil for the purpose of producing Marseilles soap of first quality, 100 cwts. of olive oil yield 175 cwts. of mottled soap; by using mixtures of olive and rape or other seed oils, the yield of soap is reduced to 170, or even less; in either case the yield is reduced by 5 or 6 per cent., when old or fermented is employed instead of new good oil.

The manufacturing expenses are calculated at Marseilles at the rate of 17f. 25c. (nearly 13*s.* 10*d.*) per 100 kilogrammes of fatty matter employed, which require .72 kilogrammes of soda for their saponification.

Mottled soap has a marbled, or streaky appearance, that is to say, it has veins of a bluish colour, and resembling granite in their disposition or arrangement. The size and number of these veins or speckles, and the proportion which they bear to the white ground of the soap, depend not only on the more or less rapid cooling of the soap after it has been cleansed, that is, transferred from the copper to the frame; but also on the quality and kind of the fat, grease, or oil employed, and on the manner in which it has been treated in the copper. A soap which has not been sufficiently boiled at the last stage of the manufacture is always tender. The blue or slate colour of the streaks or veins of mottled soap is due to the presence of an alumino-ferruginous soap interposed in the mass, and frequently also to that of sulphide of iron, which is produced by the reaction of the alkaline sulphides contained in the soda-lye upon the iron, derived from the soda-ash itself, and from the iron pans and other utensils employed in the manufacture, or which is even purposely introduced in the state of solution of protosulphate of iron. This introduction, however, is never resorted to, we believe, in this country. The veins or streaks disappear from the surface to the centre by keeping, because the iron becomes gradually peroxidised. A well-manufactured mottled soap cannot contain more than 33, 34, or at most 36 per cent. of water, whereas genuine curd soap contains 45, and yellow soap at least 52 per cent. of water, and sometimes considerably more than that. It is evident, in effect, that the mottling being due to the presence of sulphide of iron held in the state partly of demi-solution and of suspension, the addition of water would cause the colouring substances to subside, and a white, unicoloured, or 'fitted' soap would be the result. This addition of water, technically called *fitting*, is made when the object of the manufacturer is to obtain a unicoloured soap, whether it be curd or yellow soap. After *fitting*, the soap contains, therefore, an additional quantity of water, which sometimes amounts to 55 per cent.: the interest of the consumer would, therefore, clearly be to buy mottled soap in preference to yellow or white soap; the mottling, when not artificially imitated, being a sure criterion of genuineness; for the addition of water, or of any other substance, would, as was just said, infallibly destroy the mottling. To yellow or curd soap, on the contrary, incredible quantities of water may be added. The writer has known five pails of water (15 gallons) added to a frame (10 cwts.) of already *fitted* soap, so that the soap, by this treatment, contained upwards of 60 per cent. of water, to which common salt had previously been added. The proportion of water in fitted soap has also been augmented, in some instances, by boiling the soap in high-pressure boilers before *cleansing*. As cocoa-nut oil has the property of absorbing one-third more water, when made into soap, than any other material, its consumption by the soap-maker has, within the last twenty-five years, augmented to an extraordinary extent; and, moreover, the patent taken in 1857 by Messrs. Blake and Maxwell, of Liverpool, for the invention of Mr. Kottula, which will be described presently, has, we believe, increased the demand for that species of oil in a notable degree. We said that the mottling, inasmuch as it was indicative of genuineness, was the more economical soap to buy; unfortunately, mottled soap has the drawback of not being so readily soluble as yellow soap, and the goods washed with it are more difficult to rinse; but the process patented by Messrs. Blake and Maxwell enabling the manufacturer to manufacture with cocoa-nut oil a soap to which the mottling is artificially impaired, by means of ultramarine, black or brown oxide of manganese, in such a perfect manner as almost to defy detection, mottling has thus ceased to be a safe outward sign of genuineness, as far as regards the article which it pretends to represent. That description of soap, however, has specific qualities: it is almost perfectly neutral, and it will not bear more than a definite proportion of water; so that, although it contains more of that liquid than ordinary mottled soap, more than a certain fixed quantity cannot be forced into it; hence it also forms a standard soap, like the ordinary mottled, although that standard is different from, and inferior to, the latter. The process in question is briefly as follows:—Take 80 cwts. of palm oil, made into soap in the usual way, with two changes of lye, grained with strong lye, or lye in the usual manner, but that the lye leaves the curd perfectly free; pump the spent lye away, and add 32 cwts. of cocoa-nut oil, 60 cwts. of lye, at 20° of Beaumé's aëreometer, and then gradually 14 cwts. of lye, at 14° Beaumé. Boil until the whole mass is well saponified. Put now from 6 to 7 lbs. of ultramarine in water, or weak lye, stir the whole well, and pour it into the soap through the rose of a watering-pot; boil the whole for about half an hour, or an hour, and cleanse it in the ordinary wooden frames or in iron frames surrounded by matting, or other covering, so that the soap may not cool too rapidly; the above proportions will yield 212 cwts. of soap, with a beautiful blue mottle.

Manufacture of Yellow or Resin Soap.—We have already said that resin, though not capable of forming a soap with soda, readily dissolves in that alkali, either in the caustic or in the carbonated state, with which it forms a kind of soapy mass of a viscid or treacly nature; hence fat of some kind, in considerable proportion must be used along with the resin, the *minimum* being equal parts; and then the soap is far from being good. As alkaline matter cannot be neutralised by resin, it preserves its peculiar acrimony in a soap poor in fat, and is ready to act too powerfully upon woollen and all other animal fibres to which it is applied. It is said that rancid tallow serves to mask the strong odour of resin in soap more than any oil or other species of fat. From what we have just said, it is obviously needless to make the resin used for yellow soaps pass through all the stages of the saponifying process; nor would this indeed be proper, as a portion of the resin would be carried away, and wasted with the spent lyes. The best mode of proceeding, therefore, is first of all to make the hard soap in the usual manner, and at the last service or charge of lye, namely, when this ceases to be absorbed, and preserves in the boiling-pan its entire causticity, to add the proportion of resin intended for the soap. In order to facilitate the solution of the resin in the soap, it should be reduced to coarse powder, and well incorporated by stirring with the rake. The proportion of resin is usually from one-third to one-fourth the weight of the tallow. The boil must be kept up for some time with an excess of caustic lye; and when the paste is found, on cooling a sample of it to acquire a solid consistency, and when diffused in a little water, not to leave a resinous varnish on the skin, we may consider the soap to be finished. The maker next proceeds to draw off the superfluous lyes, and to purify the paste. For this purpose, a quantity of lyes at 80° B. being poured in, the mass is heated, worked well with a rake, then allowed to settle, and drained of its lyes. A second service of lyes at 4° B., is now introduced, and finally one at 2°; after each of which there is the usual agitation and period of repose. The pan being now skimmed, and the scum or *fob* removed for another operation, the soap is laded off by hand-pails into its frame-moulds. A little palm oil is occasionally employed in the manufacture of yellow soap, in order to correct the flavour of the resin and brighten the colour. This soap, when well made, ought to be of a fine wax-yellow hue, be transparent upon the edges of the bars, dissolve readily in water, and afford, even with hard pump-water, an excellent lather.

The frame-moulds for hard soap are composed of strong wooden bars, made into the form of a parallelogram, which are piled over each other, and bound together by screwed iron rods that pass through them. A square well is thus formed, which in large soap-factories is sometimes 10 feet deep, and capable of containing a couple of tons of soap. For plain yellow or curd soaps, iron frames are now used instead of wooden ones, in almost every factory.

Mr. Sheridan some time since obtained a patent for combining silicate of soda with hard soap, by triturating them together in the hot and pasty state with a crutch in an iron pan. In this way from 10 to 30 per cent. of the silicate may be introduced. Such soap possesses very powerful detergent qualities, but it is apt to feel hard and be somewhat gritty in use. The silicated soda is prepared by boiling ground flints in a strong caustic lye, till the specific gravity of the compound rises to nearly double the density of water. It then contains about 35 grains of silica, and 46 of soda-hydrate, in 100 grains.[1]

Hard soap, after remaining two days in the frames, is at first divided horizontally into parallel tablets 3 or 4 inches thick, by a brass-wire; and these tablets are again cut vertically into an oblong nearly square bars, called 'wedges' in Scotland.

The soap-pans used in the United Kingdom are made of cast iron, and in three separate pieces joined together by iron-rust cement. The following is their general form:—The two upper frusta of cones are called curbs; the third, or undermost, is the pan to which alone the heat is applied, and which, if it gets cracked in the course of boiling, may easily be lifted up within the conical pieces, by attaching chains or cords for raising it, without disturbing the masonry in which the curbs are firmly set. The surface of the hemispherical pan at the bottom, is in general about one-tenth part of the surface of the conical sides.

The white ordinary tallow soap of the London manufacturers, called curd soap,

[1] By the writer's own experiments upon the liquid silicate made at Mr. Gibbs's excellent soap factory.

consists, by the writer's experiments, of fat, 52; soda, 6; water, 42 = 100. Nine-tenths of the fat, at least, is tallow.

With respect to the manufacture of sulphated soap, the process is as follows:—

To every ton of soap made in the usual way and ready to be cleansed and crystallised, add sulphate of soda (Glauber's salt) in the proportion of about 1 cwt. or more, according to the quality of the goods employed. The Glauber's salt should first be dissolved by turning steam into it, or in a steam-pan, in its own water of crystallisation; it is then added to the finished soap, and the whole must be crutched until the mass has become so stiff that it cannot be crutched any longer. In the evidence before the Privy Council, in the month of July 1855, this process was found by their Lordships of such public value that the patent right was extended for three years.

This process, however, has been superseded by another which Dr. Normandy patented in the month of August 1855. In effect it had been found that whereas sulphate of soda is more soluble in lukewarm than in either cold or boiling water, the temperature of the weather in summer time interfered with or altogether prevented the formation of the crystals, and that as the crystals of this salt contain ten equivalents of water, the maker of sulphated soap was put to the trouble and expense of the carriage of this, to him useless, water of crystallisation.

Soft Soap.—The manufacture of soft soap differs greatly from that of hard soap; as, in this case, nothing is separated from the mixture in the boiler; and the alkali employed is potash, and not soda. The mode of obtaining a caustic lye of potash is exactly the same as with soda, except that the weak lyes are used in place of water for a subsequent operation, and not pumped up into the boiler. The materials employed as fats are mixtures of the vegetable and animal oils, as rape, and the fish oil called 'Southern.' For the best kinds of soft soap, a little tallow is added to these, which produces a peculiar kind of mottling or crystallisation in the soap, that confers additional value upon it. These oils or fats are merely boiled with the strong caustic potash-lye, until thorough combination has taken place, and so much of the water of the lye is evaporated that, when a portion of the soap is poured upon a cold slab and allowed to rest for a few minutes, it assumes the consistency of soft butter. As soon as this happens, the whole is run out into little casks, where it cools; it is thus sent into the market. Of course no atomic arrangement can be traced in so variable a compound; and hence its analysis presents no point of interest. The employment of soft soap is daily becoming more and more limited.

The principal difference between soaps with base of soda, and soaps with base of potash, depends upon their mode of combination with water. The former absorb a large quantity of it, and become solid; they are chemical hydrates. The others experience a much feebler cohesive attraction; but they retain much more water in a state of mere mixture.

Three parts of fat afford, in general, fully five parts of soda-soap, well dried in the open air; but three parts of fat or oil will afford from six to seven parts of potash-soap of moderate consistency. This feebler cohesive force renders it apt to deliquesce, especially if there be a small excess of the alkali. It is therefore impossible to separate it from the lyes; and the washing or *relargage*, practised on the hard-soap process is inadmissible in the soft. Perhaps, however, this concentration or abstraction of water might be effected by using dense lyes of muriate of potash. Those of chloride or sulphide of sodium change the potash into a soda-soap, by double decomposition. From its superior solubility, more alkaline reaction, and lower price, potash-soap is preferred for many purposes, and especially for scouring woollen yarns and stuffs.

Soft soaps are usually made in this country with whale, seal, olive, and linseed oils, and a certain quantity of tallow; on the Continent, with the oils of hempseed, sesame, rapeseed, linseed, poppy-seed, and colza; or with mixtures of several of these oils. When tallow is added, as in Great Britain, the object is to produce white and somewhat solid grains of stearic soap in the transparent mass, called *figging*, because the soap then resembles the granular texture of the fig.

The potash-lyes should be made perfectly caustic, and of at least two different strengths; the weakest being of sp. gr. 1·05; and the strongest, 1·20, or even 1·25. Being made from the potashes of commerce, which contain seldom more than 60 per cent., and often less, of real alkali, the lyes correspond in specific gravity to double their alkaline strength; that is to say, a solution of pure potash of the same density would be fully twice as strong. The following is the process followed by respectable manufacturers of soft soap (*savon vert*, being naturally or artificially green) upon the Continent.

A portion of the oil being poured into the pan, and heated to nearly the boiling point of water, a certain quantity of the weaker lye is introduced; the fire being kept up so as to bring the mixture to a boiling state. Then some more oil and lye are added alternately, till the whole quantity of oil destined for the pan is introduced. The ebullition is kept up in the gentlest manner possible, and some stronger lye is occasionally added, till the workman judges the saponification to be perfect. The boiling becomes progressively less tumultuous, the frothy mass subsides, the paste grows transparent, and it gradually thickens. The operation is considered to be finished when the paste ceases to affect the tongue with an acrid pungency, when all milkiness and opacity disappear, and when a little of the soap placed to cool upon a glass-plate assumes the proper consistency.

A peculiar phenomenon may be remarked in the cooling, which affords a good criterion of the quality of the soap. When there is formed around the little patch an opaque zone, a fraction of an inch broad, this is supposed to indicate complete saponification, and is called the *strength;* when it is absent, the soap is said to want its *strength.* When this zone soon vanishes after being distinctly seen, the soap is said to have *false strength.* When it occurs in the best form the soap is perfect, and may be secured in that state by removing the fire, and then adding some good soap of a previous round to cool it down, and prevent further change by evaporation.

200 lbs. of oil require for their saponification, 72 lbs. of American potash of moderate quality, in lyes at 15° B.; and the product is 460 lbs. of well-boiled soap.

If hempseed oil has not been employed, the soap will have a yellow colour, instead of the green, so much in request on the Continent. This tint is then given by the addition of a little indigo. This dye-stuff is reduced to fine powder, and boiled for some hours in a considerable quantity of water, till the stick with which the water is stirred presents, on withdrawing it, a gilded pellicle over its whole surface. The indigo paste diffused through the liquid, is now ready to be incorporated with the soap in the pan before it stiffens by cooling.

Estimation of the quantity of water in soap:—Take about 1,000 grains of the soap under examination, cut into small and thin slices, not only from the outside, which is always drier, but from the interior of the sample, so that the whole may represent a fair average; mix the mass well together, and of this weigh accurately 100 grains; place it in an oven heated to a temperature of 212° Fahr., until it is quite dry, weighing it occasionally until no loss or diminution of weight is observed, the difference between the original and the last weight, the loss, indicates, of course, the proportion of water. The loss of water in mottled soap and in soft soap should not be more than 30 to 35 per cent.; in white or yellow soap from 36 to at most 50 per cent.

If the soap is sulphated, the amount of sulphate employed may be determined by taking 200 grains of the sample, dissolving it in a capsule with boiling water, adding to the boiling solution as much hydrochloric acid as is necessary to render the liquid strongly acid, and therefore to decompose the soap entirely throwing the whole in a filter previously wetted with water, adding to the filtrate an excess of chloride of barium, washing thoroughly the white precipitate so produced, igniting and weighing it; every grain of sulphate of baryta thus obtained represents 1·467 grain of crystallised sulphate of soda.

If the soap contains clay, chalk, silica, dextrine, fæcula, pumice-stone, ochre, plaster, salt, gelatine, &c., dissolve 100 grains of the suspected soap in alcohol, with the help of a gentle heat; the alcohol will dissolve the soap and leave all these impurities in an insoluble state. Good mottled soap should not leave more than 1 per cent. of insoluble matter, and white or yellow soap still less. All soap to which earthy or siliceous matter has been added is opaque instead of transparent at the edges, as is the case with all genuine or fitted and sulphated soap. The drier the soap, the more transparent it is.

Bone-soap, or glue-soap, is recognised by its unpleasant odour of glue and its dark colour, its want of transparency at the edges; that made with the fat of the intestines of animals has a disgusting odour of fæces.

When uncombined silica has been added to soap, its presence may be readily detected by dissolving the suspected soap in alcohol, as before, when the silica will be left in an insoluble state; but if the silica is in the state of silicate of soda or of potash, it is necessary to proceed as follows:—Dissolve a given weight of the suspected soap in boiling water, and decompose it by the gradual addition of moderately dilute hydrochloric acid, until the liquor is strongly acid; boil the whole for one or two minutes longer and allow it to cool in order that the fatty acids having separated and become hard, may be removed. Evaporate the acid liquor to *perfect dryness,* and the perfectly dry mass treated with boiling water will leave an insoluble residue which may be identified as silica by its grittiness, which is recognised by rubbing it in the capsule with a glass rod. This white residue should then be collected on a filter, washed, dried, ignited, and weighed.

The proportion of alkali (potash or soda) may be easily determined by an alkalimetrical assay as follows:—

Take 100 grains of the soap under examination, and dissolve them in about 2,000 grains of boiling water; should any insoluble matter be left, decant carefully the superincumbent solution and test it with dilute sulphuric acid of the proper strength, exactly as described in the article ALKALIMETRY.

The proportion of alkali contained in soap may also be ascertained by incinerating a given weight of soap in an iron or platinum spoon, crucible, or capsule, treating the residue with water, filtering and submitting the filtrate to an alkalimetrical assay. This method, however, cannot be resorted to when the soap contains sulphates of alkalis, because the ignition would convert such salts, or a portion thereof, into carbonates of alkali, which by saturating a portion of the test-sulphuric acid would give an inaccurate result.

The proportion of oil or fat in soap is ascertained by adding 100 grains of pure white wax free from water to the soap-solution, after supersaturation with an acid, and heating the whole until the wax has become perfectly liquid, and has become perfectly incorporated with the oil or fat which has separated by the treatment with an acid. The whole is then allowed to cool, and the waxy cake obtained is removed, heated in a weighed crucible or capsule to a temperature of about 220° Fahr. in order to expel all the water, after which the whole is weighed; the increase above 100 grains (the original weight of the wax) indicates, of course, the quantity of grease, fat, or oil contained in the soap. This addition of wax is necessary only when the fatty matter of the soap is too liquid to solidify well in cooling. Good soap ordinarily contains from 6 to 8 per cent. of soda; from 60 to 70 per cent. of fatty acids and resin, and from 30 to 35 per cent. of water.

The nature of the fat of which a given sample of soap has been made is more difficult to detect, yet by saturating the aqueous solution of the mass under examination with an acid, collecting the fatty acids which then float on the surface, and observing their point of fusion, the operator at any rate will thus be enabled to ascertain whether the soap under examination is identical with the sample from which it may have been purchased, and whether it was made from tallow, or from oil, &c.

SOAP-BARK. A few years since a peculiar bark was introduced into the European trade, and recommended to be employed instead of soap for washing and cleaning printed goods, woollens, and silks, and especially for the delicate colours of ladies' dresses, &c. This soap-bark is externally black, but internally the liber consists of layers of yellowish-white. The bark is remarkable for its density, as it sinks in water. The cause of this is the great quantity of mineral substances in its ashes, there being 13·935 per cent. of the internal parts, dried at low temperature and 18·50 per cent. when dried at 100° C. The ashes consist largely of carbonate of lime, which forms 2·60 per cent. of the 13·935, and appears as small crystalline needles, isolated or in groups, in the cells of the liber, not only between its concentric rings but in every part of it. They glitter in the sun, resembling under the microscope, the aragonite form of the crystallised carbonate of lime.

The soap-wort (*Saponaria officinale*) is sometimes used for scouring and cleaning dresses. Several of this family of caryophyllaceous plants (*Dianthus, Lychnis, Gypsophila, Silene*) are remarkable for this property in a greater or less degree. By chemical means there has been extracted from these roots the *Saponine* (or *Struthiine*), a special substance, and to this, notwithstanding the very small quantity contained in the roots, the singular power is attributed of making emulsions, and of being used for soap in washing. The soap-wort of the Levant (*Gypsophila*) is, to this day, employed in the East for washing and cleaning silks and shawls. It is generally used in the Mediterranean districts of France and Spain; the French called it *herbe aux foulons* (the fuller's plant). The *Saponaire*, or *Savonière* of the French, is the root of a kind of *Lychnis*. Saponine was found by Henry and Boutron Charland in the bark of the *Quillaja saponaria*, a tree of the family of rosaceous plants, and a native of Huanaco, in Peru. Ferdinand Lebœuf made mention of this bark in 1850 for its richness in saponine, and recommended it for pharmaceutical use in preparing emulsions of oils, resins, balsams, and several other medicaments. He mentions likewise the bark of the *Yallhoy* (*Monnina polystachya*) as containing saponine. The fruits of *Sapindus saponaria*, known as 'soap-berries,' are used in America and the West Indies for washing linen.

SOAPSTONE. See STEATITE.

SODA. NaO (**Na^2O**). This is the oxide of the metal sodium, and can only be obtained in the free state by the combustion of the metal itself in dry air or oxygen gas. Another oxide appears to exist, but the composition is uncertain, and it is of no commercial value. Soda (*oxide of sodium*), thus prepared, is a white solid, which absorbs moisture rapidly, the whole of which cannot be again removed by heat alone, the hydrate NaO.HO (**NaHO**) remaining. This hydrate of soda, which is largely used in the manufacture of soap, is not prepared from the anhydrous oxide, but by removing the carbonic acid from carbonate of soda by the means of hydrate of lime. When the soda is required in the solid state, the carbonate of lime thus formed is allowed to settle, the clear supernatant liquid is poured off and evaporated to dryness, fused in a silver vessel, and cast into sticks.

The following is a table of the quantities of real soda (NaO) in the solutions of different specific gravities.—*By Richter.*

Spec. grav.	Soda per cent.	Spec. grav.	Soda per cent.	Spec. grav.	Soda per cent.	Spec. grav.	Soda per cent.

SODA-ALUM. See ALUM.

SODA, BIBORATE OF. See BORACIC ACID, and BORAX

SODA, BISULPHATE. $NaO.HO.2SO^3$ (**$NaHSO^4$**). This is obtained in the same manner as bisulphate of potash, with which it corresponds.

SODA, CARBONATE OF (*Kohlensaures Natron*, Ger.), is the 'soda' of commerce in various states, either crystallised, in lumps, or in a crude powder called 'soda-ash.' It exists in small quantities in certain mineral waters; as, for example, in those of Seltzer, Seydschutz, Carlsbad, and the volcanic springs of Iceland, especially the Geyser; it frequently occurs as an efflorescence in slender needles upon damp walls, being produced by the action of the lime upon the sea-salt present in the mortar. The mineral soda is the sesquicarbonate, to be afterwards described.

Of manufactured soda, the variety most anciently known is *barilla*, the incinerated ash of the *Salsola soda*. This plant is cultivated with great care by the Spaniards, especially in the vicinity of Alicant. The seed is sown in light low soils, which are embanked towards the sea-shore, and furnished with sluices, for admitting an occasional overflow of salt water. When the plants are ripe, the crop is cut down and dried; the seeds are rubbed out and preserved; the rest of the plant is burnt in rude furnaces, at a temperature just sufficient to cause the ashes to enter into a state of semi-fusion, so as to concrete on cooling into cellular masses comparatively compact. The most valuable variety of this article is called *sweet barilla*. It has a greyish-blue colour, and becomes covered with a saline efflorescence when exposed for some time to the air. It is hard and difficult to break; when applied to the tongue, it excites a pungent alkaline taste.

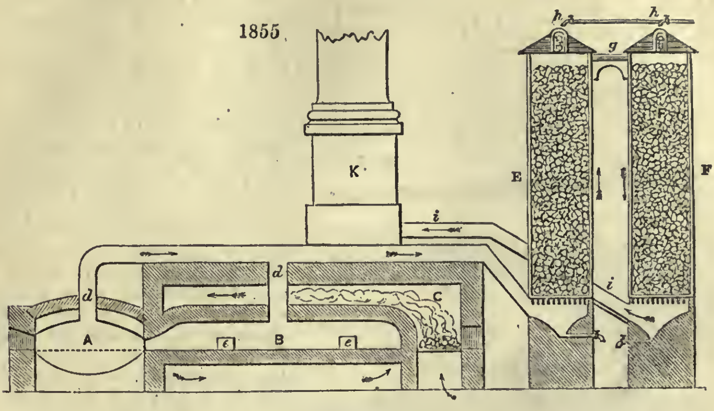
Another method of manufacturing crude soda, is by burning sea-weed into *kelp*. Formerly, very large revenues were derived by the proprietors of the shores of the Scottish islands and Highlands, from the incineration of sea-weeds by their tenants, who usually paid their rents in kelp; but since the tax has been taken off salt, and the manufacture of a crude soda from it has been generally established, the price of kelp has fallen low, its principal use being now to obtain iodine. See BARILLA, IODINE, KELP.

The crystals of soda carbonate, as well as the soda-ash of British commerce are now made altogether by the decomposition of sea-salt.

Soda-manufacture. The manufacture divides itself into three branches:—1. The conversion of sea-salt, or common salt (chloride of sodium), into sulphate of soda. 2. The decomposition of this sulphate into crude soda, called *black balls* by the workmen. 3. The purification of these balls, either into a dry white soda-ash or into crystals.

Preparation of Sulphate of Soda. The decomposition of common salt is effected by sulphuric acid in furnaces of which *fig.* 1855 is a section. A, the smaller of the two compartments which compose the furnace, is of cast iron; into this (*the decomposer*) from five to six hundred weight of common salt are introduced, and an equal weight of sulphuric acid, of specific gravity 1·6, is gradually mixed with it; a gentle heat being applied to the outside, enormous volumes of hydrochloric acid gas are disengaged, and pass off by the flue, *d*, to the condensing towers, E and F; these towers are filled with fragments of broken coke or stone, over which a continuous stream of water is caused to trickle slowly from *h h*. A steady current of air is drawn through the furnace and condensing towers, by connecting the first tower with the second, as represented at *g*, and the second tower with the main chimney, K, of the works. In the first bed of the furnace, about half of the common salt is decomposed, leaving a

1855.



mixture of bisulphate of soda and common salt, which requires a greater heat for the expulsion of this latter portion of hydrochloric acid; for this purpose it is pushed through a door into the *roaster*, or second division, B, of the furnace.

The reaction in the first bed of the furnace is represented as follows:—

$$\underbrace{2NaCl}_{\text{Common salt.}} + \underbrace{2HO.SO^3}_{\text{Sulphuric acid.}} = \underbrace{NaO.SO^3.\ HO.SO^3}_{\text{Bisulphate of soda.}} + \underbrace{HCl}_{\text{Hydrochloric acid.}} + \underbrace{NaCl.}_{\text{Common salt.}}$$

$$\mathbf{2NaCl + H^2{=}SO^4 = NaHSO^4 + HCl + NaCl}$$

By the higher temperature obtained in the second part of the furnace, the bisulphate of potash reacts on the undecomposed chloride of sodium, yielding neutral sulphate of soda and a fresh quantity of hydrochloric acid.

$$\underbrace{NaO.SO^3.\ HO.SO^3}_{\text{Bisulphate of soda.}} + \underbrace{NaCl}_{\text{Common salt.}} = \underbrace{2(NaO.SO^3)}_{\text{Sulphate of soda.}} + \underbrace{HCl.}_{\text{Hydrochloric acid.}}$$

$$\mathbf{NaHSO^4 + NaCl = Na^2SO^4 + HCl}$$

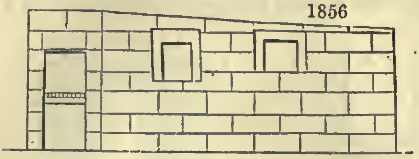
The hydrochloric acid gas, as it is liberated from B, passes off through the flue, *d*, and is carried on to the condensing towers. Heat is applied to the outside of the roaster, B; the smoke, C, circulating in separate flues around the chamber, in the direction indicated by the arrows, but never coming into contact with the salt-cake in B.

The process used at present in the Tyne district differs but little from that above described, with the exception that in the decomposition of the mixture of bisulphate of soda and common salt, in the second portion of the furnace, the smoke and products of combustion from the fire, are allowed to come in contact with the materials, and the hydrochloric acid which is then given off is carried into condensing towers filled with bricks over which water is continually slowly running, and the dilute hydrochloric acid, thus obtained, is used for the liberation of carbonic acid in the manufacture of bicarbonate of soda. The first part of the furnace is a circular metal pan, and the hydrochloric acid from this, being unmixed with smoke, &c., is condensed apart from the other.

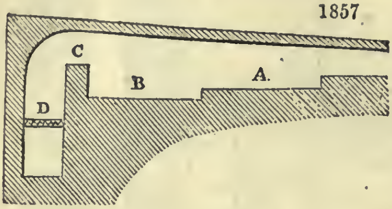
The next step in the manufacture is the decomposition of the sulphate of soda into sulphide of sodium, and its subsequent conversion into carbonate of soda. This is effected in the following manner:—The dry sulphate of soda, obtained by the process above described, is mixed with small coal and chalk, or limestone, in about the following proportions: sulphate of soda 3 parts, chalk 3½ parts, and coal 2 parts. It is necessary that these materials should be first separately ground, and sifted into a tolerably fine powder, and then carefully mixed, as a great deal depends on the attention to these points. The mixture is then subjected to heat in a reverberatory furnace, *figs.* 1856, 1857, 1858.

In the section *fig.* 1857, there are two hearths in one furnace, the one elevated above the level of the other by the thickness of a brick, or about three inches. A is the preparatory shelf, where the mixture to be decomposed is first laid in order to be thoroughly heated, so that when transferred to the lower or decomposing hearth, B,

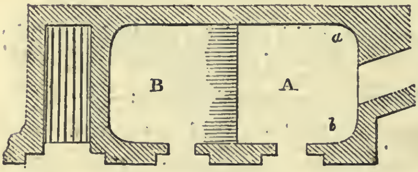
1856



1857



1858



it may not essentially chill it, and throw back the operation. C is the fire-bridge, and D is the grate. In the horizontal section, or ground plan, *fig.* 1858, we see an opening in the front corresponding to each hearth. There is a door, as shown in the side view or elevation of the furnace, *fig.* 1856; and each door is shut by an square iron frame filled with a fire-tile or bricks, and suspended by a chain over a pulley fixed in any convenient place. (See COKE.) The workman, on pushing up the door lightly, makes it rise, because there is a counter-weight at the other end of each chain, which balances the weight of the frame and bricks. In the ground plan, only one smoke-flue is shown; and this construction is preferred by many manufacturers; but others choose to have two flues, one from each shoulder, as at *a*, *b*; which two flues afterwards unite in one vertical chimney, from 25 to 40 feet high; because the draught of a soda furnace must be very sharp. Having sufficiently explained the construction of this improved furnace, we shall now proceed to describe the mode of making soda with it.

The quantity of the mixture required for a charge depends, of course, on the size of the furnace. This charge must be shovelled in upon the hearth, A, or shelf of preparation (*fig.* 1857); and whenever it has become hot (the furnace having been previously brought to bright ignition), it is to be transferred to the decomposing hearth or laboratory, B, by an iron tool, shaped exactly like an oar, called *the spreader*. This tool has the flattened part from 2 to 3 feet long, and the round part, for laying hold of and working by, from 6 to 7 feet long. Two other tools are used: one, a rake, bent down with a garden hoe at the end; and another, a small shovel, consisting of a long iron rod terminated like a piece of iron plate, about 6 inches long, 4 broad, sharpened and tipped with steel, for cleaning the bottom of the hearth from adhering cakes or crusts. Whenever the charge is shoved by the sliding motion of the oar down upon the working hearth, a fresh charge should be thrown into the preparation shelf, and evenly spread over its surface.

The hot and partially-carbonised charge being also evenly spread upon the hearth, B, is to be left untouched for about ten minutes, during which time it becomes ignited, and begins to fuse upon the surface. A view may be taken of it through a peep-hole in the door, which should be shut immediately, in order to prevent the reduction of the temperature. When the mass is seen to be in a state of incipient fusion, the workman takes the oar and turns it over breadth by breadth in regular layers, till he has reversed the position of the whole mass, placing on the surface the particles which were formerly in contact with the hearth. Having done this, he immediately shuts the door, and lets the whole get another decomposing heat. After five or six minutes, jets of flame begin to issue from various parts of the pasty-consistenced mass. Now is the time to incorporate the materials together, turning and spreading by the oar, gathering them together by the rake, and then distributing them on the reverse part of the hearth; that is, the oar should transfer to the part next the fire-bridge the portion of the mass lying next the shelf, and *vice versâ*. The dexterous management of this transposition characterises a good soda-furnacer. A little practice and instruction will render this operation easy to a robust clever workman. After this transposition, incorporation, and spreading, the door may be shut again for a few minutes, to raise the heat for the finishing off. Lastly, the rake must be dexterously employed to mix, shift, spread, and incorporate. The jets, called *candles*, are very numerous, and bright at first; and whenever they begin to fade, the mass must be raked out into cast-iron moulds, placed under the door of the laboratory to receive the ignited paste.

One batch being thus worked off, the other, which has laid undisturbed on the shelf, is to be shoved down from A to B, and spread equally upon it, in order to be treated as above described. A third batch is then to be placed on the shelf.

The product thus obtained is called 'black balls,' which, of course, vary in their composition. The following is the composition, according to Richardson, of the Newcastle 'black balls,' from the balling furnaces:—

Carbonate of soda 9·89, hydrate of soda 25·64, sulphide of calcium 35·57, carbonate of lime 15·67, sulphate of soda 3·64, chloride of sodium 0·60, sulphide of iron 1·22, silicate of magnesia 0·88, carbon 4·28, sand 0·44, and water 2·17 = 100.

The *principal* changes which take place in this process may be represented by the following equations:—

$$\underbrace{NaO.SO^3}_{\text{Sulphate of soda.}} + \underbrace{4C}_{\text{Carbon.}} = \underbrace{NaS}_{\text{Sulphide of sodium.}} + \underbrace{4CO}_{\text{Carbonic oxide.}}$$

$$(\mathbf{Na^2SO^4} + \mathbf{2C^2} = \mathbf{Na^2S} + \mathbf{4CO}).$$

then—

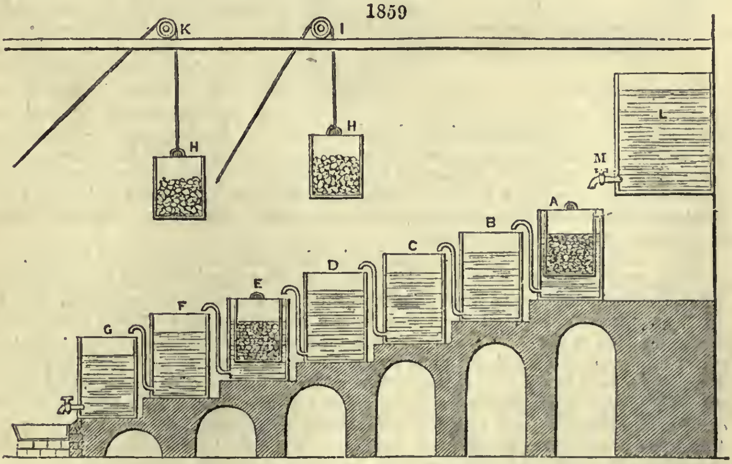
$$\underbrace{NaS}_{\text{Sulphide of sodium.}} + \underbrace{CaO.CO^2}_{\text{Chalk.}} = \underbrace{NaO.CO^2}_{\text{Carbonate of soda.}} + \underbrace{CaS}_{\text{Sulphide of calcium.}}$$

$$(\mathbf{Na^2S} + \mathbf{CaCO^3} = \mathbf{Na^2CO^3} + \mathbf{CaS}).$$

In the first place, the sulphate of soda is deoxidised by the coal, with the formation of sulphide of sodium and carbonic oxide, which latter takes fire and forms the 'candles,' above mentioned; in the next place, the sulphide of sodium and carbonate of lime (chalk) decompose each other, forming carbonate of soda and sulphide of calcium; and from the fact of some of the chalk being converted into caustic lime by the heat of the furnace, there is also formed by it some caustic soda; the sulphide of calcium itself is only sparingly soluble in water, but is rendered still less so by the excess of lime which is present, forming with it an oxysulphide, which is much less soluble than the sulphide of calcium alone.

This *black ball*, or *ball alkali*, is then treated with warm water to extract the soluble matters. This is effected in the district of Newcastle-on-Tyne in vessels, 8 or 10 feet square and 5 or 6 feet deep, furnished with false bottoms; the first waters are strong enough for boiling down, for getting 'yellow salt,' as it is termed; the after-washings, which are weaker, are used for fresh quantities of 'ball alkali.' Care must be taken not to use the water too hot, as the oxysulphide of calcium would be decomposed, and the liquor thus take up much sulphide of calcium.

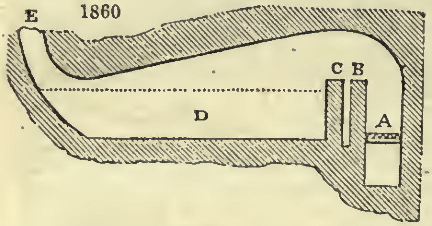
1859



An apparatus used in some places for lixiviating the black ball is shown in the accompanying drawing, *fig.* 1859. Its object is to extract the largest quantity of soluble matter with the smallest quantity of water. The black ball is placed in perforated sheet-iron vessels, H H, which can be raised or lowered into outer lixiviating vessels, also made of iron, by means of the cords and pulleys, I, K. When a charge is received from the furnace, it is introduced into the lowest vessels, G, where it is submitted to the dissolving action of a liquid already highly charged with alkali from digestion upon the black ash contained in the tanks above it; after a certain time, this charge is raised by the rope from G into the tank F, where it is submitted to a weaker liquid, and so on, successively. The alkali at each stage becomes more completely exhausted, and the residue is successively submitted to the action of weaker lye, till at length, in A, it is acted on by water only, supplied from the cistern, L. When fresh water is admitted from M, to the top of the vessel, A, as it is specifically lighter than the saline solution, it lies upon its surface, and gradually displaces the solution from A, through the bent tube, whilst the water takes its place; the liquid thus displaced from it, acts in like manner upon that contained in B; and this displacement proceeds simultaneously through each successive tier of the arrangement, until the concentrated lye flows off from G, and is transferred to the evaporating pans. The residue which remains after this treatment contains nearly all the sulphur present in the ball alkali, in the form of oxysulphide of calcium, together with the other insoluble portions, and is of no value; it accumulates to an immense extent in large soda works, and is thus a source of annoyance. Many trials have been made to obtain the sulphur contained in it, and to use it for the reproduction of sulphuric acid, but without much success hitherto.

The solution obtained by thus lixiviating the ball soda, contains principally carbonate of soda and hydrate of soda, as well as some sulphide and chloride of sodium, and a little sulphate of soda. It is allowed to settle; then the clear liquor is drawn off into evaporating vessels. These may be of two kinds. The surface-evaporating furnace, shown in *fig.* 1860, is a very admirable invention for economising vessels, time, and fuel. The grate A, and fire-place, are separated from the evaporating laboratory D, by a double fire-bridge B, C, having an interstitial space in the middle, to arrest the communication of a melting or igniting heat towards the lead-lined cistern D. This cistern may be 8, 10, or 20 feet long, according to the magnitude of the soda-work, and 4 feet or more wide. Its depth should be about 4 feet. It consists of sheet lead, of about 6 pounds weight to the square foot, and it is lined with one layer of bricks, set in Roman or hydraulic cement, both along the bottom and up the sides and ends. The lead comes up to the top of *c*, and the liquor, or lye, may be filled in to nearly that height. Things being thus arranged, a fire is kindled upon the grate A; the flame and hot air sweep along the surface of the liquor, raise its temperature there rapidly to the boiling point, and carry off the watery parts in vapour up the chimney E, which should be 15 or 20 feet high, to command a good draught. But, indeed, it will be most economical to build one high capacious chimney stack, as is now done at Glasgow, Manchester, and Newcastle, and to lead the flues of the several furnaces above described into it. In this evaporating furnace the heavier and stronger lye goes to the bottom, as well as the impurities, where they remain undisturbed. Whenever the liquor has attained to the density of 1·3, or thereby, it is pumped up into evaporating cast-iron pans, of a flattened somewhat hemispherical shape, and evaporated to dryness while being diligently stirred with an iron rake and iron scraper.

1860



This alkali gets partially carbonated by the above surface-evaporating furnace.

When pure carbonate is wanted, that dry mass must be mixed with its own bulk of ground coal, sawdust or charcoal, and thrown into a reverberatory furnace, like *fig.* 1857, but with the sole all upon one level. Here it must be exposed to a heat not exceeding 650° or 700° F.; that is, a little above the melting heat of lead; the only object being to volatilise the sulphur present in the mass, and carbonate the alkali. Now, it has been found, that if the heat be raised to distinct redness, the sulphur will not go off, but will continue in intimate union with the soda. This process is called *calking*, and the furnace is called a *calker furnace*. It may be 6 or 8 feet long, and 4 or 5 feet broad in the hearth, and requires only one door in its side, with a hanging iron frame filled with a fire-tile or bricks, as above described.

This carbonating process may be performed upon several cwts. of the impure soda, mixed with sawdust, at a time. It takes three or four hours to finish the desulphuration; and it must be carefully turned over by the oar and the rake, in order to burn the coal into carbonic acid, and to present the carbonic acid to the particles of caustic soda diffused through the mass, so that it may combine with them.

When the blue flames cease, and the saline matters become white, in the midst of the coaly matter, the batch may be considered as completed. It is raked out, and when cooled, lixiviated in great iron cisterns with false bottoms, covered with mats. The watery solution being drawn off clear by a plug-hole, is evaporated either to dryness, in hemispherical cast-iron pans, as above described, or only to such a strength that it shows a pellicle upon its surface, when it may be run off into crystallising cisterns of cast-iron or lead-lined wooden cisterns. The above dry carbonate is the best article for the glass manufacture.

Instead of this last process of roasting with sawdust, Gossage decomposes the sulphide of sodium present in the lye obtained from the ball soda, by means of the hydrated oxide of some metal, as of lead, thus forming sulphide of lead, and hydrate of soda; this is then converted into carbonate by passing a stream of carbonic acid through it. The precipitated sulphide of lead is decomposed by hydrochloric acid, thus generating sulphuretted hydrogen, which is burnt and converted into sulphuric acid; the lead is then converted again into hydrated oxide by means of lime. This process saves the trouble, time, and fuel used in evaporating to dryness twice as in the ordinary process.

Various attempts have been made to obtain processes which shall supersede the process above described, of manufacturing carbonate of soda from common salt.

Sulphate of iron, being a cheap article, has been heated with common salt, instead of using sulphuric acid; sulphate of soda is formed, and the chloride of iron, being volatile, passes away. By roasting iron or copper pyrites directly with chloride of sodium, sulphate of soda has been obtained, and it has been found possible by this means also to extract the metal from ores of copper or tin with advantage, which are otherwise too poor to work. Mr. Tilghman effects the decomposition of chloride of sodium by steam at a high temperature, in the presence of alumina. Precipitated alumina is made up into balls with chloride of sodium, and exposed to a current of steam in a reverberatory furnace strongly heated. Hydrochloric acid is expelled, and the alumina unites with the soda. When cold, this compound of alumina and soda is decomposed by a current of carbonic acid, and the carbonate of soda is dissolved, and thus separated from the alumina, which may be again used. Another process is that of MM. Schlœsing and Rolland. They dissolve the chloride of sodium in water, and then pass ammonia into it, and afterwards carbonic acid; bicarbonate of ammonia is first produced, and then double decomposition takes place; chloride of ammonium is formed, and the more sparingly soluble bicarbonate of soda is precipitated in crystalline grains; it is then separated from the liquid and pressed, to free it as much as possible from the chloride. This bicarbonate of soda is converted into the monocarbonate by heat, and the carbonic acid thus evolved is used again; the solution, from which the bicarbonate has separated, is boiled to drive off any ammonia that it may contain, as carbonate of ammonia, which is collected; the solution is then boiled with lime, which liberates the ammonia from the chloride of ammonium, and thus little loss is sustained.

There are three carbonates of soda:—

Monocarbonate. $NaO.CO^2 + 10HO$ (**$Na^2CO^3 + 10H^2O$**). This is the salt which is obtained in the ordinary soda-manufacture. In the crystalline state, it generally contains ten equivalents of water of crystallisation, or sixty-three per cent., but has been obtained with only eight, five, and even one equivalent of water. It effloresces in a dry atmosphere, at the same time absorbing carbonic acid. It is very soluble in water, requiring only twice its weight of water at 60° for solution, and even melts in its own water of crystallisation when heated, and eventually by increase of temperature becomes anhydrous. It is generally found in commerce in large crystals, which belong to the oblique prismatic system. It is strongly alkaline, and acts on the skin, dissolving the outside cuticle. It is largely used in the manufacture of soap, glass, &c.

Sesquicarbonate. $2(NaO.CO^2),HO.CO^2$ (**$2Na^2CO^3,H^2CO^3$**). This salt is frequently found native. See NATRON.

Bicarbonate. $NaO.CO^2,HO.CO^2$ (**$NaHCO^3$**). This salt is found in some mineral waters, as those of Carlsbad and Seltzer; and is obtained from the waters of Vichy in large quantities.

It is prepared by saturating the monocarbonate with carbonic acid, for which purpose several methods are employed.

1. *By passing carbonic acid into a solution of the monocarbonate.* A cold saturated solution of the monocarbonate of soda is made, and carbonic acid obtained by the action of hydrochloric acid on marble or chalk, is passed into it; the bicarbonate forms and precipitates to a great extent, and is then collected, and pressed to remove as much of the adhering liquid as possible. A fresh portion of the

monocarbonate is dissolved in the mother-liquor, and the passage of carbonic acid through it repeated. By this method a pure bicarbonate is obtained, but the process is costly.

2. *By exposing solid monocarbonate of soda to an atmosphere of carbonic acid gas.* This is known as Smith's process. The crystals of the monocarbonate are placed on shelves, slightly inclined to allow the water to run off, in a large box, containing a perforated false bottom; carbonic acid is passed into this box under pressure, which latter is scarcely necessary, since the monocarbonate so rapidly absorbs the carbonic acid. When the gas ceases to be absorbed, the salt is taken out and dried by a *gentle* heat.

The crystals are found to have lost their water of crystallisation, and to have become opaque and porous, and a bicarbonate, still, however, retaining their original shape. These are ground between stones like flour, care being taken to avoid the evolution of much heat.

3. Its formation by the action of bicarbonate of ammonia has been already described.

Bicarbonate of soda crystallises in rectangular four-sided prisms, which require about ten parts of cold water to dissolve them, and if the solution be boiled, it loses carbonic acid, becoming first sesquicarbonate, and ultimately monocarbonate. As usually met with in commerce this salt is a white powder. Its taste is slightly alkaline. It is largely used in medicine, for making seidlitz powders, &c., but the salt generally found in the shops is only a sesquicarbonate, or a mixture of bicarbonate and sesquicarbonate.

The latest obtainable returns, show that the materials used on the Tyne in producing soda, and its alkaline manufactures, amount to 1,070,000 tons annually, consisting chiefly of pyrites, salt, chalk, coal, and manganese, the value of which is about 850,000*l.* This outlay produces:—

	Tons.		Tons.
Soda crystals	86,000	Caustic soda	3,720
Alkali	74,000	Epsom salts	590
Bicarbonate of soda	11,000	Glauber salts	20
Sulphate of copper	200	Oil of vitriol	9000
Sulphate of soda	2,400	Hyposulphite of soda	400
Bleaching powder	27,000	Muriatic acid	700
		Chloride of manganese	1,300
		Total tons.	216,330

Having an aggregrate value of 1,929,825*l.*

The products of the Lancashire chemical works are about the same, the total for all England being:—

	£
Raw materials	1,700,525
Manufactured article	3,813,604

The remarkable extension of the Alkali trade will be seen by the following statement of Exports:—

In the manufacture of carbonate of soda from common salt, there was always a considerable escape of muriatic acid, which was highly injurious to all surrounding vegetation. This led to the passing of a Bill to regulate this manufacture.

The Alkali Act of July 28, 1863, is 'An Act for the more effectual Condensation of Muriatic Acid Gas in Alkali Works.' An alkali work is defined by the Act to be 'every work for the manufacture of alkali, sulphate of soda, or sulphate of potash, in which muriatic acid is evolved.' It is required that 'every alkali work shall be carried on in such a manner as to secure the condensation to the satisfaction of the inspector, derived from his own examination or from that of a sub-inspector, of not less than 95 per centum of the muriatic acid gas evolved therein.'

Alkali Exported in 1873.

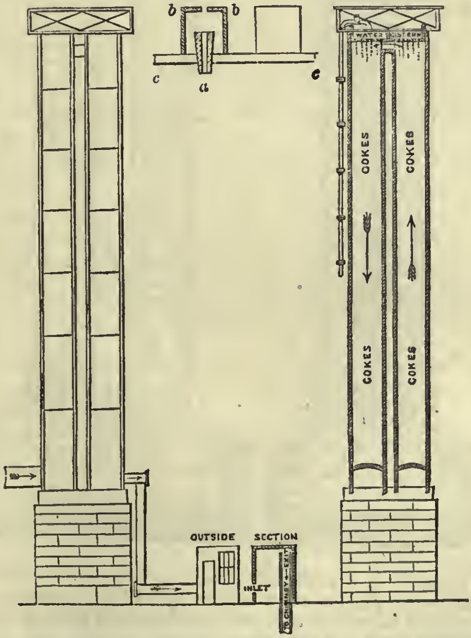
If we estimate the escape of muriatic acid gas at 1,000 tons per week before the passing of the Alkali Act, or at least before the introduction of the Alkali Bill into Parliament, we may be considered as taking a very moderate view of the question.

1861



1862

a, Wooden plug, with hole through the centre. *b* is a covering of earthenware which is nearly submerged, thus closing entirely the top of the tower when the water is admitted. *c c*, Bottom of water-cistern; the water passes through the side of *b b* close to *c c*, thus hermetically sealing the apertures. The floor of the water-cisterns at the top of each tower is covered with the wooden plugs as above and their coverings.

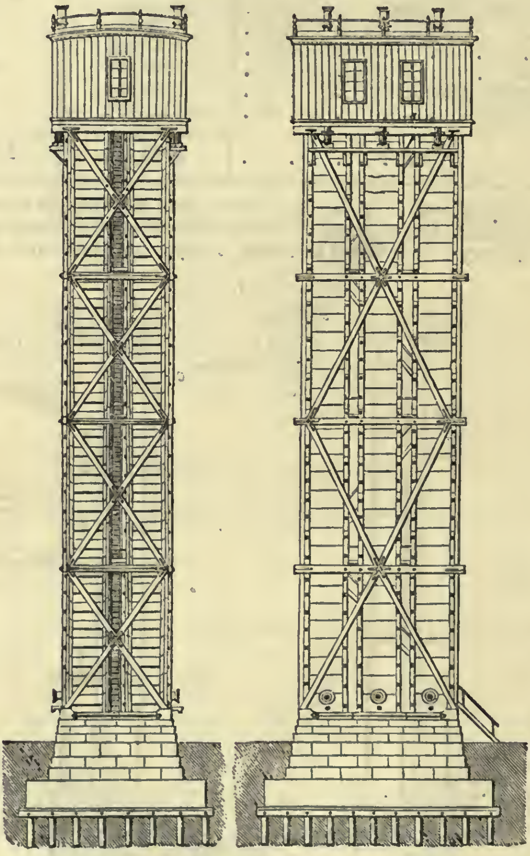
This supposes 2,324·96 to have been already condensed, and is a very favourable view of the case. The 1,000 tons left uncondensed are equal to 4,000 tons of 25 per cent. acid, and under one-third of the total amount evolved in the process of decomposing salt by sulphuric acid in the United Kingdom. This quantity amounts to 208,000 tons per annum.

Condensation is promoted by cold and by water mainly, but next to these we must add contact of surfaces and time.

Air with a small quantity of muriatic acid in it will appear misty in moist weather, though the amount may be less than 0·003 per cent. It will pass rapidly through tubes well cooled and still appear misty, but let it pass between broken pieces of coke or through extremely narrow moist passages and it will be perfectly cleared. The floating particles too minute to fall seem to be filtered out as we filter fine precipitates. The mode of gaining extensive surface is chiefly by the use of coke in the towers.

Other modes have been adopted of filling the condensers. Fire-bricks are used in many cases, and especially at the lower part of condensers used for open roasters.

1863 1864



A *condenser* generally is a tower filled with moistened very porous or non-porous material, in pieces so large as to allow the passage of air and water through the interstices, and so small as to prevent that passage from being made without contact of the air or gases with the water and the solids present.

It is built generally in the form of a square tower. It is from 3 to 6 feet square equally from base to summit, and from 5 to 125 feet high. This height includes the pedestal and the cistern above the condensing portion of the tower. See *fig.* 1862.

1st. The simplest form of condenser allows the gas to enter below whilst the uncondensed portion escapes into the air at the top.

2nd. The uncondensed gases of the first tower may be sent into the top of the second tower, down which they may pass and thence either to the chimney or to a third and fourth tower.

3rd. A tower may be divided in two parts. The gases may pass up one side and down the other. This merely treats one as if it were two.

4th. The gases may pass up one tower and down earthenware pipes to the bottom of the second tower, up which they rise. By this method the gases pass up the towers only, and down tubes only.

5th. Condensers may be vessels of stone or of earthenware; when of stone they may be several feet in length, breadth, or depth. In these vessels a large amount of acid is frequently condensed before it passes to the towers. The gases may pass through several of these tanks.

6th. As the gases come from the roaster very hot, it is found of advantage to cool them before they enter the condenser. This is done by allowing them to pass along earthenware pipes for a great distance before entering the condensers. When these pipes are not used, the condenser is heated very highly and filled more or less with hot instead of cold water. This is the case sometimes to such an extent as to warm the whole tower. A great supply of water cools the tower but weakens the acid, and may even obstruct the passage of the gas too far.

7th. The first condenser is made large enough to condense all the gas, or several may be required. The greater part of the gas may be removed by one or more towers, leaving a small amount to be condensed by a post-condenser flushed with a great excess of water. This acid is not intended for use. Sometimes several condensers are connected with one post-condenser for a final washing. A greater amount of space and water being required to remove acid when it exists to the extent of only two or three per cent., the acid from these washings is often very dilute, sometimes so much as not to be sensible to the taste.

Figs. 1863 and 1864 are drawings in elevation of the fine towers at Messrs. Allhusen's. The stairs are entirely within the enclosure made by the six towers, and can be ascended with perfect safety. The chamber at the top contains the cistern and arrangements for the distribution of the water. At the very top are openings for the uncondensed gases. There are two rows of three towers, making six towers, for the pan-gases.

SODA FELSPAR. Usually called *Albite*. See FELSPAR.

SODA, HYPOCHLORITE OF. NaO.ClO (**NaClO**). This is obtained in the same manner as hypochlorite of lime, or by decomposing a solution of this latter by carbonate of soda. Its uses are the same as those of the hypochlorite of lime.

SODA, HYPOSULPHITE OF. This is now largely prepared for photographic purposes. See HYPOSULPHITE of SODA.

SODA, NITRATE, OF. NaO,NO^5 (**$NaNO^3$**). Syn. *cubic nitre; Chile saltpetre.* (*Nitrate de soude*, Fr.; *Würfelsalpeter*, Ger.) This important salt is found native in immense quantities in Chili and Peru. It is, in some parts, found in beds of several feet in thickness. As found in nature it is tolerably pure, the principal impurities being chlorine, sulphuric acid, and lime. Nitrate of soda can be formed artificially by saturating nitric acid with soda or its carbonate, and evaporating the solution.

Nitrate of soda is extensively and economically employed as a source of nitric acid. It is also used for the purpose of being converted by double decomposition with chloride of potassium into nitrate of potash. (See NITRATE OF POTASH.) It is employed as a manure.

A good sample of nitrate of soda should not contain more than two per cent. of chloride of sodium. The nitric acid may be determined by the process described under NITRATE OF POTASH.

Nitrate of soda is not applicable for the preparation of gunpowder or fireworks. partly in consequence of its tendency to attract moisture from the air, and partly owing to the fact that mixtures made in imitation of gunpowder, but having nitrate of soda in place of nitrate of potash. It has, however, been prepared and used for blasting-powder, with some apparent advantage. See CUBIC NITRE.

SODA, NITRITE OF. NaO,NO^3 (**$NaNO^2$**). This salt is not unfrequently employed as a source of nitrous acid, especially in researches on the volatile organic bases. Nitrite of soda possesses some advantages over nitrite of potash, owing to the comparative ease with which it is prepared.

SODA, PHOSPHATES OF. Several of these are known, but are not important in the arts. The principal are the normal tribasic phosphate, the well-known rhombic phosphate, the pyrophosphate, and the metaphosphate of soda.

SODA, SULPHATE OF. $NaO.SO^3 + 10HO$ (**$Na^2SO^4 + 10H^2O$**). This salt is obtained as a residue in several chemical processes, as in the manufacture of hydrochloric and nitric acids, &c., but owing to the enormous quantity used in the manufacture of carbonate of soda, it is made purposely as described under SODA, CARBONATE OF. It is known as *Glauber's salt*, and has been found native near Madrid, nearly pure, deposited at the bottom of some saline lakes, in anhydrous octahedra, called *Thénardite*, and also combined with sulphate of lime, as *Glauberite*.

It crystallises in oblique rhombic prisms which belong to the oblique prismatic system. Its taste is saline, and bitterish. It is very efflorescent, and loses all its ten equivalents of water by mere exposure to the atmosphere, at common temperatures.

SODA, SULPHITE OF. $NaO.SO^2 + 10HO$ ($\mathbf{Na^2SO^3 + 10H^2O}$). This salt is prepared largely for removing the last traces of chlorine from the bleached pulp obtained in the manufacture of paper, and is hence called *antichlore*.

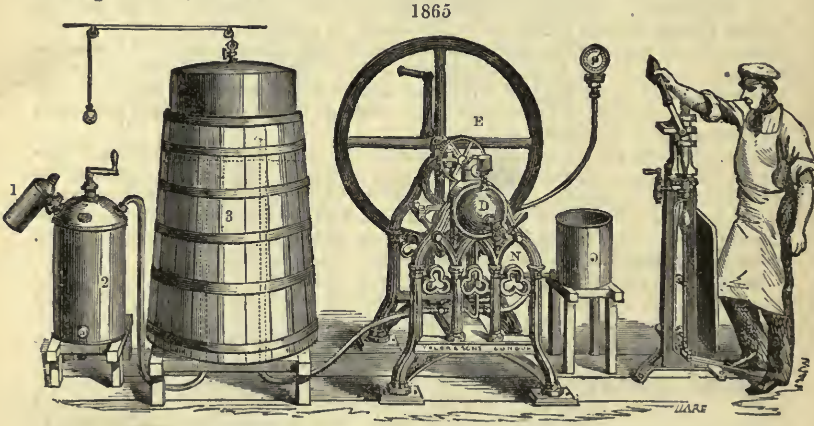
It is prepared by passing sulphurous acid gas through a solution of carbonate of soda, or on the large scale, by passing sulphurous acid gas, obtained by burning sulphur in the air, over crystals of carbonate of soda. It crystallises in oblique prisms, and is efflorescent, like the sulphate of soda, which it much resembles. Its taste is sulphurous, and it possesses a slight alkaline reaction.

A *bisulphite of soda* also exists, which forms irregular opaque crystals.

SODA-WATER. A favourite beverage, formed by super-saturating a solution of carbonate of soda with carbonic acid, produced under considerable pressure.

The accompanying wood-engraving represents the improved arrangements of the soda-water machine, as fixed for use, manufactured by Messrs. J. Tylor and Sons of 2 Newgate Street, London.

1865



To use this machine, it is necessary to fill the solution-pan o, with solution of soda, about one ounce of bicarbonate of soda to 2 gallons of water. Usually this solution is made in a large cistern of slate, or wood lined with lead, from which it is conveyed to the solution-pan, by means of a pipe and tap. The gasometer-tub (3) is filled with water up to a constant level, above which the opening of the pipe coming from the solution-pan is kept, while the other pipe, connected with the generator 2, is kept well under the water. The bell of the gasometer being down, about 14 lbs. of powdered whiting is mixed with water, to the consistency of cream, and poured into the generator (2) till it is about two-thirds full, when it is carefully closed. Next screw the leaden acid bottle (1) on to the generator. Take off the small cap on the top of bottle, and put in about a quart of diluted sulphuric acid—half acid and half water—and replace the cap. This should be mixed in an open vessel. Muriatic or nitric acid may be used, if sulphuric acid cannot be obtained. Swing the bottle slightly round, causing a little acid to fall into the whiting and water, at the same time turning round the agitator, the handle of which is on the top of the generator. As soon as the acid is mixed with the whiting and water, gas is generated and passes up the pipe into the rising bell, which it elevates by its pressure. The end of the other pipe is turned down below the surface of the water, so that the gas passing through it may become cooled and purified. The operation of making the gas should be conducted slowly, the acid bottle being so moved that only a small quantity of acid falls into the generator at a time, otherwise the gas would be generated too quickly, and throw the whiting and water into the pipe, and probably injure the generator.

When the addition of acid and the turning of the agitator fails to produce more gas, then the whiting is exhausted, and must be removed. It is important that this should be done after each time of using, before the whiting sets hard, or there will be a difficulty in getting it out, and a liability of straining or breaking the fan of the agitator.

The first time of using there will be a quantity of air in the bell, which is discharged by opening the cock. When the gas has a pungent smell it is fit for use.

The gas-tap and water-tap are provided with index-plates, which regulate the supply of gas and water to the pump of machine; they must be partly opened or closed by the person working the machine to suit the requirements. The machine must not be worked with the water-tap open alone. The machine being set to work the gas is drawn down the pipe, which stands above the level of the water, through the other pipe, and is forced into the condenser (D), where an agitator, worked by the spur-wheel (E), revolving rapidly, mixes it with the water which is drawn from the solution-pan O in like manner. When the pressure is up the safety valve will lift, and soda-water may be bottled from the nose (N). A pressure gauge may be recommended as very useful in enabling the person working the machine to keep the pressure uniform.

SODIUM. (*Symb.* Na; *At. Wt.* 23.) This metal was discovered by Sir H. Davy, almost immediately after potassium, and by the same means, viz., by exposing a piece of moistened hydrate of soda to the action of a powerful voltaic battery, the alkali being placed between a pair of platinum plates connected with the battery.

By this process only very small quantities can be obtained, but processes have since been devised which provide it in almost any quantity, and since the demand for sodium in the manufacture of aluminium by Wöhler's process, principally by the exertions of M. C. St.-Claire Deville, the cost of it has been considerably diminished. The process now adopted is the same as that for obtaining potassium. An intimate mixture of carbonate of soda and charcoal is made by igniting in a covered crucible a salt of soda containing an organic acid, as the acetate of soda, &c., or by melting ordinary carbonate of soda in its water of crystallisation and mixing with it, while liquid, finely-divided charcoal, and evaporating to dryness; this mixture is mixed with some lumps of charcoal and placed in a retort, which is generally made of malleable iron, but owing to the difficulty of getting them sufficiently large, earthenware or fire-clay retorts have been used with success, and sometimes these are lined with or contain a trough of malleable iron. These retorts are so placed in a furnace that they are uniformly kept at a heat approaching to whiteness.

The principal reaction which takes place in the retort, is the reduction of the soda by the charcoal, which is thus converted into carbonic oxide, which escapes through an aperture in the receiver made on purpose.

Sodium is a silver-white metal, very much resembling potassium in every respect; it is so soft at ordinary temperatures that it may be easily cut with a knife or pressed between the finger and thumb; it melts at 194° Fahr., and oxidises rapidly in the air, though not so rapidly as potassium. Its sp. gr. is 0·972. When placed upon the surface of cold water it decomposes it with violence, but does not ignite the hydrogen which is liberated, unless the motion of the sodium be restrained, when the cooling effect is much less. When a few drops of water are added to sodium the hydrogen liberated immediately inflames, and such is also the case if it be put on hot water; when burning it produces a yellow flame, and yields a solution of soda. The principal use of sodium is, as before stated, in the manufacture of aluminium, which is now carried on to a considerable extent.

SODIUM, BROMIDE OF. This salt resembles the bromide of potassium.

SODIUM, CHLORIDE OF. See SALT.

SODIUM, IODIDE OF. This exists in considerable proportion in the ash of burnt sea-weeds. See KELP.

SODIUM, OXIDES OF. When sodium is burnt in oxygen gas or in air, two different oxides are produced, viz. the protoxide and binoxide. These oxides very much resemble the corresponding oxides of potassium.

SODIUM, SULPHIDES OF. Several of these are known, resembling the corresponding salts of potassium, but they are of no importance in the arts.

SOJA. The legumes of *Soja hispida* are used in the preparation of soy, and are imported to this country from India.

SOLANINE. A poisonous alkaloïd of doubtful constitution, contained in various plants of the species *Solanum*, as *S. nigrum*, *S. Dulcamara*, and in the potato (*S. tuberosum*). It is remarkable that in the shoots of potatoes which have sprouted in dark cellars the quantity of solanine is greater than in the shoots which have germinated normally. Solanine requires reinvestigation.

SOLAZZI JUICE. A name given to the best kind of Spanish liquorice, Solazzi being the maker's name. See LIQUORICE.

SOLDERING. The process of uniting together pieces of metal, by the interposition of a fusible alloy, which is called either soft or hard solder, according as its fusing point is low or high. One process is called by its inventor, M. de Richemont, *autogenous*, because it takes place by the fusion of the two edges of the metals themselves, without interposing another metallic alloy, as a bond of union. See AUTOGENOUS SOLDERING.

SOLDERS. Alloys which are employed for the purpose of joining together metals are so called. They are of various kinds, being generally distinguished into hard and soft. Upon the authority of Holtzappfel, the following receipts for solder are given. and these have been adopted, because, after a long and particular inquiry in the workshops, we learn that they are regarded as very superior to any others recommended:—

Pewterers' Solder. (*a*) 2 Bismuth, 4 lead, 3 tin. (*b*) 1 Bismuth, 1 lead, 2 tin.

Soft Spelter Solder. Equal parts of copper and zinc.

Coarse Plumbers' Solder. (*a*) 1 tin, 3 lead, melts at about 500° Fahr. (*b*) 2 tin, 1 lead, melts at about 360° Fahr.

Spelter Solder. ·12 ozs. of zinc to 16 ozs. of copper.

SOLFERINO. See ANILINE RED.

SOMBRERITE. An impure phosphate of lime, from the island of Sombrero, in the West Indies. It appears to have been produced by the action of water, which having filtered through guano, has acted on a coral rock, whereby the carbonate of lime of the coral-limestone has been converted into a phosphate.

SOORANJEE, called also *Morindin*, a dye-drug prepared from the root of the *Morinda citrifolia*. See Crookes's 'Practical Handbook of Dyeing and Calico-Printing.' See AAL.

SOOT (*Noir de fumée, Suie*, Fr.; *Russ, Flatterruss*, Ger.) is the pulverulent charcoal condensed from the smoke of wood or coal-fuel.

SORBIC ACID is the same with malic acid. See MALIC ACID.

SORGHO. The name of a species of grass, the *Holcus* or *Sorghum saccharatum*. See BROOM CORN.

SORGHUM. A sugar-yielding grass has been introduced into the south of Europe and North America, the cultivation of which has extended with wonderful rapidity in the United States, in regions far to the north of those adapted to the sugar-cane. The seeds of this plant are a good grain, similar to the Durra so extensively cultivated in the East Indies and in Africa. The Durra (*Sorghum vulgare*), sorgho, or Indian millet, may be said to be the principal corn-plant of Africa; and the sugar-grass, or shaloo (*Sorghum saccharatum*) may be regarded as a superior kind of Durra.

The sugar-grass was introduced into Europe in 1851 by the Count de Montigny, the French Consul at Shanghai, who sent a package of seed to the Geographical Society of Paris, only one seed of which germinated, and from this plant a small quantity of ripe seed was produced; for eight hundred of which Messrs. Vilmorin, Andrieux, and Co. seed-merchants in Paris, paid eight hundred francs. Another portion of the same crop passed into the hands of the Count de Beauregard, and from these sources this seed was distributed over Europe and to America in 1857. Two years later, Mr. Wray took seeds from Africa to America, and two classes are now recognised there: the Chinese, or *sorgo*, and the African, or *Imphee*. The juice is expressed by mills, of which there are many kinds in use, wrought either by steam, water, or horses. The juice, as obtained from the mill, contains many impurities; dust and earth, small fragments of cane, and green vegetable-matter; these are in part removed by filtering through a straw filter, but more completely by skimming during the process of boiling; the syrup thus obtained is of a very good quality. The processes employed in procuring sugar from the sugar-cane in tropical countries are equally applicable in the case of the sugar-grass.

SOVEREIGN. The sovereign is the standard of value in Great Britain, and its weight is determined by the law that twenty pounds troy weight of standard gold shall be coined into 934½ sovereigns. To obtain the exact weight of one sovereign, reduce the pounds to grains and divide by the number of coins. A sovereign is thus found to weigh 123·2744783306581059 grains, and as it is usual to deliver the coin to the Bank in journey weights of 701 sovereigns, each journey should weigh, if it be standard work, 180·0321027287319442215 ounces; and a million sovereigns should weigh 256821·8298555377 troy ounces, in round numbers about 7·8618 tons.—G.F.A.

SOY is a liquid condiment, or sauce, imported chiefly from China. It is prepared with a species of white haricots, wheat-flour, common salt, and water; in the proportions respectively of 50, 60, 50, and 250 pounds. The haricots are washed, and boiled in water till they become so soft as to yield to the fingers. They are then laid in a flat dish to cool, and kneaded along with the flour, a little of the hot water of the decoction being added from time to time. This dough is next spread an inch or an inch and a half thick upon the flat vessels (made of thin staves of bamboo), and when it becomes hot and mouldy, in two or three days, the cover is raised upon bits of stick, to give free access of air. If a rancid odour is exhaled, and the mass grows green, the process goes on well; but if it grows black, it must be more freely exposed to the air. As soon as all the surface is covered with green mouldiness, which usually happens in eight or ten days, the cover is removed, and the matter is placed in the sunshine for several days. When it has become as hard as a stone, it is cut into small fragments, thrown into an earthen vessel, and covered with the 250 pounds of water having the salt dissolved in it. The whole is stirred together, and the height at which the water stands is noted. The vessel being placed in the sun, its contents are stirred up every morning and evening; and a cover is applied at night to keep it warm and to exclude rain. The more powerful the sun the sooner the soy will be completed; but it generally requires two or three of the hottest summer months. As the mass diminishes by evaporation, well-water is added; and the digestion is continued till the salt-water has dissolved the whole of the flour and the haricots; after which the vessel is left in the sun for a few days, as the good quality of the soy depends on the completeness of the solution, which is promoted by regular stirring. When it has at length assumed an oily appearance, it is poured into bags, and strained. The clear black liquid is the soy, ready for use.

SPANISH GRASS. See ESPARTO and PAPER.

SPAR, HEAVY or **PONDEROUS.** Sulphate of baryta. See BARYTA.

SPARRY IRON ORE, or **SPATHIC IRON.** (Syn. *Chalybite*, *Siderite*, *Siderose*, *Brown Spar*, &c.) Spathose iron ore has been largely worked on the Brendon Hills, in Somersetshire, and it is also found on Exmoor, and in Perranzabuloe, and at the iron mines on the north coast of Cornwall. It also occurs at Weardale in Durham. See IRON.

SPECIFIC GRAVITY designates the relative weight of different bodies under the same bulk: thus a cubic foot of water weighs 1,000 ounces avoirdupois; a cubic foot of coal, 1,350; a cubic foot of cast iron, 7,280; a cubic foot of silver, 10,400; and a cubic foot of pure gold, 19,200: numbers which represent the specific gravities of the respective substances, compared with water = 1,000. See GRAVITY, SPECIFIC.

SPECTRUM, *Solar* or *Prismatic*. If a pencil of solar light is admitted through a small hole, into a dark room, and allowed to fall upon the edge of a prism, a beautifully-coloured flame-like image is formed upon the opposite wall; the order of colours being red, orange, yellow, green, blue, indigo, and violet, the red being the least refrangible ray, and the violet the most so of the ordinary visible rays. Careful examination proves the yellow ray to be the most luminous; the red ray the most calorific ray; and the violet to possess the most energetic chemical power. Heat-rays, invisible under ordinary conditions exist below the red band; some of them having peculiar powers, are known as the parathermic rays; and chemical rays extend, with much power, far beyond the violet end of the visible spectrum. Luminous rays are also rendered visible at the most refrangible end of the spectrum by throwing the spectral image into a solution of sulphate of quinine, or on a piece of uranium glass, and some other substances; these are called the *fluorescent* rays. With this brief description of the Newtonian spectrum, as it is often called, (Sir Isaac Newton, being the first who investigated its striking phenomena) our readers must be satisfied. The practical applications of our knowledge form the subject of the next article.

SPECTRUM ANALYSIS. Dr. Wollaston was the first who observed the existence of non-luminous spaces or dark lines in the solar spectrum. Dr. Ritchie proved that these lines were dependent on absorption, and showed how they could be *increased in visible numbers by artificial means*. Fraunhofer, however, was the first to make a full investigation of them, and to publish a map of them; hence they have been generally called Fraunhofer's Lines.

These lines are of so fixed a character in relation to the coloured bands of the spectrum, that if it is desired to indicate with great precision any special rays of the spectrum, they are referred to by letters or numbers. The position the lines occupy have been determined by a careful examination of the map of Fraunhofer, and the very complete delineation of those lines published in the 'Philosophical Transactions' for 1859, by Sir David Brewster and Dr. Gladstone. Fraunhofer laid down on his map 354 lines, but Sir David Brewster says: 'In the delineations which I have executed, the spectrum is divided into more than 2,000 visible and easily recognised portions, separated from each other by lines more or less marked.'

The origin of these dark lines,—spaces in which there is no light,—can scarcely be said to be yet satisfactorily resolved. Fraunhofer, and others following him, thought that the light emitted from the photosphere was, from the first, deficient in those rays, or that they were lost, either by absorption in passing through the solar atmosphere, or obtained possibly in passing through that of the earth. Ångström, who also discovered many *bright lines* in the spectra from artificial lights, advanced some highly philosophical views in 1855. The dark lines of the solar spectrum, and the bright ones observable in the spectra obtained from artificial lights, were investigated by Professor Wheatstone, Dr. W. A. Miller, Mr. Fox Talbot and Sir John Herschel. These investigators proved that the spectra obtained from the light emitted from incandescent mineral bodies differ from that obtained from the sun; that the lines from artificial sources of light are, in many cases, peculiar; and that, in the majority of instances, *bright lines* appear to take their place. So rigidly exact were the positions and characters of the lines obtained from differently-coloured flames, that both Wheatstone and Miller suggested the adoption of spectral or prismatic analysis, as a means of determining the presence of exceedingly minute quantities of any substance. The more recent investigation of Bunsen and Kirchoff have, from their high interest, again drawn attention to this subject. These lines have been employed in the analysis of the solid mass of the sun itself; and the extreme delicacy of the indications is proved from the discovery of two new metallic bodies, one called *Cæsium* (meaning bluish-grey), and the other *Rubidium* (from the Latin *rubidus*, which was used to express the darkest red colour), which existed in infinitesimally small quantities in some mineral waters of Germany. *Thallium* was afterwards discovered by Mr. W. Crookes, and *Indium* by Professor Richter, by means of the spectrum. To render the phenomena, and the hypothesis involved, intelligible within the short space which can be given to the subject to those who may not have studied it, it is necessary to recapitulate, and enter a little into detail. The image produced by decomposing a white sunbeam consists of certain brilliantly-coloured rays, but those rays are crossed by spaces giving no light. The dark lines are always found in the same places in the solar spectrum, but they vary in number under different aspects of the sun and varying conditions of the earth's atmosphere. When the sun shines in its meridian splendour from a clear sky, the number of dark lines is slightly different from those observed when the sun, being near the horizon, has to penetrate a greater depth of atmosphere. 'It is,' says Dr. Gladstone, 'a most beautiful and striking sight to observe the gradual appearance of those characteristic lines as the sun descends towards the horizon,' proving that some of these non-luminous spaces are due to terrestrial atmospheric absorptions. To quote again the same authority: 'That the earth's atmosphere has much to do with the manifestations of those lines, is beyond all question, and the analogy' (alluding to some very striking experiments made by Dr. Miller) 'of such gases as nitrous acid or bromine vapour, *suggests the idea that they may originate wholly in the air that encircles our globe.*' The spectra, obtained from some artificial sources of light, exhibit the coloured rays shading one into the other; while those produced by some others consist of a series of *luminous bands*, separated by dark spaces; and *these luminous bands are frequently found to coincide with the dark lines of the solar spectrum.* Dr. W. A. Miller observed that an intense yellow ray observable in the spectra, obtained from the flames coloured with soda, lime, strontia, baryta, zinc, iron, and platinum, and, according to Ångström, in the electric light of *every metal burnt* by him, had the same refrangibility as the line D in the solar spectrum.

Pyrotechnic displays will have made the least scientific of our readers acquainted with the fact, that we may, by burning certain mineral substances, produce very intensely-coloured lights. Soda, or common culinary salt, gives a monochromatic yellow; strontia produces the red fires of our theatres; barytes, the pale green of ghost scenes; copper burns with a green flame, iron with a yellow-brown one, and lithium with a brilliant crimson. Now, if these flames be examined through a prism, or if a concentrated pencil from those artificial sources of coloured light be passed through one, we obtain well-marked spectral images.

The next step in the process of the investigation instructs us in the fact, that the vapours producing those coloured flames are opaque in their own rays. That is to say, if we produce a yellow soda-flame, and from it obtain a spectrum showing the peculiar soda lines in their bright yellow colour, and then impregnate the air with some soda-vapour, by volatilising soda between the flame and the spectrum, the *bright yellow line* becomes at once *a black line.* This holds true for all the substances which have yet been examined. The coloured bright lines are converted into dark lines, if the rays from the coloured flames are made to permeate vapours of the same constitution as those which produced the particular spectrum under examination.

Kirchoff and Bunsen lay great stress upon the sodium spectrum, as proving the extreme delicacy of this mode of analysis. The yellow line, the only one seen, is coincident with the dark line D of Fraunhofer. This beautiful bright yellow line is observable when less than 1-20,000,000th of a part of soda-vapour is mixed with air. From the circumstance of the air of these islands having almost always some saline matter floating in it, the yellow line of the sodium spectrum is rarely absent. The lithium spectrum gives two sharply-defined lines: one a bright red, the other a yellow one, the former apparently corresponding with line five between B and

C of Brewster's spectrum; it is not easy to determine accurately with which of the dark lines this yellow line is coincident. Strontium gives six red, one orange, and one blue line. Calcium and its salts, a bright green line, an intensely bright orange line, and the paler intermediate bands. Barium gives well-defined green lines, some yellow lines, varying in intensity, an orange line, and indications of red.

Incandescent gases and vapours give off light of certain definite degrees of refrangibility, or they furnish spectra consisting of certain fixed lines; and those incandescent gases or vapours absorb light of the same degree of refrangibility as that which they emit. This is (reasoning by analogy) only the expression in relation to *light* of the celebrated statement made in regard to *sound*, *that a body absorbs all the oscillations which it can propagate*.

Spectrum analysis has been applied with success to determine the moment when in the process of making steel by the Bessemer process the whole of the carbon is exhausted. For a full account of Spectrum Analysis, see Watts's 'Dictionary of Chemistry.'

SPECULUM METAL. The metal employed in the mirrors of reflecting telescopes. The late Earl of Rosse, who was eminently successful in the production and polishing of large specula, says, in his paper published in the *Transactions of the Royal Society*, 'Tin and copper, the materials employed by Newton in the first reflecting telescope, are preferable to any other with which I am acquainted, the best proportions being 4 atoms of copper to one of tin, in fact, 126·4 parts of copper to 58·9 of tin.'

Mr. Ross remarks that when the alloy for speculum metal is perfect, it should be white, glassy, and flaky. Copper in excess imparts a reddish tinge, and when tin is in excess the fracture is granulated and less white. Mr. Ross pours the melted tin into the copper when it is at the lowest temperature at which a mixture by stirring can be effected; then he pours the metal into an ingot, and, to complete the combination, remelts it in the most gradual manner, by putting the metal into the furnace almost as soon as the fire is lighted. Trial is made of a small portion taken from the pot immediately prior to pouring.

SPEISS. A compound of nickel, arsenic, and sulphur, containing small quantities of cobalt, copper, and antimony; it is found at the bottom of crucibles in which smalt is manufactured. See COBALT.

SPELTER or **SPELTRUM.** See ZINC.

SPERMACETI; the *Cetine* of Chevreul. In certain species of the *cachalot* whale, as the *Physeter macrocephalus*, and the *tursio*, *microps*, and *orthodon*, as also the *Delphinus edentulus*, the fat of some parts of their bodies contains a peculiar substance, called spermaceti. The head is the principal part from whence it is obtained. In the right side of the nose and upper surface of the head of the whale, is a triangular-shaped cavity, called by the whaler's, 'the case.' Into this the whalers make an opening, and take out the liquid contents (oil and spermaceti) by a bucket.

The dense mass of cellular tissue beneath the case and nostril, and which is technically called the 'junk," also contains spermaceti, with which and oil its tissue is infiltrated. The spermaceti from the *case* is carefully boiled alone and placed in separate casks, when it is called 'head matter.' This 'head matter' consists of spermaceti and oil. For the purpose of separating the spermaceti from the oil, it is cooled, when the spermaceti congeals, and is separated by being thrown into large filter bags, when the oil filters through, leaving the spermaceti behind; the solid thus obtained is subjected to compression in hair-bags, placed in an hydraulic press. It is then melted in water, and the impurities skimmed off. Then it is remelted in a weak solution of potash to remove the last particles of oil, washed in water, and fused in a tub by the agency of steam, laded into tin pans, and allowed slowly to cool, when it forms a white, semi-transparent, brittle, lamellar, crystalline mass. Commercial spermaceti usually contains a minute portion of sperm oil, which may be removed by boiling with alcohol; the spermaceti dissolves and again separates on cooling, in order to obtain it perfectly pure, this process must be repeated until the alcohol separates no more oil.

When absolutely pure, spermaceti is a white laminated substance, without taste, and most odourless, and in this case it is called *cetine*. By the addition of a few drops of alcohol or almond oil, it may be powdered. At 60° its sp. gr. is 0·943. It melts at 120°, and at 670° may be sublimed unchanged. It is insoluble in water, slightly soluble in alcohol, and much more so in ether; it is also soluble in the fatty and volatile oils, and if the solution be saturated when hot, the greater part of the spermaceti separates on cooling.

Spermaceti is only saponified with difficulty, in which process it is separated into two distinct substances: one, $C^{32}H^{34}O^{2}$ ($\mathbf{C^{16}H^{34}O}$), belonging to the series of alcohols, is called *cetylic* (*ethalic*) *alcohol*; and the other *cetylic* (*ethalic*) *acid*, $C^{32}H^{32}O^{4}$ ($\mathbf{C^{16}H^{32}O^{2}}$);

the first is a crystallisable fat, whose melting point is nearly the same as that of spermaceti itself, but it is much more soluble in alcohol; it is readily sublimed without decomposition. Cetylic acid stands to cetylic alcohol in the same relation as acetic acid to ordinary alcohol, and may be actually procured from it by oxidation. It resembles in many respects margaric acid. By oxidation by nitric acid spermaceti yields a large quantity of succinic acid.

Spermaceti is a cetylate of oxide of cetyl, and represents in the cetyl series the acetic ether of the common alcohol series. It may also be regarded as a palmitate of cetyl.

SPERM WHALE. *Physeter macrocephalus.* The animal inhabiting the Pacific and Indian Oceans which produces the sperm oil and spermaceti.

SPHENE. A compound of titanate and silicate of lime. See TITANIUM.

SPHEROIDAL STATE. The name given by Boutigny to the condition assumed by water when projected upon red-hot plates or into red-hot vessels. The fluid gathers into a spheroïdal drop, moving with a quick intestinal motion, but under this condition the temperature never rises to the boiling point. See EVAPORATION.

SPICES. See the separate articles on different kinds of spice.

The Spices imported in 1873 *and* 1874 *of which we have returns are the following:*

SPIEGELEISEN. A term applied to a particular variety of highly carburised pig-iron, usually containing a proportion of manganese. It is produced when smelting ores containing iron and manganese, under conditions which, with ordinary ores, would produce grey iron; that is with a large proportion of fuel to charge, very basic slags from the use of a large quantity of flux, and dense and hot blast. The name is derived from the largely facetted structure of the fracture, which resembles plates of glass. The structure is developed by cooling the iron under the slag, and is not indicative of the proportion of manganese. The amount of carbon is a maximum of 6 per cent., whilst the manganese may reach 15 per cent. Beyond this amount the carbon diminishes, and the bladed structure disappears, while the alloy becomes known as *ferro-manganese.*

The principal localities for the manufacture are in the Rhenish provinces of Prussia, where it is made from the spathic ores of Siegen, mixed with brown and red iron-ores of the same locality, and from foreign countries; low-class manganese-ores from Nassau being used to increase the proportion of manganese when deficient. Under favourable circumstances from ¼ to ⅓ of the manganese in the charge passes into the slag; whilst from ¾ to ½ is reduced. In this country the ore used is principally the manganesiferous brown ores of Carthagena, or mixtures of iron-ores with others containing manganese. The average of the best Rhenish spiegeleisen contains about 10 per cent. of manganese. It was formerly used for re-carburizing the overblown metal in the Bessemer converter, but now an alloy richer in manganese is generally preferred. The lower quality of spiegeleisen is used for conversion into wrought iron in the puddling furnace.

Spiegeleisen is made in America from Franklinite, and in Sweden from Knebelite.

As the conditions of working are similar to those in producing grey iron all the phosphorus contained in the ore will be reduced; it is therefore necessary to be as careful in selecting the materials for spiegeleisen as in making Bessemer pig-iron.

The iron made from ores with a smaller proportion of manganese than can be used for making spiegeleisen is known as *spiegelig* or *weiss-strahlig*, which has either small facetted, or a columnar, fracture. A pig-iron of this class, containing about 2 per cent. of manganese, is made at Weardale, in Durham, from the spathic ores in the lead mines of that district. See STEEL.

SPINDLE-TREE OIL. See OILS.

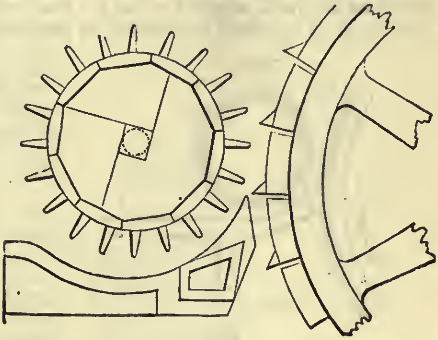
SPINEL or **SPINELLE.** See RUBY.

SPINET, THE. A musical instrument which was much admired by our grandmothers. It had some resemblance in shape to a modern semi-grand piano, but was much smaller, and, though sufficiently pleasing, very much less effective in tone. It was played similarly to the modern method, by means of keys putting in motion a mechanism to touch a single string, which emitted the sound on being struck. The instrument being small, and its mechanism slight and simple, its price was proportionately moderate, and the spinet was thus within the reach of those who could not afford the more pretentious and elaborate harpsichord.

The *Clavicord* was a similar instrument, but smaller; and instead of being struck by a jack, the strings were pressed by brass-pins projecting from the end of the keys. It was sometimes called a clarichord, and occasionally the manuchord. Under these names, the spinet is often confounded.

SPINNING. The greatest improvement hitherto made in forming textile fabrics, since the era of Arkwright, is due to Mr. G. Bodmer of Manchester. By his patent inventions, the several organs of a spinning-factory are united in one self-acting and self-supplying body—a system most truly *automatic.* His most comprehensive patent was obtained in 1824, and was prolonged by the Judicial Committee of the Privy Council, for 7 years after the period of 14 years was expired. It contained the first development of a plan by which fibres of cotton, flax, &c., were lapped and unlapped through all the operations of cleaning and blowing, carding, drawing, roving, and spinning; in the latter, however, only as far as the operation of feeding is concerned. The patent of 1824 was the beginning; the result of which was several other patents for improvements.

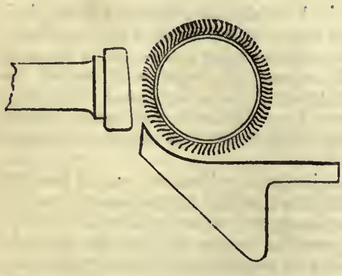
1866



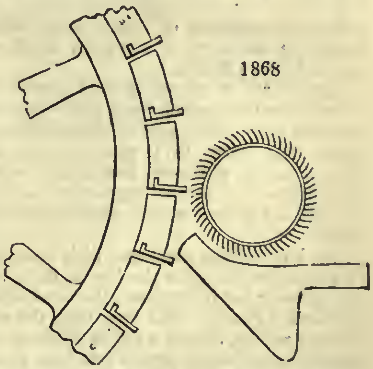
By a machine generally called a Devil or Opener ('*Wolf*,' in German), which consists of a feeding-plate set with teeth, and a roller covered with spikes (see *fig.* 1866), the cotton is cleared from its heaviest dirt and opened. This machine delivers the cotton into a room or on to a travelling-cloth, from which it is taken, weighed in certain portions, and spread upon cloth in equal portions; this is then rolled up, and placed behind the first blower.

The first blower has a feeding-plate like *fig.* 1867 without teeth, and over this plate the cotton is delivered to the operation of the common beaters, from which it is received into a narrow compartment of 4½ or 5 inches broad, and wound, by means of his lap-machines, upon rollers in beautifully level and well-cleaned lays. Eight of these narrow laps are then placed behind a second blower, of a similar construction to the first. Instead of the common beater, however, a drum with toothed straight edges is used (see *fig.* 1868), which opens the

1867



1868

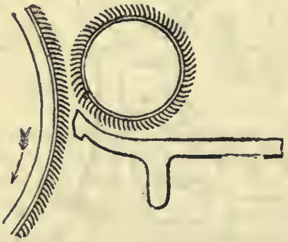


cotton still more, and separates the fibres from one another. The cotton is again formed into similar narrow laps, which are still more equal than the preceding ones, and eight of these laps are then placed behind the carding-engines. It was only by applying the lap-machine, that he succeeded in forming small laps on the blower; without this the doffing of the laps without stopping the wire-cloth could not be effected, and in doing this, an irregular lap would be formed, because of the accumulating of the falling cotton in one place while the wire-cloth was standing.

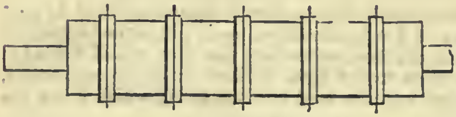
Carding Engine.—When a set of cards work together, any interruption or stoppage of a single carding-engine causes a defect in the produce of the whole lap. Interruptions occurred several times a day by the stripping of the main cylinder, and during this operation, the missing band or silver was supplied out of a can, being the produce of a single carding-engine working into cans (a spare card). The more objectionable defect was, however, the difference of the product of the carding-engine after the main cylinder had been stripped; the band or silver from it will be thin and light, until the cards of the main cylinder are again sufficiently filled with cotton, when the band will again assume its proper thickness. Another irregularity was caused by the stripping of the flats or top cards, but was not so fatal as the first one. These defects were, of course, a serious drawback to the system of working, the latter of which was provided against by stripping the top cards by mechanism; the former was conquered by the invention of the self-strippers for the main cylinders; thus the carding-engine may now work from Monday morning to Saturday night without interruption, the cylinders requiring only to be brushed out every evening; the consequence is, that much time is gained, and a very equal, clean, and clear product is obtained. Old carding-engines to which he applied his feeders (see *fig.* 1869) and main cylinder-clearers produce much superior work, and increase the production from 18 to 24 per cent.

The main cylinder-clearer consists of a very light cast-iron cylinder, upon which five, six, or more sets of wire-brushes are fixed, which are caused to travel to and fro across the main cylinder; the surface or periphery of the brushes overrunning the

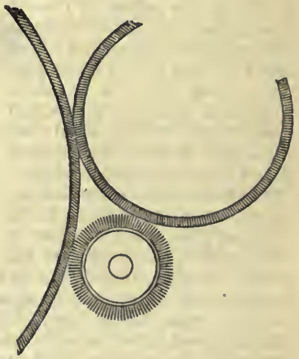
1869



1870



1871



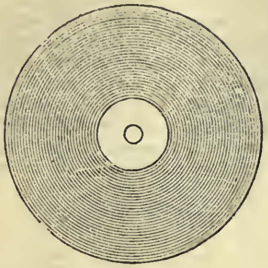
surface or periphery of the main cylinder by 8 or 19 per cent., the brushes thus lifting the cotton out of the teeth of the cards of the main cylinder, and causing the dirt and lumps to fall.

As the brushes are not above a quarter-inch in breadth and travel to and fro, it is clear that no irregularity can take place in the fleece which comes from the doffer; not more than 1-40th part of the breadth of the cylinder being acted upon at the same time. *Figs.* 1870, 1871, give an idea of the clearer: the mechanism within the clearer, and by which the brushes are caused to travel is simple and solid. The main cylinders for the carding-engines are made of cast iron, the two sets of arms and rims are cast in the same piece; when complete, they weigh 50 lbs. less than those made of wood.

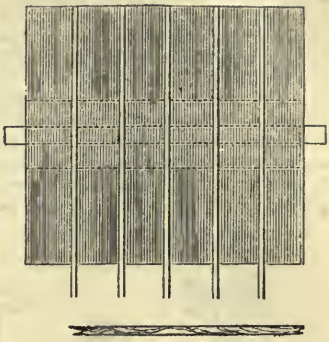
The lap machine connected with these engines is almost self-acting; a girl has only to turn a crank when the lap is full; by this turn the full lap is removed, and an empty roller put in its place, the band of cotton is cut, and no waste is made.

Drawing Frame.—The laps from the carding-engine lap-machine are put upon delivering rollers, behind a set of drawing rollers, and from them delivered upon a belt or trough, and again formed into laps similar to those from the carding-engines. The next operation formed the laps into untwisted rovings, and the next again into smaller untwisted rovings, or rovings with false twist in them. The false twist was objectionable, and a number of rovings on the same bobbin, with left and right permanent twist in them was adopted. This does very well; there is, however, a little objection to that place in which the twist changes from right to left when it comes to the last operation before spinning. The left and right hand twist is confined to the drawing-frame, which converts two laps into one roving, and forms a roller or bobbin of 14 inches diameter and 15 inches broad, with six separate and twisted rovings wound upon it. (See *figs.* 1872, and 1872*a.*) The twist is given by tubes in two directions, so that it remains in it (see *fig.* 1872*a*), the tube turns in the same

1872



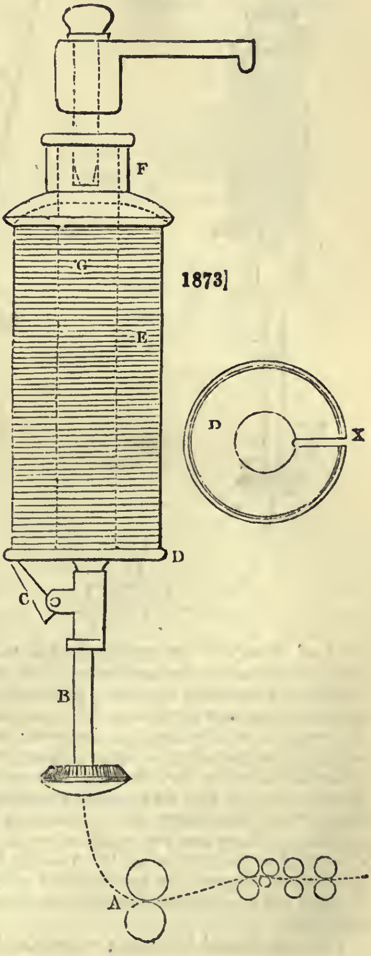
18



direction, while the roving advances 4 or 5 inches, and then turns in the other direction. These laps or bobbins are then placed behind a machine, which he calls a coil-frame, the most important arrangement of which he claimed already in his patent of 1835. It consists of a slot, with a travelling spout, without which the coils cannot be formed under pressure.

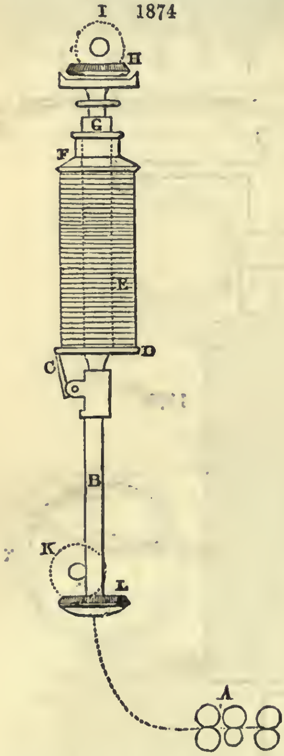
Coil Frame.—The bobbins (*fig.* 1872) are placed behind this machine, and two ends from the bobbin are passed through the drawing rollers, and formed into one untwisted silver or roving in the following manner :—When the cotton has passed through the drawing rollers and calender rollers, A, (see *fig.* 1873) it is passed through the tube, B, and the finger, C; the spindle with its disc, D, revolves in such a proportion as to take up the cotton which proceeds from the calendar rollers, A, and cause the rovings to be laid down in a spiral line closely, one by one; and as the rollers, A, work at a regular speed, it is evident that the motion of the finger, C, and the speed of the tube, B, must vary accordingly. The coil, E, is stationary, and is pressed by the lid or top, F, which slides up the spindle, G, made of tin-plate. The cotton enters through the slot, X, *fig.* 1873. It is quite evident that the finger, C, and spindle, G, only perform one and the same varying motion, which is repeated at every fresh layer, and the coil is thus built from below; it is about 8 inches in diameter and 18 inches high when compressed, and contains 4½ lbs. of cotton. There are several modes of forming these coils, but one only is shown here. These coils are placed behind the twist-coil frames in half-cans or partly open ones or troughs, or behind a winding machine, where they are wound upon rollers side by side, like the lap or bobbin shown in the drawing frame, and placed behind the twist-coil frame in this state.

1873]

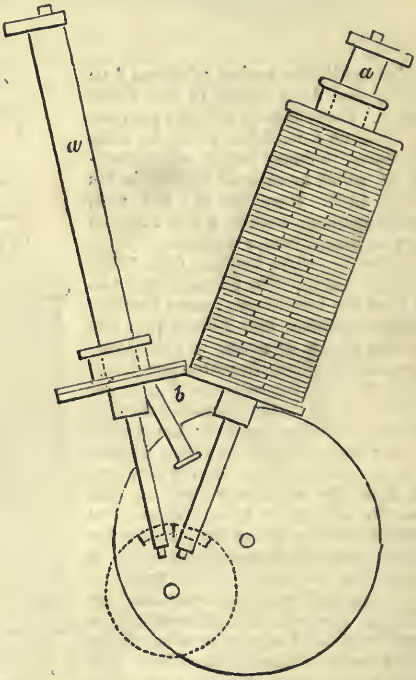


Twist-coil Frame.—This frame forms rovings into coils similar to those above explained, with this difference: that the rovings are fine, say, from 1 to 10 hanks per pound, and regularly twisted; their diameter varies from 2½ to 5 inches. The same machines produce rovings more or less fine, but the diameter of the coils does not differ. The difference of this machine from that above described consists in the dimensions of their parts, and in its having the spindle, G, and the lid or top, F, revolving, as well as the tube, B. (See *fig.* 1874.) In this machine the motion of the spindle, B, is uniform: the spindle, G, however, is connected by the bevel-wheels, H and I, with a differential motion at the end of the frame, with which the motion of the finger, C, corresponds. The skew-wheels, K and L, are connected with the drawing rollers, A. The speed of the tube, B, and the spindle, G, are so proportioned, that while the spindle, G, performs one revolution, and therefore puts one twist into the roving, the tube, B, also performs one revolution, missing so much as will be required to pass through the slot in the cap or disc, D, and lay on it as much of the roving as proceeds from the rollers, A, and in which one twist is contained. Of course the

1874



1875

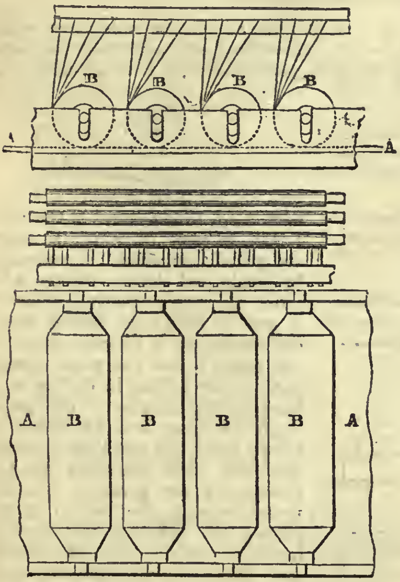


twist of these rovings can be adapted to their fineness and varied; but it is evident that, on account of the regularity of the machine and its simplicity of movement, the rovings can never be stretched, and much less twist can be put into them than can be put in the common fly-frames. These coils are put behind the spinning machines on shelves or in small cans, open in front; or they are wound from 24 to 72 ends upon bobbins, and placed upon unlap rollers behind the spinning frames.

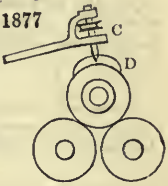
Coiling Machine for Carding Engines and Drawing Frames.—These are simple machines, which may be applied to carding engines or drawing frames of any description. They form large coils, 9 inches in diameter and 22 inches long, when on the machine. There are two spindles (see *a, fig.* 1875) on each machine, for the purpose of doffing without stopping the drawing frame and carding engines. When one coil is filled, the finger, *b*, is just brought over to the other spindle, so that the full coil is stopped and the new one begins to be formed without the slightest interruption of the machine.

Coils are formed in various ways, also in cans; but this description is sufficient to show the application of this mode of winding up bands or rovings. Several of the above-described machines are adapted with equal success to wool and flax. Winding directly from the carding engines the slivers separately upon long bobbins, twist is given in two directions, for the purpose of uniting the fibres to some extent, so that they may not only come off the bobbins without sticking to one another, but also that they may draw smoother. Another machine is used by which several rovings, say 4 or more, are put upon the same bobbin with conical ends; these bobbins are placed behind the mules or throstles, and are unwound by a belt or strap running parallel with the fluted rollers of the spinning machine, as seen in *fig.* 1876. The belt or band, A, is worked in a similar way to that described in a former patent, and the bobbins, B, rest upon and revolve upon their surface, exactly according to the speed of the belt. The most important feature in the roving machine is a metal plate, in which a slot is formed through which the rovings pass; this slot is seen in *figs.* 1877, 1878, and 1879.

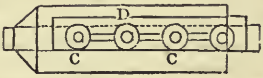
1876

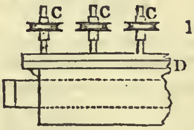


1877



1878





1879

The cotton, when coming from the drawing rollers, is passed through the twisters, C, and through the slot in the plate, D. Any convenient number of neatly-formed and perfectly separate coils can be put upon the wooden barrel or bobbin. The bobbin formed upon these machines is represented in *fig.* 1880, and the conical ends are formed by a mechanism, by which the twisters, C, are caused to approach a little more to one another, after each layer of rovings has been coiled round the barrel: the section of the bobbin is, therefore, like that shown in *fig.* 1880.

Rovings wound upon bobbins by means of tubes revolving in one direction are certainly not so fit for spinning as rovings into which a small degree of twist is put. The tube by which a twist is put in on one side and taken out at the other, curls or ruffles the cotton, and causes it to spread out as it passes between the rollers, while rovings with a little permanent twist in them are held together in the process of drawing, and thus produce smooth yarn. To remedy the evil above described, when untwisted rovings are used, the spouts or guides, through which the rovings pass into or between the drawing rollers, are made to revolve slowly, first in one, and then in the other direction, and thus a certain quantity of twist is put into the rovings while they are being prepared for spinning.

There is a little defect in the working of the rovings with reversed twist when too much or too little twist is put in them, or when the winding machine is not kept in good order. This defect proceeds from the change in the twist of the roving seen at A, *fig.* 1881; in this place the twist is not like that at B, and it would in some parts of the yarn, be detected under circumstances just described. In cases where double rovings are used, the twisters are so arranged as to put the twist in the rovings,

1881

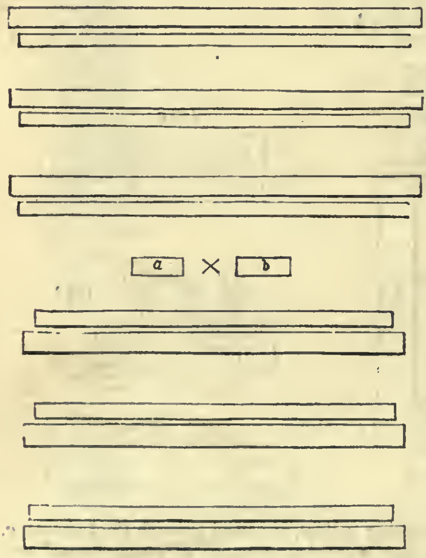
as shown in *fig.* 1882; in this case the reversing place of one roving meets the twisted place of the other, and the fault is completely rectified.

A self-actor, namely a machine in itself, which can be attached to 2, 3, or even 4 mules of almost any convenient number of spindles is sometimes employed. The

1882

mules are previously stripped of all their mechanism, except the rollers and their wheels, the carriage and spindles; all the other movements ordinarily combined with the mule are contained in the machine, which is placed between a set of mules, as

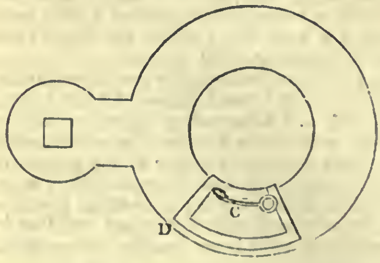
1883



1884

seen in *fig.* 1883; *a* and *b*, the self-actors, to each of which 3 mules are yoked, and which are connected by bands and shafts with the self-actor, or rather partly self-actor. A girl of fifteen or sixteen years old stands at × between *a* and *b*, and never leaves her place except, perhaps, for aiding in doffing or in banding the spindles. The gearing of the room acts by means of straps upon the machines *a* and *b*, and from these machines all the movements are given to the six mules, namely, the motion of the rollers, the spindles, the drawing out of the carriage, the after draft, &c. When the carriages are to be put up, the girl takes hold of two levers of the machine *a*, and by moving them in certain proportions, acts upon two cones and pulleys, and thus causes, in the most easy and certain manner, the carriages to run in and the yarn to be wound on the spindles. The first machine made for this purpose was completely self-acting, but it was found that the mechanism was more complicated and apt to get out of order; and as it was necessary to have a girl of a certain age to watch over the piecers for a certain number of mules, the simplified machine above described was adopted; placing the girl near these machines, from whence the whole set of mules attached to the same can be overlooked; as the creels behind the mules are not wanted in this system, this impediment to the sight of the girl would be removed.

1885



Bastard Frame.—The simple bastard frame is a throstle with mule spindles, forming cops, as seen in *fig.* 1884, and wound so hard that they can be handled about without any danger of spoiling them; in the same dimensions they contain one-third more yarn than the best cops of self-actors. The machine is extremely simple; but with them they are not able to spin advantageously upon large machines above No. 20's. The quantity this machinery produces is nearly one-third more than the best self-actor, on an equal number of spindles, and the yarn and cops are much superior. Of course there is a copping motion connected with the machine: the winding, however, is continuous, as well as the twisting, and *figs.* 1885 and 1886 will give the reader an idea of the frame. The yarn coming from the rollers, A, goes through an eye, B, to the wire, C, fixed in the flyer, D, and from thence on the mule spindle, E: as the spindle revolves, the flyer is dragged along, and by its centrifugal power winds the yarn tight upon the spindles.

SPLINT COAL. Sometimes *Splent.* A term, originating in Scotland, and applied to a hard and sometimes imperfectly-laminated variety of bituminous coal. The name appears to be derived from its splitting (Scot. *splenting*) up into flakes, or laminæ. The splint coals are a valuable variety, since they burn with great heat, and do not cake.

SPONGE. (*Éponge*, Fr.; *Schwamm*, Ger.) Although for a long time it was a disputed point whether the sponge of commerce belonged to the animal or the vegetable kingdom, its animal nature is now well proved, and sponges are regarded as a family of animals forming a class by themselves, *Porifera* or *Spongidæ*.

The sponge consists of a soft gelatinous mass, mostly supported by an internal skeleton composed of reticularly anastomosing horny fibres, in or among which are usually imbedded siliceous or calcareous spicula. Sponges are mostly marine; two or three species only being found in fresh water. In the living state they possess lively colours, and usually grow in groups, upon rock, shells, polypes, crustacea, and occasionally on sea-weeds. The horny fibres forming the skeletons of sponges are cylindrical and variously united, so as to form a network, often of great beauty. By dissolving the chalk from the sponge-formed fossil in that formation, many very delicate and regular systems of meshes may be obtained. Some beautiful siliceous sponge-skeletons have been brought to this country from the Japanese seas. The gelatinous substance covering the skeleton of sponges resembles the sarcode of which the *Amœbæ* are composed, and appears to consist of minute 'sponge particles,' those lining the internal chambers being furnished with cilia. During life, by means of these, water, entering by the small apertures, or pores, and reaching the channels, is expelled in intermittent currents through the large 'oscula.' Sponges are fixed by a kind of root, by which they hold firmly to any surface upon which they once fix themselves. Sponges may be propagated by division, but more usually by gemmules, which detach themselves from the parent body, and float about until they find a fitting resting-place, when they fix themselves and grow. Sponges adhere firmly to the rocks or other bodies upon which they grow, and are not to be detached without considerable trouble. The inhabitants of the Grecian Archipelago are trained from infancy to dive for these substances. Naturalists distinguish three kinds of sponges, each of which is composed of many species, and these form as many groups or divisions. The genus *Spongia*, which comprehends the sponges of commerce, is the type. The siliceous sponges, *Silicea*, have the body, or gelatinous portion, curiously strengthened with siliceous spicula. The calcareous sponges, *Calcarea*, have spicula of carbonate of lime supporting a sub-cartilaginous substance, which is not so soft as the coverings of the other sponges. The horny sponges, *Cornea*, have no spicula, the body is very porous and elastic, being composed of a fibro-corneous skeleton, the parts of which communicate with each other in all directions.

The sponges of commerce are obtained from the Mediterranean, Smyrna being the principal mart. Sponges are treated with muriatic (hydrochloric) acid to remove the lime; they are then dried, well beaten, and again soaked in water, which is frequently changed. Very inferior sponges are prepared for the English market by bleaching, either with hydrochloric acid or chlorine. By this means a very good colour is produced, but the sponge is rendered very rotten.

An interesting account of the sponge fishery of the Ottoman Archipelago, by M. Bilioti, the British Vice-Consul at Rhodes, appeared in the *Technologist*, from which the following particulars are abstracted:—'Sponges form the principal article of exportation from this district, and a great portion of them is sent to Great Britain. There are nearly as many different qualities of fine, common, and coarse sponges as there are spots of fishery. The sponges in this quarter are known in commerce by the names of the respective coasts where the inhabitants of the islands of the Ottoman Archipelago dive for sponges. These may be divided into five categories, besides the ordinary classification of fine, common, and coarse.'

Merchants when they purchase sponges take into consideration the form, size, and colour, the quantity of extraneous matter, such as stones and sand, which come out in proportion of their being washed more or less when fished. All this renders the trade very difficult, the more so as (with the exception of Mandruha and Bengazi, which are sold at so much a piece) the sponges are usually sold in a lump. Latterly the divers have offered their sponges for sale without sanding them (finding that it was no profit to do so), and the merchants again purchase them by weight.

A French *savant*, M. Artus, has been experimenting on the bleaching of sponges. Some good sponges were well washed in river-water. Whilst still wet, they were placed in a bath of six parts water and one part commercial hydrochloric acid, and were allowed to remain until all the carbonic acid gas was discharged. They were then washed again, and afterwards strung together and immersed in hydrochloric acid diluted with 6 per cent. of hyposulphite of soda dissolved in water. The vessel was then closed and left for 48 hours, when the sponges were taken out, washed and dried. M. Artus tried another experiment in which the quantity of hyposulphite of soda was doubled. In a third experiment the sponges were, on removal from the bath, treated with hydrochloric acid, subsequently washed, and then exposed to sulphurous acid gas. The sponges, however, by each of these processes were not thoroughly bleached, and a fourth method was tried. The sponges were well washed in hot diluted soda-lye, then placed in a bath of weak hydrochloric acid and hyposulphite of soda, using only half the quantity of hyposulphite that was used in the first experiment, and a very satisfactory result was thus obtained.

SPONTANEOUS COMBUSTION. Major Majendie has recently (1874) communicated to the Royal Artillery Institute some interesting experiments made by Mr. Galletly on this subject. It was found that cotton-waste, soaked in boiled linseed oil and wrung out, if exposed to a temperature of 170° Fahr., oxidised in 105 minutes. Raw linseed oil required from four to five hours before igniting; rape and olive oils five to six hours; lard oil four hours; castor oil one day; and, in one trial, olive oil ignited in 100 minutes. Sperm oil did not char the waste. His theory is, that the oil by being spread and finely divided among the fibres of the waste, has its absorbent power towards oxygen greatly increased, much as a bloom of iron will oxidise rapidly in process of manufacture if exposed to the air. It was also found that ignition took place more quickly with silk waste than with cotton. A scientific journal, commenting on this report, declares that the sperm oil of the experiment must have been adulterated with petroleum, which has a tendency to repress such oxidation, as it has been proved by other trials that sperm oil will rapidly absorb oxygen as certainly as other oils; but no case of spontaneous combustion has yet been reported from coal oils.

Many fires have occurred in woollen and cotton mills from the careless leaving of oily waste in warm places, especially during the summer months, and for safety it is necessary that such waste be removed daily. Shoddy mills, where the rags after being oiled are torn into fibre, are especially dangerous, as either from inferior oil used, or the adulteration of No. 1 lard oil with the dangerous cotton-seed oil, the shoddy often takes fire in the bags before leaving the works, or soon after reaching the mill where it is to be manufactured. Two other causes may aid in causing such fires: packing the material too soon and too tight, and putting on too much oil. The latter is a profitable arrangement, and too much practised. The only safety for those buying is to examine the heat of each lot as received, and, if possible, open out into a pile; or, if not, let each bag be slit open and exposed to the air. The Editor of this Dictionary was called upon to investigate the causes which led to the destruction by fire of H.M. ships the 'Imogene' and the 'Talavera' in Devonport dockyard. He traced it, beyond all question, to a large bin, in which, with great carelessness, oil, anti-attrition, oakum, and tow, which had been used by the shipwrights and others in wiping the oil from their tools after sharpening them, had been allowed to accumulate; and reported to this effect to the Admiralty.

Spontaneous combustion, arising from the rapid absorption of oxygen by the fixed oils, except petroleum, is now attracting much attention, and cannot be too much impressed on the public mind. The recent fire at Portland, Maine, is declared to have arisen from the leakage of linseed oil, stored alongside of rags. In May last two fires, discovered first in the stable, and afterwards in the dwelling of a gentleman at Bedford, Pa., were traced directly to rags saturated with linseed oil, which painters who had been graining shutters had thrown into corners. At Jamestown, New York, a workman, who had been cleaning furniture with linseed oil, threw aside his oily apron crumpled together, and in a short time it was found in a state of ignition.

SPOON MANUFACTURE. See Stamping of Metals.

SPRUCE BEER is prepared as follows:—Essence of spruce, half a pint; pimento and ginger bruised, of each 4 ounces; hops, from 4 to 3 ounces; water, 3 gallons. Boil for ten minutes, then strain and add 11 gallons of warm water, a pint of yeast, and 6 pints of molasses. Mix and allow the mixture to ferment for twenty hours.

SPRUCE, ESSENCE OF, is prepared by boiling the young tops of the *Abies nigra*, or black spruce, in water, and concentrating the decoction by evaporation.

STAINED GLASS. Under Glass, a general account of the processes for colouring glass has been given; for the manufacture, however, of stained glass for windows some special details have been reserved for this place. When certain metallic oxides or chlorides, ground up with proper fluxes, are painted upon glass, their colours fuse into its surface at a moderate heat and make durable pictures, which are frequently employed in ornamenting the windows of churches, as well as of other public and private buildings. The colours of stained glass are all transparent, and are therefore to be viewed only by transmitted light. Many metallic pigments, which afford a fine effect when applied cold on canvas or paper, are so changed by vitreous fusion as to be quite inapplicable to painting in stained glass.

The glass proper for receiving these vitrifying pigments should be colourless, uniform, and difficult of fusion; for which reason crown glass, made with little alkali, or with kelp, is preferred. When the design is too large to be contained on a single pane, several are fitted together and fixed in a bed of soft cement while painting, and then taken asunder to be separately subjected to the fire. In arranging the glass pieces, care must be taken to distribute the joinings, so that the lead frame-work may interfere as little as possible with the effect.

A design must be drawn upon paper, and placed beneath the plate of glass; though the artist cannot regulate his tints directly by his pallet, but by specimens of the colours producible from his pallet pigments after they are fired. The upper side of the glass being sponged over with gum-water, affords, when dry, a surface proper for receiving the colours, without the risk of their running irregularly, as they would be apt to do, on the slippery glass. The artist first draws on the plate with a fine pencil all the traces which mark the great outlines and shades of the figures. This is usually done in black, or at least, some strong colour, such as brown, blue, green, or red. In laying on these the painter is guided by the same principles as the engraver, when he produces the effect of light and shade by dots, lines, or hatches; and he employs that colour to produce the shades, which will harmonise best with the colour which is to be afterwards applied; but for the deeper shades, black is in general used. When this is finished, the whole picture will be represented in lines or hatches similar to an engraving finished up to the highest effect possible; and afterwards, when it is dry, the vitrifying colours are laid on by means of larger hair-pencils; their selection being regulated by the burnt specimen tints. When he finds it necessary to lay two colours adjoining, which are apt to run together in the kiln, he must apply one of them to the back of the glass. But the few principal colours to be presently mentioned, are all fast colours which do not run, except the yellow, which must therefore be laid on the opposite side. After colouring, the artist proceeds to bring out the lighter effects by taking off the colour in the proper place, with a goose-quill cut like a pen without a slit. By working this upon the glass, he removes the colour from the parts where the lights should be the strongest; such as the hair, eyes, the reflection of bright surfaces, and light parts of draperies. The blank pen may be employed either to make the lights by lines, or hatches and dots, as is most suitable to the subject.

By the metallic preparations now laid upon it, the glass is made ready for being fired, in order to fix and bring out the proper colours. The furnace or kiln best adapted for this purpose, is similar to that used by enamellers. (See Enamel, and the *Glaze-kiln*, under Pottery.) It consists of a muffle or arch of fire-clay or pottery, so set over a fire-place, and so surrounded by flues, as to receive a very considerable heat within, in the most equable and regular manner: otherwise, some parts of the glass will be melted; while, on others, the superficial film of colours will remain unvitrified. The mouth of the muffle, and the entry for introducing fuel to the fire, should be on opposite sides, to prevent as much as possible the admission of dust into the muffle, whose mouth should be closed with double-folding doors of iron, furnished with small peep-holes, to allow the artist to watch the progress of the staining, and to withdraw small trial slips of glass, painted with the principal tints used in the picture.

The muffle must be made of very refractory fire-clay, flat at its bottom, and only 5 or 6 inches high, with such an arched top as may make the roof strong, and so close on all sides as to exclude entirely the smoke and flame. On the bottom of the muffle a smooth bed of sifted lime, freed from water, about half an inch thick, must be prepared for receiving the pane of glass. Sometimes several plates of glass are laid over each other with a layer of dry pulverulent lime between each. The fire is now lighted, and most gradually raised, lest the glass should be broken; and after it has attained to its full heat, it must be kept for three or four hours, more or less, according to the indications of the trial slips; the yellow colour being principally watched, as it is found to be the best criterion of the state of the others. When the colours are properly burnt in, the fire is suffered to die away slowly, so as to anneal the glass.

STAINED GLASS-PIGMENTS. *Flesh colour.*—Take an ounce of red lead, two ounces of red enamel (Venetian glass enamel, from alum and copperas calcined together), grind them to fine powder, and work this up with spirits (alcohol) upon a hard stone. When slightly baked, this produces a fine flesh colour.

Black colour.—Take 14½ ounces of smithy scales of iron, mix them with two ounces of white glass (crystal), an ounce of antimony, and half an ounce of manganese; pound and grind these ingredients together with strong vinegar. A brilliant black may also be obtained by a mixture of cobalt blue with the oxides of manganese and iron. Another black is made from three parts of crystal glass, two parts of oxide of copper, and one of (glass of) antimony worked up together, as above.

Brown colour.—An ounce of white glass or enamel, half an ounce of good manganese; ground together.

Red, Rose, and *Brown colours* are made from peroxide of iron, prepared by nitric acid. The flux consists of borax, sand, and minium in small quantity.

Red colour may be likewise obtained from one ounce of red chalk pounded, mixed with two ounces of white hard enamel, and a little peroxide of copper.

A *red* may also be composed of rust of iron, glass of antimony, yellow glass of lead, such as is used by potters (or litharge), each in little quantity; to which a little sulphuret of silver is added. This composition well ground, produces a very fine red colour on glass. When protoxide of copper is used to stain glass, it assumes a bright red or green colour, according as the glass is more or less heated in the furnace, the former corresponding to the suboxide, the latter having the copper in the state of protoxide.

Bistres and *Brown reds* may be obtained by mixtures of manganese, orange oxide of copper, and the oxide of iron called umber, in different proportions. They must be previously fused with vitreous solvents.

Green colour.—Two ounces of brass calcined into an oxide, two ounces of minium, and eight ounces of white sand; reduce them to a fine powder, which is to be enclosed in a well-luted crucible, and heated strongly in an air-furnace for an hour. When the mixture is cold, grind it in a brass mortar. Green may, however, be advantageously produced by a yellow on one side, and a blue on the other. Oxide of chrome has been also employed to stain glass green.

A *fine Yellow colour.*—Take fine silver laminated thin, dissolve in nitric acid, dilute with abundance of water, and precipitate with solution of sea-salt. Mix this chloride of silver, in a dry powder, with three times its weight of pipe-clay well burnt and pounded. The back of the glass-pane is to be painted with this powder, for when painted on the face, it is apt to run into the other colours.

Another *yellow* can be made by mixing sulphide of silver with glass of antimony, and yellow ochre previously calcined to a red-brown tint. Work all these powders together, and paint on the back of the glass. Or silver laminæ melted with sulphur and glass of antimony, thrown into cold water, and afterwards ground to powder, afford a yellow.

A *pale yellow* may be made with the powder resulting from brass, sulphur, and glass of antimony, calcined together in a crucible till they cease to smoke; and then mixed with a little burnt yellow ochre.

The *fine yellow* of M. Merand, is prepared from chloride of silver, oxide of zinc, white-clay, and rust of iron. This mixture, simply ground, is applied on the glass.

Orange colour.—Take 1 part of silver powder, as precipitated from the nitrate of that metal by plates of copper, and washed; mix it with 1 part of red ochre and 1 of yellow, by careful trituration; grind into a thin pap with oil of turpentine or lavender, and apply this with a brush, dry, and burn in.

In the *Philosophical Magazine*, of December 1836, the anonymous author of an ingenious essay, 'On the Art of Glass-painting,' says, that if a large proportion of ochre has been employed with the silver, the stain is yellow; if a small proportion, it is orange-coloured; and by repeated exposure to the fire, without any additional colouring-matter, the orange may be converted into red; but this conversion requires a nice management of the heat. Artists often make use of panes coloured throughout their substance in the glass-house pots, because the perfect transparency of such glass gives a brilliancy of effect, which enamel painting, always more or less opaque, cannot rival. It was to a glass of this kind that the old glass-painters owed their splendid red. This is, in fact, the only point in which the modern and ancient processes differ; and this is the only part of the art which was ever really lost. Instead of blowing plates of solid red, the old glass-makers (like those of Bohemia for some time back), used to *flash* a thin layer of brilliant red over a substratum of colourless glass; by gathering a lump of the latter upon the end of their iron rod in one pot, covering with a layer of the former in another pot, then blowing out the two together into a globe or cylinder, to be opened into circular tables, or into rectangular plates. The elegant art of tinging glass red by oxide of copper, and flashing it on common crown glass, has become general within these few years.

That gold melted with flint-glass stains it purple was originally discovered and practised as a profitable secret by Kunckel. Gold has been recently used at Birmingham for giving a beautiful rose-colour to scent-bottles. The proportion of gold should be very small, and the heat very great, to produce a good effect. The glass must contain either the oxide of lead, bismuth, zinc, or antimony; for crown glass will take no colour from gold. Glass combined with this metal, when removed from the crucible, is generally of a pale rose colour; nay, sometimes is as colourless as water, and does not assume its ruby colour till it has been exposed to a low red heat, either under a muffle, or at the lamp. This operation must be nicely regulated; because a slight excess of fire destroys the colour, leaving the glass of a dingy brown, but with a green transparency like that of gold-leaf. It is metallic gold which gives the colour; and, indeed, the oxide is too easily reduced, not to be converted into the metal by the intense heat which is necessarily required.

Coloured transparent glass is applied as enamel in silver and gold *bijouterie* previously *bright-cut* in the metal with the graver or rose-engine. The cuts, reflecting the rays of light from their numerous surfaces, exhibit through the glass, richly stained with gold, silver, copper, cobalt, &c., a gorgeous play of prismatic colours, varied with every change of aspect. When the enamel is to be painted on, it should be made opalescent by oxide of arsenic, in order to produce the most agreeable effect.

The blues of vitrified colours are all obtained from the oxide of cobalt. Cobalt ore (sulphide) being well roasted at a dull red heat, to dissipate all the sulphur and arsenic, is dissolved in somewhat dilute nitric acid, and after the addition of much water to the saturated solution, the oxide is precipitated by carbonate of soda, then washed upon a filter and dried. The powder is to be mixed with thrice its weight of saltpetre; the mixture is to be deflagrated in a crucible, by applying a red hot cinder to it, then exposed to the heat of ignition, washed and dried. Three parts of this oxide are to be mixed with a flux, consisting of white sand, borax, nitre, and a little chalk, subjected to fusion for an hour, and then ground down into an enamel-powder for use. Blues of any shade or intensity may be obtained from the above, by mixing it with more or less flux.

The beautiful greenish-yellow, of which colour so many ornamental glass vessels have been lately imported from Germany, is made in Bohemia by the following process: An ore of uranium, as *Uran-ochre*, or *Uran-glimmer*, in fine powder, being roasted and dissolved in nitric acid, the filtered solution is to be freed from any lead present in it by the cautious addition of dilute sulphuric acid. The clear green solution is to be evaporated to dryness, and the mass ignited till it becomes yellow. One part of this oxide is to be mixed with three or more parts of a flux, consisting of 4 parts of red lead and 1 of ground flint; the whole fused together and then reduced to powder.

Chrome-green.—Triturate together in a mortar equal parts of chromate of potash and flowers of sulphur; put the mixture into a crucible and fuse. Pour out the fluid mass; when cool, grind and wash well with water, to remove the sulphuret of potash and to leave the beautiful green oxide of chrome. This is to be collected upon a filter, dried, rubbed down along with thrice its weight of a flux, consisting of 4 parts of red lead and 1 part of ground flints fused into a transparent glass; the whole is now to be melted and afterwards reduced to a fine powder.

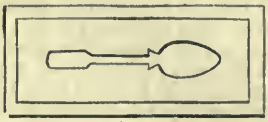
Violet.—One part of calcined black oxide of manganese, 1 of zaffre, 10 parts of the white glass pounded, and one of red lead, mixed, fused, and ground. Or gold purple (Cassius's purple precipitate), with chloride of silver, previously fused with ten times its weight of a flux, consisting of ground quartz, borax, and red lead, all melted together. Or solution of tin being dropped into a large quantity of water, solution of nitrate of silver may be first added, and then solution of gold in *aqua regia*, in proper proportions. The precipitate is to be mixed with flux and fused.

STAMPING OF METALS. The peculiar feature of improvement in the manufacture of stamped articles consists in producing the spoon, ladle, or fork perfect at one blow in the stamping machine, and requiring no further manipulation of shaping, but simply trimming off the barb or fin, and polishing the surface to render the article perfect and finished.

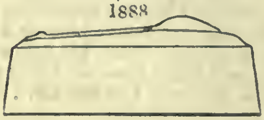
Formerly, in employing a stamping machine, or fly-press, for manufacturing spoons, ladles, and forks, it was the practice to give the impression to the handles, and to the bowls or prongs, by distinct operations of different dies, and after having so partially produced the pattern upon the article, the handles had to be bent and formed by the operations of filing and hammering.

By Mr. Haynes' improved dies, which, having curved surfaces and bevelled edges, allow of no parts of the faces of the die and counter-die to come in contact, he is enabled to produce considerable elevations of pattern and form, and to bring up the article perfect at one blow, with only a slight barb, or fin, upon its edge.

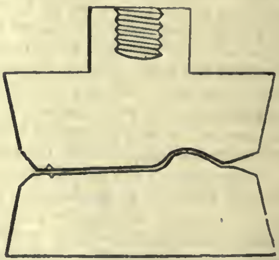
1887



1888



1889

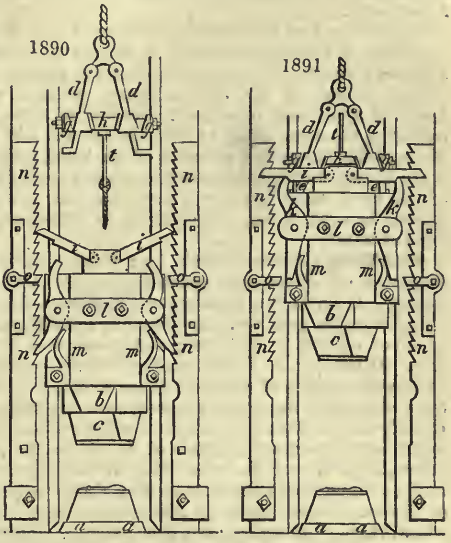


In the accompanying drawings, *fig.* 1888 is the lower or bed die for producing a spoon, seen edgewise; *fig.* 1887 is the face of the upper or counter die, corresponding;

fig. 1889 is a section, taken through the middle of the pair of dies, showing the space in which the metal is pressed to form the spoon.

To manufacture spoons, ladles, or forks, according to his improved process, Mr. Haynes first forges out the ingot into flat pieces, of the shape and dimensions of the die of the intended article; and if a spoon or ladle is to be made, gives a slight degree of concavity to the bowl part; but, if necessary, bends the back, in order that it may lie more steadily and bend more accurately, upon the lower die; if a fork, he cuts or otherwise removes portions of the metal at those parts which will intervene between the prongs; and, having thus produced the rude embryo of the intended article, scrapes its entire surface clean and free from oxidation, scale, or fire-strain, when it is ready to be introduced into the stamping machine.

He now fixes the lower die in the bed of the stamping machine, shown at *a*, *a*, in the elevations *figs.* 1890 and 1891, and fixes, in the hammer *b*, the upper or counter die, *c*, accurately adjusting them both, so that they may correspond exactly when brought together. He then places the rudely-formed article above described upon the lower die, and having drawn up the hammer to a sufficient elevation, by a windlass and rope, or other ordinary means, lets go the trigger, and allows the hammer, with the counter die to fall upon the under die, on which the article is placed; when, by the blow thus given to the metal, the true and perfect figure and pattern of the spoon, ladle, or fork is produced, and which, as before said, will only require the removal of the slight edging of barb, or fin, with polishing, to finish it.



On striking the blow, in the operation of stamping the article, the hammer will recoil and fly up some distance, and if allowed to fall again with reiterated blows, would injure both the article and the dies; therefore, to avoid this inconvenience, he causes the hammer on recoiling to be caught by a pair of palls locked into racks on the face of the standards, seen in the figures; the hammer *b*, of the stamping machine, is seen raised and suspended by a rope attached to a pair of jointed hooks or holders, *d*, *d*, the lower ends of which pass into eyes *e*, *e*, extending from the top of the hammer. When the lever or trigger *t*, is drawn forward, as in *fig.* 1890, the two inclined planes, *g*, *g*, on the axle, *h*, press the two legs of the holders, *d*, *d*, inward, and cause their hooks or lower ends to be withdrawn from the eyes, *e*, *e*, when the hammer instantly falls, and brings the dies together: such is the ordinary construction of the stamping machine.

On the hammer falling from a considerable elevation, the violence of the blow causes it to recoil and bound upwards as before mentioned; it therefore becomes necessary to catch the hammer when it has rebounded, in order to prevent the dies coming again together; this is done by the following mechanism:—

Two latch-levers, *i*, *i*, are connected by joints to the upper part of the hammer, and two pall-levers, *k*, *k*, turning upon pins, are mounted in the bridge, *l*, affixed to the hammer. Two springs, *m*, *m*, act against the lower arms of these levers, and press them outwards, for the purpose of throwing the palls at the lower ends of the levers into the teeth of the ratchet racks, *n*, *n*, fixed on the sides of the upright standards.

Previously to raising the hammer, the upper ends of the pall-levers, *k*, are drawn back, and the latches, *i*, being brought down upon them, as in *fig.* 1890, the levers, *k*, are confined, and their palls prevented from striking into the slide racks; but as the hammer falls, the ends of the latches, *i*, strike upon the fingers, *o*, *o*, fixing to the side standards, and liberate the palls, the lower ends of which, when the hammer rebounds, after stamping, catch into the teeth of the racks, as in *fig.* 1891, and thereby prevent the hammer from again descending.

STAMPS. See Dressing of Ores.

STANNATE AND STANNITE OF POTASH AND SODA. Stannates and stannites of alkalis are valuable mordants. For the stannate of soda, 22 lbs. of caustic soda are first put into an iron crucible, heated to a low red heat, till the hydrate be produced; to which 8 lbs. of nitrate of soda and 4 lbs. of common salt are introduced. When the mixture is at a fluxing heat, 10 lbs. of feathered block-tin are added, and it is stirred with an iron rod. The mass now becomes dark coloured and pasty, and ammonia is given off (the tin decomposing the water of the hydrated soda and part of the nitrate of soda). The stirring is continued, as well as the heat, till deflagration takes place, and the mass becomes red hot and pasty. This product is stannate of soda. It may be purified by solution and crystallisation.

Stannite of soda is made by putting 4 lbs. of common salt, 13½ lbs. of caustic soda, and 4 lbs. of feathered block-tin into a hot iron crucible over a fire, and stirring and boiling to dryness, and as long as ammonia is given off. What remains is stannite of soda.

To produce the tin-preparing liquour, 3 lbs. of stannate of soda are dissolved in 1 gallon of boiling water, and 3 gallons or more of cold water, to bring it to the required strength. The stannite of soda is treated in the same way.

The process of Mr. James Young is much more recent, and presents a very beautiful application of science. Instead of reducing metallic tin from the ore, and oxidating the metal again to form the stannic acid at the expense of nitric acid, Mr. Young takes the native peroxide of tin itself, and fuses it with soda. The iron and other foreign metals present in the ore are insoluble in the alkali, so that by solution of the fused mass in water, a pure stannate of soda is obtained at once. It is crystallised by evaporation, and obtained in efflorescent crystals containing nine equivalents of water.

STARCH (*Amidon*, *Fécule*, Fr.; *Stärke*, Ger.) is a white pulverulent substance, composed of microscopic spheroïds, which are bags containing the amylaceous matter. It exists in a great many different plants, and varies in the form and size of its microscopic particles. As found in some plants, it consists of spherical particles $\frac{1}{1000}$th of an inch in diameter; and in others of ovoïd particles, $\frac{1}{300}$th or $\frac{1}{400}$th of an inch. It occurs: 1. In the seeds of all the acotyledonous plants, among which are the several species of corn, and those of other *Gramineæ*. 2. In the round perennial tap roots, which shoot up an annual stem; in the tuberose roots, such as potatoes, the *Convolvulus batatas* and *C. edulis*, the *Helianthus tuberosus*, the *Jatropha manihot*, &c., which contain a great quantity of it. 3. In the stems of several monocotyledonous plants, especially of the palm tribe, whence sago comes; but it is very rarely found in the stems and branches of the dicotyledonous plants. 4. It occurs in many species of lichen. Three kinds of starch have been distinguished by chemists; that of wheat, that called *inuline*, and lichen-starch. These three agree in being insoluble in cold water, alcohol, ether, and oils, and in being converted into sugar by either dilute sulphuric acid or diastase. The main difference between them consists in their habitudes with water and iodine. The first forms with hot water a mucilaginous solution, which constitutes, when cold, the paste of the laundress, and is tinged blue by iodine; the second forms a granular precipitate, when its solution in boiling-hot water is suffered to cool, which is tinged yellow by iodine; the third affords, by cooling the concentrated solution, a gelatinous mass, with a clear liquid floating over it, that contains little starch. Its jelly becomes brown-grey with iodine.

Ordinary Starch.—This may be extracted from the following grains:—Wheat, rye, barley, oats, buckwheat, rice, maize, millet, spelt; from the siliquose seeds, as peas, beans, lentiles, &c.; from tuberous and tap roots, as those of the potato, the orchis, manioc, arrow-root, batata, &c. Different kinds of corn yield very variable quantities of starch. Wheat differs in this respect, according to the varieties of the plant, as well as the soil, manure, season, and climate. See Bread.

Wheat partly damaged by long keeping in granaries may be employed for the manufacture of starch, as this constituent suffers less injury than the gluten; and it may be used either in the ground or unground state.

With unground wheat.—The wheat being sifted clean, is to be put into cisterns, covered with soft water, and left to steep till it becomes swollen and so soft as to be easily crushed between the fingers. It is now to be taken out, and immersed in clear water of a temperature equal to that of malting-barley, whence it is to be transferred into bags, which are placed in a wooden chest containing some water, and exposed to strong pressure. The water rendered milky by the starch being drawn off by a tap, fresh water is poured in, and the pressure is repeated. Instead of putting the swollen grain into bags, some prefer to grind it under vertical edge-stones, or between a pair of horizontal rollers, and then to lay it in a cistern, and separate the starchy liquor by elutriation with successive quantities of water well stirred up with it. The residuary matter in the sacks or cisterns contains much vegetable albumen and gluten, along with the husks; when exposed to fermentation, this affords a small quantity of starch of rather inferior quality.

The above milky liquor, obtained by expression or elutriation, is run into large cisterns, where it deposits its starch in layers successively less and less dense; the uppermost containing a considerable proportion of gluten. The supernatant liquor being drawn off, and fresh water poured on it, the whole must be well stirred up, allowed again to settle, and the surface-liquor withdrawn. This washing should be repeated as long as the water takes any perceptible colour. At the first turbid liquor contains a mixture of gluten, sugar, gum, albumen, &c., it ferments readily, and produces a certain portion of vinegar, which helps to dissolve out the rest of the mingled gluten, and thus to bleach the starch. It is, in fact, by the action of this fermented or soured water, and repeated washing, that it is purified. After the last deposition and decantation, there appears on the surface of the starch a thin layer of a slimy mixture of gluten and albumen, which being scraped off, serves for feeding pigs or oxen; underneath will be found a starch of good quality. The layers of different sorts are then taken up with a wooden shovel, transferred into separate cisterns, where they are agitated with water, and passing through fine sieves. After this pap is once more well settled, the clear water is drawn off, the starchy mass is taken out, and laid on linen cloths in wicker baskets, to drain and become partially dry. When sufficiently firm, it is cut into pieces which are spread upon other cloths, and thoroughly desiccated in a proper drying-room, which in winter is heated by stoves. The upper surface of the starch is generally scraped to remove any dusty matter, and the resulting powder is sold in that state. Wheat yields, upon an average, only from 35 to 40 per cent. of good starch. It should afford more by skilful management.

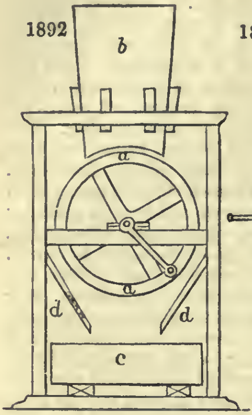
With crushed wheat.—In this country, wheat crushed between iron rollers is laid to steep in as much water as will wet it thoroughly; in four or five days the mixture ferments, soon afterwards settles and is ready to be washed out with a quantity of water into the proper fermenting vats. The common time allowed for the steep is from 14 to 20 days. The next process consists in removing the stuff from the vats into a stout round basket set across a back below a pump. One or two men keep going round the basket, stirring up the stuff with strong wooden shovels, while another keeps pumping water, till all the *farina* is completely washed from the bran. Whenever the subjacent back is filled, the liquor is taken out and strained through hair-sieves into square frames or cisterns, where it is allowed to settle for 24 hours; after which the water is run off from the deposited starch by plug-traps at different levels in the side. The thin stuff, called *slimes*, upon the surface of the starch, is removed by a tray of a peculiar form. Fresh water is now introduced, and the whole being well mixed by proper agitation, is then poured upon fine silk sieves. What passes through is allowed to settle for 24 hours; the liquor being withdrawn, and then the slimes, as before, more water is again poured in, with agitation, when the mixture is again thrown upon the silk sieve. The milky liquor is now suffered to rest for several days,—4 or 5,—till the starch becomes settled pretty firmly at the bottom of the square cistern. If the starch is to have the blue tint, called Poland, fine smalt must be mixed in the liquor of the last sieve, in the proportion of 2 or 3 lbs. to the cwt. A considerable portion of these slimes may, by good management, be worked up into starch by elutriation and straining.

The starch is now fit for *boxing*, by shovelling the cleaned deposit into wooden chests, about 4 feet long, 12 inches broad, and 6 inches deep, perforated throughout and lined with thin canvas. When it is drained and dried into a compact mass, it is turned out by inverting the chest upon a clean table, where it is broken into pieces 4 or 5 inches square, by laying a ruler underneath the sake, and giving its surface a cut with a knife, after which the slightest pressure with the hand will make the fracture. These pieces are set upon half-burned bricks, which by their porous capillarity imbibe the moisture of the starch, so that its under surface may not become hard and horny. When sufficiently dried upon the bricks, it is put into a stove (which resembles that of a sugar-refinery), and left there till tolerably dry. It is now removed to a table, when all the sides are carefully scraped with a knife; it is next packed up in the papers in which it is sold; these packages are returned into the stove, and subjected to a gentle heat during some days; a point which requires to be skilfully regulated.

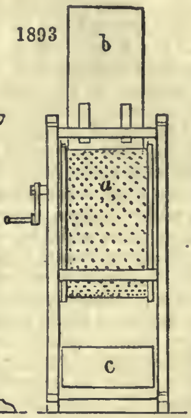
During the drying, starch splits into small prismatic columns, of considerable regularity. When kept dry, it remains unaltered for a very long period. When it is heated to a certain degree in water, the envelopes of its spheroïdal particles burst, and the farina forms a mucilaginous emulsion, magma, or paste. When this apparent solution is evaporated to dryness, a brittle, horny-looking substance is obtained, quite different in aspect from starch, but similar in chemical habitudes. When the moist paste is exposed for two or three months to the air in summer, the starch is converted into sugar, to the amonnt of one-third or one-half of its weight, into gum and gelatinous starch, called *amidine* by De Saussure, with occasionally a resinous matter. This curious change goes on even in close vessels.

Starch from Potatoes.—The potatoes are first washed in a cylindrical cage formed of wooden spars, made to revolve upon a horizontal axis, in a trough filled with water to the level of the axis. They are then reduced to a pulp by a rasping machine, similar to that represented in *figs.* 1892, 1893; where *a* is a wooden drum, covered with sheet iron, roughened outside with numerous prominences, made from punching out holes from the opposite side. It is turned by a winch fixed upon each end of the shaft. The drum is enclosed in a square wooden box, to prevent the potato-mash from being scattered about. The hopper, *b*, is attached to the upper frame, has its bottom concentric with the rasp-drum, and nearly in contact with it. The pulp-chest, *c*, is made to slide out, so as when full to be readily replaced by another. The two slanting boards, *d*, *d*, conduct the pulp into it. A moderate stream of water should be made to play into the hopper upon the potatoes, to prevent the surface of the rasp from getting foul with fibrous matter. Two men, with one for a relay, will rasp, with such a machine, from 2½ to 3 tons of potatoes in 12 hours.

1892



1893



The potato-pulp must be now elutriated upon a fine wire- or hair-sieve, which is set upon a frame in the mouth of a large vat, while water is made to flow upon it from a spout with many jets. The pulp meanwhile must be stirred and kneaded by the hand, or by a mechanical brush-agitator, till almost nothing but fibrous particles are left upon the sieve. These, however, generally retain about 5 per cent. of starch. which cannot be separated in this way. This parenchyma should therefore be subjected to a separate rasping upon another cylinder. The water, turbid with starch, is allowed to settle for some time in a back; the supernatant liquor is then run by a cock into a second back, and after some time into a third, whereby the whole starch will be precipitated. The finest powder collects in the last vessel. The starch thus obtained, containing 33 per cent. of water, may be used either in the moist state, under the name of *green fecula*, for various purposes, as for the preparation of dextrine and starch-syrup, or it may be preserved under a thin layer of water, which must be renewed from time to time, to prevent fermentation; or lastly, it may be taken out and dried.

Washing apparatus have been contrived by Lainé, Dailly, Huck, Vernies, Stolz, and St.-Etienne. These are contrivances for working very large quantities of potatoes in a short time. Huck's machine is stated to work 30,000 lbs. of potatoes daily, and in trials made with St.-Etienne's rasp and starch machinery, in Paris, which was driven by two horses, nearly 18 cwts. of potatoes were put through all the requisite operations in one hour, including the pumping of the water. The product in starch amounted to from 17 to 18 per cent. of the potatoes. The quicker the process of potato-starch making, the better is its quality. Völker proposed a process of rotting the potato to separate the starch.

Horse-chestnuts have been largely used at Nanterre, near Paris, in the manufacture of starch.
