In the manufacture of potato-starch, a considerable quantity of the product is lost, owing to the strong affinity which the starch has for the fibre of the potato. M. Anthon stated some years ago that the manufacturer obtains only two-thirds of the starch, the remainder being left in the pulp. He suggested that this third may be utilised, by converting it into sugar by means of either malt or dilute sulphuric acid. By employing 10 per cent. of the acid to the dry fibre, the saccharification is complete in about two hours and a half; but if only 3 or 4 per cent. of acid is used, the boiling must be continued for at least 5 hours. Ten per cent. of malt effected the conversion in 6 hours. Mr. Calvert has given the following analysis of the potato:—Water, 74; starch, 20; the remainder being fibrous, earthy, and alkaline matters.

Starch from certain foreign plants.—1. From the pith of the *Sago Palm.* See Sago.

2. From the roots of the *Maranta arundinacea*, of Jamaica, the Bahamas, and other West India Islands, the powder called arrow-root is obtained, by a process analogous to that for making potato-starch. See Arrow-root.

3. From the roots of the *manioc*, which also grows in the West Indies, as well as in Africa, the *cassava* is procured, by a similar process. The juice of this plant is poisonous, from which the wholesome starch is deposited. When dried with stirring upon hot iron plates, it agglomerates into small lumps, called *tapioca*; being a gummy fecula. See Cassava.

The characters of the different varieties of starch can be learnt only from microscopic observation; by which means also their sophistication or admixture may be readily ascertained.

Starch, from whatever source obtained, is a white soft powder, which feels crispy, like flowers of sulphur, when pressed between the fingers; it is destitute of taste and smell, unchangeable in the atmosphere, and has a specific gravity of 1·53.

For the saccharine changes which starch undergoes by the action of *diastase*, see Fermentation.

Lichenine, a species of starch obtained from Iceland moss (*Cetraria islandica*), as well as *Inuline*, from elecampane (*Inula Helenium*), are rather objects of chemical curiosity than of manufactures. See Lichens.

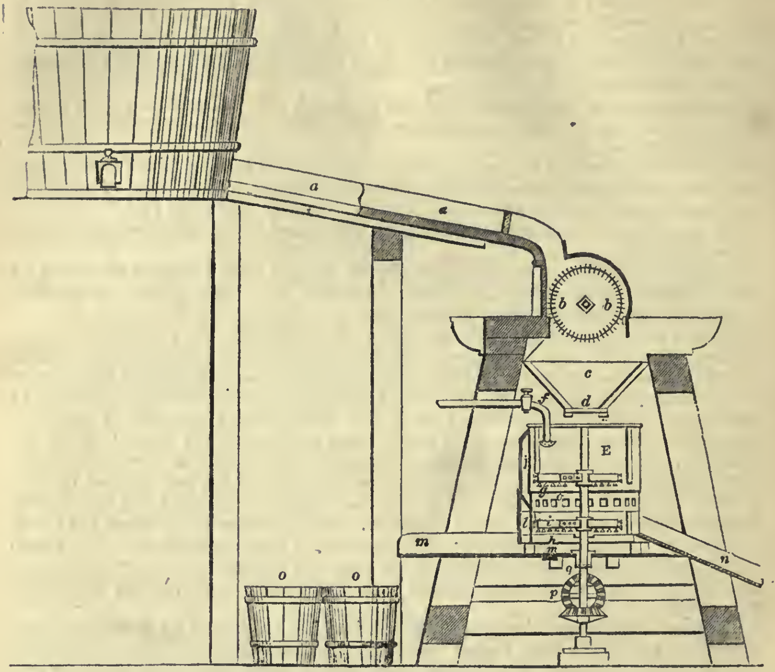
There is a kind of starch made in order to be converted into gum for the calico-printer. This conversion having been first made upon the great scale in this country, has occasioned the product to be called British gum. The following is the process pursued in a large and well-conducted establishment near Manchester:—A range of four wooden cisterns, each about 7 or 8 feet square and 4 feet deep, is provided. Into each of them 2,000 gallons of water being introduced, 12½ loads of flour are stirred in. The mixture is set to ferment upon old leaven left at the bottom of the backs, during 2 or 3 days. The contents are then stirred up, and pumped off into 3 stone cisterns, 7 feet square and 4 feet deep; as much water being added, with agitation, as will fill the cisterns to the brim. In the course of 24 hours the starch forms a firm deposit at the bottom; and the water is then syphoned off. The gluten is next scraped from the surface, and the starch is transferred into wooden boxes, pierced with holes, which may be lined with coarse cloth, or not, at the pleasure of the operator.

The starch, cut into cubical masses, is put into iron trays, and set to dry in a large apartment, two stories high, heated by a horizontal cylinder of cast iron traversed by the flame of a furnace. The drying occupies two days. It is now ready for conversion into gum, for which purpose it is put into oblong trays of sheet iron, and heated to the temperature of 300° Fahr. in a cast-iron oven, which holds four of these trays. Here it concretes into irregular semi-transparent yellow-brown lumps, which are ground into fine flour between mill-stones, and in this state brought to the market. In this roasted starch, the vesicles being burst, their contents become soluble in cold water. British gum is not convertible into sugar, as starch is, by the action of dilute sulphuric acid; nor into mucic acid, by nitric acid; but into the oxalic; and it is tinged purple red by iodine. It is composed, in 100 parts, of 35·7 carbon, 6·2 hydrogen, and 58·1 oxygen; while starch is composed of 43·5 carbon, 6·8 hydrogen, and 49·7 oxygen. See Dextrine.

Manufacture of Starch from Rice, &c.—Starch prepared from rice or maize by alkali is said not to require boiling—a point of great importance in its use; and, being less hygrometric than wheat-starch, retains a more permanent stiffness and glaze. The rough starch obtained in the process is valuable for feeding purposes, and for stiffening coarse fabrics.

Fig. 1894 represents in section the powerful and ingenious mechanical grater, or rasp (*râpe*), now used in France. *a a* is the canal, or spout, along which the previously well-washed potatoes descend; *b b* is the grater, composed of a wooden cylinder, on whose round surface circular saw rings of steel, with short sharp teeth, are planted pretty close together. The greater the velocity of the cylinder, the finer is the pulp. A cylinder 20 inches in diameter revolves at the rate of from 600 to 900 times a minute, and it will convert into pulp from 14 to 15 hectolitres (about 300 imperial gallons) of potatoes in an hour. Potatoes contain from 15 to 22 per cent. of dry fecula. The pulp, after leaving the rasp, passes directly into the apparatus for the preparation of the starch. *c* is a wooden hopper for receiving the falling pulp, with a trap-door, *d*, at bottom. E, is the cylinder-sieve of M. St.-Etienne; *f*, a pipe ending in a rose-spout, which delivers the water requisite for washing the pulp, and extracting the starch from it; *g g*, a diaphragm of wire-cloth, with small meshes, on which the pulp is exposed to the action of the brushes, *i i*, moving with great speed, whereby it gives out its starchy matter, which is thrown out by a side aperture into the spout *n*. The fecula now falls upon a second web of fine wire-cloth, and leaves upon it merely some fragments of the parenchyma or cellular matter of the potato, to be turned out by a side opening in the spout, *n*. The sifting

1894



or straining of the starch likewise takes place through the sides of the cylinder, which consists also of wire-cloth; it is collected into a wooden spout, *m*, and is thence conducted into the tubs *o o*, to be deposited and washed. *p* is a mitre-toothed wheel-work, placed on the driving-shaft, and gives motion to the upright axis or spindle, *q q*, which turns the brushes, *i*, *i*.

STARCHING AND STEAM-DRYING APPARATUS. For a description of these processes, and of the machinery for accomplishing them, see BLEACHING and CALICO-PRINTING.

STATUARY PORCELAIN. See POTTERY.

STEAM is water in its vaporiform state. The varied and important applications of steam as a mechanical power would appear to render a consideration of its laws of the utmost importance. The circumstance that our spinning and weaving machinery, our pumping engines, our ships, our carriages, our hammers, our lathes, and our presses, are all moved by this power, seems to demand a full consideration of steam in a work devoted to *Arts, Manufactures, and Mines*, into each division of which it enters as an important element. But the limits assigned to the entire work renders it impossible to treat in any way commensurate with its importance this great mechanical power. It is, therefore, thought advisable to confine attention to a few general and well-established principles only. For especial information on the subject, the reader is referred to W. J. Macquorn-Rankine's 'Manual of the Steam-Engine;' Tredgold 'On the Steam-Engine;' De Pambour 'On the Theory of the Steam-Engine,' and 'On the Locomotive Engine;' Arago *Sur les Machines à Vapeur*; Regnault's papers in the *Mémoires* and *Comptes Rendus* of the Academy of Sciences, &c.

Steam is a chemical compound of oxygen and hydrogen, in the proportion of 8 parts by weight of oxygen, to 1 of hydrogen. Its composition by volume is such, that the quantity of steam which, if it were a perfect gas, would occupy 1 cubic foot at a given pressure and temperature, contains as much oxygen as would, if uncombined, occupy half a cubic foot, and as much hydrogen as would, if uncombined, occupy 1 cubic foot, at the same pressure and temperature; so that steam, if it were a perfect gas, would occupy two-thirds the space which its constituents occupy when uncombined. Hence is deduced the following composition of the weight of one cubic foot of steam would have at the temperature of 32° Fahr., and pressure of one atmosphere (or 14·7 lbs. on the square inch), if steam were a perfect gas, and if it could exist at the pressure and temperature stated.

Data from the Experiments of Regnault.

	lb.
Half a cubic foot of oxygen at the pressure of one atmosphere and temperature, 32°	0·044628
1 cubic foot of hydrogen	0·005592
1 cubic foot of steam in the ideal state of perfect gas, at one atmosphere and 32°	0·050220

If steam were a perfect gas, the weight of a cubic foot could be calculated for any given pressure and temperature by the following formula:—

Weight of a cubic foot = 0·05022 lb. × pressure in atmosphere =

$$\times \frac{493^{\cdot\circ}2}{\text{Temp.} + 4{\cdot}61^{\circ}2}.$$

For example, at one atmosphere of pressure, and 212°, the weight of a cubic foot of steam would be:

$$0{\cdot}05022 \times \frac{493^{\cdot\circ}2}{673^{\cdot\circ}6} = 0{\cdot}03679 \text{ lb.}$$

But steam is known not to be a perfect gas; and its actual density is greater than that which is given by the preceding formula, though to what extent is not known by direct experiment. The most probable method of indirectly determining the density of steam, is by computation from the latent heat of evaporation, from which it appears that at one atmosphere and 212°, the weight of a cubic foot of steam is probably 0·03679 lb. The greatest pressure under which steam can exist at a given temperature is called the *pressure of saturation* for steam of a given temperature. The temperature is called the *boiling point* of water under the given pressure. The pressure of saturation is the only pressure at which steam and liquid water can exist together in the same vessel at a given temperature.

It becomes necessary to understand correctly the method of determining fixed temperatures by certain phenomena taking place at them. Thus ice begins to melt at a point, which we call the *freezing point*, marked 32° upon the scale devised by Fahrenheit (see THERMOMETER), and we determine the *boiling point* of water to be 212° on the same scale, under the average atmospheric pressure of 14·7 lbs. on the square inch; 2116·4 lbs. on the square foot; 29·992 inches of the column of mercury. At this latter point water ceases to be *liquid*, and becomes vaporiform. From 32° to 212°, all the heat which has been poured into the water has effected no change of physical condition, but the higher temperature being reached, a new condition is established, and steam is produced; this steam then beginning to act according to certain fixed laws.

A cubic inch of water evaporated under the ordinary atmospheric pressure is converted into a cubic foot of steam.

A cubic inch of water evaporated under the atmospheric pressure gives a mechanical force equal to what would raise a ton weight one foot high.

These are the effects produced at 212° under the above-named pressure.

Careful experiments have determined, within very small limits of error, the following facts:—Steam under pressure of 35 lbs. per square inch, and at the temperature of 261°, exerts a force equal to a ton weight raised one foot; under the pressure of 15 lbs. and at the temperature of 213°, it is 2,086 lbs., or about seven per cent. less; and under 70 lbs. and at 306° it is 2,382 lbs., or nearly six and a half per cent. more than a ton raised a foot. It is sufficient for all practical purposes to assume that each cubic inch evaporated, whatever be the pressure, develops a gross mechanical effort equivalent to a ton weight raised one foot.

As a given power is produced by a given rate of evaporation, to determine this the following rules are applicable:—

To produce the force expressed by one horse-power, the evaporation per minute must develop a mechanical force equal to 33,000 lbs., or about 15 tons raised 1 foot high. Fifteen cubic inches of water would accordingly produce this effect, which, without evaporation, would be equivalent to 900 cubic inches per hour. To find, therefore, the gross power developed by a boiler, it would be only necessary to divide the number of cubic inches of water evaporated per hour by 900. If, therefore, to 900 cubic inches be added the quantity of water per hour necessary to move the engine itself, independently of its load, we shall obtain the quantity of water per hour which must be supplied by the boiler to the engine for each horse-power, and this will be the same whatever may be the magnitude or proportions of the cylinder.

STEAM BOILERS. Did space allow of our entering on a consideration of this important subject, which it does not, it would not properly fall within the scope of this Dictionary: we therefore refer to the Dictionary of Engineering, and to Mr. W. Fairbairn's papers in the 'Transactions of the Royal Society.'

STEAM-ENGINE. Steam-engines are divided into *condensing* and *non-condensing*, corresponding with those which are worked by steam at *high-pressure* and at *low-pressure* respectively. The form of the engine is varied according as it is a *stationary*, a *locomotive*, or a *marine* engine. For descriptions of the various forms, the reader must be referred to special treatises upon the subject, such as Rankine 'On the Steam-Engine.'

STEARIC ACID. (*Talgsäure*, Ger.) Chevreul's discovery of the constitution of fats, led to the present processes for the manufacture of stearic acid. The original experiments were published in 1823, and Gay-Lussac, with Chevreul in 1825, took patents for the manufacture of fatty acids. Pure stearic acid is prepared, according to its discoverer, Chevreul, in the following way:—Make a soap by boiling a solution of potash and mutton-suet in the proper equivalent proportions; dissolve one part of that soap in 6 parts of hot water, then add to the solution 40 or 50 parts of cold water, and set the whole in a place whose temperature is about 52° Fahr. A substance falls to the bottom, possessed of pearly lustre, consisting of the bi-stearate and bi-margarate of potash; which is to be drained and washed upon a filter. The filtered liquor is to be evaporated, and mixed with a small quantity of acid necessary to saturate the alkali left free by the precipitation of the above bi-salts. On adding water to it afterwards, the liquor affords a fresh quantity of bi-stearate and bi-margarate. By repeating this operation with precaution, we finally arrive at a point when the solution contains no more of these solid acids, but only the oleic. The precipitated bi-salts are to be washed and dissolved in hot alcohol, of specific gravity 0·820, of which they require about 24 times their weight. During the cooling of the solution, the bi-stearate falls down, while the greater part of the bi-margarate, and the remainder of the oleate, remain dissolved. By repeatedly dissolving in alcohol, and crystallising, the bi-stearate will be obtained alone, as may be proved by decomposing a little of it in water at a boiling heat, with muriatic acid, letting it cool, washing the stearic acid obtained, and exposing it to heat, when, if pure, it will not fuse in water under the 158th degree of Fahrenheit's scale. If it melts at a lower heat, it contains more or less margaric acid. The purified bi-stearate being decomposed by boiling in water along with any acid, as the muriatic, the disengaged stearic acid is to be washed by melting in water, then cooled and dried.

Stearic acid, prepared by the above process, contains combined water, from which it cannot be freed. It is insipid and inodorous. After being melted by heat, it solidifies at the temperature of 158° Fahr., and affects the form of white brilliant needles grouped together. It is insoluble in water, but dissolves in all proportions in boiling anhydrous alcohol, and on cooling to 122°, crystallises therefrom in pearly plates; but if the concentrated solution be quickly cooled to 112°, it forms a crystalline mass. A dilute solution affords the crystallised acid in large white brilliant scales. It dissolves in its own weight of boiling ether of 0·727, and crystallises on cooling in beautiful scales, of changing colours. Its distils over *in vacuo* without alteration; but if the retort contains a little atmospheric air, a small portion of the acid is decomposed during the distillation; while the greater part passes over unchanged, but slightly tinged brown, and mixed with traces of empyreumatic oil. When heated in the open air, and kindled, stearic acid burns like wax. By analysis it is found to contain in 100 parts, carbon 75·6, hydrogen 12·6, and oxygen 11·8, which agrees with the formula $C^{36}H^{36}O^{4}$ (**$C^{18}H^{36}O^{2}$**). Stearic acid displaces, at a boiling heat in water, carbonic acid from its combinations with the bases; but in operating upon an alkaline carbonate, a portion of the stearic acid is dissolved in the liquor before the carbonic acid is expelled. The decomposition is founded upon the principle, that the stearic acid transforms the salt into a bicarbonate, which is decomposed by the ebullition.

Of late years lime has been had recourse to, with perfect success, and has become subservient to a great improvement in candle-making. Lime was first successfully used by De Milley in 1831. The stearine block now made by many London houses, though containing not more than 2 or 3 per cent. of wax, is hardly to be distinguished from the purified produce of the bee. The first process is to boil the fat with quicklime and water in a large tub by means of perforated steam-pipes distributed over its bottom. About 11 parts of dry lime are fully equivalent to 100 of stearine and oleine mixed; but as the lime is in the state of hydrate, 14 parts of it will be required when it is perfectly pure; in the ordinary state, however, as made from average good limestone, 16 parts may be allowed. After a vigorous ebullition of 3 or 4 hours, the combination is pretty complete. The stearate being allowed to cool to such a degree as to admit of its being handled, becomes a concrete mass, which must be dug out with a spade, and transferred into a contiguous tub, in order to be decomposed with the equivalent quantity of sulphuric acid diluted with water, and also heated with steam. Four parts of concentrated acid will be sufficient to neutralise 3 parts of slaked lime. The saponified fat now liberated from the lime, which is thrown down to the bottom of the tub in a state of sulphate, is skimmed off the surface of the watery menstruum into a third contiguous tub, where it is washed with water and steam.

The washed mixture of stearic, margaric, and oleic acids, is next cooled in tin pans; then shaved by large knives fixed on the face of a fly-wheel, called a tallow-cutter, preparatory to its being subjected in canvas or caya bags to the action of a powerful hydraulic press. Here a large portion of the oleic acid is expelled, carrying with it a little of the margaric. The pressed cakes are now subjected to the action of water and steam once more, after which the supernatant stearic acid is run off, and cooled in moulds. The cakes are then ground by a rotatory rasping-machine to a sort of mealy powder, which is put into canvas bags, and subjected to the joint action of steam and pressure in a horizontal hydraulic press of a peculiar construction, somewhat similar to that which has long been used in London for pressing spermaceti. The cakes of stearic acid thus freed completely from the margaric and oleic acids, are subjected to a final cleansing in a tub with steam, and then melted into hemispherical masses called 'blocks.' When these blocks are broken, they display a highly crystalline texture, which would render them unfit for making candles. This texture is therefore broken down or comminuted by fusing the stearine in a plated copper pan, along with one-thousandth part of pulverised arsenious acid, after which it is ready to be cast into candles in appropriate moulds. See CANDLE.

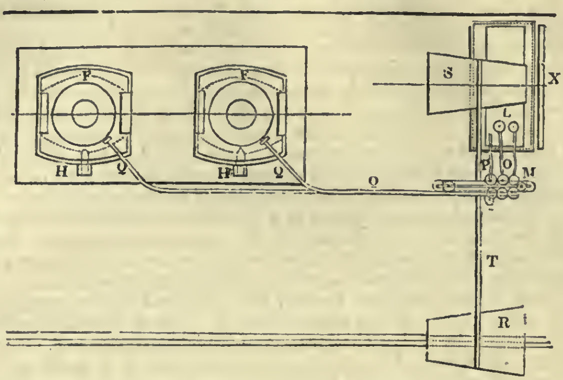
Moinier and Boutigny introduced a process by which the production of stearic acid has been considerably increased. Two tons of tallow and 900 gallons of water are introduced into a large rectangular vat of about 270 feet capacity. The tallow is melted by means of steam admitted through a pipe coiled round the bottom, and the whole kept at the boiling point for an hour, during which a current of sulphurous acid is forced in. At the end of this period 6 cwts. of lime, made into milk with 350 gallons of water, are added. The mixture soon acquires consistency, and becomes frothy and viscid. The whole is now agitated, in order to regulate the ebullitions and prevent the sudden swelling up of the soapy materials. The pasty appearance of the lime soap succeeds, and it then agglomerates into small nodular masses. The admission of sulphurous acid is now stopped; but the injection of the steam is continued until the small masses become hard and homogeneous. The whole period occupies eight hours, but the admission of sulphurous acid is discontinued at the end of about three hours. The water containing the glycerine is run off through a tube into cisterns prepared to receive it. The arrangements for producing sulphurous acid are retorts into which are put sulphuric acid and pieces of wood; upon the application of heat the sulphurous acid passes off, and is conveyed by leaden pipes into the vessel containing the tallow. The lime-soap formed is then moistened with 12 cwts. of sulphuric acid at 152° Fahr., diluted with 50 gallons of water. The whole is thoroughly agitated, and the steam cautiously admitted, so as not to dilute the acid too much until the decomposition is general at all points. This occupies about three hours, and in two or three hours more the sulphate of lime has collected at the bottom, while the fatty acids are floating on the surface of the solution of the sulphate of lime. Several processes of washing with steam and water are necessary to ensure the removal of the sulphate of lime, &c., and after settling for four hours, the fatty acids are forced through a fixed syphon into a vat, where they are again washed with water; they are then syphoned at last into a trough lined with lead, on the bottom of which are placed leaden gutters pierced below by long pegs of wood. The fatty acids are then placed in cloths, and subjected to pressure in the stearine cold press as described below.

It is important for the fatty acids to cool slowly, for thus the confused crystallisation is prevented, and the expulsion of the oleic acid facilitated. When the cakes are solid they are placed between sacks of horse-hair, and submitted to a second pressure at high temperature. The whole is covered with oil-skin, and the temperature raised to 158°·5 Fahr., when pressure is applied. The heat slowly falls to 113° Fahr., and ultimately reaches 95° to 80° Fahr. This operation lasts about an hour. The cakes of stearic acid are sorted according to colour and transparency, and about 20 cwts. are then introduced into a vat constructed of wood lined with sheet-iron. This is boiled by means of steam admitted through a leaden pipe, which is afterwards employed in heating a stove. Water acidulated is first employed, and afterwards pure water. When the materials are boiling, the whites of twenty-two eggs are introduced, and the albumen is intimately mixed by the violent ebullition. As soon as the albumen is coagulated, the whole is allowed to cool, and the stearic acid is removed to another apartment, where it is kept in a state of agitation to prevent the formation of crystals, and allow the cooling to be as gradual as possible. It is now fit for candles.

The cold hydraulic press, as mounted by Messrs. Maudslay and Field, for squeezing out the oleic acid from saponified fat, or the oleine from cocoa-nut lard, is represented

Scale of 3-20ths of an inch to the foot.

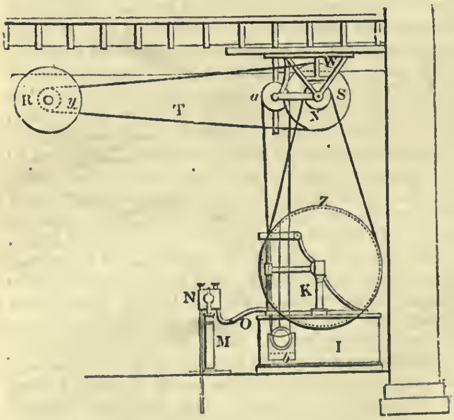
1895



in plan in *fig.* 1895, in side view of pump in *fig.* 1896, and in elevation, *fig.* 1897, where the same letters refer to like objects.

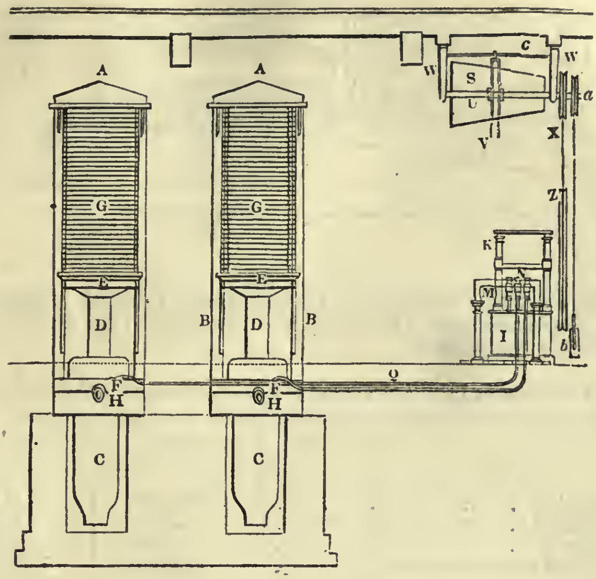
A, A, are two hydraulic presses; B, the frame; C, the cylinder; D, the piston or ram; E, the follower; F, the recess in the bottom to receive the oil; G, twilled woollen bags, with the material to be pressed, having a thin plate of wrought iron between each; H, apertures for the discharge of the oil; I, cistern in which the pumps are fixed; K, framing for machinery to work in; L, two pumps, large and small, to inject the water into the cylinders; M, a frame containing three double branches; N, three branches, each having two stops or plugs, by which the action of one of the pumps may be intercepted from, or communicated to, one or both of the presses; the large pump is worked at the beginning of the operation, and the small one towards the end; by these branches, one or both presses may be discharged when the operation is finished; O, two pipes from the pumps to the branches; P, pipe to return the water from the cylinders to the cisterns; Q, pipes leading from the pumps through the branches to the cylinders; R, conical drum, fixed upon the main shaft Y, driven by the steam-engine of the factory; S, a like conical drum to work the pumps; T, a narrow leather strap to communicate the motion from R to S; U, a long screw bearing a nut, which works along the whole length of the drum; V, the fork or guide for moving the strap T; W, W, two hanging bearings to carry the drum S; X, a pulley on the spindle of the drum S; Y, the main shaft; Z, fly-wheel with groove on the edge, driven by the pulley X; on the axis of S, is a double crank, which works the two pumps L. *a* is a pulley on the end of the long screw, U; an endless cord passes twice round this pulley, and under a pulley fixed in the weight, *b*; by laying hold of both sides of this cord, and raising or lowering it, the forked guide V, and the leather strap T, are moved backwards or forwards, by means of the nut fixed in the guide, so as to accelerate or retard at pleasure the speed of the working of the pumps; *c* is a piece of iron, with a long slit, in which a pin, attached to the fork V, travels, to keep it in the vertical position.

1896



The accompanying *fig.* 1898, is a view both of the exterior and the interior of the saponifying tun of a stearine factory; where the constituents of the tallow are

1897



combined with quicklime, by the intervention of water and steam: *a* is the upright shaft of iron, turned by the bevel-wheel above, in gear with another bevel-wheel on the moving shaft, not shown in this figure. This upright shaft bears several arms, *d*, furnished with large teeth. The tun is bound with strong hoops of iron, and its contents are heated by means of a spiral tube laid on the bottom, perforated with numerous holes, and connected by a pipe with a high-pressure steam-boiler.

1898

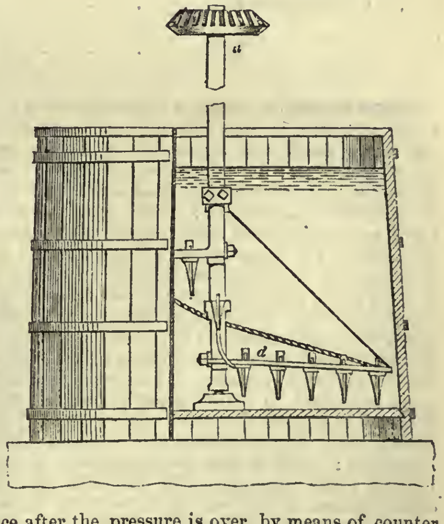


Fig. 1899 (next page) represents a longitudinal section of the horizontal hydraulic press for depriving stearic acid, as also spermaceti, of all their fluid oily impurities. *a* is the cylinder of the press; *b*, the ram or piston; *d d*, iron plates previously heated, inclosing hair and flannel bags and placed between every two cakes to facilitate the discharge of their oily matter; *e*, *e*, solid iron end of the press, made to resist great pressure; it is strongly bolted to the cylinder *a*, so as to resist the force of the ram; *g*, *g*, are rods for bringing back the ram *b* into its place after the pressure is over, by means of counter weights suspended to a chain, which passes over the pulleys *h*, *h*; *i*, *i*, a spout and a sheet-iron pan for receiving the oily fluid.

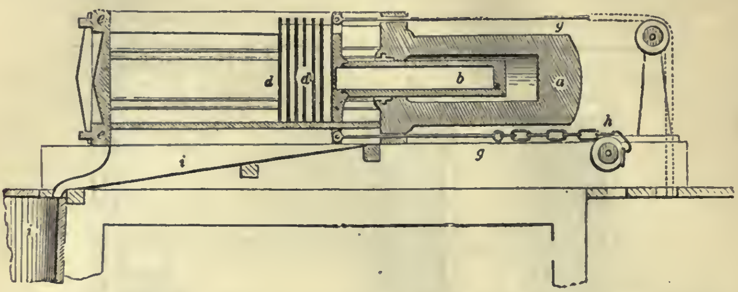
STEARINE (from Gr. *στέαρ*, *stear*, 'tallow'). The solid portions of fats are known by this term, the fluid portions being called *oleine*, from *ἔλαιον*, *elaion*, 'oil.' If melted tallow be dissolved in about eight times its weight of ether, on cooling the oleine alone remains dissolved, the stearine crystallises, and can be rendered absolutely pure

1899



by washing with ether. Stearine is a solid transparent substance, easily reduced to powder. At one time stearine was an object of manufacture; but the production of stearic acid has superseded it.

We Imported in 1873 *the following quantities of Stearine and Tallow:—*

STEATITE, or *Soapstone* (*Speckstein*, Ger.), is a massive variety of *talc.* It has a greyish-white or greenish-white colour, often marked with dendritic delineations, and occurs massive; it has a dull or fatty lustre; a coarse splintery fracture, with translucent edges; a shining streak; it writes feebly; is soft, and easily cut with a knife, but somewhat tough; does not adhere to the tongue; feels very greasy; infusible before the blowpipe; specific gravity from 2·6 to 2·8. It is found frequently in small contemporaneous veins traversing serpentine in all directions, as at Portsoy in Shetland, in the limestone of Icolmkiln, in the serpentine of Cornwall, in Anglesey, in Saxony, Bavaria (at Bayreuth), Hungary, &c. The chemical composition of steatite is silica 62·14, magnesia 32·92, water 4·94, being sometimes contaminated with and coloured with a little iron, manganese, or chrome. It is occasionally used in the manufacture of porcelain. It makes the biscuit semi-transparent, but rather brittle, and apt to crack with slight changes of heat. It is employed for polishing serpentine, marble, gypseous alabaster, and mirror-glass; as the basis of cosmetic powder; and as an ingredient in anti-attrition pastes, sold under the name of *French Chalk*; it is dusted in powder upon the inside of boots, to make the feet glide easily into them; when rubbed upon grease-spots in silk and woollen clothes, it removes the stains by absorption; it enters into the composition of certain crayons, and is used itself for making traces upon glass, silk, &c. The spotted steatite, cut into cameos and calcined, assumes an onyx aspect. Soft steatite forms excellent stoppers for the chemical apparatus used in distilling or subliming corrosive vapours. Lamellar steatite is *talc* See Talc.

STEEL (*Acier*, Fr.; *Stahl*, Ger.) is a carburet of iron, more or less freed from foreign matter, and may be produced by two processes opposed to each other: first, by working pig-iron, which contains 4 to 5 per cent. of carbon, in a suitable furnace, until such carbon is reduced to the quantity required for constituting steel, which is about 1 per cent.; the second method is to heat iron bars in contact with charcoal, until they have absorbed that quantity of carbon which may be required.

Steel may be classed into three kinds:

1st. Natural steel, which is manufactured from pig-iron direct.

2nd. Cemented or converted steel, which is produced by the carbonisation of wrought iron.

3rd. Cast-steel which is produced by the fusion of either natural or cemented steel, but principally from the latter.

The various kinds of iron which are used for the manufacture of steel were formerly imported from Sweden, Norway, and Russia; but the high price of Swedish and other steel-iron has compelled the consumers to look elsewhere for a supply of suitable iron, and to offer every encouragement to English manufacturers so to improve their steel-irons as to render them suitable for the production of steel.

England now furnishes a large quantity of iron suitable for steel purposes, which may be estimated at 20,000 tons per annum; this iron is manufactured with great care, often with an admixture of charcoal pig-iron, and various chemical reagents, which are added at the caprice of each manufacturer.

It is of the highest importance that the iron used for steel purposes should be as pure as possible; those irons which have long enjoyed the highest reputation are manufactured from the Dannemora ores in Sweden; the whole of the steel-irons produced in that country are smelted from the magnetic and red oxides containing usually 60 per cent. of metal.

Natural or German steel is so called because it is produced direct from pig-iron, the result of the fusion of the spathose iron ores alone, or in a small degree mixed with the brown oxide. This crude-iron contains 4 to 5 per cent. of carbon and 4 to 5 per cent. of manganese. Karsten, Hassenfratz, Marcher, and Réaumur, all advocate the use of grey pig-iron for the production of steel; indeed they distinctly state that the best qualities cannot be produced without it; they state that the object of working it in the furnace is to clear away all foreign matters, but there can be no advantage gained by retaining the carbon and retaining it with the iron. The theory is incorrect, although it is supported by such high authorities. Grey-iron contains the maximum quantity of carbon, and consequently remains for a longer time in a state of fluidity than iron containing less carbon; the metal is not only mixed up with the foreign matter it may itself contain, but also that with which it may become mixed in the furnace in which it is worked. This prolonged working, which is necessary in order to bring highly-carbonised metal into a malleable state, increases the tendency to produce silicated oxides of iron; which mixing with the steel produced renders it 'red short,' and destroys many good qualities which the pig-iron may have originally possessed. In Austria, where a large quantity of natural steel is produced, the fluid metal is tapped from the blast-furnace into a round hole; water is sprinkled on the surface which chills it, and thus forms a cake about half an inch thick. This is taken from the surface, and the operation is again performed until the whole is formed into cakes, they are then piled edgewise in a furnace, and covered with charcoal, and heated to a full red heat for about 48 hours; by this process much of the carbon is discharged. These cakes are then used for producing steel in the refinery. A much superior quality is thus obtained with greater economy. It appears that the most perfect plan for manufacturing the steel is to free the crude metal as much as possible from its impurities whilst in a fluid state. The furnaces used for the production of natural steel are like the refineries in which charcoal-iron is produced. In all countries their *general* construction is the same, but each has its own peculiar mode of working. We find therefore, the German, the Styrian, the Carinthian, and several other distinct methods, yet all producing steel from crude-iron directly, although pursuing different modes of operation. These differences arise from the nature of the pig-iron each country produces, and the peculiar habits of the workmen. These modified processes do not affect the *theory* of the manufacture of the steel, but rather accommodate themselves to the peculiar character of the metal produced.

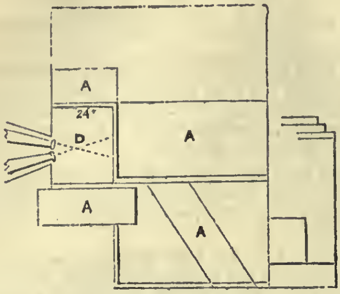
Fig. 1900 shows a ground-plan of the furnace; *fig*, 1901 an elevation; and *fig.* 1902 the form of the fire itself and the position of the metal within it. The fire, D, is 24 inches long and 24 inches wide; A, A, A, are metal plates, surrounding the furnace.

Fig. 1901 shows the elevation, usually built of stone, and braced with iron bars. The fire, G, is 16 inches deep and 24 inches wide; before the tuyère, at B, a space is left under the fire, to allow the damp to escape, and thus keep the bottom dry and hot.

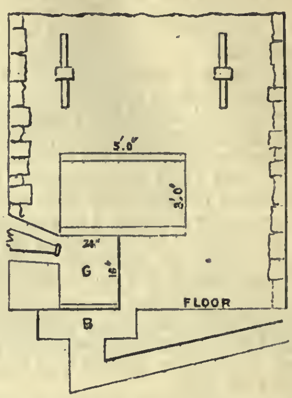
In *fig.* 1902 there are two tuyères, but only one tuyère iron, which receives both the blast nozzles, which are so laid and directed that the currents of air cross each other, as shown by the dotted lines; the blast is kept as regular as possible, so that the fire may be of one uniform heat, whatever intensity may be required.

Fig. 1902 shows the fire itself, with the metal, charcoal, and blast. A is a bottom of charcoal, rammed down very close and hard. B is another bottom, but not so

1900

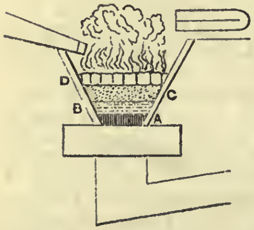


1901



closely beaten down; this bed of charcoal protects the under one, and serves also to give out carbon to the loop of steel during its production. C is a thin stratum of

1902



metal, which is kept in the fire to surround the loop. D shows the loop itself in progress.

When the fire is hot, the first operation is to melt down a portion of pig-iron, say 50 to 70 pounds according as the pig contains more or less carbon; the charcoal is pushed back from the upper part of the fire, and the blast, which is then reduced, is allowed to play upon the surface of the metal, adding from time to time some hammer-slag, or rich cinder, the result of the previous loop. All these operations tend to *decarbonise* the metal to a certain extent; the mass begins to thicken, and at length becomes solid. The workman then draws together the charcoal and melts down another portion of metal upon the cake; this operation renders the face of the cake again fluid, but the operation of decarbonisation being repeated in the second charge, it also thickens, incorporates itself with the previous cake, and the whole becomes hard; metal is again added until the loop is completed. During these successive operations, the loop is never raised before the blast, as it is in making iron, but it is drawn from the fire and hammered into a large bloom, which is cut into several pieces, the ends being kept separated from the middle or more solid parts, which are the best.

This operation, apparently so simple in itself, requires both skill and care; the workman has to judge, as the operation proceeds, of the amount of carbon which he has retained from the pig-iron; if too much, the result is a very raw, crude, untreatable steel; if too little, he obtains only a steelified iron; he has also to keep the cinder at a proper degree of fluidity, which is modified from time to time by the addition of quartz, old slags, &c. It is usual to keep from two to three inches of cinder on the face of the metal, to protect it from the direct action of the blast. The fire itself is formed of iron plates, and the two charcoal-bottoms rise to within nine inches of the tuyère, which is laid flatter than when iron is being made. This position of the tuyère causes the fire to work more slowly, but it ensures a better result.

The quantity of blast required is about 180 cubic feet per minute. Good workmen make 7 cwts. of steel in 17 hours. The waste of the pig-iron is from 20 to 25 per cent., and the quantity of charcoal consumed is 240 bushels per ton. The inclination of the tuyère is 12 to 15 degrees. The flame of the fire is the best guide for the workmen. During its working it should be a red bluish colour. When it becomes white the fire is working too hot.

When, care has been taken in melting down each portion of metal, and a complete and perfect layer of steel has been obtained after each successive melting, when the cinder has had due attention, so that it has been neither too thick nor too thin, and the heat of the fire regulated and modified during the progressive stages of the process, then a good result is obtained; a fine-grained steel is produced, which draws under the hammer, and hardens well. However good it may be it possesses one great defect; it is this. During its manufacture, *iron* is produced along with the steel, and becomes so intimately mixed up with it, that it injures the otherwise good qualities of the steel; the iron becomes, as it were, interlaced throughout the mass, and thus destroys its hardening quality. When any tool or instrument is made from natural steel, unless it has been well refined, it will not receive a *permanent* cutting edge; the iron part of the mass, of course, not being hard, the tool cuts only upon the steel portion; the edge, therefore, very soon becomes destroyed. There is another defect in natural steel, but it is of less importance. When too much carbon has been left, the steel is raw and coarse, and it draws very imperfectly under the hammer; the articles manufactured from such steel often break in hardening; thus it is evident, that in producing this kind of steel, every care, skill, and attention is required at the hands of the workman.

The raw steel, being imperfect, is not considered so much an article of commerce with the manufacturer, but it is sold to the steel-refiners, who submit it to a process of welding. The raw steel-bloom is drawn into bars one or two inches wide and half an inch thick, or less; a number of these are put together and welded; these bars are then thrown into water, and they are broken in smaller pieces to examine the fracture; those bars which are equally steelified are mixed together. In manufacturing refined steel, the degree of hardness is selected to suit the kind of article which it is intended to make. A bar, two to three feet long, forms the top and bottom of the bundle, but the inside of the packet is filled with the small pieces of selected steel. This packet is then placed in a hollow fire, and carefully covered from time to time with pounded clay, to form a coat over the metal, and preserve it from the oxidising influence of the blast. When it is at a full welding heat it is placed under a hammer, and made as sound and homogeneous as possible; it is again cut, doubled together, and again welded. For very fine articles, the refining is increased by several doublings, but this is not carried at present to so great an extent as formerly, since cast steel is substituted, being in many cases cheaper.

Natural steel being expensive, many attempts were made in Westphalia to produce a kind of steel by puddling pig-iron in a peculiar manner; a patent was taken out in England by Mr. Riepe, and a considerable quantity of this steel was produced. In Mr. Riepe's description of this process, he says:—

'I employ the puddling furnace in the same way as for making wrought iron. I introduce a charge of about 280 lbs. of pig-iron, and raise the temperature to redness. As soon as the metal begins to fuse and trickle down in a fluid state, the damper is to be partially closed in order to temper the heat. From 12 to 16 shovelsful of iron cinder discharged from the rolls or squeezing machine are added, and the whole is to be uniformly melted down. The mass is then to be puddled with the addition of a little black oxide of manganese, common salt, and dry clay, previously ground together. After this mixture has acted for some minutes, the damper is to be fully opened, when about forty pounds of pig-iron is to put into the furnace, near the fire-bridge, upon elevated beds of cinder prepared for that purpose. When this pig-iron begins to trickle down, and the mass on the bottom of the surface begins to boil and throw out from the surface the well-known blue jets of flame, the said pig-iron is raked into the boiling mass, and the whole is then well mixed together. The mass soon begins to swell up, and the small grains begin to form in it and break through the melted cinder on the surface. As soon as these grains appear, the damper is to be three-quarters shut, and the process closely inspected while the mass is being puddled to and fro beneath the covering layer of cinder. During the whole of this process the heat should not be raised above cherry-redness, or the welding heat of shear-steel. The blue jets of flame gradually disappear, while the formation of grains continues, which grains very soon begin to fuse together, so that the mass becomes waxy, and has the above-mentioned cherry redness. If these precautions are not observed, the mass would pass more or less into iron, and no uniform steel product could be obtained. As soon as the mass is finished so far, the fire is stirred to keep the necessary heat for the succeeding operation: the damper is to be entirely shut, and part of the mass is collected into a ball, the remainder always being kept covered with cinder slack. This ball is brought under the hammer, and then worked into bars. The same process is continued until the whole is worked into bars. When I use pig-iron made from sparry iron ore, or mixtures of it with other pig-iron, I add only about 20 lbs. of the former pig-iron at the later period of the process, instead of about 40 lbs. When I employ Welsh or pig-iron of that description, I throw 10 lbs. of best plastic clay, in a dry granulated state, before the beginning of the process, on the bottom of the furnace. I add, at the later period of the process, about 40 lbs. of pig-iron as before described, but strew over it clay in the same proportion as just mentioned.'

This steel is very useful for ships' plates, being very strong and rigid, and thus requiring less weight of metal; it may also eventually be used for rails and a great variety of purposes, for which at present strong charcoal or scrap iron is used.

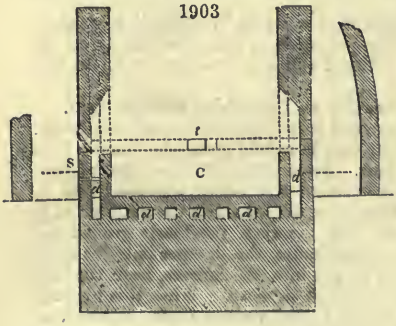
The Paal process may be considered as an improvement upon natural steel, the object being as far as possible to carbonise the iron fibres which this kind of steel always contains. The process is based upon the old one of Vanaccio: it consists in plunging iron into a bath of melted metal. The carbon of the metal combines with the iron, and in a very short time converts it into steel. This process was carried further by Vanaccio, who contrived to add wrought iron to the metal until he had decarbonised it sufficiently; this was found to produce a steel, but unfit for general use. That produced by plunging iron into metal was found to be a very hard steel on the outside, but iron within; while that produced by adding iron to the metal was found too brittle to be drawn. The Paal method, however, was a decided improvement in the manufacture of refined natural steel. The packets, as already described in the refinement of natural steel, are welded and drawn to a bar; whilst hot they are plunged into a bath of metal for a few minutes, by which the iron contained in the raw steel becomes carbonised, and thus a more regular steel is obtained than that produced by the common process. The operation requires great care, for if the bars of steel be left in the metal too long they are more or less destroyed, or perhaps entirely melted.

The foregoing kinds of steel may be classed under the first head of natural steel, being manufactured from the *crude iron direct.*

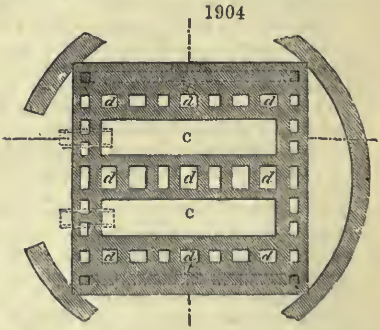
The next process is the production of steel by introducing carbon into malleable iron which is the reverse of the process already described. The iron to be converted is placed in a furnace, stratified with carbonaceous matter, and on heat being applied the iron absorbs the carbon, and a new compound is thus formed.

At a very early period charcoal was found to harden iron, and to give it a better and more permanent cutting edge. It seems probable that from hardening small objects bars of iron were afterwards submitted to the same process. To Réaumur certainly

1903

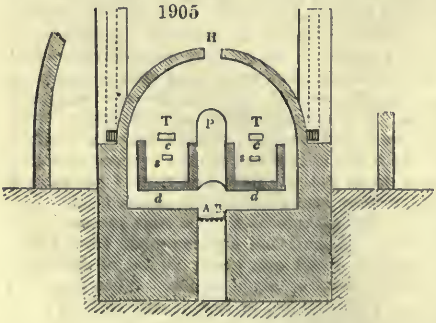


1904



belongs the merit of first bringing the process of conversion to any degree of perfection. His work contains much information on the theory of cementation; and although his investigations are not borne out by the practice of the present day, yet the first principles laid down by him are now the guide of the converter. Our furnaces are much larger than those used by Réaumur, and they are built so as to produce a more uniform and economical result. The furnace of cementation in which bar iron is converted into blistered steel is represented in *figs.* 1903, 1904, and 1905.

1905



It is rectangular, and covered in by a semicircular arch, in the centre of which there is a circular hole left, 12 inches diameter, which is opened when the furnace is cooling. It contains two chests, called 'pots,' c, c, made either of fire-stone or fire-bricks: each 'pot' is 3 feet wide, 3 feet deep, and 12 feet long. One is placed on one side, and the other, on the contrary side of the fire-grate, A B, which occupies the whole length of the furnace, and is 13 to 14 feet long; the grate is 15 to 16 inches broad, and the bars rest from 10 to 12 inches below the inferior plane or bottom level of the 'pots;' the height of the arch at the centre is 5½ feet above the top of the 'pots,' the bottoms of which are nearly level with the ground, so that the bars of iron do not need lifting so high when charging them into the furnace. The flame rises between the two 'pots;' it passes also below and around them, through the horizontal and vertical flues, *d*, and issues from the furnace through the six small chimneys, H, into a large conical space which is built around the whole furnace, 30 to 40 feet high, open at the top. This cone increases the draft of the furnace, and carries away the smoke. There are three openings in the front of the arch: two, T, *fig.* 1905, above the pots serve to admit and remove the bars; they are about 8 inches square; in each a piece of iron is placed upon which the bars slide in and out of the furnace. The workman enters by the middle opening, P, to arrange the bars, which he lays flat in the pots and spreads a layer of charcoal, ground small, between each layer; the bars are laid near each other, excepting those next to the side of the pot, which are placed an inch from it; the last stratum of iron is covered with a thick layer of charcoal, and the whole is carefully covered with loamy earth, 4 to 5 inches thick. The iron is gradually heated; in about four days it has become fully heated through, and the furnace has then attained its maximum heat, which is maintained for 2 or 3 days, until the first test bar is drawn out; the heat is afterwards regulated, according to the degree of hardness which may be required. The iron is converted in 8 days if for soft steel, and in 9 to 11 days if for harder purposes.

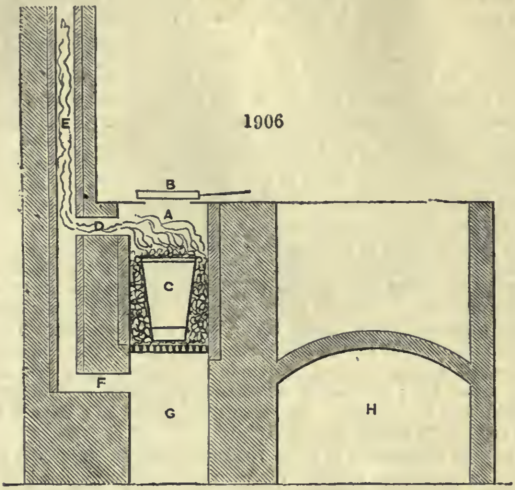
Conversion usually commences in 60 to 70 hours after the furnace is lighted. The pores of the iron being opened by heat, the carbon is gradually absorbed by the mass of the bar, but the *carbonisation* or conversion is effected, as it were, in layers. To explain the theory in the clearest manner, suppose a bar to be composed of a number of laminæ; the combination of the carbon with the iron is first effected on the surface, and gradually extends from one lamina to another, until the whole is carbonised. To effect this complete carbonisation, the iron requires to be kept at a considerable uniform heat for a length of time. Thin bars of iron are much sooner converted than thick ones. Réaumur states, in his experiments, that if a bar of iron $\frac{7}{16}$ths of an inch thick is converted in 9 hours, a bar $\frac{3}{16}$ths of an inch would require 36 hours to attain the same degree of hardness. The carbon introduces itself *successively*, the first lamina or surface of a bar combining with a portion of the carbon with which it is in contact, gives a portion of the carbon to the second lamina, at the same time taking up a fresh quantity of carbon from the charcoal; these successive combinations are continued until the whole thickness is converted: from which theory it is evident that from the exterior to the centre the dose of carbon becomes proportionately less. Steel so produced cannot be said to be perfect; it possesses in some degree the defect of natural steel, being more carbonised on the surface than at the centre of the bar. From this theory we perceive that steel made by cementation is different in its character from that produced directly from crude metal. In conversion the carbon is made successively to penetrate to the centre of the bar, whilst in the production of natural steel, the molecules of metal which compose the mass are *per se* charged with a certain percentage of carbon necessary for their steelification; not imbibed, but obtained by the decarbonisation of the crude iron down to a point requisite to produce steel.

Bar steel is also used for manufacturing shear steel. It is heated, drawn to lengths 3 feet long, then subjected to a welding heat, and some six or eight bars are welded together, precisely as described in the refinement of natural steel; this is called single shear. It is further refined by doubling the bar, and submitting it to a second welding and hammering; the result is a clearer and more homogeneous steel. During the last few years the manufacture of this steel has been limited, mechanics preferring a soft cast steel, which is much superior, when properly manufactured, and which can be very easily welded to iron.

The process of melting bar steel, and thus producing cast steel, was first practically carried on by Mr. Huntsman of Attercliffe: the process itself is very simple. *Fig.* 1906 shows a cross section of the furnace commonly used.

The furnace A, is square, lined with fire-stone 12 inches by 22 wide, and 36 inches deep from the grate-bar to the under side of the cover B. C is a crucible, of which two are placed in one 'melting-hole.' D is the flue into the chimney, E, which is about 40 feet high, lined with fire-brick. There is an air-flue, which is used to regulate the draught at F. G is the ashpit, and H the cellar which is arched over.

The steel is broken in pieces and charged into the crucible, which is placed on a stand and provided with a cover; coke is used as a fuel, and an intense heat is obtained. The crucible is charged three times during the day, and is then burnt through; the first charge is usually 36 lbs.; which requires from 3 to 4 hours to melt it; the



second charge is about 32 lbs., which is melted in about 3 hours; the last charge is 29 to 30 lbs., which does not require more than 2 to $2\frac{1}{2}$ hours to become perfectly melted. The consumption of coke averages $3\frac{1}{2}$ tons per ton of cast steel. When the steel is completely fluid the crucible is drawn from the furnace, and the steel poured into a cast-iron mould; the result is an ingot, which is subsequently rolled or hammered according to the wants of the consumer.

Although the melting of cast steel is a simple process, yet, on the other hand, the manufacture of cast steel suitable for the various wants of those who consume it requires an extensive knowledge.

1907

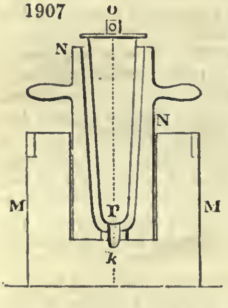


Fig. 1907 represents the mould for making the crucibles used for melting cast steel. Each manufacturer makes his own; M, M, is a solid block of wood let into the floor, having a hole which admits a round piece of iron fixed in the centre of the plug P. The material of which the crucible is made consists of 22 lbs. of fire-clay got from Stannington, near Sheffield, from the neighbourhood of Burton-on-Trent, or Stourbridge; 2 lbs. of the old crucible after it has been used, ground to powder, and about $\frac{1}{2}$ lb. of ground coke. These quantities are sufficient for one crucible of the ordinary size. This composition is trodden for 8 or 10 hours on a metal-floor; it is then cut into pieces of 26 to 28 lbs.; each piece is rolled round nearly to the size of the mould into which it is introduced, and the plug P is driven down with a mallet; the mould is furnished with a moveable bottom: when the pot is made, the mould is lifted up by the two handles, and fixing the bottom on a post, the mould falls, and leaves the crucible upon it.

Cast steel may be wanted for the engraver. It may be produced apparently perfect, and with a clear surface, but may be so improperly manufactured, that when the plate has been engraved and has to be hardened, it is found covered with soft places. The trial is even greater when the engraving is transferred by pressure to another plate. It is, therefore, evident that a steel-maker must not only attend to the intrinsic quality of his steel, but he has to use his judgment as regards the degree of hardness and tenacity which it should possess.

In manufacturing the commoner description of steel, particularly cast steel made from English iron, black oxide of manganese may be added to the steel in the crucible, and acts as a detergent. The oxygen unites with a portion of the carbon in the steel, forming carbonic oxide gas, which acts upon the imperfectly metallic portions of the steel used, and liberates the metal whilst the deleterious matter is taken up and forms a slag with the manganese. There has been a great controversy regarding the invention which originated with Mr. Heath. This substance is not generally used when the Dannemora irons are melted, as they are very pure, and the addition of an oxide partially destroys the temper of the steel.

Indian Steel, or Wootz.—The wootz ore consists of the magnetic oxide of iron, associated with quartz in proportions which do not seem to differ much, being generally about 42 of quartz and 58 of magnetic oxide. Its grains are of various size, down to a sandy texture. The natives prepare it for smelting by pounding the ore, and winnowing away the stony matrix, a task at which the Hindoo females are very dexterous. The manner in which iron ore is smelted and converted into wootz or Indian steel, by the natives at the present day, is probably the very same that was practised by them at the time of the invasion of Alexander; and it is a uniform process from the Himalaya Mountains to Cape Comorin. The furnace or bloomery in which the ore is smelted is from 4 to 5 feet high; it is somewhat pear-shaped, being about 2 feet wide at bottom, and 1 foot at top; it is built entirely of clay, so that a couple of men can finish its erection in a few hours, and have it ready for use the next day. There is an opening in front about a foot or more in height, which is built up with clay at the commencement, and broken down at the end of each smelting operation. The bellows are usually made of a goat's-skin, which has been stripped from the animal without ripping open the part covering the belly. The apertures at the legs are tied up, and a nozzle of bamboo is fastened in the opening formed by the neck. The orifice of the tail is enlarged and distended by two slips of bamboo. These are grasped in the hand, and kept close together in making the stroke for the blast; in the returning stroke they are separated to admit the air. By working a bellows of this kind with each hand, making alternate strokes, a pretty uniform blast is produced. The bamboo nozzles of the bellows are inserted into tubes of clay, which pass into the furnace at the bottom corners of the temporary wall in front. The furnace is filled with charcoal, and a lighted coal being introduced before the nozzles, the mass in the interior is soon kindled. As soon as this is accomplished, a small portion of the ore, previously moistened with water, to prevent it from running through the charcoal, but without any flux whatever, is laid on the top of the coals, and covered with charcoal to fill up the furnace.

In this manner ore and fuel are supplied; and the bellows are urged for 3 or 4 hours, when the process is stopped; and the temporary wall in front being broken down, the bloom is removed by a pair of tongs from the bottom of the furnace. It is then beaten with a wooden mallet, to separate as much of the scoriæ as possible from it, and while still red hot, it is cut through the middle, but not separated, in order merely to show the quality of the interior of the mass. In this state it is sold to the blacksmiths, who make it into bar iron, The proportion of such iron made by the natives from 100 parts of ore is about 15 parts. In converting the iron into steel, the natives cut it into pieces, to enable it to pack better in the crucible, which is formed of refractory clay mixed with a large quantity of charred husk of rice. It is seldom charged with more than a pound of iron, which is put in with a proper weight of dried wood chopped small, and both are covered with one or two green leaves; the proportions being in general 10 parts or iron to 1 of wood and leaves. The mouth of the crucible is then stopped with a handful of tempered clay, rammed in very closely, to exclude the air. The wood preferred is the *Cassia auriculata*, and the leaf that of the *Asclepias gigantea* or the *Convolvulus laurifolius*. As soon as the clay plugs of the crucibles are dry, from twenty to twenty-four of them are built up in the form of an arch, in a small blast furnace; they are kept covered with charcoal, and subjected to heat urged by a blast for about two hours and a half, when the process is considered to be complete. The crucibles being now taken out of the furnace and allowed to cool, are broken, and the steel is found in the form of a cake, rounded by the bottom of a crucible. When the fusion has been perfect, the top of the cake is covered with striæ, radiating from the centre, and is free from holes and rough projections; but if the fusion has been imperfect, the surface of the cake has a honeycomb appearance, with projecting lumps of malleable iron. On an average, four out of five cakes are more or less defective. These imperfections have been tried to be corrected in London by remelting the cakes, and running them into ingots; but it is obvious that when the cakes consist partially of malleable iron and of unreduced oxide, simple fusion cannot convert them into good steel. When care is taken, however, to select only such cakes as are perfect, to remelt them thoroughly, and tilt them carefully into rods, an article has been produced which possesses all the requisites of fine steel in an eminent degree.

The natives prepare the cakes for being drawn into bars by annealing them for several hours in a small charcoal furnace, actuated by bellows; the current of air being made to play upon the cakes while turned over before it; whereby a portion of the combined carbon is probably dissipated, and the steel is softened; without which operation, the cakes would break in the attempt to draw them. They are drawn by a hammer of a few pounds weight.

Hardening and *tempering* steel is a delicate operation. Small articles of cutlery are usually hardened by first heating them to a red heat and plunging them in water; saws and such articles are, when heated, plunged into oil. All articles are tempered by carefully heating them when hardened, and the degree of temper is indicated by a change in the colour of the surface, which is first straw-coloured, then blue, and deep blue: colour is thus made the most delicate test for the degree of temper given: after this operation, steel is found to expand a little. Alloys of steel have been very carefully made by Messrs. Stoddart and Faraday; but it can hardly be said that any alloy has at present been found to give any addition to the intrinsic quality of steel. The empiric titles of 'silver steel,' 'meteoric steel,' &c., may be regarded simply as fanciful names to recommend the article, either as a raw material, or in a manufactured state.

Those articles called 'run steel' are made by melting pig-iron and pouring it into moulds of sand in which the required article has been moulded; they are then packed in round iron pots, about 12 inches diameter and 16 to 18 inches high, along with hæmatite iron ore crushed to powder; these pots are packed in a furnace, and heat is applied from 24 hours to several days; the oxygen abstracts the carbon from the metal of which the articles are made, and they become to a certain extent malleable, so much so, that pieces a quarter of an inch thick may be bent almost double, and can be drawn out under a hammer. Forks, table-knives, scissors, and many other cheap articles are so made; also a vast variety of parts of cotton and flax machinery are so manufactured, especially those parts which are difficult to forge.

'Damascus' or 'damasked steel' is made by melting together iron and steel, or bars of steel of high and low degrees of carbonisation; it may also be produced by melting hard and soft steel in separate crucibles, mixing them together whilst fluid, and immediately pouring the mixture into an ingot mould; the damask is shown by the application of dilute acid to the surface when brightened. The analysis of a genuine Damascus sword-blade has shown that it is not a homogeneous steel, but a mixture of steel and iron.

Bessemer's Steel.—The undoubted success, and therefore the general adoption of this process for converting iron into steel, which derives its name from its inventor, renders it necessary that a full description of the process should be given.

The facility which the blast-furnace affords, of at once separating from the ores of iron the greater part of the extraneous matters which they contain, has rendered its employment almost universal, as a preliminary process in the production of malleable iron.

The crude metal thus obtained, although separated from a large proportion of its impurities, is nevertheless found to be intimately combined with carbon and silicum, and generally with sulphur, phosphorus, manganese, and some other substances, in comparatively minute quantities; the decarbonisation of the iron, and the separation of these substances, as far as is practicable, claims the first care of the manufacturer. For this purpose the crude metal is either formed into pigs, which are afterwards remelted in the 'finery furnace,' or it is run, while still in a fluid state, from the blast-furnace direct into the finery fire, where it is subjected to the action of blasts of air, directed downwards upon its surface, at a particular angle. The crude metal, thus acted upon by the oxygen of the air, is in about three hours sufficiently decarbonised and refined, to render it suitable for the puddling process; it is therefore run out of the 'finery' and formed into a large flat plate, which is of an extremely hard and brittle character, and presents physically no approach whatever to the malleable state. The hard and brittle mass, thus formed, is easily broken by the hammer into pieces of a size suitable for the puddling furnace, to which it is conveyed, in order to be more completely decarbonised and rendered malleable.

Iron on the verge of fusion loses its power of cohesion, and readily crumbles down into a coarse powder. This property is common to pig and to refined iron, and advantage is taken of it in the puddling process. The workman watches the temperature and appearance of the metal, and seizing the proper moment, divides the masses of refined iron into small fragments, which he spreads about the furnace, and finally breaks it down into a kind of coarse sand. The metal, in this divided state, exposes a large extent of surface to the refining action of the fluid cinder, as well as to the volume of air constantly passing through the furnace. By increasing the heat, the granulated mass swells up and emits numerous jets of blue flame. At this point the puddler diligently stirs and works the metal, until the flame appears of a whiter colour, and the metal becomes clotty and tenacious, or as the workmen term it, 'comes to nature;' after which, the iron is gathered into balls, and is then removed, as quickly as possible, to the squeezer, where much of the fluid scoriæ and other mechanically mixed impurities are driven out, leaving a mass or billet of iron, composed of thousands of separate fragments of metal, the entire surface of every one of which is more or less coated with dry oxide, or fluid silicate of the oxide of iron. The great pressure exerted by the squeezer suffices to so far remove the fluid coating of contiguous particles as to bring their surfaces into actual contact, and consequently to effect an union at such parts.

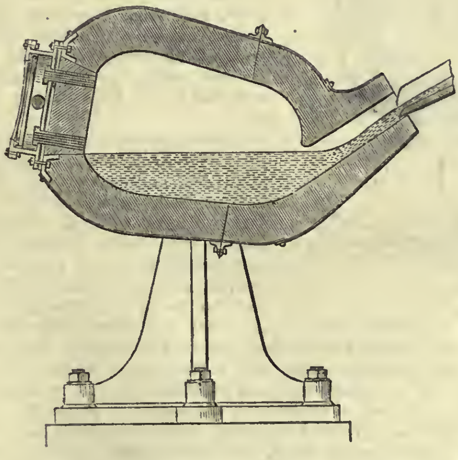
In the puddling process, the granules of metal gradually pass from the state of brittle finery-iron to steel, and passing that point, through every gradation of hard, medium, and soft steel, eventually arrive at the softest stage of decarbonised iron. The time occupied in these changes varies with the size of the granules, their temperature, and the extent to which each is exposed to the action of the air passing through the furnace.

It need not be a matter of surprise that when it was first proposed, by Mr. Bessemer, to convert crude pig-iron into malleable iron, while in a fluid state, and to retain the fluidity of the metal for a sufficient time to admit of its being cast into moulds, without the employment of any fuel in the process, that his proposition was almost generally looked upon as a mere day-dream, which the practical man felt bound to disbelieve.

Chemical investigation soon pointed out the real source of the difficulties which surrounded the Bessemer process. It was found that, although the metal could be wholly decarbonised, and the silicium be removed, the quantity of sulphur and phosphorus was but little affected. As different samples were carefully analysed, it was ascertained that the red shortness was always produced by sulphur, when present to the extent of one-tenth per cent., and that cold shortness resulted from the presence of a like quantity of phosphorus. It therefore became necessary to remove these substances. Steam and pure hydrogen gas were tried, with more or less success, in the removal of sulphur, and various fluxes, composed chiefly of silicates of the oxides of iron and manganese, were brought in contact with the fluid metal during the process, and the quantity of phosphorus was thereby reduced.

In manufacturing tool-steel of the highest quality, it was found preferable, for several reasons, to use the best Swedish pig-iron, and when converted into steel, by the Bessemer process, to pour the fluid steel into water, and afterwards to remelt the

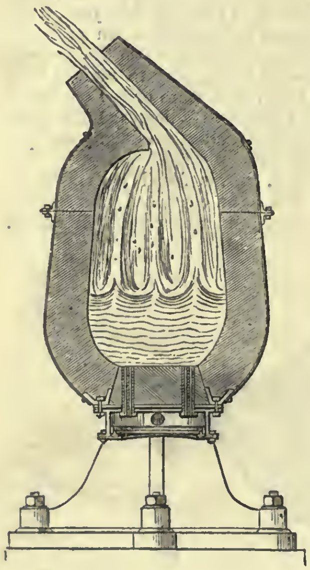
1908



shotted metal in a crucible, as is at present practised with blister steel, by which system the small ingots required for this particular article are more perfectly and more readily made. The production of first-class steel by the new process, although a mater of deep interest in one of the smaller branches of the iron trade, still left untouched that great source of this country's prosperity, the manufacture of malleable iron. It was, therefore, impossible to rest content without accomplishing this, the original object of the invention. On examining into the stores of mineral wealth so abundant in these islands, it was found that iron ore of the requisite purity existed as red hæmatite in vast beds. There are also extensive veins of spathose ore or carbonate of iron, and magnetic ores.

'The form of converting vessel which has been found most convenient, and by which superior specimens are produced, is shown in *fig.* 1908. The vessel is mounted on axes, at or near its centre of gravity. It is constructed of boiler-plates, and is lined either with fire-brick, road-drift, or 'ganister' (a local name in Sheffield for a peculiar kind of powdered stone), which resists the heat better than any other material yet tried, and has also the advantage of cheapness. The vessel having been heated, is brought into the position shown in *fig.* 1908, so that it may receive its charge of melted metal, without either of the tuyères being below the surface. No action can, therefore, take place until the vessel is made to assume the position shown in *fig.* 1909. The process is thus in an instant brought into full activity, and small though powerful jets of air spring upward through the fluid mass. The air expanding in volume, divides itself into globules, or bursts violently upwards, carrying with it some hundredweights of fluid metal, which again falls into the boiling mass below. Every part of the apparatus trembles under the violent agitation thus produced, a roaring flame rushes from the mouth of the vessel, and as the process advances, it changes its violet colour to orange, and finally to a voluminous pure white flame. The sparks, which at first were large, like those of ordinary foundry iron, change to small hissing points, and these gradually give way to soft floating specks of bluish light, as the state of malleable iron is approached. There is no eruption of cinder as in the early experiments, although it is formed during the process; the improved shape of the converter causes it to be retained, and it not only acts beneficially on the metal, but it helps to confine the heat, which during the process, has rapidly risen from the comparatively low temperature of melted pig-iron, to one vastly greater than the highest known welding heats, by which malleable iron only becomes sufficiently soft to be shaped by the blows of the hammer; but here it becomes perfectly fluid, and even rises so much above the melting-point as to admit of its being poured from the converter into a founder's ladle, and from thence to be transferred to several successive moulds. The thin shell, or skull of the ladle, shows the extreme fluidity of the metal, and also how little of it is solidified in the ladle during the time of casting.

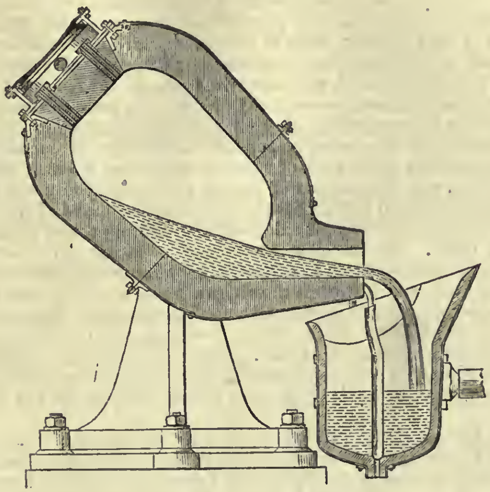
1909



'The oxygen of the air appears, in this process, first to oxidize the silicium, producing silicic acid, and next to seize the carbon which is eliminated, while the silicic acid, uniting with the oxide of iron, obtained by the combustion of a small quantity of metallic iron, thus produces a fluid silicate of the oxide of iron, or 'cinder,' which is retained in the vessel, and assists in the purification of the metal. The increase of temperature which the metal undergoes, and which seems so disproportionate to the quantity of carbon and iron consumed, is doubtless owing to the favourable circumstances under which combustion takes place. There is no intercepting material to absorb the heat generated, and to prevent its being taken up by the metal; for heat is evolved at thousands of points, distributed throughout the fluid, and when the metal boils, the whole mass rises far above its natural level, forming a sort of spongy froth, with an intensely vivid combustion going on in every one of its numberless ever-changing cavities. Thus, by the mere action of the blast, a temperature is obtained in the largest masses of metal, in ten or twelve minutes, that whole days of exposure in the most powerful furnaces would fail to produce.'

The changes in the colour and volume of the flame, and the kind of sparks thrown off, afford easy modes of judging of the state of the metal, since these are given off exteriorly, and are not interfered with by the flame of the fuel, as in the puddling furnace. The sound which the metal produces in the suspended vessel affords also a good indication to the workman. Indeed, few processes appeal so strongly to the external senses. All mere judgment on this point has, however, been rendered unnecessary, by the more certain indications, of an apparatus, which registers on a dial the exact number of cubic feet of air passed through the metal, whereby the precise degree of hardness of the steel is regulated at pleasure; its quality, in all cases, being dependent on the quantity of air passed through it; other circumstances being alike. When, therefore, the desired quantity of air has passed through the metal, the vessel is turned on its axis, and the fluid steel is poured out, as shown at *fig.* 1910.

1910



It is then received in the casting-ladle, which is attached to the arm of a hydraulic crane so as to be brought readily over the moulds. The ladle is provided with a fire-clay plug at the bottom, the raising of which, by means of a suitable lever, allows the fluid steel to descend in a clear, vertical stream into the moulds. As soon as the first mould is filled, the plug valve is depressed, and the metal is prevented from flowing until the casting-ladle is moved over the next mould, when, by raising the plug, the second mould is filled in a similar manner; and so on, until all the moulds are filled. After the discharge of the metal from the vessel, the process should be repeated without delay, since the temperature of the interior of the vessel is greater after the first charge than it was before, and consequently it is in a better condition for the process. The vessel may be moved on its axis by suitable gearing, but it is considered preferable to use hydrostatic pressure to effect every movement of the crane and of the vessel; so that when operating on from 5 to 10 tons at a single charge, the director of the process can, from a distant point, and with his own hands, effect every movement required, by merely working the handles which turn on, or off, the pressure of the water. He has also charge of the blast-cock, whilst the dial for registering the number of cubic feet of air is before him; and thus, by the control of one responsible man, charges of several tons of crude cast iron may be converted into malleable iron, or into steel, in a few minutes, and be cast into ingots of any desired form and weight, suitable for large shafts, or for rolling into rails, merchant bars, or plates.

The slags of the Bessemer process vary considerably in composition from those of the puddling furnace, being much more acid and approximate to the pyroxene formula. At Hörde, in Westphalia, a crystallised slag has been obtained which yielded, by analysis: silica, 44·73; protoxide of iron, 20·59; protoxide of manganese, 32·74; lime, 1·53; magnesia, 0·17 = 99·76.

Oxygen-ratio of silica to bases = 23·85 : 12·43.

Specific gravity, 3·08.

The crystals were found to be of the regular augite form, the angles being intermediate between those of the natural minerals, Pajsbergite and Babingtonite, as is also their composition.

The enormously high temperature developed by the action of cold air on molten cast iron in the Bessemer process is obviously due to the extreme rapidity with which the operation takes place, and the advantageous form of the converter for concentrating the heat developed. For, although the reactions and consequently the heat produced are in no way different from those of other finery processes, whether in the open fire or reverberatory furnace—carbon, silicon, manganese, and some iron being burnt in either case, with the production of carbonic oxide, silicates of protoxide of iron and manganese, and malleable iron—we have, in the blowing of a charge weighing five tons an amount of work done in about two and a half to three days in its performance in the puddling furnace. It has been pointed out by Jordan, that the principal part of the heat developed in the process is due to the combustion of silicon, which when oxidised to silicic acid, combines with protoxide of iron, and other bases, and remains in the bath in the form of slag; while in the case of carbon, a considerable portion of the heat is expended in volatilising the carbonic oxide produced, which escapes at the temperature of the melted metal, and burns to waste at the mouth of the converter. If the calorific power of silicon be assumed to be the same as that of carbon, the amount of heat produced by the combustion of one kilogramme of silicon to silicic acid will be 8,000 units,[1] when burnt in pure oxygen, or 6,382 in air; the difference between the two quantities corresponding to the amount required to heat up the inert nitrogen. Under the latter condition, one kilogramme of carbon will produce only 475 effective units, being the difference between 2,473 units theoretically developed and 1,998 units carried off by the gaseous products carbonic oxide and nitrogen, supposing them to escape at a temperature of 1400°. The use of steam instead of air as an oxidising agent, is, in the case of the combustion of iron or carbon, always disadvantageous on account of the great amount of heat required to free the oxygen from its combination with hydrogen, which is not reproduced to the same extent in the subsequent formation of carbonic oxide or protoxide of iron. With silicon, however, the conditions are somewhat different, as there is a small sensible gain. This will explain the reason why the use of steam in the refinery is only recommended for a few minutes at the commencement of the operation, that is, as long as free silicon remains in the pig-iron under treatment.

By applying the quantities given above to the calculation of the amount of heat developed in the blowing in one ton of Bessemer pig-iron of the ordinary quality produced in the south of France (which has the following composition per ton of 1,000 kilogrammes: carbon, 42·50; silicon, 20·00; iron and manganese, 937·50 = 1000·00), Jordan arrives at the following results:—

	Kilogrammes		Units of heat
The combustion of	20	of silicon produces . . .	127,648
,,	42·5	of carbon produces . . .	20,176
,,	87·5	of iron and manganese produces	66,237
		Or a total of .	214,061

If we take the specific heat of molten malleable iron at 0·16, the amount of heat developed will be sufficient to raise the temperature of the metal, which is supposed to be completely decarbonised, about 1350° above that of the cast iron when run into the converter.

The great heating power of silicon is, therefore, to be regarded as the reason for the use of dark-grey iron in the Bessemer process; under ordinary circumstances, about 2 or 2·5 per cent. silicon being considered as essential. Jordan states that in the steel works in the south of France the process could only be carried out by running the cast iron directly from the blast-furnace into the converter. The amount of silicon as a heat-producer in the Bessemer process may be, to some extent, taken by manganese; as is the case in Styria, where the cast iron used is smelted from the spathic ores. It is, however, less advantageous, because the deficiency in silica, which is required to flux the protoxide of manganese formed, can only be supplied by the destruction of the siliceous lining of the converter. The corrosive action of manganese on the hearths of blast-furnaces where spathic ores are smelted has already been noticed.

Although silicon is an essential component of good Bessemer pig-iron, it is of importance that the amount per cent. should be somewhere about the same as, or not very much more than that of the carbon. An excess of the former element, works prejudicially in two ways: first, it gives rise to an increased waste of iron in the slag; and secondly, it cannot be completely removed before the whole of the carbon is burnt away, so that it may happen in the blowing of such metal, that, although the process is apparently complete, as determined by the usual indication of the cessation of the flame from the converter, sufficient silicon is retained in the decarbonised metal to render the finished steel brittle and useless. Snelus gives the following analyses in illustration of this point:—

[1] This is in excess of the real amount, which has recently been determined to be 7,000. Jordan's original figures are however preserved, as the quantities are only given as approximations, for the purpose of illustrating the theory of the process, and not as absolute numerical determinations.

	I.	II.	III.	IV.

Ratio of carbon to silicon	1·6 : 1	2·7 : 1	2·4 : 1	4·8 : 1	19 : 1	17 : 1

I., melted charge of pig; II., metal at end of first stage, 6 minutes from start; III., metal after blowing 9 minutes; IV., over-blown metal, 13 minutes from start, before adding spiegeleisen; V., steel from ingot; VI., steel from finished rail.

The difference in the amount of copper, which is much larger in the Styrian steel than in that from Dowlais, is to be attributed to the fact that the pig-iron used in the former is entirely smelted from spathic ore, while in the latter only the spiegeleisen is due to that source. Copper pyrites, in small quantity, is almost invariably present in spathic carbonates, and however carefully they may be washed and weathered, some copper, as a general rule, is reduced and passes into the iron in the blast-furnace.

The progress of the conversion of the charge can be controlled to some extent by observing the spectrum given by the flame with the spectroscope; and more particularly the moment of complete decarbonisation may be determined with considerable accuracy, especially if the flame be bright and free from smoke. The spectrum produced when the combustion is most active is characterised by groups of numerous lines in the yellow and green portions, that of sodium being the most prominent and the first to appear among the former. There is also a well-defined group of lines in the blue field, and under the most favorable conditions the violet and red lines of potassium and lithium, together with an extra violet line accompanying the former are seen. For this, however, an instrument of great defining power and an extremely bright flame are essential. When the metal is completely decarbonised, the yellow and green lines disappear, but the sodium is persistent, sometimes even after the tipping of the converter. On the addition of the spiegeleisen, the whole of the lines reappear with great brilliancy. When there is much manganese in the cast iron employed, as is the case in Styria, the use of the spectroscope is difficult, owing to the brown smoky character of the flame.

At Seraing, it has been found that the disappearance of the dark absorption-bands, which alternate with the bright lines, can be more readily determined than the latter, which often reappear after their apparent extinction, and is therefore to be preferred as admitting of much closer and easier observation.

The exact chemical character of the spectrum of the Bessemer flame has not as yet been made out, although it has been the cause of considerable controversy, there being two different opinions as to its origin. One of these supposes the lines to be due to carbonic oxide, and their cessation to the complete combustion of the carbon; while the other considers that they are mainly produced by manganese, and that their sudden disappearance may be accounted for by the diminution in the amount of the metal volatilised until the quantity present in the flame is reduced below that necessary to produce them, it having been found that for the detection of manganese by the spectroscope much larger quantities must be employed than are sufficient to produce the ordinary reaction with soda on platinum-foil before the blowpipe.

Another indication of the progress of the operation is that afforded by the character of the slag. This has been employed in Austria and Sweden. An iron rod is inserted into the converter, and when brought out a portion of the slag adheres to the point. So long as any carbon remains unconsumed a peculiar brownish tint is observed; but as soon as the point of total decarbonisation is reached, the slag assumes a dead black colour, with a peculiar metallic lustre, characteristic of the presence of protoxide of iron, in considerable quantity. This test is said to be capable of great precision in the hands of experienced workmen.

The largest series of Bessemer converters hitherto erected are those at Barrow-in-Furness. They are arranged in two groups, of which one has four converters, taking 7½-ton charges, and the other a similar number of a smaller size, holding 6 tons each. The former are 9½ feet in greatest diameter, and 14¾ feet high. In all cases the proportion occupied by the melted metal is very small as compared with the entire capacity of the converter, a large empty space being required in order to prevent the ejection of the fluid contents when the boiling is at the highest point.

In Sheffield the loss of weight on the pig-iron employed is about 15 per cent. in addition to 7½ per cent. in the reverberatory melting furnace, or 22½ per cent. in all. With 3-ton converters the lining has to be renewed after blowing 250 tons; but the tuyères wear out much quicker, and must be replaced after making 10 tons, that is, after every third or fourth operation.

The number of charges made daily is not more than four for each converter, as although the actual blowing does not require more than fifteen or twenty minutes, a considerable time is required for the accessory operations of melting the pig-iron, the solidification and removal of the castings, and the arrangements of the moulds.

The ingots, when drawn from the moulds, like those obtained from steel melted in crucibles, are always more or less unsound, and require to be compacted by hammering. For this purpose, they are raised to a bright red heat in a reheating furnace, care being taken to keep the hearth filled with smoking flame in order to prevent the carbon from burning away. They are then hammered, and at a second heat swaged down to the form of the first groove of the rolling mill, when intended for bars or rails. The length of the ingot is extended from 4½ to 8 feet under the hammer. In rolling rails two heats are required in addition. Spherical shots are cast a little larger than the size required, and afterwards reduced to the proper figure and dimensions by a steam-hammer with hemispherical swages.

Most metals, it must be observed, on losing their fluidity, lose for the moment their power of cohesion. Malleable iron, however, passes from the fluid into the pasty state, in which it possesses the property of welding, which forms so well-known and remarkable a peculiarity of that metal. Taking advantage of this fact, Mr. Bessemer tried an experiment on manufacturing iron, direct from the fluid metal, into endless sheets, in a manner analogous to that by which paper is now made of any length; this has not, however, been much used.

Considerable discussion has arisen respecting the introduction of manganese in the Bessemer steel, both as to its value in producing a superior metal, and as to the discovery of its value in the process. These questions were satisfactorily answered in a communication read before the British Association at Birmingham in 1865, to which those who are interested in the process are referred.

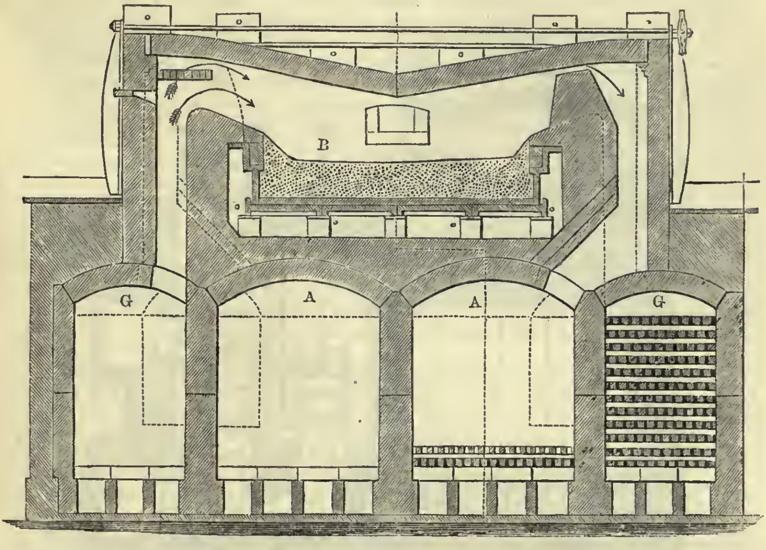
Siemens-Martin Process.—The production of cast steel in the reverberatory furnace, by dissolving malleable scrap in molten cast iron according to the method proposed by Heath, Price, and Nicholson, and others, has of late been brought to a considerable degree of perfection by the use of the regenerative gas-furnace, which gives an intense heat without requiring an oxidising or cutting draught; as is the case with ordinary stack-draught furnaces. The process was first carried out on a working scale by Martin of Sireuil, near Paris, who has given his name jointly with that of Siemens to the process. The furnace is represented in longitudinal and transverse section in *figs.* 1911 and 1912. The regenerators A A and G G are placed below the bed in the usual manner, the former being employed for heating air and the latter for gas. The bed B is made of finely-ground quartz sand, consolidated by pressure, with strong heating, and is supported on cast-iron plates, which are kept cool by a circulation of air. The surface of the bed is flat, with a slight inclination towards the top hole, which is placed below the middle working-door, on the front of the furnace. The ladle, which has a similar arrangement for running out the steel through a hole in the bottom, to that employed in the Bessemer process, is mounted upon wheels, and travels upon a railway, the ingot-moulds being arranged in a straight line in the pit below.

According to the size of the furnace, the charge may be from 35 cwts. to 5 tons. The materials used are good pig-iron, such as that employed for Bessemer steel-making, wrought iron in the form of bars, malleable scrap, or Bessemer steel cross-ends and waste, and spiegeleisen. The pig-iron is first melted, and the malleable iron or steel is added in small quantities at a time; care being taken to raise it to a white heat by exposure to the stream of gas on the bridges before immersing it in the bath of molten cast iron.

The reversal of the gas- and air-valves takes place every 20 minutes. As soon as the entire charge is dissolved, a sample of the metal is taken out in a small wrought-iron ladle, and after casting, is cooled in water and broken.

The heat is continued with an oxidising flame until the assay-sample, although suddenly cooled, gives a perfectly soft and tough metal, indicating the point of total decarburisation. When the spiegeleisen is added, care should be taken to charge it

1911



through the hole nearest to the bridge, which at the time is on the flue side of the furnace. When it is melted, which usually takes about 20 minutes time, the charge is stirred, in order to mix the contents as uniformly as possible: an operation which must be done quickly, in order to prevent loss of manganese in the slag. The contents of the furnace are then run into the ladle and cast into ingots in the usual way, the same precautions being observed as in the Bessemer process. Usually three charges are made in 24 hours. The yield per charge of 35 cwts. is from 32 to 33 cwts. of ingots, the ordinary loss being 8½ per cent., or in the most favourable case, about 6 per cent. The furnace must be let down for repairs at intervals of six weeks at the longest.

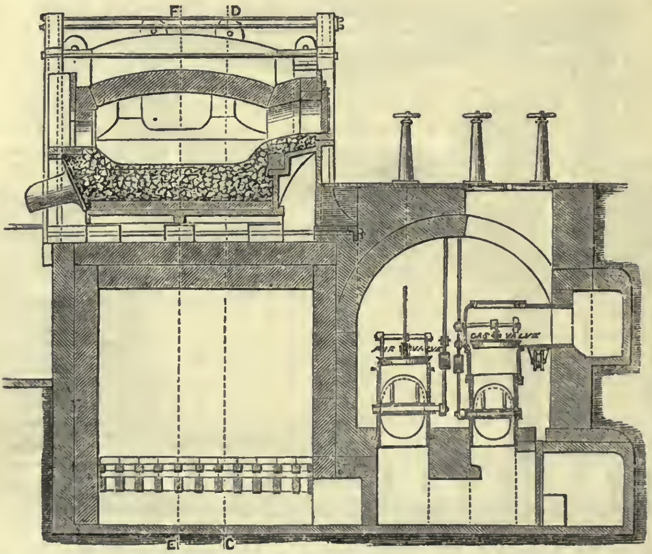
This process is of great advantage for the working-up of the waste of Bessemer steel-works, which cannot safely be added to the charge in the converter; a plan which has been tried, but not with success. Puddled bars, made specially, cut into proper lengths, and good scrap, such as that obtained in the neighbouring tin-plate forges, are the principal forms of malleable iron used in South Wales.

Another modification of the Siemens process consists in the use of finely-divided iron in the spongy state produced by the reduction of a pure red or brown hæmatite by a current of carbonic oxide at a red heat, instead of bars or other manufactured forms of malleable iron. In the newest arrangement adopted for this purpose, the finely-divided spongy iron produced in upright retorts is made to pass into a gas-furnace with an enclosed bed, where it is consolidated by immersion into a melted magnetic oxide of iron, produced by the partial reduction of hæmatite, sufficient lime being incorporated with the mass to flux the silica of the ore. These agglomerated masses are then treated in the bath of pig-iron, producing steel directly by the oxidising action of the magnetic oxide in the carbon in the melted metal. The above process has since been abandoned in favour of the rotatory furnace described under the article Iron.

In a lecture delivered by Dr. C. Wm. Siemens before the Chemical Society, he thus described his process of producing cast steel upon the open hearth of a regenerative furnace. Two processes are employed at the Landore works: the Siemens-Martin process, which consists, as already stated, in dissolving scrap-metal or steel in a bath of pig-metal, to which spiegeleisen is finally added; and the ore-reducing process, in which pig-metal and ore in a more or less reduced condition is employed.

The process chiefly employed at the Landore works consists of introducing on the bed of an intensely-heated regenerative gas-furnace, as shown in *figs.* 1911 and 1912, about 6 tons of pig-metal, which may be No. 3 or 4 hæmatite pig. When a fluid-bath has been formed, oxide of iron, which should by preference have been smelted beforehand with such proportions of lime or other fluxing materials as to form with the silica in the ore and in the pig-metal, a convenient slag, is added; or natural ores may be used in their raw condition if they contain lime and manganese, as for example,

1912



the African Mokta ore. When about 30 cwts. of this ore have been dissolved (with ebullition,) in the metallic bath, it is found that a sample taken from it contains only about 1 per cent. of carbon: a point which can easily be detected by the eye of the workman by a peculiar bright appearance of the sample when chilled in water and broken by the hammer.

Considerable difficulty was experienced to find a material to resist the excessive heats necessary for carrying out this process: ordinary Dinas bricks, which are considered the most refractory material in general use, would be rapidly melted; but a brick specially prepared by crushing pure quartz-rock, and mixing it with no more than 2 per cent. of quick-lime to give cohesion, answers well. The hearth of the furnace is made of white sand with a small admixture of more fusible fine sand, which mixture sets exceedingly hard at a steel melting-heat, and possesses the advantage of combining into a solid mass with fresh materials introduced between the charges to make up for wear and tear. The hearth and the furnace-roof, if of the materials just specified, are very little attacked when the Siemens-Martin process is used, although the heat must be sufficient to maintain wrought iron containing only a trace of carbon in a perfectly fluid condition. If pig-metal and ore (fused together with the necessary amount of flux) is used, the furnace also stands well, but the use of raw ore entails the disadvantage of a more rapid destruction of the furnace; even magnetic oxide of the purest description necessitates the addition of raw lime for the formation of a fusible slag, and the dust arising from the lime and sand through the decrepitation of the ore, causes the silica-bricks to melt away rapidly, so that, after perhaps two months' usage, the 9-inch arch of the furnace is reduced to the thickness of from 1 to 2 inches. It is evident that silica is, chemically speaking, an objectionable material to be used in the construction of these furnaces, because it prevents the formation of basic slags, and that a furnace constructed of pure alumina or lime would be preferable. M. Le Chatelier suggested, some years ago, the use of *Bauxite* (from Beaux in France, where it was first discovered), a mineral consisting chiefly of alumina, for making the furnace-beds, but Dr. Siemens was not able to succeed with this, owing to the great contraction of the mass when intensely heated, and non-cohesion with the same material introduced for the purpose of repair. In attempting to construct the sides and roof of the furnace of Bauxite bricks, these were not found to be equal in heat-resisting power to silica-bricks, which latter are indeed unobjectionable, except when raw ore and limestone are used. See BAUXITE.

STEEL, HARDENING OF. Steel may be hardened by plunging it into cold water. Prussiate of potash and other salts are used for producing especial degrees of hardness. See TEMPERING OF STEEL.

STEMPLES. A *mining term.* Strong pieces of timber, driven betwixt the sides of a vein, at short distances apart, to support the walls.

STEREOCHROME. A name given to a process of stereotyping, the printing of which is effected in colours. It is a term also used for the art of painting, with silica fluids for mixing the colours.

STEREOSCOPE (from Gr. *στερεός*, *stereos*, 'solid,' and *σκοπεῖν*, *skopein*, 'to see'). An instrument invented by Professor Wheatstone, and modified by Sir David Brewster, by means of which two images of the same object, depicted on paper,—as those images would be depicted upon the retina of each eye—are resolved into an apparent solid of three dimensions. The reflecting stereoscope of Professor Wheatstone was constructed by means of two mirrors, set at right angles to each other, so that while the right eye observed a reflected image of a picture placed on the right-hand side of the instrument, the left eye saw a reflected image of that on the left, and, as a result, saw—not two plane pictures, but one solid image. The refracting stereoscope, which is generally used, consists of two semi-lenses. This is a lens which is divided in the middle, and the two halves, with the edges towards each other, placed in a frame, at a distance from each other corresponding with the distances of the eyes apart. For the best result, two pictures are obtained by photography, as nearly as possible of the same character as the pictures impressed respectively upon the retina of each eye. See Hunt's 'Manual of Photography.'

STEREOTYPE PRINTING signifies printing by fixed types or by a cast typographic plate. This plate was formerly always, and is still sometimes, made as follows:—The form, composed in ordinary types, and containing, one, two, three, or more pages, inversely as the size of a book, being laid flat upon a slab, with the letters looking upwards, the faces of the types are brushed over with oil, or, preferably, with plumbago (black lead). A heavy brass rectangular frame of three sides, with bevelled borders adapted exactly to the size of the pages, is then laid down upon the chase,[1] to circumscribe three sides of its typography; but the fourth side, which is one end of the rectangle, is formed by placing near the types, and over the hollows of the chase, a single brass bar, having the same inwards-sloping bevel as the other three sides. The complete frame resembles that of a picture, and serves to define the area and thickness of the cast, which is made by pouring the pap of Paris-plaster into its interior space up to a given line on its edges. The plaster-mould, which soon sets, or becomes concrete, is lifted gently off the types, and immediately placed upright on its edge in one of the cells of a sheet-iron rack mounted within the cast-iron oven. The moulds are here exposed to air heated to fully 400° Fahr., and become perfectly dry in the course of two hours. As they are now friable and porous, they require to be delicately handled. Each mould, containing generally two pages octavo, is laid, with the impression downwards, upon a flat cast-iron plate, called the floating-plate; this plate being itself laid on the bottom of the dipping-pan, which is a cast-iron square tray, with its upright edges sloping outwards. A cast-iron lid is applied to the dipping-pan and secured in its place by a screw. The pan having been heated to 400° in a cell of the oven, under the mould-rack, previous to receiving the hot mould, is ready to be plunged into the bath of melted alloy contained in an iron pot placed over a furnace, and it is dipped with a slight deviation from the horizontal plane, in order to facilitate the escape of the air. As there is a minute space between the back or top surface of the mould and the lid of the dipping-pan, the liquid metal on entering into the pan through the orifices in its corners, floats up the plaster along with the iron plate on which it had been laid, thence called the floating-plate, whereby it flows freely into every line of the mould, through notches cut in its edge, and forms a

[1] Chase (*chassis*, Fr., 'frame'), and quoin (*coin*, Fr., 'wedge'), are terms which show that the art of printing is indebted to our French neighbours for many of its improvements.

layer or lamina upon its face, of a thickness corresponding to the depth of the border. Only a thin metal film is left upon the back of the mould. The dipping-pan is suspended, plunged, and removed, by means of a powerful crane, susceptible of vertical and horizontal motions in all directions. When lifted out of the bath, it is set in a water-cistern, upon bearers so placed as to allow its bottom only to touch the surface. Thus the metal first concretes below, while by remaining fluid above, it continues to impart hydrostatic pressure during the shrinkage attendant on refrigeration. As it thus progressively contracts in volume, more metal is fed into the corners of the pan, in order to keep up the pressure upon the mould, and to secure a perfect impression, as well as a solid cast.

The whole process is greatly improved by the employment of a prepared bibulous paper, instead of the plaster-of-Paris. The paper employed was originally of French manufacture, but is now made in England. Four sheets of tissue and one sheet of brown paper being pasted together, it forms one sheet. The form of type being ready, a sheet of this prepared paper is placed upon it, and it is then beaten into the face of the type by hard hand-brushes. It is then filled in the blank parts with paste, when the whole is then covered by a thicker sheet of paper, and it is then passed under a heated press for about two minutes to dry. On removing the paper it is found to have received a most perfect impression of the type. This impressed paper mould is then placed in an iron box, which is fixed in a nearly vertical position, and the heavy cover being carefully closed, there only remains between it and the mould exactly the space which is necessary to ensure a proper thickness to the type-metal. All being prepared, the melted metal is poured into the mould. It flows, of course at once to the bottom of the mould, and as the liquid is rapidly supplied, the whole is filled, and, as in the case already given, some pressure is obtained by the head of metal above the paper-mould. The mass of metal (iron) forming the casting box, in comparison with the thin plate of type-metal, ensures a rapid chilling of the latter, so that the plate can be removed in a very short time. The impression thus obtained is exceedingly perfect; and the whole process is one of great simplicity and exactness, and is capable of being executed with great rapidity.

'The Times' and other daily newspapers are regularly printed from stereotype-plates; but most of the machines for taking the matrices, were invented by Mr. Sweet, at 'The Times' office, and save one half of the time used by beating the form with brushes, each plate being cast and placed on the machine in about a quarter of an hour.

The advantages of a solid block over a form of loose type will be sufficiently obvious to all; and, but for the security which is afforded by the use of the solid plate, there would be great risk in driving the printing machinery at such high rates of speed as are employed in 'The Times' office and other offices, where they require to throw off a very large impression within a very limited time. See PRINTING and PRINTING MACHINERY.

STILL. See DISTILLATION.

STIPPLE ENGRAVING is a process which was practised by Bartolozzi, Ryland, and others, in imitation of chalk-drawings of the human figure. Stipple is performed with the graver, which is so managed as to produce the tints by small dots, rather than by lines, as in the ordinary method. It is very soft in its effect, but inferior to the more legitimate mode of engraving. See ENGRAVING.

STOCKING MANUFACTURE. See HOSIERY.

STONE is earthy matter, condensed into so hard a state as to yield only to the blows of a hammer, and therefore well adapted to the purposes of building. Such was the care of the ancients to provide strong and durable materials for their public edifices, that but for the desolating hands of modern barbarians in peace and in war, most of the temples and other public monuments of Greece and of Rome would have remained perfect at the present day, uninjured by the elements during 2,000 years. The contrast, in this respect, of the works of modern architects, especially in Great Britain, is very humiliating to those who boast so loudly of social advancement; for there is scarcely a public building of recent date which will be in existence one thousand years hence. Many of the most splendid works of modern architecture are hastening to decay, in what may be justly called the very infancy of their existence. This is remarkably the case with the bridges of Westminster and Blackfriars; the foundations of which began to perish most visibly in the very lifetime of their constructors.

Stones for building, it is stated, may be proved as to their power of resisting the action of frost, by the method, first practised by M. Brard, and afterwards by MM. Vicat, Billaudel, and Coarad, engineers of the bridges and highways in France. The operation of water in congealing within the pores of a stone may be imitated by the action of a salt, which can increase in bulk by a cause easily produced; such as efflorescence or crystallisation, for example. Sulphate of soda, or Glauber's salt, answers the purpose perfectly, and it is applied as follows:—

Average samples of the stones in their sound state, free from shakes, should be sawed into pieces 2 or 3 inches cube, and numbered with China-ink or a graving tool. A large quantity of Glauber's salt should be dissolved in hot water, and the solution should be left to cool. The clear saturated solution being heated to the boiling point in a saucepan, the several pieces of stone are to be suspended by a thread in the liquid for exactly one half-hour. They are then removed and hung up each by itself over a vessel containing some of the above cold saturated solution. In the course of 24 hours, if the air be not very damp or cold, a white efflorescence will appear upon the stones. Each piece must be then immersed in the liquor in the subjacent vessel, so as to cause the crystals to disappear, be once more hung up, and dipped again whenever the dry efflorescence forms. The temperature of the apartment should be kept as uniform as possible during the progress of the trials. According to their tendency to exfoliate by frost, the several stones will show, even in the course of the first day, alterations on the edges and angles of the cubes; and in five days after efflorescence begins, the results will be manifest, and may be estimated by the weight of disintegrated fragments, compared to the known weight of the piece in its original state, both taken equally dry. In opposition to this, Mr. C. H. Smith, one of the commissioners for selecting the stone for the Houses of Parliament, states—'Such treatment, compared with that of nature, will be found to vary materially, both in detail and result. If Glauber's salt expands in changing from a fluid to a crystalline state, it is so little as to be inappreciable; whereas water increases considerably in bulk while freezing.' Many experiments selected from the Report on Stone for the New Houses of Parliament (March 1839), show that in M. Brard's treatment the effect is in most instances opposite to that of the action of the weather on stones which have been exposed to its influence many years. Some of the specimens well known to decay rapidly in a building disintegrated least of all by Brard's process; others of the most durable quality disintegrated more than all the rest, under similar treatment; consequently Brard's method of testing is not to be depended upon, and is liable to lead to erroneous conclusions.

The most important building-stones of the United Kingdom are the following:—

Granites—produced chiefly in Cornwall, Devonshire, Leicestershire, Aberdeenshire, and in Wicklow and Carlow.

Porphyries, Syenites, Elvans—obtained from Cornwall, Devonshire, Leicestershire, and many parts of Scotland and Ireland.

Sandstones—the chief quarries of which are in Yorkshire, Derbyshire, Shropshire, Surrey, &c., and in several of the Scottish counties. The Darley Dale, Craigleith, and other celebrated stones, belong to this class.

Millstone Grit is found largely in Derbyshire, in Yorkshire, and indeed in most of the coal-producing districts.

Dolomites, or Magnesian Limestones—Yorkshire, Durham, Northumberland, Derbyshire, and Nottinghamshire, produce these stones abundantly.

Oolites. The Bath Stone and Portland Stone are well-known examples of this stone; the stone from the quarries of Ancaster and of Ketton are also fine specimens of the class.

Limestones. These are very varied; the Purbeck marble, the Derbyshire marbles, the Lias beds, the Devonian Limestone, and the well-known Mountain Limestone being examples.

Slates. These are obtained in very great abundance in North Wales, in Devonshire, and in Cornwall; in some parts of Scotland and of Ireland.

Such are the principal varieties, although many others exist which are exceedingly useful. Most of the above will be found described under their respective heads.

STONE, ARTIFICIAL, for statuary and other decorations of architecture, has been made for several years with singular success at Berlin, by Mr. Feilner. His materials are nearly the same with those of English pottery; and the plastic mass is fashioned either in moulds or by hand, being in fact a Terra-Cotta, which see. His kilns were peculiar in form, and economical in fuel, but they were in but few respects different from the pottery-kilns already described. See Kiln.

Many ingenious arrangements have been made for the construction of artificial stone. We might, of course, group under this head many varieties of clay-wares and cements.

Amongst all the numerous plans which have been devised, few of them have altogether succeeded; they have either proved too expensive in the manufacture, or they have not endured the test of time.

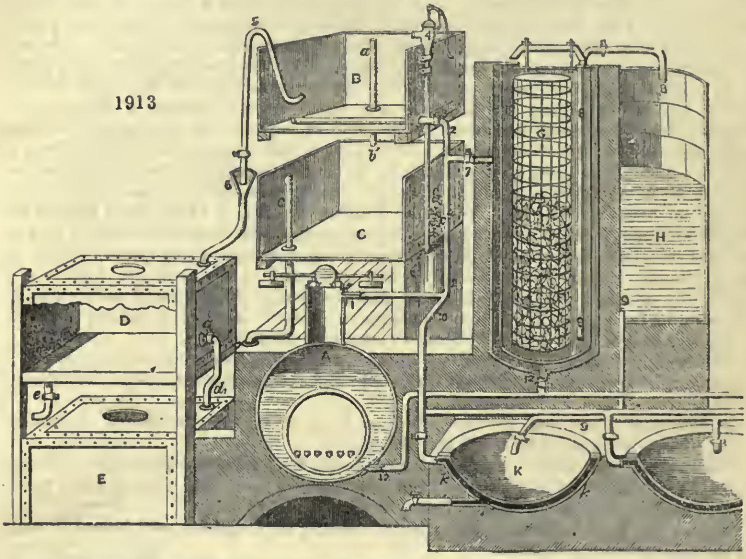
Mr. Buckwell proposed the following:—Taking fragments of stone sufficiently large to go freely into his mould, he fills up the interstices with stones of various sizes, and then pours in a mixture of chalk and Thames mud or Mersey mud burnt together. This cement being poured into the mould, the whole is rammed together by falling hammers, and as the mould is perforated, the water is forced out, and the resulting stone is so hard, when removed from the mould, that it rings when struck. It will be evident to those acquainted with hydraulic mortars and the application of concrete, that this is only an improved concrete. The cost of production has been too great to admit of the general introduction of this artificial stone.

Ransome's Patent Siliceous Stone, being the most successful attempt to produce a permanent stone artificially, requires further attention.

After numerous failures, it occurred to Mr. Ransome that a solution of silica as a cementing material would be superior to any other, and he accordingly started on the inquiry after an easy method of producing a solution of flints.

The accompanying illustration (*fig.* 1913) gives a sectional view of the apparatus employed in preparing the solution of silica which Mr. Ransome employs.

1913



A is a steam-boiler, capable of generating a sufficiency of steam for heating the dissolving and evaporative vessels, and usually worked at a pressure of about 70 lbs. to the square inch. B is the upper lye-tank for dissolving the carbonate of soda. It is supplied with steam by the pipes 1, 2, 3, communicating with the boiler.

The first operation is to reduce the ordinary soda-ash of commerce to the condition of caustic soda. For this purpose the ash is first dissolved in the tank B, the water in which is heated by means of the perforated steam-pipe *b*. A quantity of quick-lime is then added, and the mixture well stirred. The soda is by this means deprived of the carbonic acid which it contains, by the quick-lime forming with it a carbonate of lime. To ascertain when the lye is quite caustic, a small portion is taken out in a test-tube, and a few drops of hydrochloric acid added. If there is no effervescence, it may be assumed that the soda is entirely deprived of its carbonic acid, and is consequently caustic. When the lime, now converted into chalk, has subsided to the bottom of the tank, the clear supernatant lye is drawn off by the syphon 5, into the funnel 6, leading into a closed vessel D, to prevent the carbonic acid of the atmosphere combining with it, and destroying its causticity. When the lye has been drawn off from B, the sediment remaining at the bottom of the tank is allowed to fall into the lower tank C, by withdrawing the plug *a*, from the pipe b^1. Any undissolved crystals of the carbonate of soda which have been entangled among the particles of the lime are now washed out and pumped back to the upper tank B, where it forms a portion of the next charge.

The clear caustic soda being contained in the closed tank D, has a further process of depuration to undergo before it is ready to be used as a solvent for the flints. The ordinary soda-ash of commerce is always more or less adulterated with a sulphate of soda, which although an inert substance in itself, if allowed to remain in the cement subsequently makes its appearance in an efflorescence on the surface of the finished stone. To get rid of the sulphate, the caustic solution of soda has added to it, in the tank D, a quantity of caustic baryta, obtained by burning the commercial carbonate of baryta with wood-charcoal. The caustic baryta seizes upon the sulphuric acid contained in the sulphate of soda, and forms with it an insoluble sulphate of baryta, which is precipitated on the bottom of the tank. The depurated lye is then drawn off by the pipe *d*, into the lower closed tank E, and the sulphate-of-baryta sediment passes off by the cock at the bottom. From E, the prepared solution of the caustic soda is pumped into the vertical boiler or digester F. This digester, in which the process of dissolving the flints is effected, is a cylindrical vessel, having a steam-jacket, *f*, into which steam from the boiler A is supplied by the pipes 1, 2, *y*. The inner cylinder F, is provided with a wire-basket G, reaching the whole length of the vessel, and serving to hold a collection of nodules of common flint. When F has been filled with the caustic lye, and the basket with flints, the manhole at the top is closed and well screwed down, so as to be able to resist a pressure of at least 60 lbs. on the square inch. The cock at *y* is then opened, and the full pressure of steam from the boiler passes into the jacket *f*, and causes the lye in F to rise to the same temperature. The condensed steam in the jacket *f* returns to the boiler by the pipe 12, which it enters below the water-line. The pressure maintained in the digester is generally about 60 lbs., and this is continued about 36 hours; at the end of which time the strength of the solution is tested. The workmen employed to superintend this part of the process generally use the tongue as the most delicate test. If the solution has a decidedly caustic alkaline taste, they conclude that there is still too much free soda in the cement, and the boiling is allowed to continue until the cement has a slightly sweetish taste, which occurs when the alkali has been nearly neutralised by combination with the silicic acid of the flints. A more scientific mode of testing the strength of the solution is to take a wine-glassful and drop a little hydrochloric acid into it; by this means the whole of the silica in the solution is thrown down by the acid combining with the soda, so as to form chloride of sodium. The precipitated silica presents an appearance resembling half-dissolved snow, and its comparative volume gives a good idea of the strength of the solution of the alkaline silicate.

When it is judged that the alkali has taken up as much of the silica as it is capable of doing, at the temperature to which it is subjected in the digester, the stop-cock *y*, in the steam-pipe communicating with the jacket, is shut, and a cock in the pipe 8 is opened. The pressure of the steam in F then forces the fluid silicate, through the pipe 8, into the vessel H, where it is allowed to stand for a short time to deposit any sediment which it may contain. From H it is then conveyed by the pipe 9 to the evaporating pan, K, which has a steam-jacket, *k*, supplied with steam by the pipe 10. The cement is then boiled in the evaporating pan until it becomes of the consistency of treacle, when it is taken out. The specific gravity of the cement when ready for use is about 1·600. The general proportions of the materials used in making up the artificial stone are about the following:—

10 pints of sand, 1 pint of powdered flint, 1 pint of clay, and 1 pint of the alkaline solution of flint.

These ingredients are first well mixed in a pug-mill, and kneaded until they are thoroughly incorporated, and the whole mass becomes of a perfectly uniform consistency. When worked up with clean raw materials, the compound possesses a putty-like consistency which can be moulded into any required form, and is capable of receiving very sharp and delicate impressions.

The peculiarity which distinguishes this from other artificial stones consists in the employment of silica both as the base and the combining material. Most of the varieties of artificial stone hitherto produced are compounds, of which lime, or its carbonate, or sulphate, forms the base; and in some instances they consist in part of organic matters as the cement, and having inorganic matters as the base.

To produce different kinds of artificial stone, adapted to the various purposes to which natural stones are usually applied, both the proportions and the character of the ingredients are varied as circumstances require. By using the coarser description of grits, grinding stones of all kinds can be formed, and that with an uniformity of texture never met with in the best natural stones. Any degree of hardness or porosity may also be given, by varying the quantity of silicate employed and subjecting it to a greater or less degree of heat.

For some descriptions of goods a portion of clay is mixed with the sand and other ingredients, for the double purpose of enabling the material to stand up during the process of firing in the kiln and to prevent its getting too much glazed on the surface.

The plastic nature of the compound allows of the most complex and undercut patterns being moulded with greater ease than by almost any other material we are acquainted with, if we except gutta-percha, which, however, has the drawback of being affected by common temperatures.

In attempting, however, to carry out this plan, Mr. Ransome found that two difficulties of a rather formidable character presented themselves. It was found that, in the process of desiccation, the surface of the stone parted with the moisture contained in the soluble silicate, and became hardened into a tough impervious coating, which prevented the moisture escaping from the interior of the mass. Any attempt to dislodge the water retained in combination with the silicate in the interior of the stone, by raising the temperature of the whole above 212°, had merely the effect of breaking this outer skin of desiccated silicate, and rendering the surface cracked and uneven.

Instead, therefore, of allowing the stones to be dried in an open kiln, they were placed in a closed chamber or boiler, surrounded with a steam-jacket, by which the temperature of the interior chamber could be regulated. In order that no superficial evaporation should take place while the stones were being raised to the temperature of the steam in the jacket, a small jet of steam was allowed to flow into the chamber, and condense among and on the surface of the goods; until, as the temperature of the interior of the stones rose to 212° and upwards, they became enveloped in an atmosphere of steam, which effectually prevented any hardening of the surface. The minute vents or spiracles formed by the steam as it was generated in the interior of the masses, remained open, when the vapour contained in the closed chamber was allowed slowly to escape, and afforded a means of egress to any moisture which might still be retained among the particles of sand and cement. The whole of the moisture contained in the silicate of soda having been thus vaporised before it left the stone, an opportunity was afforded it by opening a communication with the external atmosphere, to pass off, leaving the interior of the stone perfectly dry. Simple as this arrangement may seem, we will venture to say that not one of our readers has hit upon the expedient through his own cogitations on the subject.

The process, in effect, consists in stewing the stones in a closed vessel, and when all the moisture which they contain is converted into vapour, allowing it to escape, so that no one part of the mass can be dried before another. By this means Mr. Ransome was enabled to desiccate his artificial stone without any risk of the cracking or warping which had hitherto been the result of his attempts to harden them by exposure in an open stove.

After being thoroughly dried they are taken to the kiln, but, instead of being placed in *seggars* or boxes of clay, as is usually done in the potter's kiln, the goods are first bedded up with dry sand, to prevent any risk of their bending or losing their shape while burning. Flat slabs of fire-clay are then used to separate the various pieces laterally, and similar slabs are placed over them to form a shelf, on which another tier of goods is placed. The temperature of the kiln is very gradually raised for the first twenty-four hours; the intensity is then augmented until at the end of forty-eight hours a bright red heat is attained, when the kiln is allowed to cool gradually, for four or five days, when the goods are ready to be taken out.

From being composed almost entirely of pure siliceous matter, this artificial stone is not acted upon by acids, and is apparently quite insoluble, even in boiling water.

By proportioning the amount of cement, and varying the character of the sand which enters into the composition of the stone, it can be made porous or non-porous, as may be desired. The average absorbent power of artificial sandstone is less than that of the Bolsover Moor Dolomite used in the erection of the Houses of Parliament, and a little more than that of the Cragleith Sandstone.

An improvement in the manufacture of Ransome's Stone, or, as it is sometimes called *Apœnite*, was made and patented by the inventor in 1872.

It was found in practice that the process of washing the Ransome stone so as to completely remove all traces of the chloride of sodium, from large masses was open to objection; it was both tedious and expensive, especially in localities where there was a difficulty in obtaining a good supply of water at a reasonable cost, besides which in producing so large an amount of chloride of sodium which had afterwards to be removed as a waste product at a considerable cost. The bulk of the alkali, which was by far the most expensive ingredient in its composition, was ejected instead of being utilised, for still further increasing the density, strength, and hardness of the stone. Some years since a siliceous deposit was discovered at the base of the Chalk Hills in Surrey, possessing some very peculiar properties, amongst others, that of being readily soluble in a solution of caustic soda or potash at a moderately low temperature. Messrs. Paine and Way, in the 12th volume of the Journal of the Royal Agricultural Society, in a paper entitled 'On the Strata of the Chalk Formation,' thus describes the soluble silica deposit:—'Immediately above the gault, with the upper member of which it insensibly intermingles, lies a soft white-brown rock, having the appearance of a rich limestone. It is very remarkable on account of its low specific gravity, and still more so considering its position, by reason of the very small quantity of carbonate of lime which it contains. It is one of the richest subsoils of the whole chalk series, being admirably adapted for the growth of hops, wheat, beans, &c.

'The section of rock at Farnham is about 40 feet in thickness. The analysis gives as follows:—

	Per cent.
Combined water and a little organic matter	4·15
Soluble in dilute acids, 57·10:	
Silicic acid (silica)	46·28
Carbonic acid	none.
Sulphuric acid	trace.
Phosphoric acid	ditto.
Chlorine	none.
Lime	0·26
Magnesia	·07
Potash	·79
Soda	·43
Protoxide and peroxide of iron	6·12
Alumina	3·15
Insoluble in acids, 38·75:	
Lime	2·91
Magnesia	traces.
Potash	1·51
Soda	·60
Alumina, with a little oxide of iron	14·20
Silicic acid and sand	19·59
	100·00'

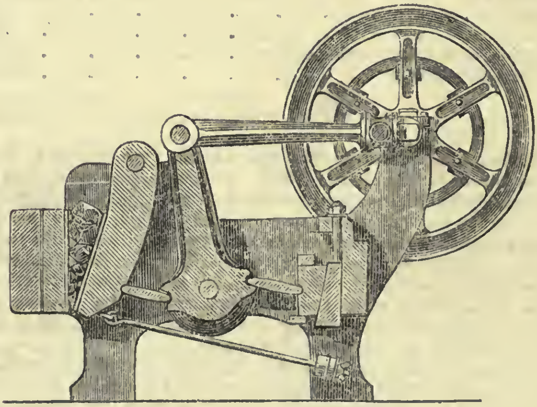
The same authors contributed another article to the 14th volume of the 'Journal,' on 'the Silica Strata of the Lower Chalk,' in which they state that 'when the former paper was published, they were not unaware that this stratum contained a large proportion of silica in the form which chemists call "soluble;" but that they wished, before making public their discovery, to ascertain whether it existed in sufficient quantity to render it available for agricultural use.' They then detail the result of their researches during the intervening two years, as far as they concern agriculture, mentioning all the localities in which this stratum may be found in England, and the various ways of employing it beneficially as a manure. They allude to the fact that it will be found useful in its application to the arts.

Taking advantage of this peculiarity, Mr. Ransome commenced a series of experiments, in order to determine if it were possible without the use of chloride of calcium, to produce a stone in all respects equal in quality to what had hitherto been made, and in this he succeeded. By mixing, in lieu of the chloride of calcium, suitable quantities of lime, (or substances containing lime), and the natural soluble silica above alluded to, with sand and a solution of silicate of soda or potash, which when intimately incorporated are moulded in the usual way, and allowed to harden gradually, as silicate of lime is formed by the decomposition of alkaline silicate produced by the action of the lime, the mass becomes thoroughly indurated, and in a very short time is converted into a very compact stone, capable of sustaining extraordinary pressure, and increasing in strength and hardness with age. Upon this improvement, Dr. T. Sterry Hunt makes the following remarks:—After expressing his satisfaction at the beautiful results arrived at by Mr. Ransome, who after years of experiment, had solved satisfactorily and completely a great industrial problem, he stated that he had followed with the more interest the labours of Mr. Ransome during many years, from the fact that he himself had formerly carried on, in 1857–58, a series of experiments very similar in character and in chemical results, in his endeavours to find out the method by which certain soft earthy rocks, consisting in great part of silica and carbonate of lime, have become hard and crystalline. Dr. Sterry Hunt had shown by researches in the laboratory, and also by observations of limestone strata in the vicinity of eruptive rocks, that a reaction between silica and carbonate of lime takes place in the presence of carbonate of soda, by which the alkali brought about, little by little, the solution of the silica, and its union with the lime to form a hard silicate of lime. This is nature's method. The action of alkali in dissolving the silica and then again giving it up to the lime, was an example of many of the so-called actions by presence, which are really cases of ordinary chemical affinity acting under peculiar conditions. It was reserved for Mr. Ransome, by using both the lime and the silica in their free, soluble and active forms, and by bringing in the alkali already combined with a portion of silica, to make this curious reaction very rapid, and to show that the product forms a cementing material which is available for binding particles of sand into hard stone-like masses. Mr. Ransome has also shown that the small amount of alkali used in the process itself, unites with the successive portions of silicate of lime formed, and becomes locked up in an insoluble compound, as is the case with alkali in granite rocks. Hence the new artificial stone, unlike the earlier products obtained by Mr. Ransome and by others, contains no soluble salts to be got rid of.

STONE- and ORE-CRUSHERS. Among the many modern forms of application, whereby mechanical devices are brought in aid of, and made to supersede, ordinary manual labour, there are few that have a wider range of utility than those which deal with the ores, stones, and rocks, and prepare them by reduction and comminution for the metallurgical and other processes on which so many of the arts and manufactures depend.

Mr. H. R. Marsden, of the Soho Foundry, Leeds, has long been known in connection with Blake's ore-crusher and stone-breaker, characterised by a peculiar 'toggle-motion.' The recent improvements are based substantially upon the Blake machine, but with novelties in details and in arrangement, constituting a new combination machine (see *fig.* 1914). An improved 'cubical' jaw is the most recent addition to the efficacy of these machines, for use when it is desirable or essential that the reduced material

1914

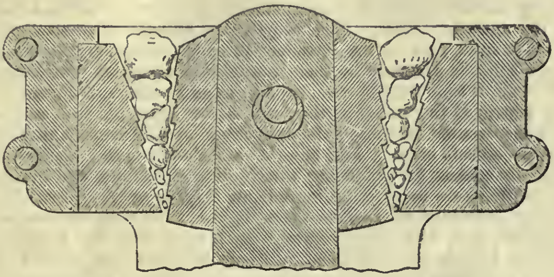


should be well and evenly broken up to a regular gauge and cubical form, as, more particularly in the case of road-metal. The construction of this jaw is simple, and consists in an extension of the lower end, and giving a curved form backwards to the moveable jaw; thus, the orifice of delivery is made to terminate a parallel channel of some 3 or 4 inches in length, wherein the corrugations of the fixed and moveable jaws are so arranged as to alternate the one with the other, *i.e.*, ridge against furrow, and *vice versâ;* and the action of this jaw leaves little to be desired in regard to the evenness and regularity of the resulting sample of broken stone; whence it is called 'cubical.' The combination of the steam-engine, crusher and screen upon one bed is generally adopted. This combined machine is useful for the breaking up and disintegration of all kinds of ores for the ironmaster and the miner in general. For these purposes the jaws can be changed according to the special degree of comminution desired; and this system is being adopted to replace rolls in various operations of grinding, on account of the fineness and evenness of the resulting material. A machine thus calculated to operate upon the most refractory materials, exercising powerful strains and destructive effects, while remaining itself comparatively unaffected, and capable of withstanding, without material depreciation, the great and 'constant' fatigue of such operations, is, it must be admitted, a valuable adjunct to the manufacturing processes in which it is available.

Another stone- and ore-crushing machine has been introduced by Mr. J. C. Cole, of the Montpelier Ironworks, Walworth, and it is especially adapted for the production of concrete or for crushing to very small fragments any mineral or stone. It has become necessary of late to produce such machines as will cost the smallest amount for transit, at the same time being equal to any work; and the manner in which this apparatus appears to answer renders it an important adjunct to or in connection with stampers,

&c., as the material produced is very regular, and nothing escapes the jaws of this particular machine larger than ⅝-inch cube, of which size it is capable of producing about 25 tons of material per day. The crushing jaws are arranged on each side of the main shaft, and at every revolution two strokes are given, which renders it double acting; and, if found necessary or requisite, one pair of jaws may be set to such a gauge as to produce larger material than the others, or both may be set either to a fine or

1915



coarse gauge (*fig.* 1915). In practice it is found necessary to reduce large pieces to about 2-inch cubes in one side of the machine. They are then placed in the other and reduced to fine material, and by this means a very large amount of work is done with very little power. The action of this machine will be readily understood without a drawing. All the bearings are protected from dust, and the apparatus is so simple that every part may be got at with ease. The machine does not weigh more than 30 cwts., and for mining enterprise, colonial or otherwise, this is of importance. There is no overflow, and all pieces of stone put into the hoppers are reduced in equal proportions. There are only three bearings in the whole apparatus. The crushing surfaces do not weigh more than 1 cwt. each, and are easily replaced.

A powerful stone-crushing machine has also been introduced by Mr. Goodman.

STONE, PRESERVATION OF. The attention of the scientific world has for some time past been directed to the importance of providing a means for protecting the stone of our public buildings from the ravages of time and the injurious effects of the polluted atmosphere of our manufacturing and populous districts.

The principal cause of the ruinous decay which is so apparent in the national edifices, churches, mansions, &c., of this country, is generally admitted to be the absorption of water charged with carbonic or other acid gases, which by its chemical action either decomposes the lime or argillaceous matter forming the combining medium uniting the several siliceous or other particles of which the stone is composed, or mechanically disintegrates those particles by the alternate expansion and contraction caused by variations of temperature.

Many processes have from time to time been suggested, and several patents secured, for filling up the pores of the stone, and thus preventing the admission of these deleterious agents, but they have been mostly if not entirely composed of oleaginous or gummy substances or compounds, which, although possessing for a time certain preservative properties, become decomposed themselves upon exposure, and constantly require to be renewed; whilst from the nature of these applications the discoloration necessarily produced is highly objectionable.

The process of silicatisation introduced by Kuhlmann has the disadvantage of requiring some considerable time before the atmosphere can do its work of effecting the necessary combination between the silica applied in solution to the stone, and the lime contained in it, and therefore when it is applied to the external parts of any building it is liable to be washed out before solidification has been secured. Mr. Frederick Ransome, advancing from his siliceous-stone process a step farther, meets the condition by effecting a chemical change at once within the stone. Mr. Ransome thus describes his process:—

The mode of operation is simply this:—The stone or other material, of which a building may be composed, should be first cleaned by the removal of any extraneous matter on the surface, and then brushed over with a solution of silicate of soda or potash (the specific gravity of which may be raised to suit the nature of the stone or other material); this should be followed by a solution of chloride of calcium, applied also with a brush; the lime immediately combines with the silica, forming silicate of lime in the pores of the stone; whilst the chloride combines with the soda, forming chloride of sodium, or common salt, which is removed at once by an excess of water. From the foregoing description it will be apparent that this invention has not only rendered the operation totally independent of any condition of the atmosphere in completing the process, but the work executed is unaffected by any weather, even the most excessive rains. Experience has shown that where once applied to the stone it is impossible to remove it, unless with the surface of the stone itself.

The application is one of extreme simplicity, and the material used perfectly indestructible. The rationale of the process is thus explained :—A liquid will enter any porous body to saturation, whilst a solid cannot go any farther than the first interstices next the surface. Take, then, two liquids capable of producing, by mutual decomposition, a solid, and by the introduction of these liquids into the cells of any porous body, a solid is produced by their mutual decomposition internally ; *ergo*, if a solid could not go in as a solid it cannot come out as a solid, and chemical decomposition having destroyed the solvents, they will never again be in a state of solution. The patentee has secured to himself the application of this important principle ; and whilst we name silicate of soda and chloride of calcium as the agents under mutual decomposition by contact for producing the chloride of sodium and the imperishable silicate of lime, there are many other ingredients capable of producing like results.

Several large buildings in London—the Baptist Chapel in Bloomsbury, amongst others,—Glasgow, and other cities, have been treated with Mr. Ransome's process ; a portion of the Houses of Parliament has been experimented on, and the result, so far as the time which has passed can test its merits, has been satisfactory.

STONEWARE. (*Faïence*, Fr. ; *Steingut*, Ger.) See Pottery.

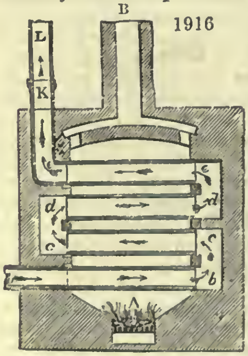
STORAX ; STYRAX. *Liquid storax* is obtained from the storax plant, *Styrax officinale.* The finest is a pellucid liquid, having the consistency and tenacity of Venice turpentine, a brownish colour and a vanilla-like odour. The common, which is imported from Trieste in casks, is opaque, of a grey colour, and of the consistency of bird-lime. This has been frequently confounded with liquid-ambar. Storax is employed in perfumery, and yields an odour, when sufficiently dilute, exactly resembling the fragrance of the jonquil. See Ambar, Liquid ; Perfumery.

Common storax ; Styrax calamita.—This is imported in large round cakes, of a brown or reddish-brown colour. 'It appears to consist of some liquid resin mixed with fine sawdust or bran.'—*Pereira.*

Storax in the tear.—This is imported in yellowish or reddish-white tears, about the size of peas. There are some other varieties, but these are not of sufficient importance to be noticed here. Storax has but little use, except as a pharmaceutical article.

STOVE (*Poêle, Calorifère*, Fr. ; *Ofen*, Ger.) is a fire place, more or less close, for warming apartments. When it allows the burning coals to be seen, it is called a stove-grate. Hitherto stoves have rarely been had recourse to in this country for heating our sitting-rooms; the cheerful blaze and ventilation of an open fire being generally preferred. Some arrangements have been introduced for close stoves, in which charcoal or coke was burnt, and which required little or no chimney. When coke or charcoal is burned very slowly in an iron box, the carbonic acid gas which is generated, being half as heavy again as the atmospheric air, cannot ascend in the chimney at the temperature of 300° Fahr.; but regurgitates into the apartment through every pore of the stoves, and poisons the atmosphere. The large stoneware stoves of France and Germany are free from this vice; because, being fed with fuel from the outside, they cannot produce a reflux of carbonic acid into the apartment, when their draught becomes feeble, as inevitably results from the obscurely burning stoves which have the doors of the fireplace and ash-pit immediately above the hearth-stone.

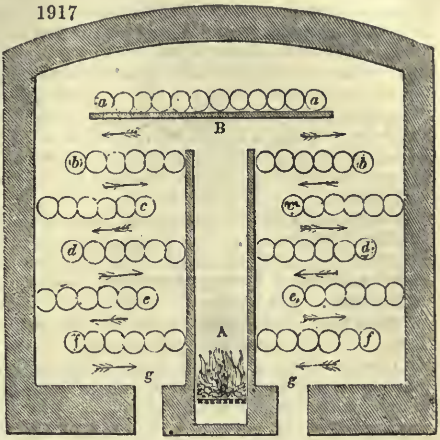
1916



Stoves when properly constructed may be employed both safely and advantageously to heat entrance-halls upon the ground story of a house; but care should be taken not to vitiate the air by passing it over ignited surfaces, as is the case with most of the patent stoves now foisted upon the public. *Fig.* 1916 exhibits a vertical section of a stove which has been recommended for power and economy; but it is highly objectionable as being apt to scorch the air. The flame of the fire A, circulates round the horizontal pipes of cast iron, *b b, c c, d d, e e*, which receive the external air at the orifice *b*, and conduct it up through the series, till it issues highly heated at K, L, and may be thence conducted wherever it is wanted. The smoke escapes through the chimney B. This stove has evidently two prominent faults: first, it heats the air-pipes very unequally, and the undermost far too much ; secondly, the air, by the time it has ascended through the zigzag range to the pipe *e e*, will be nearly of the same temperature with it, and will therefore abstract none of its heat. Thus the upper pipes, if there be several in the range, will be quite inoperative, wasting their warmth upon the sooty air.

Fig. 1917 exhibits a transverse vertical section of a far more economical and powerful stove, in which the above evils are avoided. The products of combustion of the fire A, rise up between two brick walls, so as to play upon the bed of tiles B, where, after communicating a moderate heat to the series of slanting pipes whose areas are represented by the small circles *a a*, they turn to the right and left, and circulate round the successive rows of pipes, *b b*, *c c*, *d d*, *e e*, and finally escape at the bottom by the flues *g*, *g*, pursuing a somewhat similar path to that of the burned air among a bench of gaslight retorts. It is known that two-thirds of the fuel have been saved in the gasworks by this distribution of the furnace. For the purpose of heating apartments, the great object is to supply a vast body of genial air; and, therefore, merely such a moderate fire should be kept up in A, as will suffice to warm all the pipes pretty equally to the temperature of 220° Fahr.; and, indeed, as they are laid with a slight slope, are open to the air at their under ends, and terminate at the upper in a common main pipe or tunnel, they can hardly be rendered very hot by any intemperance of firing. If the tubes be made of stoneware, its construction will cost very little; and they may be made of any size, and multiplied so as to carry off the whole effective heat of the fuel, leaving merely so much of it in the burned air as to waft it fairly up the chimney.

1917



Open fire places are, and probably will ever remain, favourites in this country. There is no doubt that the ordinary arrangement of our fireplaces is very defective. Much heat is lost—there is not an equal diffusion, and those sitting in the apartment are exposed to annoying draughts of cold air. Arranged as our buildings are, it is not easy to perceive how any very great improvement could be made so long as we desire the enjoyment of an open fire and the luxury of light and air.

In the greater number of stoves proper, the objections are obvious to every one. In the more common kinds of stove the fire is surrounded directly by the surface to be heated, which, being placed unprotected in the room, radiates heat and warms the air by direct contact. All such are liable to become overheated, and then the unpleasant smell imparted to the air is highly objectionable. Such stoves also dry the air, and the result is that headaches and other annoying sensations are produced. The common stoves need not be described. Dr. Arnott introduced, many years since, a stove in which the arrangements were very complete; and as the combustion was regulated with much facility, they were economical. The chief feature of Arnott's stove was a mode of adjusting the amount of air supplied to the fire. A regulating valve is fitted to the aperture of the ash-pit, consisting of a frame nicely balanced, and turning with the slightest force upon a centre; to this is attached a steel-yard, in which are several holes for the insertion of a weight. This determines exactly the size of the opening, and of course regulates the quantity of air admitted to the fire.

In these stoves there is a tendency, when the stove is not heated above 250° or 300°, to the formation of considerable quantities of carbonic acid, which finds its way into the room from the ashpit-door; and when the combustion is languid, carbonic oxide is often formed, which passes away by the chimney unconsumed, involving a loss of heat.

Space will not admit of our describing the Dutch or American stoves, which are mainly modifications of the ordinary forms, which are sufficiently well known.

It would, perhaps, be no exaggeration to say that with close stoves, heating apparatus, and other arrangements, in which there is no appearance of warmth, a *much higher temperature of the atmosphere is required to make it even feel* as warm as in that of an apartment heated by an open fire. Indeed, it may be fairly asserted that most persons will tolerate inconvenience and submit to expense, provided they see the cheerful blaze of the open fire, which they are at liberty to approach at will.

One of the large pyro-pneumatic stove-grates, when in full operation, is found to be capable of heating an apartment containing 50,000 cubic feet of air. In a very large church, containing upwards of 175,000 cubic feet of air, and capable of accommodating a congregation of 1,500 persons, four of these stoves of moderate size, arranged in convenient positions towards the angles of the building, so that every individual of the congregation may see the fire, are found to be sufficient in the coldest weather, and do not even require to be sustained in full action, except during a few hours in the morning. One of these stove-grates placed in the hall or lower part of a staircase, warms and tempers the internal climate of a large house, and gives the whole building a plentiful supply of pure fresh air. One of the smaller grates is capable of warming a large room. And whether in dwelling-houses, schools, churches, or apartments, the arrangements can readily be brought into operation at a moderate cost, and without any (beyond the most trifling) interference with existing structural arrangements.

STRAHLKIES. The German name for radiated pyrites.

STRAHLSTEIN. The fibrous varieties of hornblende (actinolite) are known to German mineralogists under this name. See HORNBLENDE.

STRASBURG TURPENTINE. See ABIES.

STRASS. See PASTES.

STRATA. Sedimentary rocks are generally spread out in layers called *strata*, whence they are known as *stratified rocks*. These strata exhibit a definite sequence; and the following table will show the order in which the several 'formations,' or groups of fossiliferous strata succeed each other in the British Isles, commencing with the uppermost, or most recent:—

1. *Tertiary* or *Cainozoic.*	2. *Secondary* or *Mesozoic.*		3. *Primary* or *Palæozoic.*	
Pliocene.	Cretaceous.	Chalk.		Permian.
Miocene.		Upper Greensand.	Carboniferous.	Coal-Measures.
Eocene.		Gault.		Millstone Grit.
		Neocomian.		Yoredale Rocks.
		Wealden.		Devonian.
	Jurassic.	Purbeck.	Upper Silurian.	Ludlow.
		Portland.		Wenlock.
		Kimmeridge Clay.		Upper Llandovery.
		Coral Rag.	Lower Silurian.	Lower Llandovery.
		Oxford Clay.		Bala Beds.
		Cornbrash.		Llandeilo.
		Great Oolite.		Arenig.
		Inferior Oolite	Cambrian.	Tremadoc Slates.
		Lias.		Lingula Flags.
		Rhætic Beds.		Menevian.
		Trias.		Laurentian.

STRAWBERRY. The fruits of various species of *Fragaria*, such as *F. vesca*, *F. elatior*, &c. They belong to the natural order *Rosaceæ*.

STRAW-HAT MANUFACTURE. The mode of preparing the Tuscany or Italian straw is by pulling the bearded wheat while the ear is in a soft milky state, the corn having been sown very close, and of consequence produced in a thin, short, and dwindled condition. The straw, with its ears and roots, is spread out thinly upon the ground in fine hot weather, for 3 or 4 days or more, in order to dry the sap; it is then tied up in bundles and stacked, for the purpose of enabling the heat of the mow to drive off any remaining moisture. It is important to keep the ends of the straw air-tight, in order to retain the pith, and prevent its gummy particles from passing off by evaporation.

After the straw has been about a month in the mow, it is removed to a meadow and spread out, that the dew may act upon it, together with the sun and air, and promote the bleaching, it being necessary frequently to turn the straw while this process is going on. The first process of bleaching being complete, the lower joint and root is pulled from the root, leaving the upper part fit for use, which is then sorted according to qualities; and after being submitted to the action of steam, for the purpose of extracting its colour, and then to a fumigation of sulphur, to complete the bleaching, the straws are in a condition to be platted or woven into hats and bonnets, and are in that state imported into England in bundles, the dried ears of the wheat being still on the straw.

Straw cannot be bleached by a solution of chloride of lime, as this preparation always turns the straw yellow. For this purpose, a cask open at both ends, with its seams papered, is to be set upright a few inches from the ground, having a hoop nailed to its inside, about six inches beneath the top, to support another hoop with a net stretched across it, upon which the straw is to be laid in successive handfuls loosely crossing each other. The cask having been covered with a tight overlapping lid, stuffed with lists of cloth, a brazier of burning charcoal is to be inserted within the bottom, and an iron dish containing pieces of brimstone is to be put upon the brazier. The brimstone soon takes fire, and fills the cask with sulphurous acid gas, whereby the straw gets bleached in the course of three or four hours. Care should be taken to prevent such a violent combustion of the sulphur as might cause black burned spots, for these cannot be afterwards removed. The straw after being aired and softened by spreading it on the grass for a night, is ready to be split, preparatory to dyeing. Blue is given by a boiling-hot solution of indigo in sulphuric acid, called *Saxon blue*, diluted to the desired shade; yellow, by decoction of turmeric; red, by boiling hanks of coarse scarlet wool in a bath of weak alum-water, containing the straw; or directly, by cochineal salt of tin, and tartar. Brazil-wood and archil are also employed for dyeing straw. For the other colours, see their respective titles in this Dictionary.

STREAM-WORKS. The name given by the Cornish miners to alluvial deposits of tin ore.

STREET MUD. This is a day of utilisation. We have already found out plans for turning old clothes into money, for making our fields fertile by using the refuse, and now the proverb 'cheap as dirt' seems likely to lose all its force. 'The Engineer,' speaking of the wet mud called 'Macadam milk,' which covers the streets of Paris in the rainy season, says: 'An adventurous individual has found an application for this stuff, and at the same time, it is said, an income of 400*l.* a year for himself. He collects the "milk," allows it to settle in large tanks, passes the precipitate through silk sieves, and forms it afterwards into what we call Flanders bricks for knife-cleaning, which sell at a franc each.'

Upon this Mr. John Phillips remarks, 'that by a similar process, and from similar material, stone or brick for cleaning or polishing steel and brass, and which is locally known as "rotten stone," has been for many years, and still is, manufactured at the Aller Works, near Newton Abbot. The roads in the neighbourhood which supply the raw material are macadamised with flints, which especially adapts it for this purpose. If credit is due anywhere for this utilisation of waste, let it not be monopolised by France, but let Devonshire claim its fair share.'

STRETCHING MACHINE. Cotton goods and other textile fabrics, either white or printed, are prepared for the market by being stretched in a proper machine, which lays all their warp and woof yarns in truly parallel positions. A very ingenious and effective mechanism of this kind was made the subject of a patent by Mr. Samuel Morand, of Manchester, in April 1834, which serves to extend the width of calico pieces, or of other cloths woven of cotton, wool, silk, or flax, after they have become shrunk in the processes of bleaching, dyeing, &c. The limits of this volume will not admit of its description, The Specification of the patent is published in 'Newton's Journal' for December 1835.

STRINGS, a *miner's term.* The name given by the Cornish miners to the small filamentous ramifications of a metallic vein.

STRINGY-BARK TREES. The great stringy-bark gum-trees of Australia are various species of *Eucalyptus.* They are so called in consequence of the bark separating in fibrous layers.

STRIPPING LIQUID, SILVERSMITH'S, consists of 8 parts of sulphuric acid and 1 part of nitre.

STROMEYERITE. A sulphide of copper and silver, found in Siberia, Silesia, Chili, and Peru.

STRONTIA (*oxide of strontium,* SrO), one of the alkaline earths, of which *strontium* is the metallic basis, occurs in a crystalline state, as a carbonate (*strontianite*) in the lead mines of Strontian in Argyleshire—whence its name. The sulphate (*celestine*) is found crystallised near Bristol, in New Red marl, and in several other localities; but strontian minerals are rather rare. The pure earth is prepared exactly like baryta, from either carbonate or the sulphate. It is a greyish-white porous mass, infusible in the furnace, not volatile, of a specific gravity between 3·0 and 4·0: 3·9231 (*Karsten*); having an alkaline reaction on vegetable colours, an acrid, burning taste, sharper than lime, but not so corrosive as baryta, potash, or soda. It becomes hot when moistened, and slakes into a white pulverulent hydrate, dissolves at 60° in 50 parts of water, and in much less at the boiling point, forming an alkaline solution, called *strontia*-water, which deposits crystals in four-sided tables as it cools.

These contain 60·9 per cent. of water, are soluble in 52 parts of water at 60° and in 2·4 parts of boiling water; when heated they part with 50 per cent. of water, but retain the other parts, even at a red heat. The dry earth consists of 84·6 of base, and 15·4 of oxygen. It is readily distinguished from baryta, by its inferior solubility, and by its soluble salts giving a red tinge to flame, while those of baryta give a greenish tinge. Fluosilicic acid precipitates the salts of the latter earth, but not those of the former. The compounds of strontia are not poisonous, like those of baryta. The only preparation of strontia used in the arts is the NITRATE.—H. W. B.

STRONTIA, CARBONATE OF. $SrO.CO^2$ (**$SrCO^3$**). See STRONTIANITE.

STRONTIA, NITRATE OF. $SrO.NO^5$ [**$Sr(NO^3)^2$**]. *Nitrate de strontiane*, Fr.; *Salpetersaurer Strontian*, Ger.) This salt is usually prepared from the sulphide of strontium, obtained by decomposing the sulphate with charcoal, by strong ignition of the mixed powders in a crucible. This sulphide being treated with water, and the solution being filtered, is to be neutralised with nitric acid, as indicated by the test of turmeric-paper; care being taken to avoid breathing the noxious sulphuretted hydrogen gas, which is copiously disengaged. The neutral nitrate being properly evaporated and set aside, affords colourless, transparent, slender, octahedral crystals. It has a cooling, yet somewhat acrid taste; is soluble in 5 parts of cold, and in one half-part of boiling water. Its principal use is the preparation of 'red fire' for pyrotechnic works and theatrical effects. A very beautiful exhibition of red fire is obtained by preparing a gun-paper, by treating ordinary bibulous paper with nitric and sulphuric acids, and then well washing it; when quite free from acid, it is to be dried, and then saturated with a solution of the chloride or nitrate of strontia.—H. W. B. See PYROTECHNY.

STRONTIA, SULPHATE OF. $SrO.SO^3$ (**$SrSO^4$**). See CELESTINE.

STRONTIANITE. Native carbonate of strontia.

STRONTIUM. The metallic base of the earth strontia; first obtained by Sir Humphry Davy, in 1808. It is prepared in the same way as barium. See BARIUM. See Watts's 'Dictionary of Chemistry.'

STRYCHNINE. $C^{42}H^{22}N^2O^4$ (**$C^{21}H^{22}N^2O^2$**). The bitter poisonous principle contained in the different *species* of *Strychnos*. It is usually extracted for commercial purposes from the nux-vomica bean, the seed of the *S. nux vomica*. It is a well-marked alkali, and yields a great number of crystalline salts with acids and metallic chlorides. Its true constitution has been fully made out by the researches of Messrs. Nicholson and Abel. Although a most valuable medicine in paralytic affections, when employed in very small doses, it is a dangerous remedy in unskilful hands, and has been the cause of numerous deaths arising from carelessness, without reckoning the many who have been destroyed by it at the hands of the poisoner. Some years ago a panic was occasioned by a rumour of its employment for the purpose of giving a bitter flavour to beer; this has been shown to be incorrect. Still the quantities of it produced annually by various manufacturers could not fail to excite attention and uneasiness. As much as 1,000 ounces have been known to be purchased at one time. It has been proved, however, that the chief use is for the destruction of wild animals in Australia and other thinly-peopled localities. A great number of processes have been devised for its preparation; but, after having been subjected to the extractive operations, the bean is generally found almost as bitter as before, indicating a want of economy in the methods. Probably the best method of extraction would be to disintegrate the beans with strong sulphuric acid (which is without action on strychnine), and then, after the addition of excess of alkali, to dissolve out the base with benzole or chloroform. The latter being distilled off would leave the strychnine nearly pure, and only requiring crystallisation. It has been shown by John Williams, that one bean will by this process yield a considerable quantity of crystals of pure strychnine.

STUCCO. See STONE, ARTIFICIAL.

SUBERIC ACID (from *Suber*, Lat. 'cork;' *Korksäure*, Ger.) is prepared by digesting grated cork with nitric acid. It forms crystals, which sublime in white vapours when heated.

It may also be obtained by boiling nitric acid with stearic, margaric, or oleic acids.

SUBLIMATE, is any solid matter resulting from condensed vapours. See CORROSIVE SUBLIMATE.

SUBLIMATION, the process by which volatile matter is evaporised by heat, and then condensed into a crystalline mass. For example, if gum benzoin is kept in a melted state, and even a cap of paper kept above it, the benzoic acid is first volatilised, and then condensed on the paper. For an example of sublimation, see AMMONIUM, CHLORIDE OF.

SUBMARINE LAMP. M. J. D. Pasteur, of Gennep, has invented a very simple and ingenious lamp for the use of divers. The great expense and trouble connected with the use of the electric light for diving apparatus led M. Pasteur to form the idea of a much cheaper and more practical lamp to burn under water; how the atmospheric air under pressure in the helmet of the diver, by means of the air-pump, is but partially deteriorated, and M. Pasteur tried to examine whether the remaining oxygen was still sufficient to maintain the light of an ordinary petroleum-lamp. The trial which he made for that purpose succeeded perfectly. On the opening in the helmet, where, by means of the valve, the consumed air escapes into the water, is screwed an India-rubber tube, $\frac{3}{4}$-inch diameter and 4 feet long, to which the water-tight lamp was attached. The side on which the air enters the lamp was, as in the helmet, divided in such a way as to prevent the light from being blown out, and to distribute the air, as much as possible, under and around the flame. The little valve-spindle, placed upon the helmet to prevent the entrance of the water, was taken away and put on the top of the lamp. Behind the light was placed a parabolic mirror, and on the front side a convex glass; to the back was fitted a crook to carry the lamp, whether in the hand or on the breast. M. Pasteur had the satisfaction to read with this lamp under water small hand-writing, and observed at the same time that neither the carbonic acid nor the vapour of water breathed out by the diver had any influence on the illuminating powers of the flame.

SUCCINIC ACID, or *Acid of amber* (*Acide succinique*, Fr.; *Bernsteinsäure*, Ger.), was formerly obtained by the destructive distillation of amber, in which process it was accompanied by an essential oil, and a little acetic acid; it was purified by being precipitated as succinate of lead, which, after being well washed, was decomposed by the equivalent quantity of sulphuric acid; the solution of succinic acid, thus obtained, was evaporated, and allowed to cool, when the succinic acid crystallised out. It seems to exist ready formed in amber.

It is easily obtained artificially by acting on stearic or palmitic acid with nitric acid. It also occurs in the leaves of the wormwood, and in many of the resins of the pine tribe. It may likewise be obtained by fermentation from asparagin, and from malic acid, malate of lime yielding nearly one-third of its weight of it.

In order to produce it from malic acid, 3 lbs. of crude malate of lime are to be diffused through a gallon of warm water, and 4 ounces of decayed cheese added to the mixture, which is to be kept at the temperature of 100° for about a week. Carbonic acid is disengaged, whilst a mixture of crystallised carbonate and succinate of lime is deposited, and acetate of lime remains in solution.

SUCCINITE. Prof. Dana has applied this name to the insoluble resin which forms about 80 per cent. of amber. See AMBER.

SUET. The internal fat of the abdomen of the sheep. See TALLOW.

SUGAR (*Sucre*, Fr.; *Zucker*, Ger.) is, with some slight exception, the sweet constituent of vegetable and animal products. It may be distinguished into three principal species. The first, which occurs in the sugar-cane, the beet-root, and the maple, crystallises in oblique four-sided prisms, terminated by two-sided summits; it has a sweetening power, which may be represented by 100; and in circumpolarisation it bends the luminous rays to the right. The second occurs ready formed in ripe grapes and other fruits; it is also produced by treating starch with diastase or sulphuric acid. This species forms cauliflower concretions, but not true crystals; it has a sweetening power, which may be represented by 60; and in circumpolarisation it bends the rays to the left. Berthelot has shown that a moderately strong solution of glycerine, in contact with certain animal membranes, is found, after some weeks, to produce a substance with the properties of grape-sugar. One pint of glycerine in 10 pints of water is added to the membrane, which may amount to $\frac{1}{20}$th of the weight of the glycerine. The time required is 10 to 12 weeks. If putrefaction begins, it is destroyed. The third variety is found in fruits, and also in sugar which has been long boiled, or heated with acids; this is called fruit-sugar. Besides these three principal kinds, the sugar of milk, and the sugar of manna or *mannite*, are found closely allied, and may be called two other species. Allied to these is *sorbine*, extracted from the elderberry, and *mosite*, which occurs in the flesh of animals.

Sugar, extracted either from the cane, the beet, or the maple, is identical in its properties and composition, when refined to the same pitch of purity; that of the beet is said to surpass the other two, since larger and firmer crystals of it are obtained from a clarified solution of equal density. Sugar melts at 320° Fahr., and on cooling forms a transparent substance usually called *barley-sugar*. When heated to between 400° and 410° Fahr. it loses two equivalents of water and becomes brown. Sugar thus fused is no longer capable of crystallisation, and is called *caramel* by the French, and is used for colouring liqueurs. Indeed, sugar is so susceptible of change by heat, that if a colourless solution of it be exposed for some time to the temperature of boiling water, it becomes brown and partially uncrystallisable. Acids exercise such an injurious influence upon sugar, that after remaining in contact with it for a little while, though they be rendered thoroughly neutral, a great part of the sugar will refuse to crystallise. Thus, if oxalic or tartaric acid be added to sugar in solution, and boiled, no crystals of sugar can be obtained by evaporation, even though the acids be neutralised by chalk or carbonate of lime. By boiling cane-sugar with dilute sulphuric acid, and keeping it at least at 150° Fahr., it is changed into grape-sugar, and then entirely into uncrystallisable sugar. Nitric acid converts sugar into oxalic acid. Alkaline matter is likewise most detrimental to the grain of sugar; as is always evinced by the large quantity of molasses formed when an excess of lime has been used in clarifying the juice of the cane or the beet.

Manufacturers of sugar should, therefore, be particularly watchful against the formation of acid from decomposition, or the introduction of any excess of alkali, or alkaline earth.

Sugar is soluble in all proportions in water, but it takes four parts of spirits of wine of spec. grav. 0·830, and 80 of absolute alcohol, to dissolve it, both being at a boiling temperature. As the alcohol cools, it deposits the sugar in crystals. Carmelised and uncrystallisable sugar dissolve readily in alcohol. Pure sugar is unchangeable in the air, even when dissolved in a good deal of water, if the solution be kept covered in the dark; but with a very small addition of gluten, the solution soon begins to ferment, whereby the sugar is decomposed into alcohol and carbonic acid, by the action of the air; it then passes into acetic acid, when it may be still farther decomposed.

Sugar forms chemical compounds with the salifiable bases. It dissolves readily in caustic potash-lye, whereby it looses its sweet taste, and affords on evaporation a mass which is insoluble in alcohol. When the lye is neutralised by sulphuric acid, the sugar recovers partially its sweet taste, and may be separated from the sulphate of potash by alcohol, but it will no longer crystallise.

Cane-sugar is soluble in all proportions in boiling water, and in $\frac{1}{3}$ of cold.

It is sparingly soluble in alcohol of 70 pc. and insoluble in absolute alcohol. The following table, by Payen, shows the quantity of sugar contained in saccharine solutions of various specific gravity at 59° Fahr.:—

Parts of sugar		Parts of water		Specific gravity
100	dissolved in	50	give a syrup of	1·345
100	,,	60	,,	1·322
100	,,	70	,,	1·297

The following table appeared in a previous edition of this work, and has been much used:—

Sugar in one hundred parts by weight	Sp. gr. at 60°	Sugar in one hundred parts by weight	Sp. gr. at 60°
66·666	1·3260	25·000	1·1045
50·000	1·2310	21·740	1·0905
40·000	1·1777	20·000	1·0820
33·333	1·1400	16·666	1·0685
31·250	1·1340	12·500	1·0500
29·412	1·1250	10·000	1·0395
26·316	1·1110		

The annexed table, constructed by Neimann for the normal temperature of 63°, with the same object, will be found useful:—

Sugar	Water	Specific gravity	Sugar	Water	Specific gravity
0	100	1·0000	36	64	1·1582
1	99	1·0035	37	63	1·1631

The specific gravity of crystallised cane-sugar is 1·594. Crystallised cane-sugar seems to be the most complete type of sugar known. Its crystals are the largest and most regular, and its taste the sweetest. These crystals are rhomboïdal prisms, and appear largest in the form of sugar-candy. When boiled much or heated with acids it would appear that a lower form of sugar resulted, namely, grape-sugar.

At 300° sugar loses 0·6 per cent., and remains uninjured after seven hours; it melts at 320°, and at this point it seems to have lost some of its sweetness, and probably a portion of water. The same result is obtained at a lower temperature if more time is allowed. The colour is changed to an orange-yellow at 410°: the sugar loses three equivalents of water, becomes gradually brown, has an empyreumatic taste, and is called *caramel.* With a heat approaching to a red heat, carburetted hydrogen, carbonic acid, acetic acid, and empyreumatic oils are produced, and carbon remains, amounting to 25 per cent. of the original mass.

Solutions of sugar are decomposed by caustic alkaline solutions, and by hot solutions of the carbonated fixed alkalis. Under these must be included both baryta and lime, if heat is to be long used: both of these substances form compounds with sugar. The compound of sugar and lime is very soluble in cold water, but is precipitated on heating. The amount dissolved is shown to be of true equivalent, by the inquiries of Peligot, who has proposed an ingenious method of ascertaining the amount of sugar in a solution by the estimation of the lime which it will dissolve. The lime in this process is estimated alkalimetrically by means of an acid. The following table has been constructed by M. Peligot for calculating the results (see next page).

Saccharimetry.—We now come to the estimation of sugar, which is most simply performed by the hydrometer, when the solutions are pure and the kind of sugar known. But commercially it is required to ascertain the proportions of cane-sugar, uncrystallisable sugar, water, and impurities, and this is accomplished most successfully

Quantity of sugar dissolved in 100 parts of water	Density of syrup	Density of syrup when saturated with lime	100 parts of residue dried at 120° contain	
			Lime	Sugar
40·0	1·122	1·179	21·0	79·0

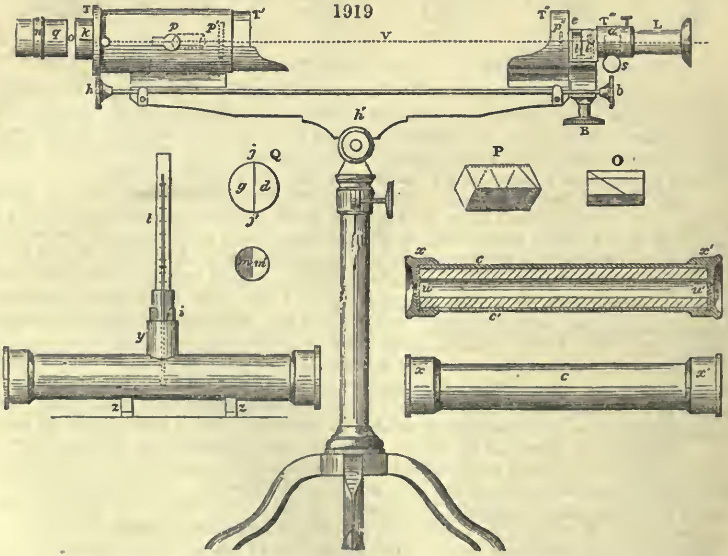
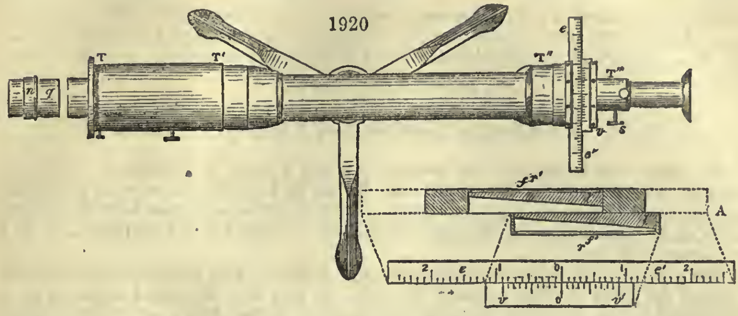
by means of the polarising saccharometer proposed by Biot and improved by Soleil. The following is a description of this beautiful instrument:—Two tubular parts, T T′, and T″ T‴, *figs.* 1919 and 1920, constitute the principal part of the saccharometer. The light enters *n*, through a Nicol's prism *q* (shown separately, *fig.* 1919, at O), and passes first an achromatic polarising prism *p* (shown separately at P) and afterwards through a plate of quartz of double rotation at *p*′, which is also shown at Q. This plate is composed of two semi-discs cut perpendicularly to the axis of crystallisation; but though exactly of equal thickness and equal rotating power, the one turns the ray to the right, while the other turns it to the left. At *p*″, the ray passes a plate of quartz of single rotation, and at *l l*′, two wedges of quartz endued with the power of rotation, but in a contrary direction to the preceding plate. These two wedges are again represented at A (*fig.* 1920), and are so made that by turning the milled head B, the sum of their thicknesses can be increased or diminished at pleasure, while the amount of thickness is shown by the ivory graduated scale *e e*′, and vernier *v v*′. Finally, the ray

1919



traverses an analysing prism *a*, and an eye-piece L. If the instrument is directed to the light the observer will see a luminous disc, bisected by a central line (produced by the junction of the two semi-discs of quartz) of exactly the same tint, but which tint may be varied at pleasure, by rotating the Nicol's prism *n*, by means of the milled head *b*. If, however, we interpose between *p'* and *p''*, the tube *c*, *fig.* 1919, filled with

1920



a solution of cane-sugar, and the ends closed with glass, the semi-discs will be *differently coloured.* Cane-sugar, possessing the power of circular polarisation, combines with the rotating power of the half-disc which turns the ray to the right, but tends to neutralise the half-disc, whose direction is the reverse. By increasing or diminishing the thickness of the wedges of quartz *l l'*, to the extent required for counteracting their rotation to the right, and causing the semi-discs to reassume the same colours, we have a means by the graduated scale *e e'*, *v v'*, of measuring the rotating power, which is exactly proportional to the amount of cane-sugar, temperatures being equal, and no foreign substance having the power of circular polarisation being present.

To apply this method, the deviation must be known which is produced by a solution of sugar of known strength. For this purpose a given weight, ϵ, of sugar is dissolved in such a quantity of distilled water that the solution occupies a given volume, V. Sufficient of this solution is taken to fill a tube of certain length, and the deviation suffered by the plane of polarisation of the luminous ray passing through this tube is measured. Let this deviation be α. Let then other quantities of sugar be dissolved in sufficient water to give the same volume of solution, V; and let the deviations produced by these solutions in the same tube be α', α'', α''', &c.; then the quantities of sugar contained in the volume, V, of these liquids will be represented by the products $\epsilon\frac{\alpha'}{\alpha}$, $\epsilon\frac{\alpha''}{\alpha}$, $\epsilon\frac{\alpha'''}{\alpha}$, &c., respectively. If the sugar examined, instead of being pure, is mixed with other but inactive substances, it is evident that these same products express the absolute weights of pure sugar contained in the weights of substances employed in the formation of the liquids of the given volume, V. It is possible to employ proof-tubes of different lengths; but it is then necessary to reduce by calculation the observed deflections to those which would have been produced in the same tube.

It often happens that solutions of sugar which have to be examined are turbid or strongly coloured. When this interferes with the examination, they must be clarified and rendered either quite colourless, or when this is not possible the colour must be at least reduced. This is often effected by precipitating the colouring-matter of the syrups with subacetate of lead; but the most accurate method is by a filter of animal-charcoal. The filtrates are then examined. When syrups contain, besides cane-sugar, other constituents which exert an action upon the plane of polarisation, the amount of cane-sugar present may be determined by inverting, by means of hydrochloric acid, the rotatory power of the cane-sugar. No other saccharine substance is, in fact, known which suffers a similar change under the same circumstances.

If, for instance, the liquid under examination contains besides cane-sugar, glucose, whose rotatory action on the plane of polarisation is in the same direction as that of cane-sugar; if α' be the deviation observed to be produced by the liquid, then α' is evidently the sum of the separate deflections of the cane-sugar x, and of the glucose, y. About one-tenth of its volume of hydrochloric acid is added to the syrup, and it is kept for ten minutes at a temperature of 140°—154°. The cane-sugar is thereby completely transformed into noncrystallisable sugar, which turns the plane of polarisation to the left, while the rotatory power of the glucose undergoes no alteration. When this change has been effected, the new deviation, α'', of the liquid is observed. It is now the difference between the deviation y, of the glucose and that of the noncrystallisable sugar derived from the cane-sugars. But the degree of dilution of the liquid having been changed by the addition of the hydrochloric acid, the deviation observed α'', must be replaced by the deviation, $\frac{10}{9}\alpha''$, which would have been observed if the inversion could have been produced without the addition of hydrochloric acid. Admitting therefore that a quantity of cane-sugar which effects a deviation, x, gives rise to a quantity of noncrystallisable sugar which effects a deviation, $r\,x$, we have—

Before the inversion, $x+y=\alpha'$.

After the inversion, $y+r\,x=\frac{10}{9}\alpha''$.

From these two equations the quantities x and y may be determined. The coefficient of inversion, r, is determined once for all by a special experiment performed upon pure cane-sugar at the temperature at which the experiments have afterwards to be made. According to Biot, this coefficient is 0·038 for hydrochloric acid at a temperature of 71·6°.

The process is the same when the cane-sugar is mixed with noncrystallisable sugar, turning the plane of polarisation to the left. In this case the initial deviation α', of the liquid is the difference between the deviation to the right r, of the cane-sugar, and the deviation z, to the left of the noncrystallisable sugar. After treating with hydrochloric acid, the deviation, α'', is composed of the deviations of the original noncrystallisable sugar, and of that produced by the action of the hydrochloric acid. We then have—

Before the inversion, $x-z=\alpha'$.

After the inversion, $z+r\,x=\frac{10}{9}\alpha''$.

It is important in examining optically noncrystallisable sugar always to employ the same temperature, because a change of temperature materially affects the rotatory power of this kind of sugar.

The Table appended on the following pages includes each degree of temperature from + 10 to + 35 Centigrade, and for qualities increasing in hundredths, this range being found sufficient for all practical purposes either in Europe or the Colonies.

To note the temperature at which the observation is made, a tube *z z*, *fig.* 1919, provided with a vertical branch, is employed. In this branch a thermometer, *t*, is placed.

The following are two examples of the use of the Table:—

1. A solution of a saccharine substance prepared in the normal proportions of weight and volume recommended, and giving before acidulation a notation on the left-hand part of the scale of	75 divisions.
And after the inversion (the temperature being + 15°) a notation in the opposite direction of	20 divisions.
Sum of the inversions	95 divisions.
2. Another liquor similarly prepared, giving before the inversion a notation on the left of	80 divisions.
And after the inversion, at the temperature of + 20°, another notation of the same direction, but only of	26 divisions.
Difference expressing the value of the inversion .	54 divisions.

The strength of the two solutions will be found thus: for the first, by seeing what is the figure of the column representing 15°, which is the nearest to the sum of the inversion, 65 divisions: it will be observed that this figure is 95·5, and that it corresponds to quality 70, shown on the same horizontal line in the last column but one, A; hence we conclude that the substance contained 70 per cent. of sugar.

As to the second solution, the figure nearest 54 is 53·6, in the column for the temperature of + 20°, and the strength sought will be 40 per cent. on the same line in the column of qualities. Finally, we shall find, besides, in the last column, B, of the table, the quantity in grammes and centigrammes of the sugar contained per litre in the solution, which is 114 grs. 45 cgrs. for the first, and 65 grs. 40 cgrs. for the second.

Other methods for the estimation of sugar have been adopted. We have already described Poligot's method by means of lime. When sugar is formed from starch, its complete saccharification may be determined by the action of sulphuric acid, for if on a strong solution of imperfectly-formed grape-sugar, nearly boiling hot, one drop of strong sulphuric acid be added, no perceptible change will ensue, but if the acid be dropped into solutions of either cane- or perfectly-formed grape-sugar, black carbonaceous particles will make their appearance.

TABLE FOR THE ANALYSIS OF SACCHARINE SUBSTANCES.

NOTE.—For liquids not submitted to acidulation the last two columns constitute a special table; in which case the figures in column A represent the number of degrees found, and those of column B the weight in grammes and centigrammes of sugar contained in a litre of liquid.

The numbers furnished by an analysis of solid sugars are necessarily comprised in the first hundred lines of the table; the thirty following lines have been added for the analysis of the principal natural saccharine fluids of high density. If liquors of a still greater density are presented, they will be comprised within the table by diluting them with a known quantity of water.

SUMS OR DIFFERENCES OF THE DIRECT AND INVERSE NOTATIONS, THE LATTER BEING DETERMINED AT A TEMPERATURE (CENTIGRADE) OF

The black oxide of copper is not affected by being boiled in solution of starch-sugar.

'If a solution of grape-sugar,' says Trommer, 'and potash be treated with a solution of sulphate of copper, till the separated hydrate be re-dissolved, a precipitate of red oxide will soon take place, at common temperatures, but it immediately forms if the mixture is heated. A liquid containing $\frac{1}{100000}$ of grape-sugar, even one-millionth part,' says he, 'gives a perceptible tinge (orange), if the light is let fall upon it.' To obtain such an exact result, very great nicety must be used in the dose of alkali, which is found extremely difficult to hit. With a regulated alkaline mixture, however, an exceedingly small portion of starch-sugar, is readily detected, even when mixed with Muscovado sugar.

Fehling has reduced this to a quantitative test, and makes a solution of copper that will keep permanently. This is seen by the following:—

40 grammes of sulphate of copper,
160 grammes of neutral tartrate of potash, or 200 grammes of tartrate of soda, dissolved and added to
700—800 cub. c. (grammes of caustic soda, specific gravity 1·12).

This is diluted with water to 1154·5 cub. c.

Of this solution 1 cub. c. = 0·0050 grape-sugar, or
0·00475 cane-sugar.

Grains may be used instead of grammes, and then 1 grain = 0·0050 grape-sugar, without change of calculation.

100 parts of grape-sugar . . .		
95 „ cane-sugar . . .		= 220·5 CuO, or 198 Cu^2O.
90 „ starch		

Urine may be tested with this. It should be first diluted 10 to 20 times with water; when the test is added, it should be boiled a few seconds, when the suboxide of copper falls. Very constant results may be obtained.

Horsley detects minute quantities of sugar by means of chromate of potash.

Of the Sugar-cane, and the extraction of sugar from it.—Though we have no direct authority for believing that the sugar-*cane* was known to the ancients, we find scattered through their writings notices of the occasional use of sweet substances different from honey.

The writers alluded to are these: Theophrastus, Dioscorides, Galen, Strabo, and Pliny; some of them speak distinctly of canes and reeds. Humboldt, after the most elaborate historical and botanical researches in the New World, arrived at the conclusion that before America was discovered by the Spaniards the inhabitants of that continent and the adjacent islands were entirely unacquainted with the sugar-canes, with any of our corn-plants, and with rice, The progressive diffusion of the cane has been thus traced out by the partisans of its oriental origin. From the interior of Asia it was transplanted first into Cyprus, and thence into Sicily, or possibly by the Saracens directly into the latter island, in which a large quantity of sugar was manufactured in the year 1148. Lafitau relates the donation made by William II., King of Sicily, to the convent of St. Benoit, of a mill for crushing sugar-canes, along with all its privileges, workmen, and dependencies: which remarkable gift bears the date of 1166. According to this author, the sugar-cane must have been imported into Europe at the period of the Crusades. The monk Albertus Aquensis, in the description which he has given of the processes employed at Acre and at Tripoli to extract sugar, says that in the Holy Land the Christian soldiers, being short of provisions, had recourse to sugar-canes, which they chewed for subsistence. Towards the year 1420, Dom Henry, Regent of Portugal, caused the sugar-cane to be imported into Madeira from Sicily. This plant succeeded perfectly in Madeira and the Canaries; and until the discovery of America, these islands supplied Europe with the greater portion of the sugar which it consumed.

The cane is said by some to have passed from the Canaries into the Brazils; but by others, from the coast of Angola in Africa, where the Portuguese had a sugar colony. It was transported, in 1506, from the Brazils and the Canaries, into Hispaniola or Hayti, where several crushing-mills were constructed in a short time. It would appear, moreover, from the statement of Peter Martyr, in the third book of his first Decade, written during the second expedition of Christopher Columbus, which happened between 1493 and 1495, that even at this date the cultivation of the sugar-cane was widely spread in St. Domingo.

Sugar was first brought to England in 1563, by Admiral Hawkins, and a century later English planters were realising great wealth in Barbadoes.

It has been supposed to have been introduced into Hayti by Columbus himself, on his first voyage, along with other productions of Spain and the Canaries, and that therefore its cultivation had come into considerable activity at the period of his second expedition. Towards the middle of the seventeenth century, the sugar-cane was imported into Barbadoes from Brazil, then into the other English West Indian possessions, into the Spanish Islands on the coast of America, into Mexico, Peru, Chili, and, last of all, into the French, Dutch, and Danish colonies.

The sugar-cane, *Arundo saccharifera*, is a plant of the graminiferous family, which varies in height from 8 to 10 or even to 20 feet. Its diameter is about an inch and a half; its stem is dense, brittle, and of a green hue, which verges to yellow at the approach of maturity. It is divided by prominent annular joints of a whitish-yellow colour. These joints are placed about 3 inches apart; and send forth leaves, which fall off with the ripening of the plant. The leaves are 3 or 4 feet long, flat, straight, pointed, from 1 to 2 inches in breadth, of a sea-green tint, striated in their length, alternate, embracing the stem by their base. They are marked along their edges with almost imperceptible teeth. In the eleventh or twelfth month of their growth the canes push forth at their top a sprout 7 or 8 feet in height, nearly half an inch in diameter, smooth, and without joints, to which the name *arrow* is given. This is terminated by an ample panicle, about 2 feet long, divided into several knotty ramifications, composed of very numerous flowers, of a white colour, apetalous, and furnished with 3 stamens, the anthers of which are a little oblong. The roots of the sugar-cane are jointed and nearly cylindrical; in diameter they are about one-twelfth of an inch; in their utmost length 1 foot, presenting over their surface a few short radicles.

The stem of the cane in its ripe state is heavy, very smooth, brittle, of a yellowish-violet, reddish, or whitish colour, according to the variety. It is filled with a fibrous, spongy, dirty-white pith, which contains very abundant sweet juice. This juice is elaborated separately in each internodary portion, the functions of which are in this respect independent of the portions above and below. The cane is propagated by cuttings or joints of proper length, from 15 to 20 inches, in proportion to the nearness of the joints, which are generally taken from the tops of the canes, just below the leaves.

There are several *varieties of the sugar-cane*. The longest known is the *Creole*, or common sugar-cane, which was originally introduced at Madeira. It grows freely in every region within the tropics, on a moist soil, even at an elevation of 3,000 feet above the level of the sea. In Mexico, among the mountains of Caudina-Masca, it is cultivated to a height of more than 5,000 feet. The quantity and quality of sugar which it yields are proportional to the heat of the place where it grows, provided it be not too moist and marshy.

1921

Another variety is the Otaheitan cane. It was introduced into the West Indies about the end of the eighteenth century. This variety, stronger, taller, with longer spaces between the joints, quicker in its growth, and much more productive in sugar, succeeds perfectly well in lands which seem too much impoverished to grow the ordinary cane. It sends forth shoots at temperatures which chill the growth and development of the creole plant. Its maturation does not take more than a year, and is accomplished sometimes in nine months. From the strength of its stem, and the woodiness of its fibres, it better resists the storms. It weighs a third more, affords a sixth more juice, and a fourth more sugar, than the common variety. It yields four crops in the same time that the creole cane yields only three. Its juice contains less feculency and mucilage, whence its sugar is more easily crystallised, and of a fairer colour.

Another variety, valuable chiefly from its hardiness, is the *purple violet* from Java. It grows from 8 to 10 feet high. This cane is covered with a resinous film, which is difficult to grind; but as the sugar yielded is of excellent quality, this variety is of considerable value in bordering cane-fields, protecting them from the inroads of cattle.

There is a caste in Ceylon, called *Jaggeraros*, who make sugar from the produce of the *Caryota urens*, or Kitul-tree; and the sugar is styled *Jaggery*. Sugar is not usually made in Ceylon from the sugar-cane; but either from the juice of the Kitul, from the *Cocos nucifera*, or the *Borassus flabelliformis* (the Palmyra Palm).

Several sorts of cane are cultivated in India.

The *Cadjoolee* (*fig.* 1921) is a purple-coloured cane; yields a sweeter and richer juice than the yellow or light-coloured, but in less quantities, and is harder to press.

It grows in dry lands. When eaten raw, it is somewhat dry and pithy in the mouth, but is esteemed very good for making sugar. It is not known to the West India planter. The leaves rise from a point 6 feet above the ground. An oblique and transverse section of the cane is represented by the parts near the bottom of the figure.

The *Pooree* is a light-coloured cane, yellow, inclining to white, deeper yellow when ripe and on rich ground. West India planters consider it the same sort as one of theirs. It is softer and more juicy than the preceding, but the juice is less rich, and produces a weaker sugar. It requires seven parts of pooree-juice to make as much *goor* as is produced from six of the cadjoolee. Much of this cane is brought to the Calcutta market, and eaten raw.

The *Cullorah* thrives in swampy lands, is light coloured, and grows to a great height. Its juice is more watery, and yields a weaker sugar also than the cadjoolee.

The manufacture of sugar in Bengal is conducted by the natives in the most primitive manner possible; the poverty and ignorance of the ryots or peasants being serious obstacles to the introduction of any system different from that practised by their forefathers. Early in June the soil is brought into a soft muddy state; slips of the cane, with one or two joints, are planted in rows about 3½ feet apart, and 18 inches asunder in the rows; when about 3 inches above ground the earth is partially loosened, and in August trenches are cut, to drain off any superfluous moisture. From 3 to 6 canes spring from each slip. When about 3 feet high the lower leaves are wrapped round the canes, and the whole from each slip supported by bamboos. The cutting commences in January or February, the canes being then 8 or 10 feet high, and 1 to 1½ inch thick, and are passed through a mill of the rudest construction, which will be fully described when sugar-mills are treated of.

The China cane is said to be extremely hardy, standing both cold and drought, and, with abundant rain, giving out as many as thirty shoots. It resists the inroads of the white ants, which cannot penetrate its hard crust, whilst it is also proof against the teeth of the jackals. It requires, however, a stronger mill for grinding than the other varieties mentioned. Mr. Wray asserts that the Salangore cane is the finest in the Straits of Singapore, and perhaps in the world. He says that he has cut five from one stool, which were of a weight of from 17lbs. to 25 lbs. They have been known to produce 7,200 lbs. of undrained sugar per acre, equal to 5,800 lbs. of dry sugar for shipping.

Dr. Livingstone stated that sugar is cultivated in the Shire Valley, as well as in many parts of Africa near the Zambesi, and may be had for as little as one halfpenny per pound.

In all the colonies of the New World the sugar-cane flowers, but it then sends forth a shoot (*arrow*), that is, its stem elongates, and the seed-vessels prove abortive. For this reason, the bud-joints must there be used for its propagation. It is said to grow to seed, however, in India. This circumstance occurs with some other plants, which, when propagated by their roots, cease to yield fertile seeds; such as the banana, the bread-fruit, the lily, and the tulip.

In the proper season for planting, the ground is marked out by a line into rows 4 or 6 feet asunder, in which rows the canes are planted from 2 to 5 feet apart. The series of rows is divided into pieces of land 60 or 70 feet broad, leaving spaces of about 20 feet, for the convenience of passage, and for the admission of sun and air between the stems. Canes are usually planted in trenches, about 6 or 8 inches deep, made with the hand-hoe, the raised soil being heaped to one side, for covering in the young cane; into the holes a negro drops the number of cuttings intended to be inserted, the digging being performed by other negroes. The earth is then drawn about the hillocks with the hoe. This labour has been, however, in many places better and more cheaply performed by the plough; a deep furrow being made, into which the cuttings are regularly planted, and the mould then properly turned in. If the ground is to be afterwards kept clear by the horse-hoe, the rows of canes should be 5 feet asunder, and the hillocks 2½ feet distant, with only one cane left in one hillock. After some shoots appear, the sooner the horse-hoe is used the more will the plants thrive, by keeping the weeds under, and stirring up the soil. Plant-canes of the first growth have been known to yield, on the brick-mould of Jamaica, in very fine seasons, 2½ tons of sugar per acre. The proper season for planting the cane-slips containing the buds, namely, the top part of the cane stripped of its leaves, and the two or three upper joints, is in the interval between August and the beginning of November. Favoured by the autumnal weather, the young plants become luxuriant enough to shade the ground before the dry season sets in; thereby keeping the roots cool and moderately moist. By this arrangement the creole canes are ripe for the mill in the beginning of the second year, so as to enable the manager to finish his crop early in June. It is a great error for the colonist to plant canes at an improper season of the year, whereby his whole system of operations becomes disturbed, and, in a certain degree, abortive.

The withering and fall of a leaf afford a good criterion of the maturity of the cane-joint to which it belonged; so that the last eight leafless joints of two canes, which are cut the same day, have exactly the same ripeness, though one of the canes be 15 and the other only 10 months old. Those, however, cut towards the end of the dry season, before the rain begins to fall, produce better sugar than those cut in the rainy season, as they are then somewhat diluted with watery juice, and require more evaporation to form sugar. It may be reckoned a fair average product, when one pound of sugar is obtained from one gallon (English) of juice.

Rattoons (a word corrupted from *rejettons*) are the sprouts or suckers that spring from the roots or stoles of the canes that have been previously cut for sugar. They are commonly ripe in 12 months; but canes of the first growth are called plant-canes, being the direct produce of the original cuttings or germs placed in the ground, and require a longer period to bring them to maturity. The first yearly return from the roots that are cut over, are called first rattoons; the second year's growth, second rattoons; and so on, according to their age. Instead of stocking up his rattoons, holing, and planting the land anew, the planter suffers the stoles to continue in the ground, and contents himself, as the cane-fields become thin and impoverished, with supplying the vacant places with fresh plants. By these means, and with the aid of manure, the produce of sugar per acre, if not apparently equal to that from plant-canes, gives perhaps in the long run as great returns to the owner, considering the relative proportion of the labour and expense attending the different systems.

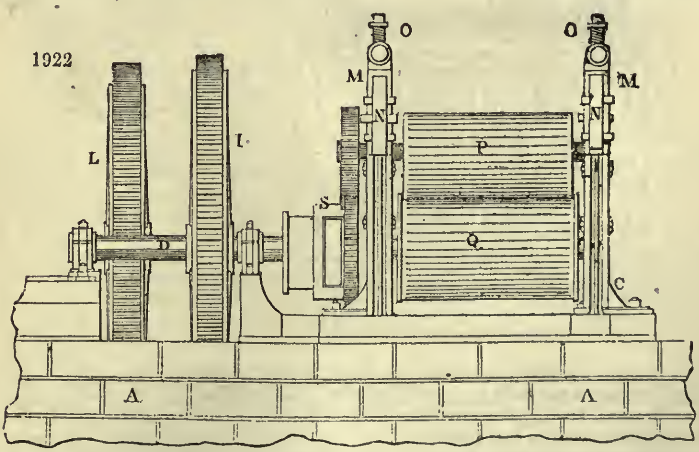
When the planted canes are ripe, they are cut close above the ground by an oblique section, and the leaves and shoots being stripped off, they are transported in bundles, in the mill-house. If the roots be then cut off a few inches below the surface of the soil, and covered up with fine mould, they will push forth more prolific offsets or rattoons than when left projecting in the common way.

The amount of sugar yielded per acre is very variously stated. In fact, the yield must vary with the different variety of canes cultivated, with the nature of the soil, the character of the season, and more than all with the more or less perfect apparatus used in manufacturing the sugar. The yield, from these causes, will vary from ½ a ton to 2½ tons of solid sugar per acre.

For the chemical examination of sugar, see Watts's 'Dictionary of Chemistry.'

Sugar Mills.—The first machines employed to squeeze the canes were mills similar to those which serve to crush apples in some cider districts, or somewhat like tan-mills. In the centre of a circular area, of about 7 or 8 feet in diameter, a vertical heavy wheel was made to revolve on its edge, by attaching a horse to a cross beam projecting horizontally from it and making it move in a circular path. The cane-pieces were strewed on the somewhat concave bed in the path of the wheel, and the juice expressed flowed away through a channel or gutter in the lowest part. This machine

1922

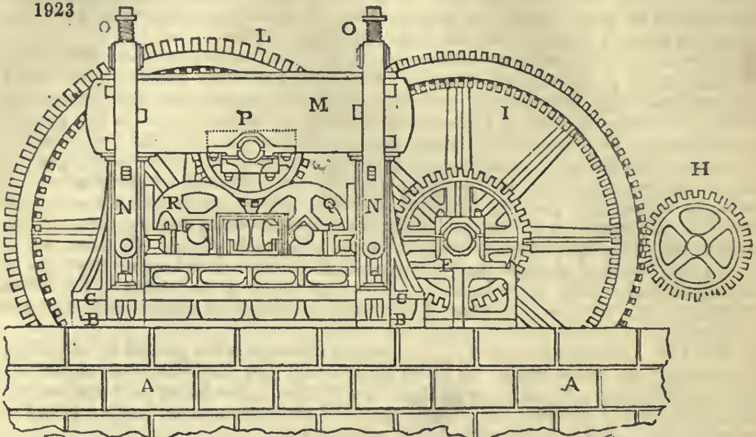


was tedious and unproductive. It was replaced by the vertical cylinder mill of Gonzales de Velosa; which has continued till modern times, with little variation of external form, but is now generally superseded by the sugar-mill, with horizontal cylinders.

Fig. 1922, front elevation of the entire mill; *fig.* 1923, end elevation, and *Fig.* 1924, horizontal plan. *Fig.* 1925, diagram, showing the dispositions of the feeding and delivering rollers, feeding board, returner, and delivering board.

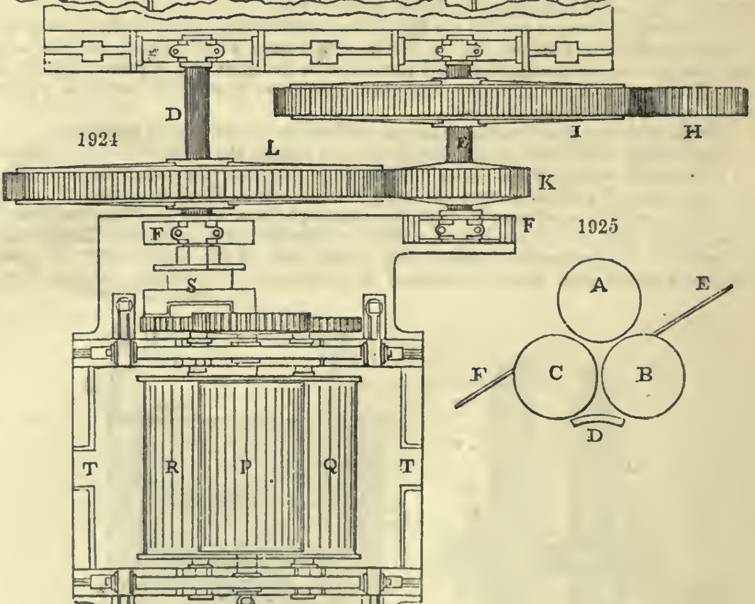
Fig. 1923, A, A, solid foundation of masonry; B, B, bed-plate; C, C, headstocks or standards; D, main shaft (seen in *fig.* 1924); E, intermediate shaft; F, F, plummer-blocks of main shaft D (seen in *fig.* 1924); H, driving pinion on the fly-wheel-

1923



1924

1925



shaft of engine; I, first motion mortise-wheel, driven by the pinion; K, second motion pinion, on the same shaft; L, second motion mortise-wheel, on the main shaft; M, brays of wood, holding the plummer-blocks for shaft D; N, wrought-iron straps connecting the brays to the standards C, C; O, O, regulating screws for the brays; P, top roller and gudgeons; Q, and R, the lower or feeding and delivering rollers; S, clutch for the connexion of the side of lower rollers Q, and R, to the main shaft (seen in *fig.* 1924); T, T, the drain-gutters of the mill-bed (seen only in *fig.* 1924).

The relative disposition of the rollers is shown in the diagram, *fig.* 1925: in which A is the top roller; B, the feeding roller; C, the delivering roller; D, the returner; E, the feeding board; F, the delivering board.

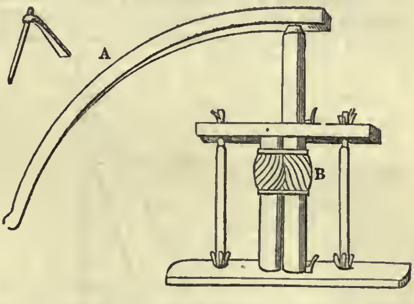
The rollers are made 2¼ inches to 2½ inches thick, and ribbed in the centre. The feeding and delivering rollers have small flanges at their ends, (as shown in *fig.* 1924), between which the top roller is placed; these flanges prevent the pressed canes or *megass* from working into the mill-bed. The feeding and top rollers are generally fluted, and sometimes diagonally, enabling them the better to seize the canes from the feeding-board. It is, however, on the whole, considered better to flute the feeding roller only, leaving the top and delivery rollers plane; when the top roller is fluted, it should be very slightly, for, after the work of a few weeks, its surface becomes sufficiently rough to bite the canes effectively. The practical disadvantage of fluting the delivering rollers, is in the grooves carrying round a portion of liquor, which is speedily absorbed by the spongy megass, as well as in breaking the megass itself, and thus causing great waste.

In working this mill, the feeding roller is kept about half an inch distant from the upper roller, but the delivering roller is placed about ⅛th of an inch from it.

The canes are thrown upon the feeding board, and spread so that they may cross each other as little as possible. They are taken in by the feeding rollers, which split and slightly press them: the liquor flows down, and the returner guiding the canes between the top and delivering rollers, they receive the final pressure, and are turned out on the mill-floor, while the liquor runs back and falls into the mill-bed. The megass, then in the state of *pith*, adhering to the skin of the cane, is tied up in bundles, and after being exposed a short time to the sun, is finally stored in the megass-house for fuel. By an improvement in this stage of the process, the megass is carried to the megass-house by a carrier chain, worked by the engine.

The sugar-mill at Chica Ballapura is worked by a single pair of buffaloes or oxen, going round with the lever A, *fig.* 1926, which is fixed on the top of the right-hand roller. The two rollers have endless screw-heads B, which are formed of four spiral grooves and four spiral ridges, cut in opposite directions, which turn into one another when the mill is working. These rollers and their heads are of one piece, made of the toughest and hardest wood that can be got, and such as will not impart a bad taste to the juice. They are supported in a thick strong wooden frame, and their distance from each other is regulated by means of wedges, which pass through mortises in the frame-planks, and a groove made in a bit of some sort of hard wood, and press upon the axis of one of the rollers. The axis of the other presses against the left-hand side of the hole in the frame-boards. The cane-juice runs down the rollers, and through a hole in the lower frame-board, into a wooden conductor, which carries it into an earthen pot. Two long-pointed stakes or piles are driven into the earth, to keep the mill steady, which is all the fixing it requires. The under part of the lowermost plank of the frame rests upon the surface of the ground, which is chosen level and very firm, that the piles may hold the faster. A hole is dug in the earth, immediately below the spout of the conductor, to receive the pot.

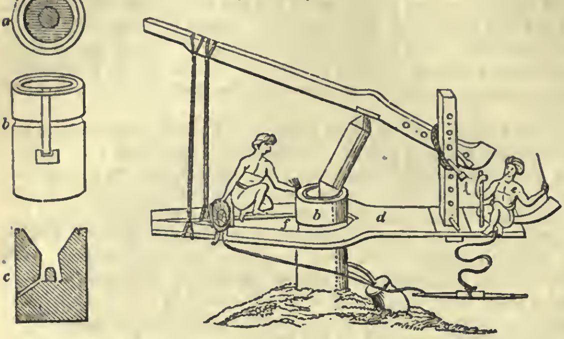
1926



The mill used in Burdwan and near Calcutta is simply two small wooden cylinders, grooved, placed horizontally, close to each other, and turned by two men, one at each end. This simple engine is said to express the juice completely, but slowly. It is very cheap, the prime cost not being two rupees; and being easily moved from field to field, it saves much labour in the carriage of the cane. Notwithstanding this advantage, so rude a machine must leave a large proportion of the richest juice in the cane-trash.

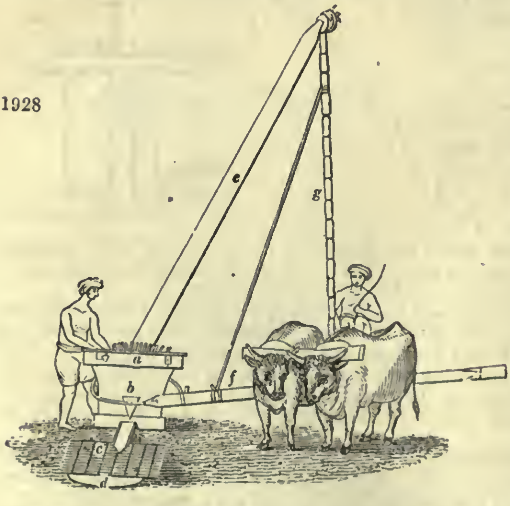
The sugar-mill of Chinapatam, *fig.* 1927, consists of a mortar, lever, pestle, and regulator. The mortar is a tree about 10 feet in length and 14 inches in diameter: *a* is a plan of its upper end; *b* is an outside view; and *c* is a vertical section. It is sunk perpendicularly into the earth, leaving one end 2 feet above the surface. The hollow is conical, truncated downwards, and then becomes cylindrical, with a hemispherical projection in its bottom, to allow the juice to run freely to the small opening that conveys it to a spout, from which it falls into an earthen pot. Round the upper mouth of the cone is a circular cavity, which collects any of the juice that may run over from the upper ends of the pieces of cane; and thence a canal conveys this juice down the outside of the mortar, to the spout. The beam *d*, is about 16 feet in length and 6 inches in thickness, being cut out from a large tree that is divided by a fork into two arms. In the fork an excavation is made for the mortar *b*, round which the beam turns horizontally. The surface of this excavation is secured by a semi-circle of strong wood. The end towards the fork is quite open, for changing the beam without trouble. On the undivided end of the beam sits the bullock-driver, *e*, whose cattle are yoked by a rope which comes from the end of the beam; and they are prevented from dragging out of the circle by another rope, which passes from the yoke to the forked end of the beam. On the arms, *f*, a basket is placed, to hold the cuttings of cane; and between this and the mortar sits the man who feeds the mill. Just as the pestle comes round, he places the pieces of cane sloping down into the cavity of the mortar; and after the pestle has passed, he removes those away that have been squeezed.

1927



The following describes the primitive rude mill and boiler used in preparing the extract of sugar-cane, and which are usually let to the ryots by the day. The mill in Dinajpur, *fig.* 1928, is on the principle of a pestle and mortar. The pestle, however, does not beat the canes, but is rubbed against them, as is done in many chemical triturations; and the moving force is two oxen. The mortar is generally a tamarind-tree, one end of which is sunk deep in the ground, to give it firmness. The part projecting, *a*, may be about 2 feet high and a foot and a half in diameter; and in the upper end a hollow is cut, like the small segment of a sphere. In the centre of this, a channel descends a little way perpendicularly, and then obliquely to one side of the mortar, so that the juice as squeezed from the cane, runs off by means of a spout, *b*, into a strainer *c*, through which it falls into an earthen pot that stands in a hole, *d*, under the spout. The pestle, *e*, is a tree about 18 feet in length, and 1 foot in diameter, rounded at its bottom, which rubs against the mortar, and which is secured in its place by a button or knob that goes into the channel of the mortar. The moving force is applied to a horizontal beam, *f*, about 16 feet in length, which turns round about the mortar, and is fastened to it by a bent bamboo. It is suspended from the upper end of the pestle by a bamboo, *g*, which has been cut with part of the root, in which is formed a pivot that hangs on the upper point of the pestle. The cattle are yoked to the horizontal beam, at about 10 feet from the mortar, move round it in a circle, and are driven by a man who sits on the beam to increase the weight of the triturating power. Scarcely any machine more

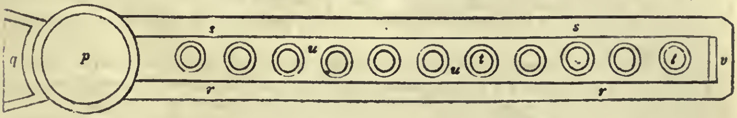
1928



miserable can be conceived; and it would be totally ineffectual, were not the cane cut into thin slices. This is a troublesome part of the operation. The grinder sits on the ground, having before him a bamboo-stake, which is driven into the earth with a deep notch formed in its upper end. He passes the canes gradually through this notch, and at the same time cuts off the slices with a kind of rude chopper.

The *boiling apparatus* is somewhat better contrived, and is placed under a s ed, though the mill is without shelter. The fireplace is a considerable cavity dug in the ground, and covered with an iron boiler, *p*, *fig.* 1929. At one side of this is an opening, *q*, for throwing in fuel; and opposite to this is another opening, which communicates with the horizontal flue. This is formed by two parallel mud walls, *r*, *r*, *s*, *s*, about 20 feet long, 2 feet high, and 18 inches distant from each other. A row of eleven earthen boilers, *t*, is placed on these walls, and the interstices, *u*, are filled with clay, which completes the furnace-flue, an opening, *v*, being left at the end, for giving vent to the smoke.

1929



The juice, as it comes from the mill, is first put into an earthen boiler that is most distant from the fire, and is gradually removed from one boiler to another, until it reaches the iron one, where the process is completed. The inspissated juice that can be prepared in twenty-four hours by such a mill, with sixteen men and twenty oxen, amounts to no more than 476 lbs.; and it is only in the southern parts of the district, where the people work night and day, that the sugar-works are productive. In the northern districts, the people work only during the day, and inspissate about one-half the quantity of juice.

Of the Manufacture of Sugar in the West Indies.—Cane-juice varies exceedingly in richness, with the nature of the soil, the culture, the season, and variety of the plant. When left to itself in the colonial climates, the juice runs rapidly into the acetous fermentation. Hence arises the necessity of subjecting it immediately to clarifying processes, speedy in their action. When deprived of its green fecula and glutinous extractive, it is still subject to fermentation; but this is now of the vinous kind. The juice flows from the mill through a wooden gutter lined with lead, and being conducted into the sugar-house, is received in a set of large pans or cauldrons, called 'clarifiers.' On estates which make on an average, during crop time, from 15 to 20 hogsheads of sugar a week, three clarifiers, of 400 gallons' capacity each, are sufficient. With pans of this dimension, the liquor may be drawn off at once by a stopcock or syphon, without disturbing the feculencies after they subside. The clarifiers are sometimes placed at one end, and sometimes in the middle of the house, particularly if it possesses a double set of evaporating pans.

Whenever the stream from the mill-cistern has filled the clarifier with fresh juice, the fire is lighted, and the *temper*, or dose of slaked lime, diffused uniformly through a little juice, is added. If an albuminous emulsion be used to promote the clarifying, very little lime will be required; for recent cane-liquor contains no appreciable portion of acid to be saturated. In fact, the lime and alkalis in general, when used in small quantity, seem to coagulate the glutinous extractive matter of the juice, and thus tends to brighten it up. Excess of lime may also be corrected by a little alum-water. Where canes grow on a calcareous marly soil, in a favourable season the saccharine matter gets so thoroughly elaborated, and the glutinous mucilage so completely condensed, that a clear juice and a fine sugar may be obtained without the use of lime.

As the liquor grows hot in the clarifier, a scum is thrown up, consisting of the coagulated feculencies of the cane-juice. The fire is now gradually urged till the temperature approaches the boiling point; to which, however, it must not be suffered to rise. It is known to be sufficiently heated, when the scum rises in blisters, which break into white froth; an appearance observable in about forty minutes after kindling the fire. The damper being shut down, the fire dies out; and after an hour's repose, the clarified liquor is ready to be drawn off into the last and largest in the series of evaporating pans. In the British colonies, these are merely numbered 1, 2, 3, 4, 5, beginning at the smallest, which hangs right over the fire, and is called the *teache*; because in it the trial of the syrup, by *touch*, is made. The flame and smoke proceed in a straight line along a flue to the chimney-stalk at the other end of the furnace. The area of this flue proceeds, with a slight ascent from the fire, to the aperture at the bottom of the chimney; so that between the surface of the grate and the bottom of the teache there is a distance of 28 inches; while between the bottom of the flue and that of the *grand*, No. 5, at the other end of the range, there are barely 18 inches.

In some sugar-houses there is planted, in the angular space between each boiler, a basin, one foot wide and a few inches deep, for the purpose of receiving the scum which thence flows off into the *grand copper*, along a gutter scooped out on the margin of the brickwork. The skimmings of the *grand* are thrown into a separate pan, placed at its side. A large cylindrical *cooler*, about 6 feet wide and 2 feet deep, has been placed in certain sugar-works near the teache, for receiving successive charges of its inspissated syrup. Each finished charge is called a *skipping*, because it is skipped or laded out. The term *striking* is also applied to the act of emptying the teache. When upon one skipping of syrup in a state of incipient granulation in the cooler, a second skipping is poured, this second congeries of saccharine particles agglomerates round the first as *nuclei* of crystallisation, and produces a larger grain; a result improved by each successive skipping. This principle has been long known to the chemist, but does not seem to have been always properly considered or appreciated by the sugar-planter.

From the above-described cooler, the syrup is transferred into wooden chests or boxes, open at top, and of a rectangular shape, also called *coolers*, but which are more properly crystallisers or granulators. These are commonly six in number; each being about 1 foot deep, 7 feet long, and 5 or 6 feet wide. When filled, such a mass is collected as to favour slow cooling, and consequently large-grained crystallisation. If these boxes be too shallow, the grain is exceedingly injured, as may be easily shown by pouring some of the same syrup on a small tray; when, on cooling, the sugar will appear like a muddy soft sand.

The due concentration of the syrup in the teache is known by the boiler, by the appearance of a drop of the syrup pressed and then drawn into a thread between the thumb and fore-finger. The thread eventually breaks at a certain limit of extension, shrinking from the thumb to the suspended finger, in lengths somewhat proportional to the inspissation of the syrup. But the appearance of granulation in the thread must also be considered; for a viscid and damaged syrup may give a long enough thread, and yet yield almost no crystalline grains when cooled. Tenacity and granular aspect must therefore be both taken into the account, and will continue to constitute the practical guides to the negro boiler, till a less barbarous mode of concentrating cane-juice be substituted for the present *naked teache*, or *sugar frying-pan*.

A viscous syrup containing much gluten and sugar, altered by lime, requires a higher temperature to enable it to granulate than a pure saccharine syrup; and therefore the thermometer, though a useful aid, can by no means be regarded as a sure guide, in determining the proper instant for *striking* the teache.

The colonial *curing-house* is a spacious building, of which the earthen floor is excavated to form the molasses-reservoir. This is lined with sheet-lead, boards, tarras, or other retentive cement; its bottom slopes a little, and it is partially covered by an open massive frame of joist-work, on which the plotting casks are set upright. These are merely empty sugar-hogsheads, without headings, having 8 or 10 holes bored in their bottoms, through each of which the stalk of a plantain-leaf is stuck, so as to protrude downwards 6 or 8 inches below the level of the joists, and to rise above the top of the cask. The act of transferring the crude concrete sugar from the crystallisers into these hogsheads, is called *potting*. The bottom holes, and the spongy stalks stuck in them, allow the molasses to drain slowly downwards into the sunk cistern. In the common mode of procedure, sugar of average quality is kept from 3 to 4 weeks in the curing-house; that which is soft-grained and glutinous must remain 5 or 6 weeks. The curing-house should be close and warm, to favour the liquefaction and drainage of the viscid molasses.

Out of 120,000,000 lbs. of raw sugar which used to be annually shipped by the St. Domingo planters, only 96,000,000 lbs. were landed in France, according to the authority of Dutrone, constituting a loss by drainage in the ships of 50 per cent. The average transport waste in the sugars of the British colonies cannot be estimated at less than ·12 per cent., or altogether upwards of 27,000 tons! What a tremendous sacrifice of property!

Syrup intended for forming clayed sugar must be somewhat more concentrated in the teache, and run off into a copper cooler, capable of receiving three or four successive skippings. Here it is stirred to ensure uniformity of product, and is then transferred by ladles into conical moulds, made of coarse pottery or of sheet iron, having a small orifice at the apex, which is stopped with a plug of wood wrapped in a leaf of maize. These conical pots stand with the base upwards. As their capacity, when largest, is considerably less than that of the smallest potting-casks, and as the process lasts several weeks, the claying-house requires to have very considerable dimensions. Whenever the syrup is properly granulated, which happens usually in about 18 or 20 hours, the plugs are removed from the apices of the cones, and each is set on an earthen pot to receive the drainings. At the end of 24 hours the cones are transferred over empty pots, and the molasses contained in the former ones is either sent to the fermenting-house or sold. The claying now begins, which consists in applying to the smoothed surface of the sugar at the base of the cone a plaster of argillaceous earth, or tolerably tenacious loam in a pasty state. The water diffused among the clay escapes from it by slow infiltration, and descending with like slowness through the body of the sugar, carries along with it the residuary viscid syrup, which is more readily soluble than the granulated particles. Whenever the first magma of clay has become dry, it is replaced by a second; and this occasionally in its turn by a third, whereby the sugar-cone gets tolerably white and clean. It is then dried in a stove, cut transversely into *frusta*, crushed into a coarse powder on wooden trays, and shipped off for Europe. Clayed sugars are sorted into different shades of colour according to the part of the cone from which they were cut. The clayed sugar of Cuba, which is sun-dried, is called 'Havannah sugar,' from the name of the shipping port.

Clayed sugar can be made only from the ripest cane-juice, for that which contains much gluten would be apt to get too much burned by the ordinary process of boiling to bear the claying operation. The syrups that run off from the second, third, and fourth applications of the clay-paste, are concentrated afresh in a small building apart, called the *refinery*, and yield tolerable sugars. Their drainings go to the molasses-cistern. The cones remain for 20 days in the claying-house before the sugar is taken out of them.

Claying is seldom had recourse to in the British plantations, on account of the increase of labour, and diminution of weight in the produce, for which the improvement in quality yields no adequate compensation. Such, however, was the esteem in which the French consumers held clayed-sugar, that it was prepared in 400 plantations of St. Domingo alone.

Sugar Refining.—The raw or Muscovado sugar, as usually imported, is not in a state of sufficient purity for use. The sugar is blended with more or less of fruit- and grape-sugars, with sand and clay, with albuminous- and colouring-matter, chiefly caramel. To separate the pure sugar, the plan formerly adopted was to add blood, eggs, and lime-water to a solution of the raw sugar, and after applying heat, to remove the thick scum of coagulated albumen, which also removed a considerable portion of colouring-matter. The clear liquid was concentrated, and the semi-crystalline mass being placed in conical moulds, as much of the molasses as would drain by gravitation was allowed to escape from the points of the moulds, and the remainder was expelled by allowing water or a solution of pure sugar to trickle through the mass of crystals. The loaves, being trimmed into shape and dried, were fit for sale.

By this process only a small proportion of the sugar was made into loaf. The method of removing the colouring-matter was crude, imperfect, and expensive; and the high temperature requisite for the fermentation of the syrup not only injured its colour, but converted a large proportion of the sugar into the uncrystallisable variety.

These defects were remedied, to a great extent, by the adoption of Howard's vacuum-pan, for the concentration of syrups under diminished atmospheric pressure, and consequently at a low temperature together with the use of filtering-beds of animal-charcoal for the removal of colouring-matter.

There are three classes of sugar-refineries in this country, the chief productions of which are, respectively:—

1st. Loaf-sugar.

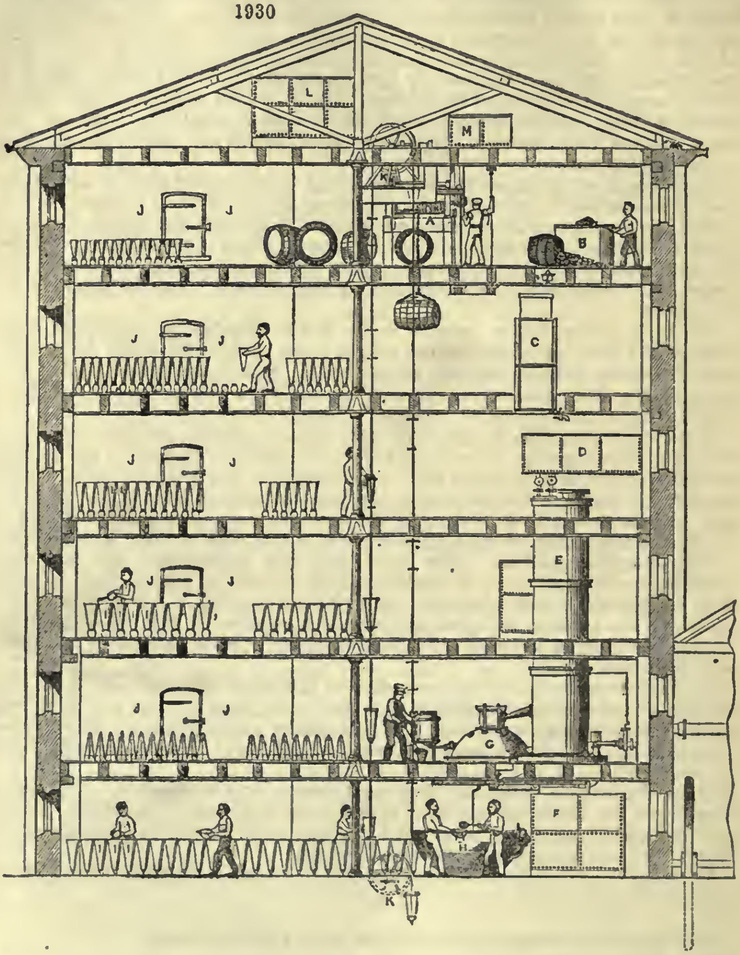
2nd. Crystals (*i.e.* large, well-formed, dry white crystals of sugar).

3rd. Crushed sugar.

In the former two, good West India, Havannah, Mauritius, or Java sugar are almost exclusively used. In the last, all classes of sugar are indiscriminately employed. The manufacture of loaf-sugar is chiefly carried on in London; of crystals, in Bristol and Manchester; of crushed sugar, in Liverpool, Greenock, and Glasgow. Besides these places, which are the chief seats of the sugar-refining trades, this branch of industry is carried on more or less at Plymouth, Southampton, Goole, Sheffield, Newton (Lancashire), and Leith. The methods vary a little in different refineries; but the following description refers to the most modern and best conducted which are to be found in this country. The general arrangements of a sugar-house are shown in *fig.* 1930.

Loaf-Sugar.—*Solution.* The raw sugar is emptied from the hogsheads, boxes, or mats, as the case may be, and discharged through a grating in the floor into a copper pan, about 8 feet in diameter. This dissolving pan is sometimes, although incorrectly, called 'a defecator,' it was formerly called 'a blow-up,' from the practice of blowing steam into it, but the practice and the name are now antiquated. Hot water is added, and the solution is facilitated by the action of an agitator, or stirrer, kept in motion by the steam-engine. The proportions of sugar and water are regulated so that the liquid attains a specific gravity of about 1·250, or 29° Beaumé, as a higher density than this would interfere with subsequent processes. A copper coil or casing to the pan, heated by steam, furnishes the means of raising the liquid to a

1930



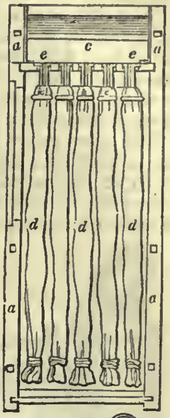
temperature of 165°. The plan of boiling the 'liquor' is becoming gradually disused. If the solution is acid, sufficient lime-water is added to make it neutral. The use of blood, which was formerly added at this stage, is in most cases dispensed with; the advantage arising from its use is readily obtained from the employment of an increased amount of animal-charcoal in a subsequent process, while the mischief arising from the introduction of nitrogenous matter so prone to decompose is avoided. Some machinery is used for crushing the hard lumps to facilitate solution.

Removal of insoluble matter.—The liquor having been brought to the requisite density and temperature, and also being perfectly neutral, is passed through the bag-filter.

The apparatus consists of an upright square iron or copper case, *a*, *a*, *fig.* 1931, about

6 or 8 feet high, furnished with doors; beneath is a cistern with a pipe for receiving and carrying off the filtered liquor; and above the case is another cistern, *c*. Into the upper cistern the syrup is introduced, and passes thence into the mouths *e*, *e*, of the several filters, *d*, *d*. These consist each of a bag of thick twilled cotton of cloth, about 2 feet in diameter and 6 or 8 feet long, which is inserted into a narrow 'sheath,' or bottomless bag of canvas, about 5 inches in diameter, for the purpose of folding the filter-bag up into a small space, and thus enabling a great extent of filtering surfaces to become pressed into one box. The orifice of each compound bag is tied round a conical brass mouth-piece or nozzle *e*, which screws tight into a corresponding opening in the bottom of the upper cistern. From 40 to 400 bags are mounted in each filter-case. The liquor which first passes is generally turbid, and must be pumped back into the upper cistern, for refiltration. The interior of the case is furnished with a pipe for injecting steam, which is occasionally used for warming the case. *Fig.* 1932 shows one mode of forming the funnel-shaped nozzles of the bags, in which they are fixed by a bayonet-catch. *Fig.* 1933 shows the same made fast by means of a screwed cap, which is more secure.

1931



1932

1933

When the bags are fouled from the accumulation of clay and a slimy substance on their inner surfaces, the filter is unpacked, the bags withdrawn from the sheaths, and well washed in hot water. This washing is usually performed with a dash-wheel, or some one of the numerous kinds of washing-machines now in use. Perhaps that of Manlove and Alliott, of Nottingham, is in greatest favour. The dirty water, with the addition of a little lime, is smartly boiled, and after some hours being allowed for subsidence, the supernatant, clear, weak solution of sugar is removed and used in the first process (solution), while the muddy residue is placed in canvas bags and subjected to pressure. The residue, technically called *scum*, is thrown away.

Removal of colour.—The liquor issuing from the bag-filters generally resembles in colour dark sherry wine. To render this colourless it is passed through deep filtering-beds of granulated burnt bones or animal-charcoal. When this substance was first introduced, beds of a few inches in depth were considered sufficient, but the quantity of charcoal used per ton of sugar has steadily increased, and filters of no less a depth than 50 feet are now sometimes used.

Cylinders of wrought or cast iron, varying in diameter from 5 to 10 feet, and in height from 10 to 50, having a perforated false bottom a couple of inches above the true one, are filled with granulated animal-charcoal.

The grain varies from the size of turnip-seed to that of peas, some refiners preferring it fine, and others coarse.

Liquor from the bag-filters is run on to the charcoal till the cylinder is perfectly filled, when the exit tap at the bottom is opened, and a stream of dense saccharine fluid, perfectly colourless, issues forth. The amount of sugar which the charcoal will discolour depends upon the age and composition of the charcoal, the degree of perfection with which the previous revivification has been performed, and the quality, colour, and density of the liquor to be operated upon. One ton of charcoal is sometimes used to purify two tons of sugar; and in at least one refinery, where inferior sugar is operated on, two tons of charcoal serve for one ton of sugar. In most provincial refineries about one ton of charcoal is used to one of sugar; but in London, from the dearness of fuel and other causes, a smaller proportion of charcoal is employed. The liquor from the charcoal filter, at first colourless, becomes slightly tinged, and in course of time, varying from 24 hours to 72, the power of the charcoal becomes exhausted, the partially decoloured syrup is passed through a fresh charcoal filter, and the sugar is washed out from the charcoal by means of hot water. The charcoal is ready to be removed for revivification, which process has already been described.

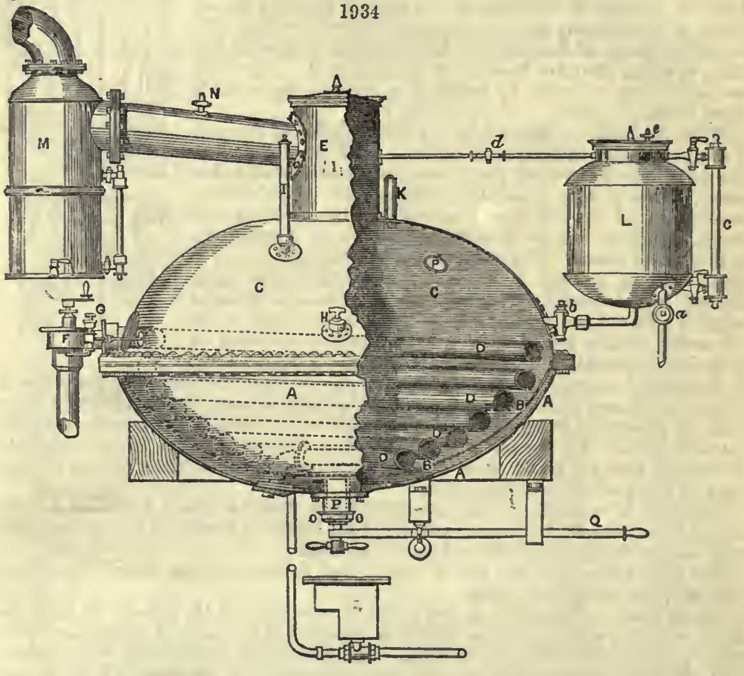
Concentration.—The next process in sugar-refining is the evaporation of the clarified syrup to the granulating or crystallising point. The more rapidly this is effected, and the less the heat to which it is subjected, the better and greater is the product in sugar-loaves. No apparatus answers the refiner's double purpose of safety and expedition so well as the vacuum-pan.

The vacuum-pan, invented by Howard, and patented in the year 1812, is an enclosed copper vessel, heated by steam, passing through one or more copper coils, and a steam-jacket. The vapour arising from the boiling solution of sugar is condensed by an injection of cold water, the arrangement of which, and the maintenance of a vacuum, closely resemble the condenser, injection, and air-pump of an ordinary condensing steam-engine.

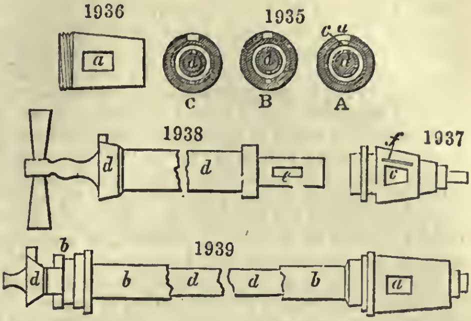
Fig. 1934 shows the structure of a single vacuum-pan. The horizontal diameter of the copper spheroid C C, is from 7 to 10 feet; the depth of the under hemisphere A, is at least 2 feet from the level of the flange; and the height of the dome-cover is from 3 to 5 feet. The two hemispheres (of which the inferior one is double, or has a steam-jacket), are put together by bolts and screws, to preserve the joints tight against atmospheric pressure.

The steam enters through the valve F, traversing the copper coil D, and filling the steam-jacket, the condensed water issuing from a small pipe below. C represents the dome of the vacuum-pan, the vapour from which, passing in the direction of N, allows any particles of sugar carried over by the violence of the ebullition to be deposited in the receiver, M.

1934



The vapour is condensed by jets of cold water issuing from a perforated pipe, and the water, uncondensed vapour, and air, are removed by the action of a powerful air-pump. L is the measure cistern, from which the successive charges are admitted into the pan; I and K represent respectively a thermometer and a barometer: the former being required to indicate the temperature of the boiling syrup, and the latter the diminished atmospheric pressure within the pan. P is the discharge cock; and H. the proof-stick, is an apparatus inserted air-tight into the cover of the vacuum-pan, and which dips down into the syrup, serving to take out a sample of it, without allowing air to enter. It is shown in detail, in *fig.* 1939, which represents a cylindrical rod, capable of being screwed air-tight into the pan in an oblique direction downwards. The upper or exterior end is open; the under, which dips into the syrup is closed, and has on one side a slit *a* (*figs.* 1936, 1939), or notch, about ½ in. wide. In this external tube, there is another shorter tube *b*, capable of moving round it, through an arc of 180°. An opening upon the under end *e*, corresponds with the slit in the outer tube, so that both may be made to coincide, *fig.* 1934, A. A plug *d*, is put in the interior tube, but so as not to shut it entirely. Upon the upper end there is a projection or pin, which catches in a slit of the inner tube, by which this may be turned round at pleasure. In the lower end of the plug there is a hole *e*, which can be placed in communication with the lateral openings in both tubes. Hence it is possible, when the plug and the inner tube are brought into the proper position, A, *fig.* 1935, to fill the cavity of the rod with the syrup, and to take it out without allowing any air to enter. In order to facilitate the turning of the inner tube within the outer, there is a groove in the under part, into which a little grease may be introduced.



1936 1935 1938 1937 1939

Whenever a proof has been taken, the plug must be placed in reference to the inner tube, as shown in *fig.* 1935, C, and then turned into the position A; when the cavity of the plug will again be filled with syrup. C must now be turned back to the former position, whereby all intercourse with the vacuum-pan is cut off; the plug being drawn out a little, and placed out of communication with the inner tube. The plug is then turned into the position B, drawn out, and the proof examined by the fingers.

The method of using the vacuum-pan varies with the character of the grain required to be produced. On commencing boiling, the syrup should be run in as quickly as possible, till the whole heating-surface is covered, when the steam is turned on, and the evaporation conducted at a temperature of from 170° to 180° Fahr. As soon as the syrup begins to granulate, the temperature becomes reduced to 160°; and finally just before the evaporation is completed, and the sugar ready to be discharged into the heater, it is further reduced, and approaches 145°, being the lowest temperature at which proof-sugar boils, 3 inches from a perfect vacuum. When the sugar-boiler ascertains, by withdrawing a sample of the syrup by means of the proof-stick, and examining it against the light between his finger and thumb, that the crystals are in a sufficiently forward state for his purpose, he adds another measureful to that already in the pan, and the same process is repeated till the whole charge has been admitted. After each successive charge the crystals continue increasing in size to the end of the operation, those first formed acting as nuclei: a *skip*, as it is technically called, or a panful of the concentrated sugar, may be made in from two to four hours from the commencement of the boiling. If a fine-grain sugar be required, greater quantities of syrup are admitted at each charge of the measure, and *vice versâ.*

Making of Loaf-sugar.—The proof-sugar at a temperature not exceeding 145° is then let down through a cock or valve in the bottom of the pan into the heater. The sugar-liquor consists at this stage of the process of a large number of small crystals floating in a medium of syrup.

The heater is an open copper pan of about the same capacity as the vacuum-pan, and is furnished with a steam-jacket and provided with an agitator,—in fact, it closely resembles the dissolving-pan used for the first process. The object to be attained in the heater is to raise the sugar to a temperature of 180°, which has been found by practice to be the point best adapted for hardening and completing the formation of the crystals, during which process the sugar is constantly stirred.

The sugar is then run out through a cock in the bottom of the heater into a ladle, from whence it is poured into moulds or cones of sheet iron strongly painted. The sizes of the moulds vary, from a capacity of 10-lb. *loaves* to that of 56-lb. *bastards*—a kind of soft brown sugar obtained by the concentration of the inferior syrups. These moulds have the orifices at their tips closed with nails inserted through pieces of cloth or India-rubber, and are set up in rows close to each other, in an apartment adjoining the heaters. Here they are left several hours, commonly the whole night, after being filled, till their contents become solid, and they are lifted next morning into an upper floor, kept at a temperature of about 100° by means of steam-pipes, and placed over gutters to receive the syrup drainings; the plugs being first removed, and a steel wire, called 'a piercer,' being thrust up to clear away any concretion from the tip. The syrup which flows off spontaneously is called 'green syrup.' It is kept separate. In the course of one or two days, when the drainage is nearly complete, some finely-clarified syrup, made from a filtered solution of fine raw sugar is poured to the depth of about an inch upon the base of each cone, the surface having been previously rendered level and solid by an iron tool, called a 'bottoming trowel.' The liquor, in percolating downwards, being already a saturated syrup, can dissolve none of the crystalline sugar, but only the coloured matter and molasses; whereby, at each successive liquoring, the loaf becomes whiter, from the base to the apex.

To economise the quantity of 'fine liquor' used, it is usual to give a first and even a second liquor of an inferior quality before applying the finishing liquor, which is a dense and almost saturated solution of fine sugar absolutely free from colour. A few moulds, taken promiscuously, are emptied from time to time, to inspect the progress of the blanching operation; and when the loaves appear to have acquired as much *colour*, according to the language of refiners, as is wanted for the particular market, they are removed from the moulds, turned on a lathe at the tips, if necessary, set for a short time upon their bases, to diffuse their moisture equally through them, and then transferred into a stove heated to 130° or 140° by steam-pipes, where they are allowed to remain for two or three days, till they are baked thoroughly dry. They are then taken out of the stove, and put up in paper for sale.

The drainage of the last portion of the liquor from the moulds is sometimes accelerated by means of a vacuum. Centrifugal action has been also proposed for this purpose, but has not been found to succeed.

The drainings from the moulds which are collected in gutters, and run into cisterns are boiled, and form an inferior quality of sugar. The drainings from this last sugar consist of treacle or syrup, which is always obtained as a final product.

Manufacture of Crystals.—The use of centrifugal action for the separation of liquids and solids has been adopted in the arts for many years; its application for the separation of syrup and sugar occurred to several individuals, but it was best effected by means of the admirable hydro-extractor, invented by Manlove and Alliott of Nottingham. Various modifications of this machine have been proposed and patented, but it is very doubtful whether anything that has been yet devised has improved upon the original machine.

The semi-fluid mass is removed to the centrifugal machines with the least possible delay, and each machine barely attains its maximum speed before the syrup is discharged. To cleanse the surface of the crystals they are washed with liquor, sprinkled in the machine by means of a watering-can, a few pints being used to each cwt.

By this process the percentage of sugar obtained from the first and each separate crystallisation is considerably less than that obtained in the making of loaf-sugar or the ordinary method of making 'crushed,' though the *total* product does not vary materially, being rather more than that of the former where the product is stove-dried and less than the latter, which is sold damp. The drainage is diluted, filtered through animal-charcoal, boiled, and passed through the centrifugal machines, and results in a second quality of sugar, the crystals being smaller. The drainage from this is treated in a similar manner, and a third quality of crystals is the result. A fourth quality of crystals is also sometimes obtained, the drainage from which is again boiled and laid aside in large moulds to crystallise for about a week, when treacle and a low quality of 'pieces' is the final result. The drainages are sometimes filtered along with inferior qualities of raw sugar.

The difficulty with which these large and beautiful crystals obtained by this process dissolve, is an obstacle to their extensive consumption; but Messrs. Finzel, of Bristol, have lately introduced a sugar in smaller crystals, which dissolves almost as readily as loaf-sugar.

Crushed Sugar.—This process closely resembles the manufacture of loaf-sugar, but the raw sugar used is generally of an inferior quality. The filtration through the animal-charcoal is in consequence not so perfect; the concentration resembles that of loaf-sugar, but the use of a heater is dispensed with, and the process of liquoring is also dispensed with where practicable. The first crystallisation is called 'crushed' and the second 'pieces,' the drainage from which goes by the name of 'syrup.' When this syrup is diluted, filtered through animal-charcoal, and concentrated, it is called 'golden syrup.'

Treatment of Molasses.—Foreign and colonial molasses, containing a large proportion of crystallisable sugar, are purchased by refiners. The Muscovado molasses from Cuba, from Porto Rico, Antigua, and Barbadoes, are esteemed the best, but the quality of molasses deteriorates as improvements in the manufacture of sugar are introduced on the plantations. The treatment of molasses formerly was simple; it was merely concentrated and allowed to stand for several weeks in large moulds to drain. The liquid was sold as treacle, and the impure soft, dark sugar, called 'bastards,' found a market amongst the poorer classes, especially in Ireland.

The better plan is to dilute the molasses, filter it through animal-charcoal, and concentrate to the crystallising-point, but without forming crystals. This readily crystallises in the moulds, and in place of the bastards and treacle, a bright yellow sugar and a fair quality of syrup are the result. Good molasses yields 40 per cent. sugar, 40 per cent. syrup, the remaining 20 per cent. being water, dirt, and loss.

Palm- or Date-sugar.—Many trees of the palm tribe yield a copious supply of sweet juice, which, when boiled down, gives a dark-brown deliquescent, raw sugar, called in India *Jaggery.* The wild date-palm and the gommuto-palm yield the largest proportion of this kind of sugar, which is chemically identical with the sugar from the cane, though the crudeness of the manufacture is very injurious to it, and causes a large proportion to assume the uncrystallisable condition. One twenty-fourth of all the cane-sugar extracted for useful purposes is obtained from the palm-tree.

Beet-root Sugar.—The extraction of sugar from beet-root, has become an important manufacture in several countries on the Continent, especially in France and Germany. It was developed in consequence of the difficulty of obtaining colonial sugar in France during the blockade in the time of Napoleon I. See BEET-ROOT.

The proportion of sugar varies very much. The average proportion of sugar extracted from beet is 6 per cent., though it is stated that 7½ per cent. is obtained in some well-conducted manufactories. In France and Belgium the average yield is 14 or 15 tons of beet to the acre, while about Magdeburg they do not exceed 10 to 12 tons, but the latter are richer in sugar.

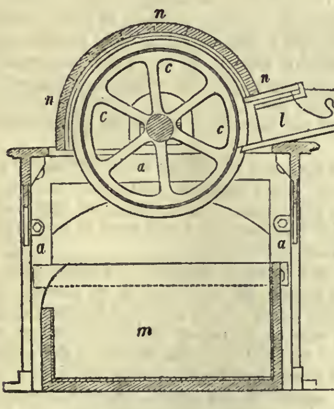
During the first year of its life the root is developed to its full size, and secretes the whole amount of sugar which, in the natural life of the plant, furnishes the material for the growth and maturity of its upper part.

The first manipulations to which the beets are exposed are intended to clear them from the adhering earth and stones as well as the fibrous roots and portions of the neck. The roots are washed by a rotatory movement upon a grating made like an Archimedes' screw, formed round the axis of a squirrel-cage cylinder, which is laid horizontally beneath the surface of water in an oblong trough. It is turned rapidly by means of a toothed wheel and pinion. The roots, after being sufficiently agitated in the water, are tossed out by the rotation at the opposite end of the cylinder.

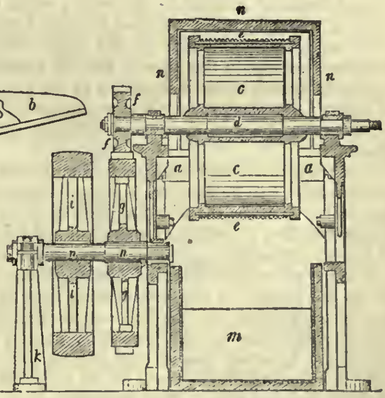
The parenchyma of the beet is a spongy mass, whose cells are filled with juice. The cellular tissue itself, which forms usually only a twentieth or twenty-fifth of the whole weight, consists of ligneous fibre. Compression alone, however powerful, is inadequate to force out all the liquor which this tissue contains. To effect this object, the roots must be subjected to the action of an instrument which will tear and open up the greatest possible number of these cells. Experiments have, indeed, proved, that by the most considerable pressure, not more than 40 or 50 per cent. in juice can be obtained from the beet; whilst the pulp procured by the action of a grater produces from 75 to 80 per cent.

The beet-root rasp is represented in *figs.* 1940, 1941. *a*, *a* is the framework of the machine; *b*, the feed-plate, made of cast iron, divided by a ridge into two parts; *c*, the hollow drum; *d*, its shaft, upon either side of whose periphery nuts are screwed

1940



1941



for securing the saw blades *e*, *e*, which are packed tight against each other by means of laths of wood; *f* is a pinion upon the shaft of the drum, into which the wheel *g* works, and which is keyed upon the shaft *h*; *i* is the driving rigger; *k*, pillar of support; *l*, blocks of wood, with which the workman pushes the beet-roots against the revolving rasp; *m*, the chest for receiving the beet-pap; *n*, the wooden cover of the drum, lined with sheet iron. The drum should make 500 or 600 turns in the minute.

By the process of M. Schützenbach the manufacture may be carried on during the whole instead of during a few winter months. At Waghäusel, near Carlsruhe, this system is adopted. The beets having been washed are rapidly cut up into small pieces, and subjected to the drying heat of a coke-fire for six hours. They lose from 86 to 84 per cent. of their weight; the dried root may be kept without injury for many months, and the sugar is extracted by infusion. At this colossal establishment, which in 1855 employed 3,000 people, and the building of which covered 12 acres of land, there were twenty infusing vessels, 12 to 14 feet deep and 7 wide. A cwt. of raw roots cost 7*d.*, and the dried root contained 46 to 47 per cent. of sugar; the capital employed was eighty millions of francs.

Whether the juice is extracted from fresh or dried beets the subsequent processes are the same. The juice, having been extracted either by infusion or by submitting the rasped pulp to hydraulic pressure, is placed in a shallow vessel, and mixed with as much milk of lime as renders it strongly alkaline, it is then boiled, generally by means of a copper coil heated by high-pressure steam. The excess of lime is removed by passing a stream of carbonic acid gas through the liquid. The gas is generally produced by forcing a stream of air through an enclosed coke-fire. The liquid is next filtered through cloth concentrated to a specific gravity of 25° B., filtered through animal-charcoal, and treated in all respects similarly to ordinary cane-sugar in a refinery. Though the vacuum-pan is employed in most beet-root establishments, there are some manufacturers who continue to evaporate in open vessels.

The large amount of water which has to be removed in the concentration of beet-root syrups involves the use of so much fuel that to economise it an ingenious apparatus has been constructed by M. Cail of Paris. The principle adopted is to use the steam generated from the ebullition of liquid in one vessel for boiling another, the steam from which in like manner boils a third.

The cultivation of the sugar-beet, so largely conducted on the Continent, has been introduced into this country. See Dr. Voelcker's paper 'On the Cultivation of Sugar-beet in England,' *Journ. Soc. Arts*, March 10, 1871.

In 1873 the total production of beet-root sugar in Europe amounted to 1,142,896 tons.

Maple-sugar.—The manufacture of sugar from the juice of a species of maple-tree, which grows spontaneously in many parts of North America, appears to have been first attempted about 1752, by some of the farmers of New England.

The sugar maple, the *Acer saccharinum* of Linnæus, thrives especially in the States of New York and Pennsylvania, and yields a larger proportion of sugar than that which grows upon the Ohio. It is found sometimes in thickets, but more usually interspersed among other trees. It is supposed to arrive at perfection in 40 years.

The extraction of maple-sugar is a great resource to the inhabitants of districts far removed from the sea, and the process is very simple. After selecting a spot among surrounding maple-trees, a shed is erected, called the *sugar-camp*, to protect the boilers and the operators from the vicissitudes of the weather. One or more augers, three-fourths of an inch in diameter; small troughs for receiving the sap; tubes of elder or sumach, 8 or 10 inches long, laid open through two-thirds of their length, and corresponding in size to the auger-bits; pails for emptying the troughs, and carrying the sap to the camp; boilers capable of boiling 15 or 16 gallons; moulds for receiving the syrup inspissated to the proper consistency for concreting into a loaf of sugar; and, lastly, hatchets to cut and cleave the fuel, are the principal utensils requisite for this manufacture. February and the beginning of March is the sugar-season.

The trees are bored obliquely from below upwards, at 18 or 20 inches above the ground, with two holes 4 or 5 inches asunder. Care must be taken that the auger penetrates no more than half an inch into the alburnum, or white bark; as experience has proved that a greater discharge of sap takes place at this depth than at any other. It is also advisable to perforate in the south face of the trunk.

The trough, which contains 2 to 3 gallons, and is made commonly of white pine, is set on the ground at the foot of each tree, to receive the sap which flows through the two tubes inserted into the holes made with the auger; it is collected together daily, and carried to the camp, where it is poured into casks, out of which the boilers are supplied. In every case it ought to be boiled within the course of two or three days from flowing out of the tree, as it is liable to run quickly into fermentation, if the weather become mild. The evaporation is urged by an active fire, with careful skimming during the boiling; and the pot is continually replenished with more sap, till a large body has assumed a syrupy consistency. It is then allowed to cool, and passed through a woollen cloth, to free it from impurities.

The syrup is transferred into a boiler to three-fourths of its capacity, and it is urged with a brisk fire, till it acquires the requisite consistency for being poured into the moulds or troughs prepared to receive it. This point is ascertained, as usual, by its exhibiting a granular aspect, when a few drops are drawn out into a thread between the finger and thumb. If in the course of the last boiling, the liquor froth up considerably, a small bit of butter or fat is thrown into it. After the molasses has been drained from the concreted loaves, the sugar is not at all deliquescent, like equally brown sugar from the cane. Maple-sugar is in taste equally agreeable with cane-sugar, and it sweetens as well. When refined it is equally fair with the loaf-sugar of Europe.

The period during which the trees discharge their juices is limited to about six weeks. Towards the end of the flow, it is less abundant, less saccharine, and more difficult to be crystallised.

The total production of maple-sugar has been estimated at 45 millions of pounds.

Potato-sugar.—The manufacture of sugar from starch derived from potatoes, from woody matter, and from rags, can be effected by treating them with sulphuric acid and heat; but the process, interesting though it is, is rarely if ever adopted at present, as the sugar is inferior in quality to that obtained from the cane, and is dearer in price.

The specific gravity of cane and beet-root sugar is 1·577, not 1·6065 as given by Berzelius and others; that of starch-sugar, in crystalline tufts, is 1·39, or perhaps 1·40, as it varies a little with its state of dryness. At 1·342 syrup of the cane contains seventy per cent. of sugar; at the same density syrup of starch-sugar contains seventy-five and a half per cent. of concrete matter, dried at 260° Fahr., and, therefore, freed from the ten per cent. of water, which it contains in the granular state. Thus, another distinction is obtained between the two sugars in the relative densities of their solutions, at like saccharine contents, per cent.

One of the most important considerations for a sugar-refiner is to furnish himself amply with bone-charcoal of the best quality, and to devote unsparing attention to the process of revivification. The theory of the action of bone-charcoal upon solutions of raw sugar and other coloured liquids need not be discussed here. See CHARCOAL.

The following Table contains the average results of many analyses made by Dr. Wallace of Glasgow, of several kinds of raw sugar as imported into Greenock and Glasgow, and of the different products of a Greenock sugar-house:—

	West India	Beet	Date	Lumps	Pieces	Bastards	Green syrup	Golden syrup	Molasses	Treacle

SUGAR OF LEAD, properly *Acetate of Lead* (*Acetate de plomb; Sel de Saturne,* Fr.; *Essigsaures Bleioxyd, Bleizucker,* Ger.), is prepared by dissolving pure litharge, with heat, in strong vinegar, made of malt, wood, or wine, till the acid be saturated. A copper boiler, rendered negatively electrical by soldering a strap of lead within it, is the best adapted to this process on the great scale. 325 parts of finely ground and sifted oxide of lead require 575 parts of strong acetic acid, of spec. grav. 7° Beaumé, for neutralisation, and afford 960 parts of crystallised sugar of lead. The oxide should be gradually sprinkled into the moderately hot vinegar, with constant stirring, to prevent adhesion to the bottom; and when the proper quantity is dissolved, the solution may be weakened with some of the washings of a preceding process, to dilute the acetate, after which the whole should be heated to the boiling point, and allowed to cool slowly in order to settle. The limpid solution is to be drawn off by a syphon, concentrated by boiling to the density of 32° B., taking care that there be always a faint excess of acid, to prevent the possibility of any basic salt being formed, which would interfere with the formation of regular crystals. Should the concentrated liquor be coloured, it may be whitened by filtration through granular bone-black.

Stoneware vessels, with salt-glaze, answer best for crystallisers. Their edges should be smeared with candle-grease, to prevent the salt creeping over them by *efflorescent vegetation.* The crystals are to be drained, and dried in a stove-room very slightly heated. It deserves remark, that linen, mats, wood, and paper, imbued with sugar of lead, and strongly dried, readily take fire, and burn away like tinder. When the mother-waters cease to afford good crystals, they should be decomposed by carbonate of soda, or by lime skilfully applied, when a carbonate or an oxide will be obtained, fit for treating with fresh vinegar. The supernatant acetate of soda may be employed for the extraction of pure acetic acid.

A main point in the preparation of sugar of lead is to use a strong acid; otherwise much time and acid are wasted in concentrating the solution. This salt crystallises in colourless, transparent, four- and six-sided prisms, from a moderately concentrated solution; but from a stronger solution, in small needles, which have a yellow cast if the acid has been slightly impure. It has no smell, a sweetish astringent metallic taste, a specific gravity of 2·345; it effloresces slightly in a dry atmosphere, and when heated above 212° Fahr. it froths up and loses all its water of crystallisation, together with some acetic acid, falling into a powder which passes slowly in the air into carbonate of lead. If heated to 536° Fahr. it is entirely liquid, and at a higher temperature is decomposed, disengaging acetic and carbonic acids, and some acetone; the residue consisting of very finely divided and very combustible metallic lead. The crystals of acetate of lead dissolve in 1½ time their weight of water at 60° Fahr., but in much less of boiling water, and in 8 parts of alcohol. The solution feebly reddens litmus-paper, although it imparts a green colour to syrup of violets. The constituents of the normal salt are, 58·71 oxide of lead, 27·08 acetic acid, and 14·21 water, in 100, or $PbO,C^4H^3O^3 + 3HO$ [$\mathbf{Pb(C^2H^3O^2)^2 + 3H^2O}$].

Acetate of lead is much used in calico-printing. It is poisonous, and ought to be prepared and handled with attention to this circumstance.

Four subacetates of lead are generally acknowledged to exist, viz.:—

Sesquibasic acetate. This is obtained by heating the neutral acetate in a capsule till the fused mass becomes white and porous; this is then dissolved in water and evaporated, when on cooling pearly laminæ separate; they are soluble in water and alcohol, and the solution possesses an alkaline reaction.

Dibasic acetate. This salt, when in solution, is known as *Goulard's extract*, and is formed by boiling together a solution of the neutral acetate and an equivalent quantity of pure litharge (oxide of lead). In the solid state it is crystalline.

Tribasic acetate. This salt is the most stable of the subsalts. It is obtained in the crystalline state, by leaving to itself a cold saturated solution of the neutral acetate, to which one-fifth of its volume of caustic ammonia has been added. It may also be made by digesting 7 parts of pure litharge with a solution containing 6 parts of the crystallised neutral acetate. It forms long silky needles, which are very soluble in water, but insoluble in alcohol. Carbonic acid transmitted through the solution precipitates the excess of oxide of lead, in the state of carbonate; a process long since described by Thénard, for making white lead.

Hexbasic acetate. This subsalt is obtained by boiling any of the other acetates with an excess of litharge. It is a precipitate, which, when examined by the microscope, presents a crystalline aspect. It is slightly soluble in boiling water, from which, in cooling, white silky needles are deposited. This salt is frequently found in commercial white lead. The solutions of subacetates are rapidly decomposed by the carbonic acid of the atmosphere.

SUINT. Quite a recent instance of improved economy is found in the treatment of the wool of sheep. It has been ascertained that sheep derive from the soil upon which they pasture a considerable amount of potash, which, after it has circulated in the blood, is secreted from the skin with the sweat, and remains, generally in connection with this, attached to the wool. Chevreul discovered, some time ago, that this peculiar mixture, known by the French as *Suint*, constitutes not less than one-third the weight of the raw merino fleece, from which it is easily removed by immersion in cold water. In ordinary wools the suint is less, the amount being about 15 per cent. of the raw fleece. Formerly it was considered as a kind of soap, mainly for the reason that the wool, besides this sometimes contained about 8 per cent, or a not inconsiderable quantity of fat. This fat, however, is usually combined with earthy matters, mostly with lime, and consequently forms a soap which is very insoluble. The soluble suint is a natural salt (sudorate of potash) arising from the combination of potash with a peculiar animal acid, of which little is known. Especial effort has lately been directed to suint, in order to obtain as much as possible of the potash eliminated from the animal, and a special industry has been established in various portions of the great French wool district, such as Rheims, Elbœuf, &c.

A company purchases from the wool-raiser the solution of the suint obtained by rinsing the wool in cold water, the price paid for it being higher in proportion as it is more concentrated. As a general thing it is maintained that a fleece weighing nine pounds contains 20 ounces of suint, which should contain about one-third part, or six to seven ounces of potash, although not more than five and one-half ounces, are perhaps directly available.

In the wool manufactories of the towns just referred to, there are nearly 60,000,000 pounds of wool washed annually, the yield of about 6,750,000 sheep. This quantity should contain over 3,000,000 pounds of pure potash. Thus the water in which the wool is washed, and which was formerly thrown away, is made to yield a product adding appreciably to the value of the wool itself, and more than covering the cost of its treatment. It is, of course, not an easy matter to utilise the solution of suint on a large scale; but, wherever the work is carried on by the wholesale, as it is in connection with all great manufacturing establishments, it will undoubtedly become a regular part of the process of manufacture.

SULPHATE OF ALUMINA AND POTASSA is common alum. See Alum.

SULPHATE OF BARYTA is the mineral called Heavy-Spar. See Baryta, Sulphate of.

SULPHATE OF COPPER, *Roman or Blue Vitriol* (*Kupfervitriol*, Ger.), $CuO.SO^3$ (**$CuSO^4$**), is a salt composed of sulphuric acid and oxide of copper, and may be formed by boiling the concentrated acid upon the metal, in an iron pot. It is, however, a natural product of many copper mines, from which it flows out in the form of a blue water, being the result of the infiltration of water over copper pyrites, which has become oxygenated by long exposure to the air in subterranean excavations. The liquid is concentrated by heat in copper vessels, and then set aside to crystallise. The salt forms in oblique four-sided tables, of a fine blue colour; has a spec. gravity of 2·104; an acerb, disagreeable, metallic taste; and, when swallowed, it causes violent vomiting. It becomes of a pale dirty blue, and effloresces slightly, on long exposure to the air; when moderately heated, it loses 36 per cent. of water, and falls into a whitish powder. It dissolves in 4 parts of water at 60°, and in 2 of boiling water, but not in alcohol; the solution has an acid reaction upon litmus-paper. When strongly ignited, the acid flies off, and the black oxide of copper remains. The constituents of crystallised sulphate of copper are oxide, 31·80; acid, 32·14; and water, 36·06. Its chief employment in this country is in dyeing, and for preparing certain green pigments. (See Scheele's and Schweinfurth Green.) In France, as well as in England, the farmers sprinkle a weak solution of it upon their grains and seeds before sowing them, to prevent them being attacked by birds and insects. See Copper.

SULPHATE OF IRON, *Green vitriol*, *Copperas* (*Couperose verte*, Fr.; *Eisenvitriol*, *Schwefelsaures Eisenoxydul*, Ger.), $FeO.SO^3$ (**$FeSO^4$**), is a compound of sulphuric acid and protoxide of iron; hence called, by chemists, the protosulphate; consisting of 26·10 of protoxide of iron, 29·90 of sulphuric acid, and 44·00 of water, in 100 parts. It may be prepared by dissolving iron to saturation in dilute sulphuric acid, evaporating the solution till a pellicle forms upon its surface, and setting it aside to crystallise. The copperas of commerce is made in a much cheaper way, by stratifying the pyrites found in the coal-measures (*Vitriolkies* and *Strahlkies* of the Germans), upon a sloping puddled platform of stone, leaving the sulphide exposed to the weather, till, by the absorption of oxygen it effloresces; lixiviating with water the supersulphate of iron thus formed, saturating the excess of acid with plates of old iron, then evaporating and crystallising. The other pyrites, which occurs often crystallised, called by the Germans *Schwefelkies* or *Eisenkies*, must be deprived of a part of its sulphur by calcination before it acquires the property of absorbing oxygen from the atmosphere, and thereby passing from a bisulphide into a sulphate. Alum-schist very commonly contains pyrites, and affords, after being roasted and weather-worn, a considerable quantity of copperas, which must be carefully separated by crystallisation from the alum.

This liquor used formerly to be concentrated directly in leaden vessels; but the first stage of the operation, is now carried on in stone canals of considerable length, vaulted over with bricks, into which the liquor is admitted, and subjected at the surface to the action of flame and heated air, from a furnace of the reverberatory kind, constructed at one end, and discharging its smoke by a high chimney raised at the other. (See SODA MANUFACTURE.) Into this oblong trough, resting on dense clay, and rendered tight in the joints by water-cement, old iron is mixed with the liquor, to neutralise the excess of acid generated from the pyrites, as also to correct the tendency to superoxidation in copperas, which would injure the fine green colour of the crystals. After due concentration and saturation in this surface-evaporator, the solution is run off into leaden boilers, where it is brought to the proper density for affording regular crystals, which it does by slow cooling, in stone cisterns.

Copperas forms sea-green, transparent, rhomboïdal prisms, which are without smell, but have an astringent, acerb, inky taste; they speedily become yellowish-brown in the air, by peroxidation of the iron, and effloresce in a warm atmosphere; they dissolve in 1·43 parts of water at 60°, in 0·27 at 190°, and in their own water of crystallisation at a higher heat. This salt is extensively used in dyeing black, especially hats; in making ink, and Prussian-blue, for reducing indigo in the blue vat, in the China blue-dye, for making the German oil of vitriol, and in many chemical and medicinal preparations.

SULPHATE OF LIME. See ALABASTER; GYPSUM; SELENITE.

SULPHATE OF MAGNESIA. See EPSOM SALTS; MAGNESIA, SULPHATE OF.

SULPHATE OF MANGANESE is prepared on the great scale for the calico-printers, by exposing the peroxide of the metal and pit-coal ground together, and made into a paste with sulphuric acid, to a heat of 400° Fahr. On lixiviating the calcined mass, a solution of the salt is obtained, which is to be evaporated and crystallised. It forms pale amethyst-coloured prisms, which have an astringent bitter taste, dissolve in 2½ parts of water, and consist of—protoxide of manganese, 31·93; sulphuric acid, 35·87; and water, 32·20, in 100 parts.

SULPHATE OF MERCURY. See MERCURY.

SULPHATE OF POTASH. See POTASH.

SULPHATE OF SODA is commonly called *Glauber's salt*, from the name of the chemist who first prepared it. See SODA, SULPHATE OF.

SULPHATE OF ZINC, called also *White Vitriol*, is commonly prepared in the Hartz, by washing the calcined and effloresced sulphide of zinc or blende, on the same principle as green and blue vitriol are obtained from the sulphides of iron and copper. Pure sulphate of zinc made be made most readily by dissolving zinc in dilute sulphuric acid, evaporating and crystallising the solution. It forms prismatic crystals, which have an astringent, disagreeable, metallic taste; they effloresce in a dry air, dissolve in 2·3 parts of water at 60°, and consist of—oxide of zinc, 28·29; acid 28·18; water, 43·53. Sulphate of zinc is used for preparing drying oils for varnishes, and in the reserve or resist pastes of the calico-printer. See ZINC.

SULPHATES are saline compounds of sulphuric acid with oxidised bases. The minutest quantity of them present in any solution may be detected by the precipitate, insoluble in nitric or muriatic acid, which they afford with nitrate or chloride of barium. They are mostly insoluble in alcohol.

SULPHIDE OF CARBON. See CARBON, BISULPHIDE OF.

SULPHITES are a class of salts, consisting of sulphurous acid, combined in equivalent proportions with the oxidised bases.

SULPHUR, *Brimstone* (*Soufre*, Fr.; *Schwefel*, Ger.), is an elementary substance of great importance. It is abundantly distributed in nature, either in the free state or in combination with other elements. In the free state it is found in three different forms: 1st, as kidney-shaped lumps, disseminated through beds of tertiary and recent formations; 2nd, in calcareous formations of Miocene age, associated with gypsum and rock-salt: it is under these circumstances that it is principally found in the mines of Sicily, which supply nearly all the sulphur of commerce in Europe; 3rd, as sublimations around the mouths of volcanoes, where it is mixed with the scoriæ and lava. The solfataras of Guadaloupe and Pouzzales supply it in this state.

The sulphur mines of Sicily, of which the principal are situated near Cattolica, Girgenti, Licata, Caltanisetta, Caltascibetta, Centorbi, and Sommatino, supply immense quantities of sulphur. According to Signor Mottura, the present annual production of Sicily is about 160,000 tons. The Romagna, Spain, and Iceland likewise supply sulphur.

Sulphur is also found largely in nature in combination, as sulphuric acid, and with metals forming sulphides; these latter combinations are known as pyrites. See PYRITES.

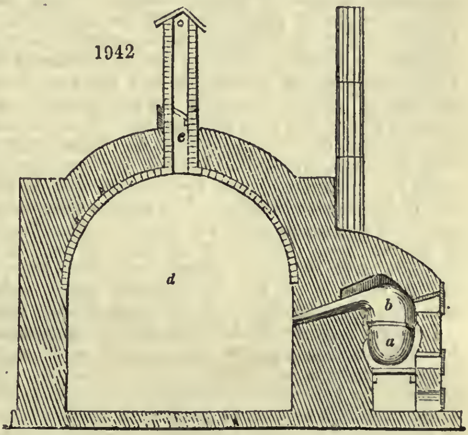
The process for the separation of the sulphur at the celebrated solfatara of

Pouzzales, near Naples, where the sulphur is condensed in considerable quantities amongst the gravel collected in the circle which forms the interior of the crater, is conducted as follows: the mixture of sulphur and gravel is dug up and submitted to distillation to extract the sulphur, and the gravel is returned to its original place, and in the course of about thirty years is again so rich in sulphur as to serve for the same process again. The distillation is effected in the following manner:—Ten earthen pots, of about a yard in height, and 4½ gallons imperial in capacity, bulging in the middle, are ranged in a furnace called a gallery; five being set on the one side, and five on the other. These are so distributed in the body of the walls of the gallery, that their belly projects partly without and partly within, while their top rises out of the vault of the roof. The pots are filled with lumps of the sulphur ore of the size of the fist; their tops are closed with earthenware lids, and from their shoulder proceeds a pipe of about 2 inches diameter, which bends down, and enters into another covered pot, with a hole in its bottom, standing over a tub filled with water. On applying heat to the gallery, the sulphur melts, volatilises, and runs down in a liquid state into the tubs, where it congeals. When one operation is finished, the pots are re-charged, and the process is repeated.

The sulphur thus obtained is still more or less impure, and in this case can only be used in the manufacture of sulphuric acid; it is therefore subjected to another process of purification, which will now be described:—

Fig. 1942 represents one of the cast-iron retorts used at Marseilles for refining sulphur, wherein it is melted and converted into vapours, which are led into a large chamber for condensation. The body, *a*, of the retort is an iron pot, 3 feet in diameter outside, 22 inches deep, half an inch thick, which weighs 14 cwts., and receives a charge of 8 cwts. of crude sulphur. The grate is 8 inches under its bottom, whence the flame rises and plays round its sides. A cast-iron capital, *b*, being luted to the top, and covered with sand, the opening in front is shut with an iron plate. The chamber *d*, is 23 feet long, 11 feet wide, and 13 feet high, with walls 32 inches thick. In the roof, at each gable, valves or flap-doors, *e*, 10 inches square, are placed at the bottom of the chimney *c*. The cords for opening the valves are led down to the side of the furnace. The entrance to the chamber is shut with an iron door. In the wall opposite to the retorts, there are two apertures near the floor, for taking out the sulphur. Each of the two retorts belonging to a chamber is charged with 7½ or 8 cwts. of sulphur; but one is fired first, and with a gentle heat, lest the brimstone froth should overflow; but when the fumes begin to rise copiously, with a stronger flame. The distillation commences within an hour of kindling the fire, and is completed in six hours. Three hours after putting fire to the first retort, the second is in like manner set in operation.

1942



When the process of distillation is resumed, after having been some time suspended, explosions may be apprehended, from the presence of atmospheric air: to obviate the danger of which, the flap-doors must be opened every 10 minutes; but they should remain closed during the setting of the retorts, and the reflux of sulphurous fumes or acid should be carried off by a draught-hood over the retorts. The distillation is carried on without interruption during the week, the charges being repeated four times in the day. By the third day, the chamber acquires such a degree of heat as to preserve the sulphur in a liquid state; on the sixth, its temperature becoming nearly 300° Fahr., gives the sulphur a dark hue, on which account the furnace is allowed to cool on the Sunday. The fittest distilling temperature is about 248°. The sulphur is drawn off through two iron pipes cast in the iron doors of the orifices on the side of the chamber opposite to the furnace. The iron stoppers being taken out of the mouths of the pipes, the sulphur is allowed to run along an iron spout placed over red-hot charcoal, into the appropriate wooden moulds.

Other forms of apparatus have been used of late years in Italy for the extraction of sulphur. The furnace most generally used is known as the *calcarone*, and consists of a circular wall of masonry, within which the ore is piled up. Steam at high pressure has also been applied to the fusion of the sulphur. See a paper by M. Pirckhey, entitled, 'Des Divers Procédés en usuage en Italie pour l'Extraction du Soufre de ses Minerais,' *Bull. d. l. Soc. de l'Ind. Min.* 1873.

According to Signor Parodi, there are now (1874) 250 sulphur mines in Sicily. The ore yields from 15 to 40 per cent. of sulphur, but the extraction is so wasteful that an average of only 14 per cent. is obtained.

In some places sulphur is obtained from the sulphides of iron and copper. In Saxony and Bohemia, they are introduced into large earthenware pipes, which traverse a furnace-gallery; and the sulphur exhaled flows into pipes filled with cold water on the outside of the furnace: 900 parts of sulphide afford from 100 to 150 parts of sulphur, and a residuum of protosulphide.

Pyrites, as a bisulphide, consisting of 45·5 parts of iron and 54·5 of sulphur, may, by proper chemical means, be made to give off one-half of its sulphur, or about 27 per cent.

The great disadvantage in the sulphur prepared from pyrites is, that some of the pyrites contain a large quantity of arsenic, and the sulphur thus obtained from them generally contains sulphide of arsenic, hence the sulphuric acid made from it would contain arsenic, and thus be unfitted for many purposes of the arts; though a tolerably good sulphuric acid may be made directly from the combustion of pyrites, instead of sulphur, in the lead-chambers. See Pyrites.

Sulphur occurs in commerce in two different forms, viz. solid, or in powder: the former is generally in sticks, and is called *lump*, *roll*, or *stick* sulphur; and the latter as *sublimed* or *flowers of sulphur*; and also the kind principally used in medicine, as *precipitated sulphur* or *milk of sulphur.* These different forms are caused by the different modes of preparation; if the sulphur be sublimed into large chambers, which are kept cool during the operation, the product will appear as a powder (*sublimed* or *flowers of sulphur*); but if the chamber be allowed to get hot, the sulphur melts, and is run off into moulds, and forms the lump sulphur. The washing of the sublimed sulphur is to remove any sulphurous or sulphuric acid, which it generally contains when taken from the chamber. The *precipitated sulphur* is formed by boiling ordinary sulphur with lime and water; the sulphur enters into combination with the lime, forming a sulphide of calcium and hyposulphite of lime, which dissolve in the water; to the filtered liquid hydrochloric acid is added, which unites with the lime and precipitates the sulphur. The sulphur thus precipitated is of a pale yellow colour, and when first precipitated will pass through a filter with the water, just as if it were in solution, from the fact of its being so finely divided. Some manufacturers use sulphuric acid instead of hydrochloric acid in this process, and therefore the milk of sulphur found in the shops is generally largely contaminated with sulphate of lime, feels gritty between the teeth, and sparkles when looked at in one direction.

Ordinary sulphur may be crystalline or amorphous; it is capable of crystallising in two different forms, and is hence said to be *dimorphous.* One form is that of acute rhombic octahedrons, belonging to the prismatic system, which is the principal form assumed by native sulphur, and may be obtained artificially by the spontaneous evaporation of a solution of sulphur in bisulphide of carbon; the second form is that of acute rhombic prisms, belonging to the oblique system, which is obtained by fusing sulphur in a crucible, and, when partly cooled, breaking the crust which is formed on the top, and pouring out the part which still remains liquid, when the part which has become solid will remain in long crystals. These crystals differ not only in shape, but also in specific gravity; the octahedral crystals having a specific gravity of 2·045, and the prisms a specific gravity of 1·982. The red tint, so common in the crystals of Sicily, and of volcanic districts, has been ascribed by some mineralogists to the presence of realgar, and by others to iron; but Stromeyer has found the sublimed orange-red sulphur of Vulcano, one of the Lipari Islands, to result from a natural combination of sulphur and selenium.

Sulphur also presents another peculiarity. At all ordinary temperatures it is solid, but it melts at 232° Fahr., and at this temperature it is as fluid as water; if the heat be now gradually raised, it will become thicker and thicker until, between 430° and 480° Fahr., it is so tenacious that the vessel containing it may be inverted for a moment without losing any of its contents; if while in this state it is cooled suddenly, as by pouring it into cold water it will remain for many hours perfectly soft and flexible, and may be drawn out into threads; it now presents none of the appearances of sulphur, and is called *amorphous sulphur.* After some time, however, it regains its former properties, becoming brittle and crystalline, and may be restored still more rapidly to its original state by melting and slow cooling. If the temperature be still raised above 480° Fahr., the sulphur between this and the boiling-point 792° Fahr., becomes again perfectly liquid. When heated in contact with the air, sulphur ignites and burns with a pale blue flame, generating sulphurous acid gas, which is employed to bleach woollen and silken goods; to disinfect vitiated air, though for this purpose it is greatly inferior to chlorine; to kill mites, moths, and other destructive insects in zoological collections; and to counteract too rapid fermentation in wine-vats, &c.

Sulphur has a slight odour, and scarcely any taste. It is a very bad conductor of heat; and a lump of sulphur, even by the heat of the hand, will produce a crackling sound, and often break in pieces. It is a bad conductor of electricity, and by friction becomes strongly charged with electricity, which is of the negative kind. Sulphur is insoluble in water and alcohol; but is dissolved by oil of turpentine and the fatty oils: the best solvent of it, however, is bisulphide of carbon. In its chemical relations it is allied to oxygen, &c. It has been known from the most remote ages, and from its kindling at a moderate temperature is employed for readily procuring fire, and lighting by its flame other bodies less combustible.

Sulphur is also employed for cementing iron bars into stones; for taking impressions from seals and cameos, for which purpose it is kept previously melted for some time to give the casts an appearance of bronze. Its principal uses, however, are for the manufactures of gunpowder and sulphuric acid.

There is another form in which sulphur is sometimes known, and this is what is termed *horse brimstone* or *black sulphur*. It is the dregs of the subliming pot after the purification of sulphur, and often contains large quantities of arsenic.

The purity of sulphur may be known by its being completely volatilisable, and by being soluble in bisulphide of carbon; any earthy impurities would in either case remain behind.

SULPHURATION is the process by which woollen, silk, and cotton goods are exposed to the vapours of burning sulphur—sulphurous acid gas.

Sulphuring-rooms are sometimes constructed upon a great scale, in which blankets, shawls, and woollen clothes may be suspended freely upon poles or cords. The floor should be flagged with a sloping pavement, to favour the drainage of the water that drops down from the moistened cloth. The iron or stoneware vessels, in which the sulphur is burned, are set in the corners of the apartment. They should be increased in number according to the dimensions of the place, and distributed uniformly over it. The windows and the entrance door must be made to shut hermetically close. In the lower part of the door there should be a small opening, with a sliding shutter, which may be raised or lowered by the mechanism of a cord passing over a pulley.

SULPHURETTED HYDROGEN, or *Hydrosulphuric acid.* Sulphur does not unite directly with hydrogen when in the free state, but when the sulphides of those metals which dissolve in dilute acids with liberation of hydrogen are treated with the same acids, they are dissolved, and the hydrogen, as soon as liberated, unites with the sulphur of the sulphide, and is evolved as sulphuretted hydrogen. Sulphide of iron is the most general substance that is used for this purpose; the action goes on without the application of heat. The following equation represents the decomposition:

$$FeS + HO.SO^3 = FeO.SO^3 + HS \quad (\mathbf{FeS + H^2SO^4 = FeSO^4 + H^2S}).$$

This substance does not yield the gas in the pure state; hence, when its purity is an object, it is obtained by the action of hydrochloric acid on tersulphide of antimony; in this case the gas is only liberated by the application of heat:

$$SbS^3 + 3HCl = SbCl^3 + 3HS \quad (\mathbf{Sb^2S^3 + 6HCl = Sb^2Cl^6 + 3H^2S}).$$

The sulphide of iron may easily be prepared by projecting into a red-hot crucible a mixture of 2½ parts of sulphur and 4 parts of iron-filings, or borings of cast iron, and excluding the air as much as possible. Another process is to raise a bar of iron to a white heat, and then rub it with a lump of sulphur, over a vessel of water, when the drops of fused sulphide fall into the water.

Sulphuretted hydrogen, at ordinary temperatures, is a colourless gas, possessing a most disgusting odour. It is liberated by many vegetable and animal substances in a state of decay. Its density is 1·171, and it contains 1 part of hydrogen and 16 parts of sulphur by weight. It possesses the properties of an acid, and its solution in water reddens litmus-paper.

At a temperature of 50°, and under a pressure of 17 atmospheres, it is condensed to a highly limpid colourless liquid, of specific gravity 0·9, and when cooled to −122° solidifies, and is then a white crystalline translucent substance, heavier than the liquid. In the undiluted state this gas is very suffocating: the best antidote is a little chlorine, which decomposes it immediately, liberating the sulphur:

$$HS + Cl = HCl + S \quad (\mathbf{H^2S + Cl^2 = 2HCl + S}).$$

It is very soluble in water, that liquid dissolving 2½ times its bulk of the gas; the solution quickly becomes milky from the deposition of sulphur, the oxygen of the air uniting with the hydrogen:

$$HS + O = HO + S \quad (\mathbf{H^2S + O = H^2O + S}).$$

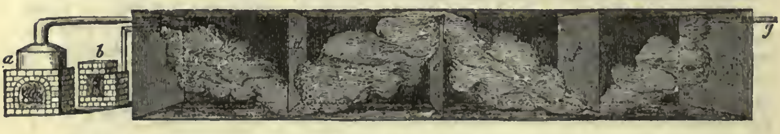
The principal use of sulphuretted hydrogen is in the laboratory for the separation of certain metals from their solutions. Being much heavier than air, it can be poured from one vessel to another.

SULPHURIC ACID, *Vitriolic Acid*, or *Oil of Vitriol.* (*Acid sulfurique*, Fr.; *Schwefelsäure*, Ger.). This important liquid now forms an extensive article of manufacture. It was formerly prepared by the distillation of sulphate of iron or green vitriol, from which it received its name of *oil of vitriol* or *vitriolic acid.* It was subsequently found that it might be produced by the combustion of sulphur, and the ultimate further oxidation of the sulphurous acid, thus obtained, by the means of nitric acid; and from time to time improvements have been made in the process, until it is now almost, perhaps entirely, perfect.

In the first place the sulphur is burnt on suitable hearths, and the sulphurous acid produced is carried by flues, together with some nitrous and nitric acids, generated in the same furnace from a mixture of nitre and sulphuric acid, into the large leaden chambers, into which steam and air are also admitted; here the different gases react on each other, and the sulphurous acid becomes converted into sulphuric acid, which falls into the dilute sulphuric acid which is placed in the bottom of the chamber, which thereby becomes stronger, and, when of sufficient strength, is drawn off, and concentrated first in leaden vessels, and finally in vessels of platinum.

The place where the sulphur is burnt is a kind of furnace, but instead of the grate, there is a stone hearth or iron plate, called the *sole*. The nitre-pot or pan is of cast iron. In it the nitre is decomposed by the sulphuric acid, and it is placed in the burner when required. The leaden chamber has the form of a parallelopiped, the size varying with the amount of work required to be done. To produce 10 tons of oil of vitriol weekly, the chamber should have a capacity of 35,000 cubic feet; or a length of 187 feet, a breadth of 12½ feet, and a height of 15 feet. The bottom is covered to the depth of 3 or 4 inches with water acidulated with sulphuric acid. These leaden chambers are sometimes divided into 3 or 4 compartments by leaden curtains placed in them, which cause the more perfect mixture of the gases. *Fig.* 1943 is a drawing of one thus divided, taken from Pereira's 'Materia Medica.'

1943



OIL OF VITRIOL-CHAMBER.

e. Leaden curtains rising from the floor to within six inches of the roof.
g. Leaden conduit or vent-tube for the discharge of uncondensible gases. It should communicate with a tall chimney to carry off these gases, and to occasion a slight draught through the chamber.

These curtains serve to detain the vapours, and cause them to advance in a gradual manner through the chamber, so that generally the whole of the sulphurous acid is converted into sulphuric acid and deposited in the water at the bottom before it reaches the discharge pipes; but as such is not always the case, there are sometimes smaller chambers, also containing water, appended to the larger, from which they receive the escaping gases before they are allowed to pass out into the air, and thus prevent loss. These smaller chambers are seen in *fig.* 1944 *c, d,* also taken from Pereira's 'Materia Medica.'

Another method for preventing this loss was contrived by M. Gay-Lussac, and made the subject of a patent in this country by his agent, M. Sautter. It consists in causing the waste gas of the vitriol-chamber to ascend through the *chemical cascade* of M. Clément Desormes, and to encounter there a stream of sulphuric acid of specific gravity 1·750. The nitrous acid gas, which is in a well-regulated chamber always slightly redundant, is perfectly absorbed by the said sulphuric acid; which, thus impregnated, is made to trickle down through another cascade, up through which passes a current of sulphurous acid, from the combustion of sulphur in a little adjoining chamber. The condensed nitrous acid gas is thereby immediately transformed into nitrous gas (binoxide of nitrogen), which is transmitted from the second cascade into the large vitriol-chamber, and there exercises its well-known reaction upon its aëriform contents. The economy thus effected in the sulphuric-acid manufacture is such that for 100 parts of sulphur, 3 of nitrate of soda will suffice, instead of 9 or 10 as usually consumed.

The flue or waste-pipe serves to carry off the residual gas, which should contain nothing but the nitrogen of the atmosphere, which has been introduced.

There are at least two plans at present in use for burning the sulphur continuously in the oven. In the one, the sulphur is laid on the hearth (or rather on the flat hearth in the separate oven, above described,) and is kindled by a slight fire placed under it; which fire, however, is allowed to go out after the first day, because the oven becomes by that time sufficiently heated by the sulphur-flames to carry on the subsequent combustion. Upon the hearth, an iron tripod is set, supporting, a few inches above it a

hemispherical cast-iron bowl (basin) charged with nitre and its decomposing portion of strong sulphuric acid. In the other plan, 12 parts of bruised sulphur and 1 of nitre, are mixed in a leaden trough on the floor with 1 of strong sulphuric acid, and the mixture is shovelled through the sliding iron door upon the hot hearth. The successive charges of sulphur are proportioned, of course, to the size of the chamber. In one of the largest, which is 120 feet long, 20 broad, and 16 high, 12 cwts. are burned in the course of 24 hours, divided into 6 charges, every fourth hour, of 2 cwts. each. In chambers of one-sixth greater capacity, containing 1,400 meters cube, 1 ton of sulphur is burned in 24 hours. This immense production was first introduced at Chaunay and Dieuze, under the management of M. Clément Desormes. The bottom of the chamber should be covered at first with a thin stratum of sulphuric acid, of sp. gr. 1·07, which decomposes hyponitric acid into oxygen and binoxide of nitrogen; but not with mere water, which would absorb the hyponitric acid vapours, and withdraw them from their sphere of action. The crystalline compound, described below, is often formed, and is deposited, at low temperatures, in a crust of considerable thickness (from one-half to one inch) on the sides of the chamber, so as to render the process inoperative. A circumstance of this kind occurred, in a very striking manner, during winter, in a manufacture of oil of vitriol in Russia; and it has sometimes occurred, to a moderate extent, in Scotland. It is called, at Marseilles, the *maladie des chambres.* It may be certainly prevented, by maintaining the interior of the chamber, by a jet of steam, at a temperature of 100° Fahr. When these crystals fall into the dilute acid at the bottom, they are decomposed with a violent effervescence, and a hissing gurgling noise, somewhat like that of a tun of beer in brisk fermentation.

The introduction of steam is a modern invention, which has vastly facilitated and increased the production of oil of vitriol. It serves, by powerful agitation, not only to mix the different gaseous molecules intimately together, but to impel them against each other, and thus bring them within the sphere of their mutual chemical attraction. This is its mechanical effect. Its chemical agency is still more important. By supplying moisture at every point of the immense included space, it determines the formation of hydrous sulphuric acid, from the compound of nitric, hyponitric, sulphurous, and dry sulphuric acids.

Besides the process here described, which is called the *continuous* process, there was another formerly adopted, called the *intermittent* process. This was also carried on in large leaden chambers, but instead of a continuous stream of air, as passes into the chambers, through the furnace by the continuous process, the chambers were opened now and then to introduce fresh atmospheric air. This process is, however, now abandoned.

By the continuous method, sulphuric acid may be currently obtained in the chambers, of the specific gravity 1·35, or 1·45 at most; but when stronger, it absorbs and retains permanently much nitrous acid gas; by the intermittent process, however, it may be obtained as dense as 1·550, or even 1·620; hence where fuel is high priced, as near Paris, this method recommended itself by economy in the concentration of the acid. In Great Britain, and even in most parts of France, however, where time, workmen's wages, and interest of capital, are the paramount considerations, manufacturers do not find it for their interest in general to raise the density of the acid in the chambers above 1·400, or at most 1·500; as the further increase goes on at a retarded rate, and its concentration from 1·400 to 1·600, in leaden pans, costs very little.

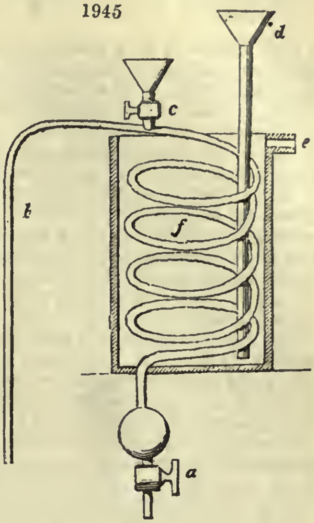
For many purposes in the arts the acid, as it is taken from the leaden chambers, is quite strong enough, and is employed under the name of 'Chamber Acid.'

At about the specific gravity of 1·35, in Great Britain, the liquid of the chambers is run off by the syphon above described, into a leaden gutter or spout, which discharges it into a series of rectangular vessels made of large sheets of lead of 12 or 14 lbs., to the square foot, simply folded up at the angles into 8 or 10 inches deep, resting upon a grate made of a pretty close row of wrought-iron bars of considerable strength, under which the flame of a furnace plays. Where coals are very cheap, each pan may have a separate fire; but where they are somewhat dear, the flame, after passing under the lowest pan of the range, which contains the strongest acid (at about 1·600), proceeds upwards with a slight slope to heat the pans of weaker acid, which, as it concentrates, is gradually run down by syphons to replenish the lower pans, in proportion as their aqueous matter is dissipated. The three or four pans constituting the range are thus placed in a straight line, but each at a different level, terrace-like.

When the acid has thereby acquired the density of 1·650, or 1·700 at most, it must be removed from the leaden evaporators, because when of greater strength it would begin to corrode them; and it is transferred into leaden coolers, or run through a long refrigeratory worm-pipe, surrounded by cold water. In this state it is introduced into glass or platinum retorts, to undergo a final concentration, up to the specific gravity of 1·842, or even occasionally 1·845. When glass retorts are used, they are set in a long sand-bath over a gallery-furnace, resting on fire-tiles, under which a powerful flame plays; and as the flue gradually ascends from the fireplace near to which it is most distant from the tiles, to the remoter end, the heat acts with tolerable equality on the first and last retort in the range. When platinum stills are employed, they are fitted into the inside of cast-iron pots, which protect the thin bottom and sides of the precious metal. The fire being applied directly to the iron, causes a safe, rapid, and economical concentration of the acid. The iron pots, with their platinum interior, filled with concentrated boiling-hot oil of vitriol, are lifted out of the fire-seat by tackle, and let down into a cistern of cold water, to effect the speedy refrigeration of the acid, and facilitate its transvasion into carboys packed in osier baskets lined with straw. Sometimes, however, the acid is cooled by running it slowly off through a long platinum syphon, surrounded by another pipe filled with cold water. *Fig.* 1945 shows a contrivance for this purpose.

The under stopcock *a* being shut, and the leg *b* being plunged to nearly the bottom of the still, the worm is to be filled with concentrated cold acid through the funnel *c*. If that stopcock is now shut, and *a* opened, the acid will flow out in such quantity as to rarefy the small portion of air in the upper part of the pipe *b*, sufficiently to make the hot acid rise up over the bend, and set the syphon in action. The flow of the fluid is to be so regulated by the stopcock *a*, that it may be greatly cooled in its passage by the surrounding cold water in the vessel *f*, which may be replenished by means of the tube and funnel *d*, and overflow at *e*.

1945



The platinum retort admits of from four to six operations in a day, when it is well mounted and managed. It has a platinum capital, furnished with a short neck, which conducts the disengaged vapours into a lead-worm of condensation; and the liquid thus obtained is returned into the lead-pans. Great care must be taken to prevent any particles of lead from getting into the platinum vessel, since at the temperature of boiling sulphuric acid, the lead unites with the precious metal, and thus causes holes in the retort. These must be repaired by soldering on a plate of platinum with gold.

Sanitary motives alone induced the makers of soda to condense their waste hydrochloric acid in the first instance; though they now discover its worth as a means of manufacturing chloride of lime, and would not again return to the nuisance-creating system if they might.

The complicated changes which take place in the leaden chambers during the conversion of the sulphurous acid into sulphuric acid, were first traced by M. Clément Desormes. He showed that hyponitric acid and sulphurous acid gases when mixed react on each other through the intervention of moisture; that there thence resulted a crystalline combination of sulphuric acid, binoxide of nitrogen, and water. That this crystalline compound was instantly destroyed by more water, with the separation of the sulphuric acid in a liquid state, and the disengagement of binoxide of nitrogen; that this gas re-constituted hyponitric acid at the expense of the atmospheric oxygen of the leaden chamber, and thus brought matters to their primary condition. From this point, starting again, the particles of sulphur in the sulphurous acid, through the agency of water, became fully oxygenated by the hyponitric acid, and fell down in heavy drops of sulphuric acid, while the binoxide of nitrogen derived from the hyponitric acid, had again recourse to the air for its lost dose of oxygen. This beautiful interchange of the oxygenous principle was found to go on, in their experiments, till either the sulphurous acid or oxygen in the air was exhausted.

They verified this proposition, with regard to what occurs in sulphuric-acid chambers, by mixing in a crystal globe the three substances, binoxide of nitrogen, sulphurous acid, and atmospheric air. The immediate production of red vapours indicated the transformation of the binoxide into hyponitric acid gas; and now the introduction of a very little water caused the proper *reaction*, for opaque vapours arose, which deposited white star-formed crystals on the surface of the glass. The gases were once more transparent, and colourless; but another addition of water melted these crystals with effervescence, when ruddy vapours appeared. In this manner the phenomena were made to alternate, till the oxygen of the included air was expended, or all the sulphurous acid was converted into sulphuric. The residuary gases were found to be hyponitric acid gas, and nitrogen without sulphurous acid gas; while unctuous sulphuric acid bedewed the inner surface of the globe. Hence, they justly concluded their new theory of the manufacture of oil of vitriol to be demonstrated.

There are some points in the manufacture of sulphuric acid which require attention.

1st. If the heat in the sulphur-furnace is too high, or when there is not a sufficient supply of air, some sulphur sublimes, and is condensed in the chamber, and at last falls into the sulphuric acid at the bottom of the chamber. By this means, not only is less sulphuric acid produced, but the sulphuric acid, when drawn from the chamber, contains some sulphur in suspension: in this case it must be allowed to stand, so as to deposit the sulphur, which may be collected, washed, dried, and again used. If the sulphur were not removed before concentrating, it would, at the temperature requisite for evaporation, decompose the sulphuric acid, with the escape of sulphurous acid gas, and hence much sulphuric acid would be lost. The reaction that would take place is represented by the following equation:—

$2(HO.SO^3)$	+	S	=	$3SO^2$	+	$2HO.$
Sulphuric acid.		Sulphur.		Sulphurous acid gas.		Water.
$\mathbf{2H^2SO^4}$	+	$\mathbf{S}$	=	$\mathbf{3SO^2}$	+	$\mathbf{2H^2O.}$

2nd. If there is not a sufficient quantity of steam admitted into the chamber, the solid compound of sulphuric acid and binoxide of nitrogen, above mentioned, would be formed on the sides of the chamber, and thus remove the oxidising agent from action, and hence a large quantity of sulphurous acid would escape by the waste-pipe unchanged.

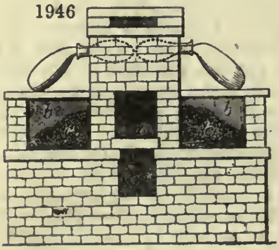
3rd. A deficiency of nitric acid in the chamber also causes great loss; the sulphurous acid, as in the former case, escaping unoxidised.

The first of these three subjects was counteracted by M. Grovelle, who, taking advantage of an idea put forth by M. Clément Desormes, constructed a furnace for burning the sulphur, so as to have a double current of air. He substituted for the sole of the furnace some parallel bars of iron, on which were placed cast-iron pans or boxes, bound together, but leaving intervals for the entrance of air between each: these were filled with sulphur, which was then ignited, and thus a plentiful supply of air was constantly kept up.

The reactions which take place in the sulphuric-acid chamber have recently been studied by Mr. H. A. Smith, who concludes, contrary to generally-received opinions, that under certain circumstances action can take place between dry sulphurous acid and nitric-acid gases without the intervention of steam. He believes that the best form of chamber should be long and not high, having, in fact, the following dimensions: length 150 feet, width 95 to 30 feet, and height 10 to 12 feet. The temperature should be kept as nearly as possible at 200° Fahr., and in starting the chamber he recommends that sulphuric acid should be run on the bottom in preference to water. See 'The Chemistry of Sulphuric Acid Manufacture,' by H. A. Smith, 1873.

Fuming, or Nordhausen Sulphuric Acid. At Nordhausen and other parts of Saxony, sulphuric acid continues to be made upon the old plan. This consists in first subjecting sulphate of iron, or green vitriol, to a gentle heat, by which it is deprived of its water of crystallisation; it is then distilled in earthenware, tubular, or pear-shaped retorts, of which a large number are placed in a gallery-furnace. *Fig.* 1946 shows the fireplace; *a b b*, chamber on each side of the fireplace, for depriving the green vitrol, *c c*, of its water.

1946



To these retorts are adapted earthenware receivers, into which some ordinary sulphuric acid is previously placed, to condense all the anhydrous sulphuric acid which comes over. The heat is raised gradually, and at last the retorts are subjected to an intense heat, which is kept up for several hours.

Some sulphurous acid gas escapes, arising from the decomposition of some of the sulphuric acid of the sulphate by the oxide of iron, and nothing remains in the retorts but sesquioxide of iron.

Anhydrous Sulphuric Acid, or Sulphuric Anhydride. This is most easily obtained by subjecting the Nordhausen sulphuric acid to a gentle heat in a glass retort, to which is adapted a dry receiver placed in ice. White fumes of anhydrous sulphuric acid come over and are condensed in the receiver. Care must be taken to avoid water coming into contact with it, as it unites with it with some violence.

It is best to have a receiver which can be hermetically sealed as soon as the operation is completed.

Properties of the different Sulphuric Acids.

Anhydrous Sulphuric Acid, or *Sulphuric Anhydride.* (SO^3.) This is a white crystalline body, very much resembling asbestos in appearance. Exposed to the air, some of it absorbs moisture, and the rest flies off in white fumes. Dropped into water it produces a hissing noise, just like red-hot iron, and in large quantities causes explosion. It melts at 66° Fahr., and boils at about 120° Fahr. The sp. gr. of the liquid, at 78° Fahr., is 1·97 (*Pereira*), and that of its vapour 3·0 (*Mitscherlich*). It does not present acid properties unless moisture be present.

Nordhausen Sulphuric Acid. $HO.SO^3,SO^3$ ($\mathbf{H^2SO^4SO^3}$). This is an oily liquid, generally of a brown colour (from some organic matter), which gives off white fumes of anhydrous sulphuric acid when exposed to the air. Its sp. gr. is about 1·9. It is imported in stoneware bottles, having a stoneware screw for a stopper. It is probably only a solution of anhydrous sulphuric acid in ordinary oil of vitriol, as, after being subjected to a gentle heat, nothing remains but the latter. It often contains several impurities. It is principally used for dissolving indigo, which it does completely without destroying the colour.

Ordinary Sulphuric Acid, or Oil of Vitriol. $HO.SO^3$ ($\mathbf{H^2SO^4}$). Sp. gr. 1·845. This is, when pure, a colourless, transparent, highly acrid, and most powerfully corrosive liquid. It is a very strong mineral acid, one drop being sufficient to communicate the power of reddening litmus-paper to a gallon of water, and produces an ulcer if placed upon the skin. It chars most organic substances. This depends upon its attraction for water, which is so great that, when exposed in an open saucer, it imbibes one-third of its weight from the atmosphere in twenty-four hours, and fully six times its weight in a few months. Hence it should be kept excluded from the air. If four parts, by weight, of the strongest acid be suddenly mixed with one part of water, both being at 50° Fahr., the temperature will rise to 300° Fahr.; while, on the other hand, if four parts of ice be mixed with one of sulphuric acid, they immediately liquefy and sink the thermometer to 4° below zero. In this last case the heat, that would otherwise have been given off, has been employed in liquefying the ice. Upon the mixing the acid and water they both suffer condensation, the dilute acid, thus formed, occupying less space than the two separately, and hence the evolution of heat. This affinity for water, which sulphuric acid possesses, is often made use of for evaporating liquids at a low temperature. The liquid is placed in a dish over another dish containing sulphuric acid, and both are placed under the receiver of an air-pump. Such is the rapidity with which the evaporation is carried on, that if a small vessel of water be so placed it will speedily be frozen. Sulphuric acid is decomposed by several substances when boiled with them; such are most organic substances, sulphur, phosphorus, and several of the metals, as mercury, copper, tin, &c.

Sulphuric acid of sp. gr. 1·845, boils at about 620° Fahr., and may be distilled unchanged. This is the best way to obtain it pure. It is a most powerful poison. If swallowed in its concentrated state, even a small quantity, it acts so powerfully on the throat and stomach as to cause intolerable agony and speedy death. Watery diluents, mixed with chalk or magnesia, are the readiest antidotes.

Ordinary oil of vitriol generally contains some sulphate of lead, which will be precipitated, as a white powder by dilution with water; since so much of it is made from iron pyrites at the present day, it contains arsenic in variable quantities. The best test for sulphuric acid, either free or combined, as soluble salts, is a salt of barium. An extremely small quantity of sulphuric acid, or a soluble salt of it, is thus easily detected by the greyish-white cloud of sulphate of baryta which it occasions in the solution. 100 parts of the concentrated acid are neutralised by 143 parts of dry pure carbonate of potash, and by 110 of dry pure carbonate of soda.

The presence of saline impurities in sulphuric acid may be determined by evaporating a certain quantity to dryness in a platinum capsule. If more than 2 grains of residue remain out of 500 of acid it may be considered impure.

Of all the acids, the sulphuric is most extensively used in the arts, and is, in fact, the primary agent for obtaining almost all the others, by disengaging them from their saline combinations. In this way nitric, hydrochloric, tartaric, acetic, and many other acids, are procured. It is employed in the direct formation of alum, of the sulphates of copper, zinc, potassa, soda; in that of sulphuric ether, of sugar by the saccharification of starch, and in the preparation of phosphorus, &c. It serves also for opening the pores of skins in tanning, for clearing the surfaces of metals, for determining the nature of several salts by the acid characters that are disengaged, &c.

The Table on next page, which shows the quantity of concentrated and dry sulphuric acid in 100 parts of dilute, at different densities, was constructed by Dr. Ure.

SULPHUROUS ACID. (SO^2.) Sulphur fumigations are mentioned by Homer, but sulphurous acid, of which these are composed, was first accurately examined by Stahl, Scheele, and Priestley, and afterwards by Gay-Lussac and Berzelius.

It escapes from the earth, in the gaseous form, in the vicinity of volcanoes, but is always prepared artificially when required for use, and for this purpose several processes are employed.

1. By heating copper-cuttings, or mercury, with concentrated sulphuric acid in a glass flask, sulphate of copper, or persulphate of mercury, and sulphurous acid are formed:

$$\underbrace{Cu}_{\text{Copper.}} + \underbrace{2(HO.SO^3)}_{\text{Sulphuric acid.}} = \underbrace{CuO.SO^3}_{\text{Sulphate of copper.}} + \underbrace{SO^2}_{\text{Sulphurous acid.}} + \underbrace{2HO.}_{\text{Water.}}$$

$$\mathbf{Cu + 2H^2SO^4 = CuSO^4 + SO^2 + 2H^2O.}$$

The sulphurous acid is passed through a wash-bottle, to remove any trace of sulphuric acid which may come over, and then through a tube containing chloride of calcium, if the gas be wanted dry; it may then be collected over mercury in the pneumatic trough, or by displacement of air; it cannot be collected over water, owing to its great solubility in that liquid.

2. By heating charcoal, or almost any organic substance, with concentrated sulphuric acid in the same apparatus as above; but in this case the sulphurous acid is contaminated with a large quantity of carbonic acid, which, however, does not interfere with it in many cases, as when employed in the manufacture of alkaline sulphites:

$$\underbrace{C}_{\text{Charcoal.}} + \underbrace{2(HO.SO^3)}_{\text{Sulphuric acid.}} = \underbrace{CO^2}_{\text{Carbonic acid.}} + \underbrace{2SO^2}_{\text{Sulphurous acid.}} + \underbrace{2HO.}_{\text{Water.}}$$

$$\mathbf{C + 2H^2SO^4 = CO^2 + 2SO^2 + 2H^2O.}$$

3. By the combustion of sulphur or iron pyrites in oxygen gas or in atmospheric air, and this is the process most generally employed on the large scale, as in the manufacture of sulphuric acid. See Sulphuric Acid.

$$\underbrace{S}_{\text{Sulphur.}} + \underbrace{O^2}_{\text{Oxygen.}} = \underbrace{SO^2.}_{\text{Sulphurous acid.}}$$

Properties. At ordinary temperatures and atmospheric pressure sulphurous acid is a colourless, transparent gas, possessing the disagreeable odour so well known to those who have burnt a sulphur-match. It is neither combustible, nor a supporter of combustion, and is always the product obtained by burning sulphur in air. It is a weak acid, and is very soluble in water, that liquid at 60° Fahr. dissolving more than thirty times its volume of the gas; the solution of sulphurous acid, thus obtained, bleaches some vegetable colours, as well as the gas itself, viz. those of roses and violets, &c., but in most cases the colours may be restored by treating with a weak acid or alkali. It cannot be respired in the pure state, as it immediately causes spasm of the glottis; but if diluted with air and then breathed, it acts as a local irritant, exciting cough, pain, and a sense of dryness of the mouth and throat. Its sp. gr. is 2·2; 100 cubic inches weighing 68·69 grains. Its solution in water may be kept any time without change, as long as air is excluded, but when air gains access to it, it is gradually converted into sulphuric acid.

SULPHURS. Impressions taken by the goldsmiths of the sixteenth century from the engravings executed on plate, paxes, &c., and which they obtained by spreading a layer of melted sulphur on the face of the plate, producing a cast *in relief* of the lines engraved. Some few of these proofs exist in the British and Continental Museums, and are known as *sulphurs*. They are amongst the rarest specimens connected with the art of engraving.

SULPHYDROMETRY. The determination of sulphur.

SUMACH, or **SHUMACH.** A species of the genus *Rhus*, used in tanning. It is known also as *sumac* and *shumac*. It consists of the ground-leaves, foot-stalks, and young twigs of several varieties of plants, technically known as sumacs, but botanically belonging to the genus *Rhus* of the Natural Order *Anacardiaceæ*. The sumac of commerce is chiefly obtained from the *Rhus Coriaria*, in the following manner:—A short time before the blooming of the plant in June or July, the younger twigs are cut off, dried in the sun, next beaten, so as to detach the leaves and flower panicles, which are next coarsely ground up by means of millstones. The shrub just named is a native of Asia, but is cultivated in many parts of Europe, more especially in Sicily, Spain, Southern France, and Hungary. Sumac is also prepared from the *Rhus Cotinus.*

In the South of France a peculiar kind of sumac is prepared, and known locally as *redout* or *redou*. It is derived from the *Coriaria myrtifolia*, or tanner's-herb, which contains a violently poisonous substance.

The leaves of the *Arbutus Uva-ursi*, better known in pharmacy than in technology, are used as sumac in Dalecarlia, Sweden.

The following are the chief varieties of sumac known in the trade:—

Sicilian Sumac.—The most esteemed article, fetching always a high price,
Spanish Sumacs.—Exported from Malaga, Priego or Mohua, Valladolid.
Portuguese Sumacs.—From Oporto.
Italian Sumacs.
French Sumacs.

The articles are classified here according to their amount of tannin.

Imports in 1873.

SUNFLOWER OIL. See OILS.

SUNN consists of the fibre of the *Crotolaria juncea*, a totally different plant from the *Cannabis sativa*, from which hemp is obtained, Sunn is grown in various places of Hindostan. The strongest, whitest, and most durable species is produced at Comercolly. It is also known as *Bengal Hemp.*

SUNSTONE. A variety of felspar, of a pale yellowish colour, found in Siberia. It is almost perfectly transparent when viewed in one direction; but by reflected light it appears full of minute golden spangles. See FELSPAR.

SUPERPHOSPHATE, properly superphosphate of lime, much used as a manure. See PHOSPHATES, and MANURE.

SUSSEX MARBLE. Thin bands of shelly limestone, occurring here and there in the Weald Clay, especially in the upper part. This limestone is principally composed of the remains of freshwater snails, a species of *Paludina*, and it has been named Sussex marble, in consequence of its great development in that county. Although the stone is not remarkable for any particular beauty of colour, being generally of a uniform bluish or greyish-green tint, the sections of the chambers of the shells give it, when polished, a pleasing appearance, and it has, in consequence, been frequently made use of in former times in the construction of tombs and sepulchral monuments in many of our older churches.—H. W. B.

SWAGES. Tools employed in shaping metals.

SWALLOW, ESCULENT (*Hirundo esculenta*). These birds construct the edible nests which form so considerable a part of Chinese commerce. It is the *Larvet* of the Japanese, the *Salangana* of some writers on the Eastern Archipelago. The nests are made of a particular species of sea-weed (see ALGÆ), which the bird macerates and bruises before it employs the material in layers, so as to form the whitish gelatinous cup-shaped nests so much prized as delicacies by the Chinese.

SWANS'-DOWN. There is a production of 500,000 puffs made annually from about 7,000 swans'-down skins, imported into Britain.

SWEEP-WASHER is the person who extracts from the sweepings, potsherds, &c. of refineries of silver and gold, the small residuum of precious metal.

SWEETMEATS. Any article prepared chiefly with sugar is so called. A considerable number are described under CONFECTIONERY.

SYCAMORE. The wood of the *Acer pseudo-platanus.*

SYENITE is a crystalline rock, consisting of orthoclase-felspar and hornblende; but the term is also frequently applied to a mixture of hornblende, orthoclase, and quartz. It takes its name from the city of Syene, in the Thebaid, near the Cataracts of the Nile, but the rock there is not a true syenite. It is an excellent building-stone, and was imported from Egypt, by the Romans, for the architectural and statuary decorations of their capital. Hornblende is the characteristic ingredient, and serves to distinguish syenite from granite, with which it has been sometimes confounded. The Egyptian Syenite, containing but little hornblende, with a good deal of quartz and mica, approaches most nearly to granite. It is equally metalliferous with porphyry. In the island of Cyprus, it is rich in copper; and in Hungary, it contains many valuable gold and silver mines. Syenite forms a considerable part of the Criffle, a hill in Galloway. The so-called 'granites' of Leicestershire more nearly approach syenites. A careful study of the rocks of the Grooby, Markham, and Bardon Hill quarries, will show a gradual change of the granitic rock, through syenite, into a greenstone-porphyry. This stone is extensively used in the metropolis and other large towns for 'pitching' and paving. Much of the 'granite' of the Channel Islands, used in the metropolis for road-metal, is a syenite, or at least a hornblendic or syenitic granite.

SYLVANITE, or *Graphic Tellurium.* A valuable ore of gold and silver, found at Offenbanya in Transylvania, in narrow veins traversing porphyry, and at Gold Hill, North Carolina. Its analysis by Petz gave: silver, 11·47; gold, 21·97; tellurium, 39·97; lead, 0·25; copper, 0·76; antimony, 0·58 = total, 100·00.

SYLVINE. Chloride of potassium; a mineral formerly of great rarity, but found of late years in abundance among the deposits of potash-salts, overlying the rock-salt of Stassfurt in Prussian Saxony, and at Kaluscz in Galicia. Sylvine is an important source of other salts of potassium.

SYMBOLS. Signs adopted by chemists to indicate the simple elements, or the combinations of them, forming a compound body. A symbolic language has been universally adopted by chemists, and the facilities it offers very strongly recommend it. The symbols H, O, S, C, stand respectively for hydrogen, oxygen, sulphur, and carbon; each elementary substance being represented by the initial letter of its Latin name. When the initial letter of any two elements are similar, as, for example, carbon, chlorine, and calcium—the first and third, or second letters of the name are taken, as Cl (Chlorine), Ca (Calcium). See ATOMIC WEIGHTS, for the symbols of all the known elements.

These symbols not only represent the element, but the relative quantities of it which enters into combination. This is, of course, an arbitrary, though convenient arrangement. The letters HO, for example, represent, not merely hydrogen and oxygen, but 1 part of hydrogen and 8 parts of oxygen, which in combination represents water. A figure placed on either of the right-hand corners of the symbol for any element indicates the number of atoms which enter into the combination spoken of, as HO^2 represents 2 atoms of oxygen combined with 1 atom of hydrogen—peroxide of hydrogen. A figure placed on the left hand doubles all that follows it up to the addition sign + or bracketed symbols: 2HO represents 2 atoms of water; KO, *kalium* or potassium and oxygen = potash; SO^2, sulphur and oxygen = sulphurous acid; KO,SO^3 represents sulphate of potash, but $KO,2SO^3$ indicates *Bi*-sulphate of potash.

A combination of symbols representing a compound body constitutes a *formula.*

SYNTHESIS is a Greek word, which signifies 'combination,' and is applied to the chemical action which unites dissimilar bodies into a uniform compound: as sulphuric acid and lime into gypsum; or chlorine and sodium into culinary salt.

SYRUP is a solution of sugar and water. Cane-juice, concentrated to a density of 1·300, forms a syrup which does not ferment in the transport home from the West Indies, and may be boiled and refined at one step into superior sugar-loaves.

T

TABASHEER. A siliceous concoction resembling hydrophane, which is formed in the interior of the stem of the large Indian bamboo.

TABBINET. A delicate kind of tabby or watered silk, produced by passing the silk through engraved rolls.

TABBY. Watered silk; the effect being produced by subjecting the silk when damp to pressure.

TABBYING, or *Watering*, is the process of giving stuffs a wavy appearance by a peculiar manipulation with the calender.

TABULAR SPAR. A silicate of lime, known otherwise as *Wollastonite*.

TACAMAHAC is a resin obtained from the *Fagara octandra*, a tree which grows in Mexico and the West Indies. It occurs in yellowish pieces, of a strong smell, and a bitterish aromatic taste.

TAFFETY is a light silk fabric, with a considerable lustre or gloss.

TALC is a mineral of which several varieties are recognised, as:—

Foliated Talc. This, the purest crystalline talc, composed of easily separable folia, presenting light green, greenish-white, and white colours. This is often found massive, disseminated in plates, imitative, or crystallised in small six-sided tables. It is splendent, pearly, or semi-metallic, translucent, flexible, but not elastic. It yields to the nail; spec. grav. 2·77. Before the blowpipe, it first whitens, and then fuses into an enamel globule. It consists of—silica, 62; magnesia, 27; alumina, 1·5; oxide of iron, 3·5; water, 6. Klaproth found $2\frac{1}{2}$ per cent. of potash in it. It is found in beds of clay-slate and mica-slate, in Aberdeenshire, Banffshire, Perthshire, Salzburg, the Tyrol, and St. Gothard.

The substance used in sheets as a cover for gas-jets, although often called talc, is really mica.

Talcose Slate. A slaty rock of a greenish-grey colour; it is massive, with tabular fragments, translucent on the edges, soft, with a white streak; easily cut or broken, but is not flexible; and has a greasy feel. It occurs in the same localities as the preceding. It is employed in the crayon-manufactures; also as a crayon itself, by carpenters, tailors, and glaziers.

Indurated Talc. An impure slaty talc, with a nearly compact texture and of superior hardness to common talc.

Soapstone or *Steatite* (*Speckstein*, Ger.); coarse grey and greyish-green massive varieties, generally granular; also of fine texture. The *Potstone*, or *Lapis ollaris*, includes the coarser granular specimens, of dark colour and more or less impure. Slabs of steatite are extensively used as fire-stones. It is often turned into ornamental articles. When ground it is used to diminish friction, and it was employed in the manufacture of some kinds of porcelain. Venetian talc is used for removing stains from woollen cloth. The fine varieties of talc, when coloured with the safflower, form a rouge for the toilet. See STEATITE.

TALLOW (*Suif*, Fr.; *Talg*, Ger.), is the concrete fat of quadrupeds and man. That of the ox consists of 76 parts of stearine and 24 of oleine; that of the sheep contains somewhat more stearine. See FAT and STEARINE.

Ox-tallow was alone used formerly, and our great supply was from Russia. Australia now, and America too, however, export to Europe a large quantity of mutton-tallow.

The drier the food upon which animals are fed the more solid is the tallow; hence the Russian tallow is the best, the animals being fed for eight months of the year on dry fodder.

In the animal the tallow exists in separate globules, and the object of melting it out is to combine all these into one mass. The *rendering* of tallow, as it is termed, consists in cutting the fat into small pieces, and placing it in a pan over a naked fire. The heat is regulated, and the first action is the bursting of the cells; these pour out their milky contents, which become clear gradually, as the water which it contains is evaporated.

Mechanical power is sometimes applied to aid in the rendering. The fat is placed under a millstone working on edge, and thus the cells are torn and crushed, and when this is once effected, the tallow separates with great ease at a moderate temperature. Dorrett employed weak sulphuric acid to act upon the tallow, by mixing this acid with boiling water, and retaining it after the fat has been placed within it, until the separation of the fatty matter is completed. Some admit steam to the melting mass, by which a larger quantity of tallow appears to be obtained. Tallow is generally so impure, that it has to be clarified by the candle-maker. This is effected by remelting the tallow, and mixing with it some substances which render insoluble the gelatinous matters, and precipitate the adventitious admixtures. See CANDLES and FAT.

Tallow and Stearine *Imported* in 1874:—

TALLOW, MINERAL. See HATCHETTINE.

TALLOW, PINEY. See OILS.

TALMI GOLD. An alloy known also as 'Abyssinian gold;' it is much used for making imitation jewellery. Dr. C. Winkler says: 'The alloy is not galvanically gilt, but is plated, that is to say, a very thin sheet of gold is made to adhere to a yellow metal (in 100 parts—copper, 90·74; zinc, 8·33) by rolling the metals together and afterwards shaping, moulding, and chiselling it by means of steel tools, the amount of gold varying from 1·03 to 0·03 per cent.' Articles made of this alloy are said to wear really well. See ABYSSINIAN GOLD.

TAMBAC. See TOMBAC.

TAMPING is a term used by miners to express the filling up of the hole which they have bored in a rock, after the gunpowder for blasting has been placed in the bottom of the hole, with sand, the *débris* of the rock, or other matters. This, being beaten hard together, presents nearly as much resistance to the mechanical force of the powder, when exploded, as the rock itself. See MINING.

TANGLE. *Laminaria digitata.* See ALGÆ.

TANNENITE. An ore of bismuth. See BISMUTH.

TANNIN, or TANNIC ACID. (*Tannin*, Fr.; *Gertstoff*, Ger.) Under the name *tannin* were formerly included all those astringent principles which were capable of combining with the skins of animals to form leather, of precipitating gelatine or of forming bluish-black precipitates with the persalts of iron, and of yielding nearly insoluble compounds with some of the organic alkalis. But it has of late years been proved that there are several different kinds of tannic acid, most of which possess an acid reaction.

These principles are widely diffused in the vegetable kingdom; most of our forest trees, as the oak, elm, pines, firs; pear and plum trees contain it in variable quantities. It is also found in some fruits. Many shrubs, as the sumach and whortleberry, also contain it in great quantities, and on that account are largely used in dyeing and tanning. The roots of the tormentilla and bistort are also powerfully astringent from containing it. Coffee and tea also contain a modification of this principle. The astringent principle in all the above mentioned (except coffee) precipitate the persalts of iron bluish-black, or if a free acid be present the solution becomes dark green. The astringent principle of many vegetables precipitate the persalts of iron of a dark green; such are catechu, kino, &c. Some few plants contain another modification of this astringent principle, which precipitates the persalts of iron of a grey colour, such are rhatany, the common nettle, &c.

Many of these tannic acids have received names which refer to the plants from which they are obtained. The most important and best known of all these is the *gallo-tannic acid*, or that which is extracted from gall-nuts. There are also *querci-tannic acid*, from the oak; *moritannic acid*, or that from the fustic (*Morus tinctoria*), &c. See LEATHER.

The Table on the next page shows the quantity of extractive matter and tan in 100 parts of the several substances there named.

TANNING. (*Tanner*, Fr.; *Gärberei*, Ger.) This is the name given to the process employed for converting the skins of animals into leather, and is strictly a chemical process, consisting in the combination of the tannic acid of the different tanning materials with the gelatine of the skins.

Many attempts have been made to quicken the tanning process, but the leather so formed is generally of inferior quality and less durable. See LEATHER.

TANSY, *Tanacetum vulgare.* A plant common to Britain, growing in waste places; sometimes placed in beds to drive fleas from them. It is very bitter, and has an aromatic odour.

TANTALUM. This is an exceedingly rare substance, found in the minerals *tantalite* and *yttro-tantalite*. It was discovered by Mr. Hatchett, in a mineral

brought from North America, and he called it, on that account, *Columbium*. Ekeberg discovered it in 1803 in the Swedish minerals, and, considering it a *new* metal, he called it *Tantalum*. Dr. Wollaston, in 1809, sought to show that Hatchett's *columbium* and Ekeberg's *tantalum* were one and the same substance; but H. Rose afterwards proved that they were distinct, and gave the name of *Niobium* to the former columbium.

Tantalum has not yet been applied to any commercial purpose.

TAP-CINDER. Puddling-furnace slag. This is a basic silicate of iron. Its general composition may be seen from the following analysis of tap-cinder from a Staffordshire furnace, by Dr. Percy: silica 23·86, protoxide of iron 39·83, peroxide of iron 23·75, protoxide of manganese 6·17, alumina 0·91, lime 0·28, sulphide of iron 0·62, phosphoric acid 6·42. See IRON and SLAG.

TAP-HOLE. The hole in a puddling furnace, through which the slag flows out.

TAPESTRY is an ornamental figured textile fabric of worsted or silk, for lining the walls of apartments; of which the most famous is that of the Gobelins Royal Manufactory, near Paris. See CARPETS, LACE, TEXTILE FABRICS, and WEAVING.

TAPIOCA. (*Manioc* and *Cipipa*, Fr.; *Weisse Sago*, Ger.) Tapioca is cassava-meal, which, while moist or damp, has been heated, for the purpose of drying it, on hot plates. By this treatment the starch-grains swell, many of them burst, and the whole agglomerates in small irregular masses or lumps. The drying to which it is subjected renders it difficult of solution. In boiling water it swells up, and forms a viscous jelly-like mass. See STARCH.

TAQUA NUT. The vegetable ivory of commerce. See IVORY, VEGETABLE.

TAR, COAL. This substance, when properly distilled, is capable of yielding naphtha, a fixed oil, and pitch, the two former of which are vastly more valuable than tar. The relative proportion of these products is, however, very variable, according to the kind and quality of the tar employed. Thus tar from the condenser is more valuable for its products than the tar of the same coal taken from the hydraulic main, and again cannel coal-tar is always superior to common coal-tar. In general we may estimate the available amount of the volatile and fixed matters of coal somewhat in the following order:—

	Naphtha	Dead oil	Pitch
Common coal-tar	3	62	35
Ordinary cannel tar	9	60	31
Boghead cannel tar	15	67	18

Of these the naphtha is in large demand for the solution of caoutchouc, the lighting of lamps, and other purposes. The dead oil contains paraffine, and is an excellent lubricator for machinery: the uses of pitch need not be enumerated. See ANILINE, GAS-COAL, DESTRUCTIVE DISTILLATION, NAPHTHA, and PETROLEUM.

TAR, WOOD (*Goudron*, Fr.; *Theer*, Ger.), is the viscid, brown-black, resino-oleaginous compound, obtained by distilling wood in close vessels, or in ovens of a peculiar construction. *Stockholm tar*, *Archangel tar*, and *American tar* come into our markets. According to Reichenbach, tar contains the peculiar proximate principles, *paraffine*, *eupion*, *creosote*, *picamar*, *pittacal*, besides pyrogenous resin or *pyretine*, pyrogenous oil or *pyroleine*, and vinegar.

The Stockholm tar is regarded as the best; we have a description of the mode in which it is prepared, by Dr. Clarke, in his 'Travels in Scandinavia':—

'The situation most favourable to the process is in a forest near to a marsh or bog, because the roots of the fir, from which tar is principally extracted, are always most productive in such places. A conical cavity is then made in the ground (generally on the side of the bank or sloping hill), and the roots of the fir, together with logs and billets of the same, being neatly trussed in a stack of the same conical shape, are let into the cavity. The whole is then covered with a turf to prevent the volatile parts from being dissipated, which, by means of a heavy wooden mallet and wooden stamper, worked separately by two men, is beaten down and rendered as firm as possible about the wood. The stack of billets is then kindled, and a slow combustion of the fir takes place as in working charcoal. During this combustion the tar exudes, and a cast-iron pan being at the bottom of the funnel, with a spout which projects through the side of the bank, barrels are placed beneath this spout to collect the fluid as it comes away. As fast as the barrels are filled they are bunged and ready for immediate exportation.' Wood-tar is obtained as a secondary product in the manufacture of acetic acid, in the dry distillation of wood.

Tar *Imported* in 1873:—

	Barrels		£
From Russia	174,280	value	239,169

Total	215,330	„	297,132

Tar *Imported* in 1874:—

238,810 Barrels; value 269,749*l.*

TARE, or *Vetch*. A well known fodder-plant (*Vicia sativa*).

TARPAULIN (from *Tar*). Canvas imbued with tar, used to cover the hatchways of a ship to prevent rain or sea water from entering the hold, and for other purposes.

TARSAS. See TRASS.

TARSIA (*Intarsiatura*, Ital.) A mosaic wood-work practised in Italy in the fifteenth century.

TARTAR (*Tartre*, Fr.; *Weinstein*, Ger.); called also *argal* or *argol*, is the crude bitartrate of potash, which exists in the juice of the grape, and is deposited from wines in their fermenting casks, being precipitated in proportion as the alcohol is formed, in consequence of its insolubility in that liquid. There are two sorts of argol known in commerce, the white and the red; the former, which is of a pale-pinkish colour, is the crust let fall by white wines; the latter is a dark red, from red wines.

The crude tartar is purified, or converted into cream of tartar, at Montpellier, by the following process:—

The argal having been ground under vertical millstones and sifted, one part of it is boiled with 15 of water in conical copper kettles tinned on the inside. As soon as it is dissolved, 3½ parts of ground pipe-clay are introduced. The solution, being well stirred and then settled, is drawn off into crystallising vessels to cool; the crystals found concreted on the sides and bottom are picked out, washed with water, and dried. The mother-water is employed upon a fresh portion of argol. The crystals of the first crop are re-dissolved, re-crystallised, and exposed upon stretched canvas to the sun and air to be bleached. The clay serves to abstract the colouring-matter. The crystals formed upon the surface are the whitest, whence the name 'cream of tartar' is derived.

Purified tartar, the bitartrate of potash, is thus obtained in hard clusters of small colourless crystals, which, examined by a lens, are seen to be transparent four-sided prisms. It has no smell, but a feebly acid taste; is unchangeable in the air, has a specific gravity of 1·953, dissolves in 16 parts of boiling water, and in 200 parts at 60° Fahr. It is insoluble in alcohol. It consists of 24·956 potash, 70·276 tartaric acid, and 4·768 water. See ARGOL; POTASH, BITARTRATE OF.

TARTAR, CREAM OF. Acid tartrate of potash.

TARTAR EMETIC. Tartrate of potash and antimony, prepared by boiling teroxide of antimony in solution of cream of tartar.

TARTARIC ACID, (*Acide tartrique*, Fr.; *Weinsteinsäure*, Ger.) This is prepared by adding gradually to a boiling-hot solution of 100 parts of tartar (*bitartrate of potash*) in a large copper boiler, 26 parts of chalk (*carbonate of lime*) made into a smooth pap with water. A brisk effervescence ensues, from the disengagement of the carbonic acid of the chalk, while its base combines with the acid excess in the tartar, and forms an insoluble precipitate of tartrate of lime. The supernatant liquor, which is a solution of neutral tartrate of potash, must be drawn off by a syphon, and decomposed by a solution of chloride of calcium (muriate of lime). 28½ parts of the dry chloride are sufficient for 100 of tartar. The tartrate of lime, from both processes, is to be washed with water, drained, and then subjected in a leaden cistern to the action of 49 parts of sulphuric acid, previously diluted with 8 times its weight of water: 100 of dry tartrate take 75 of oil of vitriol. This mixture, after digestion for a few days, is converted into sulphate of lime and tartaric acid. The latter is to be separated from the former by decantation, filtration through canvas, and elutriation of the sulphate of lime upon the filter.

The clear acid is to be concentrated in leaden pans by a moderate heat, till it acquires the density of 40° B. (sp. gr. 1·38), and then it is run off, clear from any sediment, into leaden or stoneware vessels, which are set in a dry stove-room for it to crystallise. The crystals, being re-dissolved and re-crystallised, become colourless six-sided prisms. In decomposing the tartrate of lime, a very slight excess of sulphuric acid must be employed, because pure tartaric acid would dissolve any tartrate of lime that may escape decomposition. Bone-black, previously freed from its carbonate and phosphate of lime, by muriatic acid, is sometimes employed to bleach the coloured solutions of the first crystals. Tartaric acid contains nearly 9 per cent. of combined water. It is soluble in two parts of water at 60°, and in its own weight of boiling water. In its dry state, as it exists in the tartrate of lime or lead it consists of 36·8 of carbon, 3 of hydrogen, and 60·2 of oxygen. It is much employed in calico-printing, and for making sodaic powders.

In consequence of the great variation in the constituents of argol or rough tartar, the manufacture of tartaric acid is not nearly so simple as a first glance at its several processes might lead an inexperienced individual to suppose. The theory of preparing tartaric acid seems, indeed, a remarkably easy affair; and provided the materials operated upon were pure, or of uniform quality, no kind of manufacture could put on less the appearance of risk or speculation. But too many know, to their cost, with what ready facility the whole profit, and something more, of a large operation will occasionally ooze off through a variety of unknown channels, and present a sadly defective and truncated return of saleable produce. In fact, money is not unfrequently lost in this manufacture by very old and experienced makers. The differences in argol arise from the greater or smaller amount of tartrate of lime combined with the bitartrate of potash; these differences will, in a commercial way, amount to from 5 to 25 or even 30 per cent.; and herein resides a difficulty requiring more analytical skill and chemical knowledge than is commonly found amongst practical manufacturers. We will suppose that an argol has been purchased, containing by analysis 70 per cent. of bitartrate of potash, but also, though unknown to the purchaser, containing 20 per cent. of tartrate of lime. According to the process followed, this argol would be dosed with a definite proportion of chalk or carbonate of lime, so as to produce tartrate of lime with the extra tartaric acid of the supertartrate of potash. This tartrate of lime, being insoluble, would fall and mingle with the 20 per cent. already existing; but as in practice the quantity of sulphuric acid employed for subsequent decomposition of this tartrate of lime is proportioned to the amount of chalk originally employed, it follows that the tartrate of lime naturally present in the argol is left undecomposed, and comes to be regarded as sulphate of lime, to the great loss of the manufacturer, who probably finds his more intelligent neighbour able to buy as he buys, and yet capable of underselling him in the open market.

The composition of crystallised tartaric acid, appears to be represented by the formula $C^8H^6O^{12}$ ($\mathbf{C^4H^6O^6}$). By the action of heat it loses 2HO ($\mathbf{H^2O}$), and becomes anhydrous tartaric acid. Various metamorphoses have been stated to occur in tartaric acid upon exposing it to heat. Laurent, Gerhardt, and Pasteur have investigated this matter, and have given the names of *metatartaric acid* and *isotartaric acid* to two of the results. Another acid has been investigated by Arppe, the *pyrotartaric acid*. According to Millon and Reiset, the best mode of preparing it is to distil powdered tartaric acid with powdered pumice-stone. The aqueous is separated from the oily distillate by a wet filter, and evaporated at a gentle heat, till it commences to crystallise. The crystals are digested in nitric acid, and thus the pure pyrotartaric acid is obtained.

TARTRATES are bibasic salts, composed of tartaric acid and oxidised bases, in equivalent proportions. Some of the tartrates are employed in the arts, bitartrate of potash being used as a mordant in dyeing woollen fabrics. Tartrate of chromium is sometimes used in calico-printing, and the tartrate of potash and tin in wool-dyeing.

TASMANITE. A combustible mineral found in Tasmania. See DYSODILE.

TAWING is the process of preparing the white skins of the sheep, doe, &c. See LEATHER.

TEA (*Thé*, Fr.; *Thee*, Ger.) *Thea*, the tea-plant, belongs to the natural order *Ternströmiaceæ*. Considerable discussion has taken place with reference to this important substance, some contending that green and black tea are the productions of two different plants, the *Thea viridis* producing the green tea, and the *Thea Bohea* the black tea. There is a third variety, the *Thea Assamensis*, or Assam tea, which appears to resemble both the others. Mr. Fortune appears to have proved that the green and black teas of commerce do not depend upon specific differences; but that in the northern tea districts of China the black and green teas are both obtained from the same species or variety, namely, the *Thea viridis*, while in the Canton tea districts both the varieties of tea are made from the *Thea Bohea*.

The quality of the tea depends much on the season when the leaves are picked, the mode in which it is prepared, as well as on the district in which it grows. Green tea, it is stated, is coloured by the application of an extract of indigo, of Prussian blue, and gypsum; and that the fine odour which renders the 'flowery' kinds remarkable is derived from the leaves of *Olea fragrans*, a species of camellia, and other similar plants.

To the black tea belong the varieties known as *Bohea*, *Congou*, *Campoi*, *Souchong*, *Caper*, and *Pekoe*. To the green tea, *Twankay*, *Hyson-skin*, *Hyson*, *Imperial*, and *Gunpowder*.

Brande, in his 'Manual of Pharmacy,' has given a table from which the following facts are extracted:—

100 parts of Tea		Soluble in water	Soluble in alcohol	Precipitated by jelly	Insoluble residue
Green Hyson —	Best	41	44	31	56
„	Medium	34	43	26	58
„	Lowest	31	41	24	57
Black Souchong—	Best	35	36	28	64
„	Medium	37	35	28	63
„	Lowest	35	31	23	65

The most remarkable products in tea are—1st. Tannin. 2nd. An essential oil to which it owes its aroma, and which has great influence on its commercial value. 3rd. A crystalline substance, very rich in nitrogen, *theine*, which is also met with in coffee (whence it is frequently termed *caffeine*).

Besides these three, M. Mulder extracted from tea eleven other substances, which are usually met with in all leaves. The same chemist found, in the various kinds of tea from China and Java, a little less than a half per cent. of their weight of theine. Dr. Stenhouse obtained from 1·36 to 0·98 theine from 100 parts of tea. On determining the nitrogen by M. Dumas's process, he obtained the following numbers:—

	Nitrogen in 100 parts tea dried at 230°
Pekoe tea	5·58
Gunpowder tea	6·15
Souchong tea	6·15
Assam tea	5·10

This amount of nitrogen is far more considerable than has been detected in any vegetable hitherto analysed.

The proportion of products soluble in hot water varies considerably, and depends chiefly upon the age of the leaf, which is younger, and consequently less liqueous, in the green than in the black tea. On an average, Stenhouse found in 100 parts

	Parts soluble in boiling water.
Dry black teas	43·2
Dry green teas	47·1
Black teas in their commercial state	38·4
Green teas do. do.	43·4

When an infusion of tea is evaporated to dryness, a chocolate-brown residue remains, which, when derived from green gunpowder, contains 5·35 per cent. of nitrogen; if from black souchong, 4·70 per cent. nitrogen.

The subacetate of lead throws down about half the soluble constituents contained in this infusion. The precipitate, which is of a more or less dark yellow, according to whether it is derived from green or black tea, contains the whole of the colouring-matter, the whole of the tannin, and a peculiar acid, which affords an insoluble salt of a light yellow colour with the subacetate of lead.

To determine the amount of theine, M. Mulder evaporates the infusion with caustic magnesia, and treats the residue with ether, which only dissolves out the theine. On modifying this process, Dr. Stenhouse has obtained the following quantities of theine from 100 parts of

Hyson	2·40
Another kind	2·56
Mixture in equal parts of gunpowder, hyson, imperial, caper, and pekoe	2·70
Gunpowder	4·1
Another kind	3·5

These quantities are far more considerable than have been obtained by M. Mulder; but, at the same time, they do not account for the total amount of nitrogen of the infusion in the state of theine, for the composition of theine being represented by the formula $C^8H^5N^2O^2$ (**$C^8H^{10}N^4O^2$**), and this substance containing 29·0 per cent. of nitrogen, gunpowder tea should contain 7·4 and souchong 6·5 theine in 100 parts of these teas taken in their ordinary state, if no other nitrogenous substance accompanied the theine in the solution.

The portion of tea from which boiling water extracted no more soluble principle contained in 100 parts, dried at 230°, 4·46 nitrogen for the souchong, and 4·30 for the gunpowder. These quantities, added to those of the infusion, represent very nearly the nitrogen ascertained by analysis to exist in the entire leaf.

On boiling for some time the exhausted leaves in water containing $\frac{1}{10}$th of their weight of potash, a brown liquid is obtained, which affords, on the addition of dilute sulphuric or acetic acid, a considerable flocculent and brown precipitate, which contains 8·45 per cent. of nitrogen; the product of another preparation gave 9·93. Alcohol and ether remove from this precipitate about 30 per cent. of a green substance, which appears to contain a fat acid. This product is not pure after this treatment, for it is strongly coloured and contains pectic acid; nevertheless, that which contained 8·45 nitrogen afforded 11·35 of this element after being treated with alcohol and ether.

The Chinese method of making Black Tea.—In the first place, the youngest and most tender leaves are gathered; but when there are many hands and a great quantity of leaves to be collected, the people employed nip off with the forefinger and thumb the fine end of the branch with about four leaves on, and sometimes even more, if they look tender. These are all brought to the place where they are to be converted into tea; they are then put into a large, circular, open-worked bamboo basket, having a rim all round, two fingers broad. The leaves are thinly scattered on these baskets, and then placed in a framework of bamboo, in all appearance like the side of an Indian hut without grass, resting on posts, 2 feet from the ground, with an angle of about 25°. The baskets with leaves are put in this frame to dry in the sun, and are pushed up and brought down by a long bamboo with a circular piece of wood at the end. The leaves are permitted to dry about two hours, being occasionally turned; but the time required for this process depends on the heat of the sun. When they begin to have a slightly withered appearance, they are taken down and brought into the house, where they are placed on a frame to cool for half an hour. They are then put into smaller baskets of the same kind as the former, and placed on a stand. People are now employed to soften the leaves still more, by gently clapping them between their hands with their fingers and thumb extended, and tossing them up and letting them fall, for about five or ten minutes. They are then again put on the frame during half an hour, and brought down and clapped with the hands as before. This is done three successive times, until the leaves become to the touch like soft leather; the beating and putting away being said to give the tea the black colour and bitter flavour. After this the tea is put into hot cast-iron pans, which are fixed in a circular mud fireplace, so that the flame cannot ascend round the pan to incommode the operator. This pan is well heated by a straw or bamboo fire to a certain degree. About 2 lbs. of the leaves are then put into each hot pan, and spread in such a manner that all the leaves may get the same degree of heat. They are every now and then briskly turned with the naked hand, to prevent a leaf from being burned. When the leaves become inconveniently hot to the hand, they are quickly taken out and delivered to another man with a close-worked bamboo basket ready to receive them. A few leaves that may have been left behind are smartly brushed out with a bamboo broom; all this time a brisk fire is kept up under the pan. After the pan has been used in this manner three or four times, a bucket of cold water is thrown in, and a soft brick-bat and bamboo broom used, to give it a good scouring out; the water is thrown out of the pan by the brush on one side, the pan itself being never taken off. The leaves, all hot on the bamboo basket, are laid on a table that has a narrow rim on its back, to prevent these baskets from slipping off when pushed against it. The 2 lbs. of hot leaves are now divided into two or three parcels, and distributed to as many men, who stand up to the table with the leaves right before them, and each placing his legs close together; the leaves are next collected into a ball, which he gently grasps in his left hand, with the thumb extended, the fingers close together, and the hand resting on the little finger. The right hand must be extended in the same manner as the left, but with the palm turned downwards, resting on the top of the ball of tea-leaves. Both hands are now employed to roll and propel the ball along: the left hand pushing it on, and allowing it to revolve as it moves: the right hand also pushes it forward resting on it with some force, and keeping it down to express the juice which the leaves contain. The art lies here in giving the ball a circular motion, and permitting it to turn under and in the hand two or three whole revolutions, before the arms are extended to their full length, and drawing the ball of leaves quickly back without leaving a leaf behind, being rolled for about five minutes in this way. The ball of tea-leaves is from time to time gently and delicately opened with the fingers, lifted as high as the face, and then allowed to fall again. This is done two or three times, to separate the leaves; and afterwards the basket with the leaves is lifted up as often, and receives a circular shake to bring these towards the centre. The leaves are now taken back to the hot pans, and spread out in them as before, being again turned with the naked hand, and when hot taken out and rolled: after which they are put into the drying basket, and spread on a sieve which is in the centre of the basket, and the whole placed over a charcoal fire. The fire is very nicely regulated; there must not be the least smoke, and the charcoal should be well picked.

When the fire is lighted, it is fanned until it gets a fine red glare, and the smoke is all gone off; being every now and then stirred and the coals brought into the centre, so as to leave the outer edge low. When the leaves are put into the drying basket, they are gently separated by lifting them up with the fingers of both hands extended far apart, and allowing them to fall down again; they are placed 3 or 4 inches deep on the sieve, leaving a passage in the centre for the hot air to pass. Before it is put over the fire, the drying basket receives a smart slap with both hands in the act of lifting it up, which is done to shake down any leaves that might otherwise drop through the sieve, or to prevent them from falling into the fire and occasioning a smoke, which would affect and spoil the tea. This slap on the basket is invariably applied throughout the stages of the tea-manufacture. There is always a large basket underneath to receive the small leaves that fall, which are afterwards collected, dried, and added to the other tea; in no case are the baskets or sieves permitted to touch or remain on the ground, but always laid on a receiver with three legs. After the leaves have been half-dried in the drying basket, and while they are still soft, they are taken off the fire, and put into large open-worked baskets, and then put on the shelf, in order that the tea may improve in colour.

Next day the leaves are all sorted into large, middling, and small; sometimes there are four sorts. All these, the Chinese informed the writer, become so many different kinds of teas: the smallest leaves they called Pha-ho, the second Pow-chong, the third Suchong, and the fourth, or the largest leaves, Toy-chong. After this assortment they are again put on the sieve in the drying basket (taking great care not to mix the sorts), and on the fire, as on the preceding day; but now very little more than will cover the bottom of the sieve is put in at one time; the same care of the fire is taken as before, and the same precaution of tapping the drying basket every now and then. The tea is taken off the fire with the nicest care, for fear of any particle of the tea falling into it. Whenever the drying basket is taken off, it is put on the receiver, the sieve in the drying-basket taken out, the tea turned over, the sieve replaced, the tap given, and the basket placed again over the fire. As the tea becomes crisp, it is taken out and thrown into a large receiving basket, until all the quantity on hand has become alike dried and crisp; from which basket it is again removed into the drying basket, but now in much larger quantities. It is then piled up 8 and 10 inches high on the sieve in the drying basket; in the centre a small passage is left for the hot air to ascend; the fire that was before bright and clear has now ashes thrown on it to deaden its effect, and the shakings that have been collected are put on the top of all; the tap is given, and the basket with the greatest care is put over the fire. Another basket is placed over the whole, to throw back any heat that may ascend. Now and then it is taken off, and put on the receiver; the hands, with the fingers wide apart, are run down the sides of the basket to the sieve, and the tea gently turned over, the passage in the centre again made, &c., and the basket again placed on the fire. It is from time to time examined, and when the leaves have become so crisp that they break by the slightest pressure of the fingers, it is taken off, when the tea is ready. All the different kinds of leaves underwent the same operation. The tea is now little by little put into boxes, and first pressed down with the hands and then with the feet (clean stockings having been previously put on).

There is a small room inside of the tea-house, 7 cubits square and 5 high, having bamboos laid across on the top to support a network of bamboo and the sides of the room smeared with mud to exclude the air. When there is wet weather, and the leaves cannot be dried in the sun, they are laid out on the top of this room, on the network, on an iron pan, the same as is used to heat the leaves; some fire is put into it, either of grass or bamboo, so that the flame may ascend high; the pan is put on a square wooden frame, that has wooden rollers on its legs, and pushed round and round this little room by one man, while another feeds the fire, the leaves on the top being occasionally turned; when they are a little withered, the fire is taken away, and the leaves brought down and manufactured into tea, in the same manner as if it had been dried in the sun. But this is not a good plan, and never had recourse to if it can be possibly avoided.

Preparation of factitious Green Tea. Tea is brought to Canton unprepared; as Bohea, *Soshung*, and is thrown into a hemispherical iron pan, kept very hot over a fire. The leaves are constantly stirred till they are thoroughly heated, when they are dyed, by adding, for each pound of tea, 1 spoonful of gypsum, 1 of turmeric, and 2 or 3 of Prussian blue. The leaves instantly change into a bluish-green, and after being well stirred for a few minutes, are taken out, being shrivelled by the heat. They are now sifted; the small longish leaves fall through the first sieve, and form Young Hyson: the roundest granular ones fall through the last, and constitute Gunpowder, or Choo-cha.

The observations of Liebig afford a satisfactory explanation of the cause of the great partiality of the poor, not only for tea, but for tea of an expensive and superior kind. He says, 'We shall never certainly be able to discover how men were first led to the use of the hot infusion of the leaves of a certain shrub (tea), or of a decoction of certain roasted seeds (coffee). Some cause there must be which will explain how the practice has become a necessary of life to all nations. But it is still more remarkable, that the beneficial effects of both plants on the health must be ascribed to one and the same substance (*theine* or *caffeine*), the presence of which in two vegetables, belonging to natural families, the products of different quarters of the globe, could hardly have presented itself to the boldest imagination. Yet recent researches have shown, in such a manner as to exclude all doubt, that *theine and caffeine* are in all respects identical.' And he adds, 'That we may consider these vegetable compounds, so remarkable for their action on the brain, and the substance of the organs of motion, as elements of food for organs as yet unknown, which are destined to convert the blood into nervous substance, and thus recruit the energy of the moving and thinking faculties.' Such a discovery gives a great importance to tea and coffee, in a physiological and medical point of view. See Theine. Consult Watts's 'Dictionary of Chemistry.'

Indian Teas.—The following remarks by the late Dr. Archibald Campbell on Indian teas are of interest:—

Dr. Campbell's observation led him to believe that little was known of the subject in this country, although it was 40 years since tea was first discovered in Assam, growing wild, and 30 years since it was found in the same state in Cachar. It was very satisfactory to be able to state that the Indian authorities had been roused to vigorous exertions in providing means of communication between the tea-producing districts and the seaboard. Merchants from Thibet, Cashmere, and Afghanistan had crossed the Himalayas into India, and were carrying off the teas from the factories in the north-west at highly remunerative prices, bespeaking all the crop of next year in Kumaon, and paying down half the cash in advance. Taking all circumstances into consideration, the tea prospects were brighter than the pioneers of the great Indian industry could hitherto boast of. The tea crop of India was in 1873 about 20,000,000 lbs., of which Darjeeling contributed 2,600,000, increasing at the rate of 15 per cent. per annum on the land actually under tea cultivation—*i.e.*, 14,000 acres. For the present year (1874) 21,000,000lbs., could be reckoned on, of which 3,000,000 would be from Darjeeling. There were other lands which, when cultivated, would increase the supply. Dr. Campbell dwelt upon the quantity of spurious and adulterated China teas imported into England, and the extent to which pure Indian teas were kept back from the public for the purpose of mixing to make them saleable.

Tea Imported in 1873 *with a duty of* 6*d. per lb.*

TEAK. The produce of the *Tectona grandis;* a native of the mountainous parts of the Malabar coast. The African teak is thought by some to belong to another genus (*Oldfieldia Africana*).

TEASLE or FULLER'S THISTLE (*Chardon à carder*, Fr.; *Weberdistel*, Ger.); the head of the thistle, (*Dipsacus fullonum*), is employed to raise the nap of cloth. See WOOLLEN MANUFACTURE.

TEEL OIL. See OILS.

TEETH. In a typical tooth, as developed in most mammals, the greater part is composed of a substance called *dentine*, the crown being covered with a hard *enamel*, whilst the remainder of the tooth is coated with a cortical substance known as *cement*. *Ivory* is very similar to dentine. (See IVORY.)

Dr. Robert Dundas Thomson published the analyses of teeth by Alexander Nasmyth, Esq. The following table has been constructed from those analyses:—

	Enamel		Ivory		Bone
	Human adult	Elephant	Human adult	Elephant	For comparison
Organic matter	6·160	6·80	26·81	45·65	35·93
Phosphate of lime	89·160	82·55	66·42 }	52·30	{ 51·12

TELEGRAPHS. See ELECTRO-TELEGRAPHY.

TELLURIC BISMUTH. A telluride of bismuth. See TETRADYMITE.

TELLURIUM. One of the elementary bodies, usually classed amongst the metals, but it presents so great an analogy to sulphur and selenium, that many are disposed to remove it from the metallic bodies.

Tellurium was originally found in Transylvanian gold ores; and more recently it has been found with bismuth. Tellurium has a silvery lustre; its texture is crystalline and brittle. Its specific gravity is 6·65, and its atomic weight 64·5. From its extreme rarity, and consequent cost, it has not yet found any application in the arts.

TEMPERING OF STEEL. In metallurgy the process by which a certain required character is given to steel or any other metal.

The process of hardening or tempering steel is performed with due relation to the quality of the steel and the purposes for which it is designed. In most instances the hardening is effected in water and brine: saw-blades are thus hardened, after being heated in melted lead; and sabres are heated in a choked fire of charcoal, and then swung rapidly through the air. Mint-stamps are hardened in oil. The common method of procedure in hardening is this: The steel is overheated, cooled in cold water, and then annealed or tempered, by being so far re-heated that oil and tallow will burn on its surface; or the surface is ground and polished, and the steel reheated until it assumes a certain colour. The gradations of colour consecutively follow: a light straw-yellow, violet, blue, and finally grey or black, when the steel again becomes as soft as though it had never been hardened.

TEMPLET. A gauge formed from a thin piece of metal, as a guide to the form of the work to be executed.

TENT. A portable lodge, consisting of canvas sustained by poles and stretched by cords, used for sheltering men, especially soldiers in camp, from the weather. Tents were commonly used in the earliest periods of man's history. The patriarchal tribes dwelt in tents. Layard describes one of the sculptured stones at Mosul as representing Sennacherib seated on a throne, placed at the entrance of a city. Behind the king was the royal tent supported by ropes, and an inscription, signifying 'This is the *tent* of Sennacherib, King of Assyria.' This was 700 years before Christ. We learn that Paul was a tent-maker, therefore in those days it was an important calling.

We have no space to enter into the history of tents or describe the varieties which have been used from time to time. A few words on modern tents must suffice:—

The hospital marquee is 29 feet long and 14½ feet wide and 15 feet high. This is supposed to accommodate not less than eighteen or more than twenty-four men. The height of each tent-pole is 13 feet 8 inches; the length of the ridge-pole 13 feet 10 inches; the height of the tent-walls from the ground 5 feet 4 inches. The weight of all the material of such a tent is stated by Major Rhodes to be 652 lbs.

The ventilation of tents has been admirably effected by Mr. Doyle, to whom we are indebted for the information contained in the following notes on the subject.

The old method of ventilating military tents was very defective. Ventilating openings were made at the top of the tent, but no means were provided for the admission of fresh air. The result was most unsatisfactory, as may be gathered from the following evidence given before the Sebastopol Committee:—

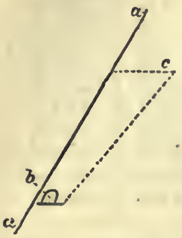
'The tents were very close indeed at night. When the tent was closed in wet weather, it was often past bearing. The men became faint from heat and closeness.'[1]

The problem then was to let in fresh air, and produce a draft without inconveniencing the soldiers as they slept.

The question attracted Mr. Doyle's notice during the period of the camp at Chobham, and it appearing to him to be one of very great importance, he undertook, with the sanction of Lord Raglan, then Master-General of the Ordnance, to try the following experiment:—

. . . .

1947



He caused two openings to be made in the wall of a tent, about 4 feet from the ground, and introduced the air between the wall and a piece of lining somewhat resembling a carriage-pocket, thus: *a a*, the wall of the tent; *b*, the opening to admit air; *c*, the lining.

It will be seen that air so introduced would naturally take an upward direction, and that this communicating with the openings at the top of the tent, would probably produce the desired effect. . . . .

The following extract from the report on this experiment will show the actual result:—

'The ventilators (Mr. Doyle's) were found of great use in clearing the tent of the fetid atmosphere consequent upon a number of men sleeping in so confined a space. The men state that the heavy smell experienced before the tent was altered is almost banished.'

In subsequent experiments the number of the new openings was increased from two to three, and a greater amount of ventilation thus obtained. The result according to an official letter of thanks received on the subject, was 'quite successful.' The improvement has been since adopted into the service, and by these very simple means one of the most fruitful causes of sickness among our soldiers in camp finally removed.

TENT, a wine, so called from the Spanish *tinto*, 'deep-coloured,' it being of a deep red colour. It comes chiefly from Galicia, or Malaga. See WINE.

TERMINALIA CHEBULA. The name of a tree common in India, which produces Myrobalans. See Crookes's 'Handbook of Dyeing.'

TERNE-PLATE. Iron-plate coated with a mixture of tin and lead, instead of pure tin.

TERRA COTTA. This term means literally *baked earth*. It is known in the arts as the material of the ancient vases, amphoræ, pateræ, lamps, statues, and bas-rilievi. Monumental vases of terra cotta have been found in the tombs, after the lapse of 2,000 years, in a fine state of preservation. The ancient terra-cotta vases are generally painted black, on a red or buff ground; but on some there are blue, yellow, and other colours. The style of ornamentation is much alike in all: a few narrow lines, or fillets, with dots, meander fretwork, laurel, ivy-leaf, and honeysuckle borders, adorning the rim, neck, and stand of the vases, the centre or body being covered with allegorical representations of gods, men, and animals. Terra cottas of the type of the early Greek, commonly called Etruscan vases, are found throughout the ancient Egyptian cities. The art of making the Greek terra cotta seems to have become extinct, about 150 years before Christ. The modes in which the Greek works were made have been subjects of much controversy among the learned in art. The body, or substance, appears to a potter, in a commercial point of view, of the lowest grade, as it is common clay, very porous, and coarse-grained. By some authors it is said they were made of clay, mixed with sand only, and by others, with clay mixed with cement. The most probable conclusion is, that some were made of clay only, some of clay and sand, and others (such as those of ground and monumental character, where it was important that the parts should be kept very true in firing), of clay mixed with potsherds and puzzolano or other detritus of lava. The works are less baked than modern pottery, and it is doubtful if it would stand exposure to the variations of such a climate as England. Among the remains of Greek pottery are gigantic amphoræ of very coarse grain, measuring as much as 8 feet in length by 3 feet in diameter, and of corresponding thickness. It is said that one of these great vessels was the tub of Diogenes. Vauquelin gives the following analysis of the Greek terra-cotta vases: silica, 53; alumina, 15; lime 8; oxide of iron, &c., 24.

The Roman terra cottas are of an entirely different character from those just described, and consist chiefly of cinerary urns, lamps, and pateræ; and these appear to have been moulded; the ornament is either incised or embossed, and odd fantastic shapes prevail.

Terra-cotta works of an architectural character are constantly met with in the

[1] Evidence of Sergeant Dawson, Grenadier Guards.

buildings erected in Italy between the 12th and 17th centuries. The clay sketches and models of Michael Angelo, and other great sculptors, were rendered in terra cottas. Bramante employed terra cotta in decoration.

The merit of reviving in England the manufacture of terra cotta belongs to Josiah Wedgwood, who in 1770 established large works in Staffordshire. About 1790 a pottery was established at Lambeth for the manufacture of decorative works; and terra cotta was made for many years by a lady of the name of Coade, and afterwards by Coade and Sealey. The chief materials used by them were the Dorset and Devonshire clays, with fine sand, flint, and potsherds. The chief portion of the old coats-of-arms above the shop-fronts of London were made of this terra cotta. About fifty years ago, Mr. Bubb, the sculptor, had a manufactory for terra cotta. The frieze of the Opera in the Haymarket is an example of his work.

To explain the mode of executing any work in terra cotta, it is best to describe the proper meaning of the words 'modelling,' 'moulding,' and 'casting.'

A model is an original work made by the sculptor in clay, and worked out by the fingers and small tools made of bone and steel, varying from about 6 to 10 inches in length. This original work of the artist is allowed to dry, and then the moulding operation commences. This process is effected by mixing plaster-of-Paris with water to the consistency of thick cream; this is spread over the model, and when it has set it is removed in sections, which, when again carefully united, form the mould, in which either clay or metal can be cast, and receive the form of the original work. For terra-cotta work, unless many copies of the original are wanted, moulds are not employed. When only one or two copies of a work are required, the original models are built up in a cellular manner, they are then dried and removed to a kiln and baked, being a perfectly original work.

When moulding is performed for terra-cotta works, sheets of clay are beaten on a bench to the consistency of glazier's putty, and pressed by the hand into the mould; according to the magnitude of the work and the weight it may have to sustain, the thickness of the clay is determined and arranged, and here consists a part of the art it would be impossible to describe, and which requires years of experience in such works to produce great works and fire them with certainty of success.

At the Crystal Palace, Sydenham, are several large works manufactured by Mr. J. M. Blashfield, who has extensive terra-cotta works at Stamford. The figure of 'Australia,' modelled by John Bell, nine feet in height, and burnt in one piece; the colossal Tritons modelled by the same artist, and other works, are examples. After the moulded article has become sufficiently dry, it is conveyed to a kiln. A slow fire is first made, and quickened until the heat is sufficient to blend and partially vitrify the material of which the mass is composed; when sufficiently baked, the kiln is allowed to cool, and the terra cotta is withdrawn.

A very fine red terra cotta, resembling that imported from Copenhagen and Belgium, has within the last few years been manufactured at Watcombe, near Torquay, in Devonshire.

TERRA DI SIENNA is a brown ferruginous ochre, employed in painting, obtained from Italy. It is a hydrous sesquioxide of iron, containing traces of arsenic; from which we may infer it is derived mainly from decomposition of arsenical pyrites. It is calcined before being used as a pigment, and is then known as *burnt* sienna. *Raw* sienna is not much employed; it contains water, which the calcined does not.

TERRA JAPONICA. See ACACIA; CATECHU; GAMBIER.

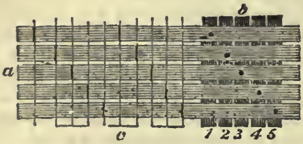
TESSERÆ. See TILES and ENCAUSTIC TILES.

TESTS are chemical reagents of any kind, which indicate, by special characters, the composition of the body to which they are applied. Analytical chemistry is based on the application of tests. See Watts's 'Dictionary of Chemistry.'

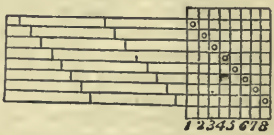
TETRADYMITE, or *Telluric Bismuth*. A telluride of bismuth, frequently containing sulphur. It is a common associate of gold.

TEXTILE FABRICS. The first business of the weaver is to adapt those parts of his loom which move the warp to the formation of the various kinds of ornamental figures which the cloth is intended to exhibit. This subject is called the *draught*, drawing or reading in, and the cording of looms. In every species of weaving, whether direct or cross, the whole difference of pattern or effect is produced, either by the succession in which the threads of warp are introduced into the heddles, or by the succession in which those heddles are moved in the working. The heddles being stretched between two shafts of wood, all the heddles connected by the same shafts, are called a leaf; and as the operation of introducing the warp into any number of leaves is called drawing a warp, the plan of succession is called the 'draught.' When this operation has been performed correctly, the next part of the weaver's business is to connect the different leaves with the levers or treddles by which they are to be moved, so that one or more may be raised or sunk by every treddle successively, as may be required to produce the peculiar pattern. These connections being made by coupling the different parts of the apparatus by cords, this operation is called the 'cording.' In order to direct the operator in this part of his business, especially if previously unacquainted with the particular pattern upon which he is employed, plans are drawn upon paper, specimens of which will be found in *figs.* 1948, 1949, &c. These plans are horizontal sections of a loom, the heddles being represented across the paper at *a*, and the treddles under them, and crossing them at right angles at *b*. In *figs.* 1948 and 1949 they are represented as if they were distinct pieces of wood, those across being the under shaft of each leaf of heddles, and those at the left hand the treddles. See WEAVING. In actual weaving, the treddles are placed at right angles to the heddles, the sinking cords descending perpendicularly as nearly as possible to the centre of the latter. Placing them at the left hand, therefore, is only for

1948



1949

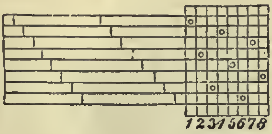


ready inspection, and for practical convenience. At *c* a few threads of warp are shown as they pass through the heedles, and the thick lines denote the leaf with which each thread is connected. Thus, in *fig.* 1948, the right-hand thread, next to *a*, passes through the eye of a heddle upon the back leaf, and is disconnected with all the other leaves; the next thread passes through a heddle on the second leaf; the third, through the third leaf; the fourth, through the fourth leaf; and the fifth, through the fifth or front leaf. One set of the draught being now completed, the weaver recommences with the back leaf, and proceeds in the same succession again to the front. Two sets of the draught are represented in this figure, and the same succession, it is understood by weavers (who seldom draw more than one set), must be repeated until all the warp is included. When they proceed to apply the cords, the right-hand part of the plan at *b*, serves as a guide. In all the plans shown by these figures, excepting one which shall be noticed, a connection must be formed, by cording, between every leaf of heddles and every treddle: for all the leaves must either rise or sink. The raising motion is effected by coupling the leaf to one end of its correspondent top lever; the other end of this lever is tied to the long march below, and this to the treddle. The sinking connection is carried directly from under the leaf to the treddle. To direct a weaver which of these connections is to be formed with each treddle, a black spot is placed when a leaf is to be raised, where the leaf and treddle intersect each other upon the plan, and the sinking connections are left blank. For example, to cord the treddle 1, to the back leaf, put a raising cord, and to each of the other four, sinking cords; for the treddle 2, raise the second leaf, and sink the remaining four, and so of the rest; the spot always denoting the leaf or leaves to be raised. The *figs.* 1948 and 1949 are drawn for the purpose of rendering the general principle of this kind of plans familiar to those who have not been previously acquainted with them; but those who have been accustomed to manufacture and weave ornamented cloths, never consume time by representing either heddles or treddles as solid or distinct bodies. They content themselves with ruling a number of lines across a piece of paper, sufficient to make the intervals between these lines represent the number of leaves required. Upon these intervals, they merely mark the succession of the draught, without producing every line to resemble a thread of warp. At the left hand, they draw as many lines across the former as will afford an interval for each treddle: and in the squares produced by the intersections of these lines, they place the dots, spots, or ciphers which denote the raising cords. It is also common to continue the cross lines which denote the treddle a considerable length beyond the intersections, and to mark by dots, placed diagonally in the intervals, the order or succession in which the treddles are to be pressed down in weaving. The former of these modes has been adopted in the remaining *figs.* to 1957; but to save room, the latter has been avoided, and the succession marked by the order of the figures under the intervals which denote the treddles.

Some explanation of the various kinds of fanciful cloths represented by these plans may serve further to illustrate this subject, which is, perhaps, the most important of any connected with the manufacture of cloth, and will also enable a person who thoroughly studies them, readily to acquire a competent knowledge of the other varieties in weaving, which are boundless. *Figs.* 1948 and 1949 represent the draught and cording of the two varieties of tweeled cloth wrought with five leaves of heddles.

The first is the regular or run tweel, which, as every leaf rises in regular succession, while the rest are sunk, interweaves the warp and woof only at every fifth interval, and as the succession is uniform, the cloth, when woven, presents the appearance of parallel diagonal lines, at an angle of about 45° over the whole surface. A tweel may have the regularity of its diagonal lines broken by applying the cording as in *fig.* 1949. It will be observed, that in both figures the draught of the warp is precisely the same, and that the whole difference of the two plans consists in the order of placing the spots denoting the raising cords, the first being regular and successive, and the second alternate.

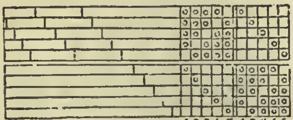
1950



1951

Figs. 1950 and 1951 are the regular and broken tweels which may be produced with eight leaves. This properly is the tweel denominated 'satin' in the silk manufacture, although many webs of silk wrought with only five leaves receive that appellation. Some of the finest Florentine silks are tweeled with sixteen leaves. When the broken tweel of eight leaves is used, the effect is much superior to what could be produced by a smaller number; for in this two leaves are passed in every interval, which gives a much nearer resemblance to plain cloth than the others. For this reason it is preferred in weaving the finest damasks. The draught of the eight-leaf tweel differs in nothing from the others, excepting in the number of leaves. The difference of the cording in the broken tweel will appear by inspecting the ciphers which mark the raising cords, and comparing them with those of the broken tweel of five leaves. *Fig.* 1952 represents the draught and cording of striped dimity of a tweel of five leaves. This is the most simple species of fanciful tweeling. It consists of ten leaves, or double the number of the common tweel. These ten leaves are moved by only five treddles, in the same manner as a common tweel. The stripe is formed by one set of the leaves flushing the warp, and the other set, the woof. The figure represents a stripe formed by ten threads, alternately drawn through each of the two sets of leaves. In this case, the stripe and the intervals will be equally broad, and what is the stripe upon one side of the cloth will be the interval upon the other, and *vice versâ.* But great variety of patterns may be introduced by drawing the warp in greater or small portions through either set. The tweel is of the regular kind, but may be broken by placing the cording as in *fig.* 1949. It will be observed that the cording-marks of the lower or front leaves are exactly the converse of the other set; for where a raising mark is placed upon one, it is marked for sinking in the other; that is to say, the mark is omitted; and all leaves which sink in the one, are marked for raising in the other; thus, one thread rises in succession in the back set, and four sink; but in the front set, four rise, and only one sinks. The woof, of course, passing over the four sunk threads, and under the raised one, in the first instance, is flushed above; but

1952



1953

where the reverse takes place, as in the second it is flushed below; and thus the appearance of a stripe is formed. The analogy subsisting between striped dimity and dornock is so great, that before noticing the plan for fancy dimity, it may be proper to allude to the dornock, the plan of which is represented by *fig.* 1953.

The draught of dornock is precisely the same in every respect with that of striped dimity. It also consists of two sets of tweeling heddles, whether three, four, or five leaves are used for each set. The right-hand set of treddles is also corded exactly in the same way, as will appear by comparing them. But as the dimity is a continued stripe from the beginning to the end of the web, only five treddles are required to move ten leaves. The dornock being chequer-work, the weaver must possess the power of reversing this at pleasure. He therefore adds five more treddles, the cording of which is exactly the reverse of the former; that is to say, the back leaves, in the former case, having one leaf raised, and four sunk, have, by working with these additional treddles, one leaf sunk and four leaves raised. The front leaves are in the same manner reversed, and the mounting is complete. So long as the weaver continues to work with either set, a stripe will be formed, as in the dimity; but when he changes his feet from one set to the other, the whole effect is reversed, and the chequers formed. The dornock pattern upon the design-paper, *fig.* 1953, may be thus explained: let every square of the design represent five threads upon either set of the heddles, which are said by weavers to be once over the draught, supposing the tweel to be one of five leaves; draw three parallel lines, as under, to form two intervals, each representing one of the sets; the draught will then be as follows:—

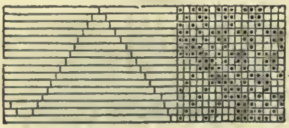
1954	4		1		4		1		1		4		1	
		4		4		1		1		1		4		4

The above is exactly so much of the pattern as is there laid down, to show its appearance; but one whole range of the pattern is completed by the figure 1, nearest to the right hand upon the lower interval between the lines, and the remaining figures, nearer to the right, form the beginning of a second range or set. These are to be repeated in the same way across the whole warp. The lower interval represents the five front leaves; the upper interval, the five back ones. The first figure 4, denotes that five threads are to be successively drawn upon the back leaves, and this operation repeated four times. The first figure 4, in the lower interval, expresses that the same is to be done upon the front leaves; and each figure, by its diagonal position, shows how often, and in what succession, five threads are to be drawn upon the leaves which the interval in which it is placed represents.

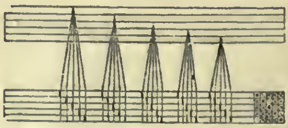
Dornocks of more extensive patterns are sometimes woven with 3, 4, 5, and even 6 set of leaves; but after the leaves exceed 15 in number, they both occupy an inconvenient space, and are very unwieldly to work. For these reasons the diaper harness is in almost every instance preferred.

Fig. 1955 represents the draught and cording of a fanciful species of dimity, in which it will be observed that the warp is not drawn directly from the back to the front leaf, as in the former examples; but when it has arrived at either external leaf, the draught is reversed, and returns gradually to the other. The same draught is frequently used in the tweeling, when it is wished that the diagonal lines should appear upon the cloth in a zigzag direction. This plan exhibits the draught and cording which will produce the pattern upon the design-paper in *fig.* 1948. Were all the squares produced by the intersection of the lines denoting the leaves and treddles, where the raised dots are placed, filled the same as on the design, they would produce the effect of exactly one fourth of that pattern. This is caused by the reversing of the draught, which gives the other side reversed as on the design; and when all treddles, from 1 to 16, have been successively used in the working, one-half of the pattern will become complete. The weaver then goes again over his treddles, in the reversed order of the numbers, from 17 to 30, when the other half of the pattern will be completed. From this similarity of the cording to the design, it is easy, when a design is given, to make

1955



1956

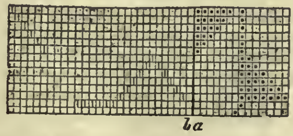


out the draught and cording proper to work it; and when the cording is given, to see its effect upon the design.

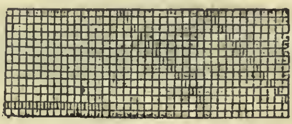
Fig. 1956 represents the draught of the diaper mounting, and the cording of the front leaves which are moved by treddles. From the plan, it will appear that five threads are included in every mail of the harness, and that these are drawn in single threads through the front leaves. The cording forms an exception to the general rules, that when one or more leaves are raised, all the rest must be sunk; for in this instance, one leaf rises, one sinks, and three remain stationary. An additional mark, therefore, is used in this plan. The dots, as formerly, denote raising cords; the blanks, sinking cords; and where the cord is to be totally omitted, the cross marks × are placed.

Fig. 1957 is the draught and cording of a spot whose two sides are similar, but reversed. That upon the plan forms a diamond, similar to the one drawn upon the design-paper in the diagram, but smaller in size. The draught here is reversed, as in the dimity plan, and the treading is also to be reversed, after arriving at 6, to complete the diamond. Like it, too, the raising marks form one-fourth of the pattern. In weaving spots, they are commonly placed at intervals, with a portion of plain cloth between them, and in alternate rows, the spots of one row being between those of the other. But as intervals of plain cloth must take place, both by the warp and woof, 2 leaves are added for that purpose. The front, or ground leaf, includes every second thread of the whole warp; the second, or plain leaf, that part which forms the intervals by the warp. The remaining leaves form the spots: the first six being allotted to one row of spots, and the second six to the next row, where each spot is in the centre between the former. The reversed draught of the first is shown entire, and is

1957



1958



succeeded by 12 threads of plain. One-half of the draught of the next row is then given, which is to be completed exactly like the first, and succeeded by 12 threads more of plain; when, one set of the pattern being finished, the same succession is to be repeated over the whole warp. As spots are formed by inserting woof of coarser dimensions than that which forms the fabric, every second thread only is allotted for the spotting. Those included in the front, or ground leaf are represented by lines, and the spot-threads between them, by marks in the intervals, as in the other plans.

The treddles necessary to work this spot are, in number, 14. Of these the two in the centre, *a*, *b*, (*fig.* 1957) when pressed alternately, will produce plain cloth; for *b* raises the front leaf, which includes half the warp, and sinks all the rest; while *a* exactly reverses the operation. The spot-treddles on the right hand work the row contained in the first six spot-leaves: and those upon the left hand, the row contained in the second six. In working spots, one thread, or shot of spotting-woof, and two of plain, are successively inserted, by means of two separate shuttles.

Dissimilar spots are those whose sides are quite different from each other. The draught only of these is represented by *fig.* 1958. The cording depends entirely upon the figure.

Fig. 1959 represents any solid body composed of parts *lashed* together. If the darkened squares be supposed to be beams of wood, connected by cordage, they will give a precise idea of textile fabric. The beams cannot come into actual contact, because, if the *lashing* cords were as fine even as human hairs, they must still require space. The thickness is that of one beam and one cord; but if the cords touch each other, it may then be one beam and two cords; but it is not possible in practical weaving to bring every thread of weft into actual contact. It may, therefore, be assumed, that the thickness is equal to the diameter of one thread of the warp, added to that of one yarn of the weft; and when these are equal, the thickness of the cloth is double of that diameter. Denser cloth would not be sufficiently pliant or flexible.

1959

1960

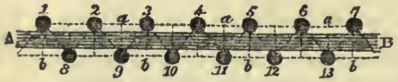
1961

Fig. 1960 is a representation of a section of cloth of an open fabric, where the round dots which represent the warp are placed at a considerable distance from each other.

Fig. 1961 may be supposed a plain fabric of that description which approaches the most nearly to any idea we can form of the most dense or close contact of which yarn can be made susceptible. Here the warp is supposed to be so tightly stretched in the loom as to retain entirely the parallel state, without any curvature, and the whole flexure is therefore given to the woof. This mode of weaving can never really exist; but if the warp be sufficiently strong to bear any tight stretching, and the woof be spun very soft and flexible, something very near it may be produced. This way of making cloth is well fitted for those goods which require to give considerable warmth; but they are sometimes the means of very gross fraud and imposition; for if the warp is made of very slender threads, and the woof of slackly twisted cotton or woollen yarn, where the fibrils of the stuff, being but slightly brought into contact, are rough and oozy, a great appearance of thickness and strength may be given to the eye, when the cloth is absolutely so flimsy that it may be torn asunder as easily as a sheet of writing-paper. Many frauds of this kind are practised.

In *fig.* 1962 is given a representation of the position of a fabric of cloth in section, as it is in the loom before the warp has been closed upon the woof, which still appears as a straight line. This figure may usefully illustrate the direction and ratio of contraction which must unavoidably take place in every kind of cloth, according to the density of the texture, the dimensions of the threads, and the description of the cloth. Let A, B, represent one thread of woof completely stretched by the velocity of the shuttle in passing between the threads of warp which are represented by the round dots, 1, 2, &c., and those distinguished by 8, 9, &c. When these threads are closed by the operation of the needles to form the inner texture, the first tendency will be to move in the direction 1 *b*, 2 *b*, &c., for those above, and in that of 8 *a*, 9 *a*, &c., for those below; but the contraction for A, B, by its deviation from a straight to a curved line, in consequence of the compression of the warp-threads 1 *b*, 2 *b*, &c., and 1 *a*, 2 *a*, &c., in closing, will produce by the action of the two powers at right angles to each other, the oblique or diagonal direction denoted by the lines 1, 8—2, 9, to the left, for the threads above, and that expressed by the lines 2, 8—3, 9, &c., to the right, for the threads below. Now, as the whole deviation is produced by the flexure of the thread A, B, if A is supposed to be placed at the middle of the cloth, equidistant from the two extremities, or *selvages* as they are called by weavers, the thread at 1 may be supposed to move really in the direction 1 *b*, and all the others to approach to it in the directions represented, whilst those to the right would approach in the same ratio, but the line of approximation would be inverted. *Fig.* 1963 represents the common fabric used for lawns, muslins, and the middle kind of goods, the excellence of which neither consists in the greatest strength, nor in the greatest transparency. It is entirely a medium between *fig.* 1960 and *fig.* 1961.

1962



1963

1964

In the efforts to give great strength and thickness to cloth, it will be obvious that the common mode of weaving, by constant intersection of warp or woof, although it may be perhaps the best which can be devised for the former, presents invincible obstructions to the latter beyond a certain limit. To remedy this, two modes of weaving are in common use, which, while they add to the power of compressing a great company of materials in a small compass, possess the additional advantage of affording much facility for adding ornament to the superficies of the fabric. The first of these is double cloth, or two webs woven together, and joined by the operation. This is chiefly used for carpets; and its geometrical principles are entirely the same as those of plain cloth, supposing the webs to be sowed together. A section of the cloth will be found in *fig.* 1964. See CARPETS.

Of the simplest kind of tweeled fabric, a section is given in *fig.* 1965.

The great and prominent advantage of the tweeled fabric in point of texture arises from the facility with which a very great quantity of materials may be put closely together. In the figure, the warp is represented by the dots in the same straight line as in the plain fabrics; but if we consider the direction and ratio of contraction, upon principles similar to those laid down in the explanation given of *fig.* 1962, we shall readily discover the very different way in which the tweeled fabric is affected.

1965

When the dotted lines are drawn at *a*, *b*, *c*, *d*, their direction of contraction, instead of being upon every second or alternate thread, is only upon every fifth thread, and the natural tendency would consequently be, to bring the whole into the form represented by the lines and dotted circles at *a*, *b*, *c*, *d*. In point, then, of thickness, from the upper to the under superficies, it is evident that the whole fabric has increased in the ratio of nearly three to one. On the other hand, it will appear, that four threads or cylinders being thus put together in one solid mass, might be supposed only one thread, or like the strands of a rope before it is twisted; but, to remedy this, the thread being shifted every time, the whole forms a body in which much agggregate matter is compressed; but where, being less firmly united, the accession of strength acquired by the accumulation of materials is partially counteracted by the want of equal firmness of junction.

The second quality of the tweeled fabric, *susceptibility of receiving ornament*, arises from its capability of being inverted at pleasure, as in *fig.* 1966. In this figure, we have, as before, four threads, and one alternately intersected; but here the four threads marked 1 and 2 are under the woof, while those marked 3 and 4 are above.

Fig. 1967 represents that kind of tweeled work which produces an ornamental effect, and adds even to the strength of a fabric, in so far as accumulation of matter can be considered in that light. The figure represents a piece of velvet cut in section, and of that kind which, being woven upon a tweeled ground, is known by the name of Genoa velvet. 1st. Because, by combining a great quantity of material in a small compass, they afford great warmth. 2nd. From the great resistance which they oppose to external friction, they are very durable. And, 3rd. Because, from the very nature of the texture, they afford the finest means of rich ornamental decoration.

1966

1967

The use of velvet cloths in cold weather is a sufficient proof of the truth of the first. The manufacture of plush, corduroy, and other stuffs for the dress of those exposed to the accidents of laborious employment, evinces the second; and the ornamented velvets and Wilton carpeting are demonstrative of the third of these positions.

In the figure, the diagonal form which both the warp and woof of cloth assume, is very apparent from the smallness of the scale. Besides what this adds to the strength of the cloth, the flushed part, which appears interwoven, at the darkly-shaded intervals 1, 2, &c., forms, when finished, the whole covering or upper surface. The principle, in so far as regards texture, is entirely the same as any other tweeled fabric.

Fig. 1968, which represents corduroy, or king's cord, is merely striped velvet. The principle is the same, and the figure shows that the one is a copy of the other. The remaining figures represent those kinds of work which are of the most flimsy and open description of texture; those in which neither strength, warmth, nor durability are much required, and of which openness and transparency are the chief recommendations.

Fig. 1969 represents common gauze, or *linau*, a substance very much used for various purposes. The essential difference between this description of cloth and all others, consists in the warp being turned or twisted like a rope during the operation of weaving, and hence it bears a considerable analogy to *lace*. The twining of gauze is not continued in the same direction, but is alternately from right to left, and *vice versâ*, between every intersection of the woof. The fabric of gauze is always open, flimsy, and transparent; but from the turning of the warp, it possesses an uncommon degree of strength and tenacity in proportion to the quantity of material which it contains. This quality, together with the transparency of the fabric, renders it peculiarly adapted for ornamental purposes of various kinds, particularly for flowering or figuring, either in the loom or by the needle. In the warp of gauze there arises a much greater degree of contraction during the weaving than in any other species of cloth; and this is produced by the turning. The twisting between every intersection of weft amounts precisely to one complete revolution of both threads: hence this difference exists between this and every other species of weaving, namely, that the one thread of warp is always above the woof, and the contiguous thread is always below.

1968

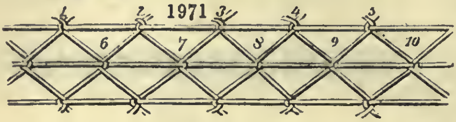
1969

Fig. 1970 represents a section of another species of twisted cloth, which is known by the name of 'catgut,' and which differs from the gauze only, by being subjected to a greater degree of twine in weaving; for, in place of one revolution between each intersection, a revolution and a half are always given; and thus the warp is alternately above and below, as in other kinds of weaving.

Fig. 1971 is a superficial representation of the most simple kind of ornamental network produced in the loom. It is called a whip-net by weavers, who use the term 'whip' for any substance interwoven in cloth for ornamental purposes, when it is distinct from the ground of the fabric. In this the difference is merely in the crossing of the warp; for it is very evident that the crossings at 1, 2, 3, 4, and 5, are of different threads from those at 6, 7, 8, and 9.

1970

1971



1972

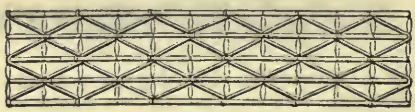


Fig. 1972 represents, superficially, what is called the 'mail-net,' and is merely a combination of common gauze and the whip-net in the same fabric. The gauze here being in the same direction as the dotted line in the former figure, the whole fabric is evidently a continued succession of right-angle triangles, of which the woof forms the basis, the gauze part the perpendiculars, and the whip parts the hypothenuses. The contraction here being very different, it is necessary that the gauze and whip parts should be stretched upon separate beams.

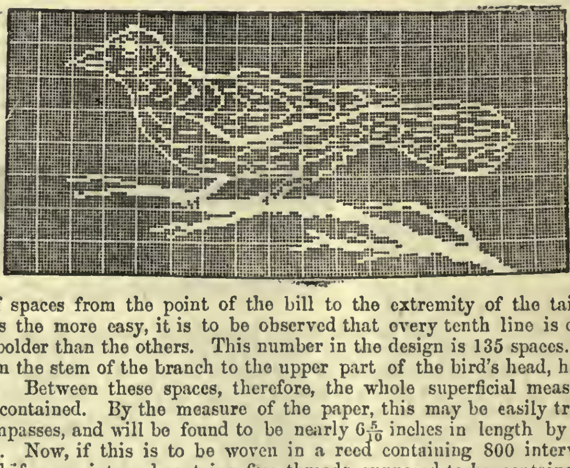
In order to design ornamental figures upon cloths, the lines which are drawn from the top to the bottom of the paper may be supposed to represent the warp; and those drawn across, the woof of the web; any number of threads being supposed to be included between every two lines. The paper thus forms a double scale, by which, in the first instance, the size and form of the pattern may be determined with great precision; and the whole subsequent operations of the weaver regulated, both in mounting and working his loom. To enable the projector of a new pattern to judge properly of its effects, when transferred from the paper to the cloth, it will be essentially necessary that he should bear constantly in his view the comparative scale of magnitude which the design will bear in each, regulating his ideas always by square or superficial measurement. Thus, in the large design, *fig.* 1973, representing a bird perched upon the branch of a tree, it will be proper, in the first place to count the

1973



number of spaces from the point of the bill to the extremity of the tail; and to render this the more easy, it is to be observed that every tenth line is drawn considerably bolder than the others. This number in the design is 135 spaces. Counting again, from the stem of the branch to the upper part of the bird's head, he will find 76 spaces. Between these spaces, therefore, the whole superficial measure of the pattern is contained. By the measure of the paper, this may be easily tried with a pair of compasses, and will be found to be nearly $6\frac{5}{10}$ inches in length by $3\frac{3}{10}$ inches in breadth. Now, if this is to be woven in a reed containing 800 intervals in 37 inches, and if every interval contains five threads, supposed to be contained between every two parallel lines, the length will be 6·24 inches, and the breadth 3·52 inches nearly; so that the figure upon the cloth would be very nearly of the same dimensions as that upon the paper; but if a 1,200 reed were used, instead of an 800, the dimension would be proportionally contracted.

A correct idea being formed of the design, the weaver may proceed to mount his loom according to the pattern; and this is done by two persons, one of whom takes from the design instructions necessary for the other to follow in tying his cords.

1974

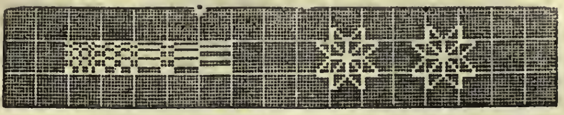


Fig. 1974 is a representation of the most simple species of table linen, which is merely an imitation of chequer-work of various sizes; and is known in Scotland, where the manufacture is chiefly practised, by the name of 'dornock.' When a pattern is formed upon tweeled cloth, by reversing the flushing, the two sides of the fabric being dissimilar, one may be supposed to be represented by the black marks, and the other by the part of the figure which is left uncoloured. For such a pattern as this, two sets of common tweeled-heddles, moved in the ordinary way, by a double succession of heddles, are sufficient. The other part of *fig.* 1974 is a design of that intermediate kind of ornamental work which is called diaper, and which partakes partly of the nature of the dornock, and partly of that of the damask and tapestry.

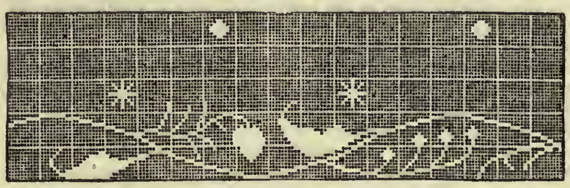
1975



The principle upon which all these descriptions of goods are woven is entirely the same, and the only difference is in the extent of the design, and the means by which it is executed. *Fig.* 1975 is a design for a border of a handkerchief or napkin, which may be executed either in the manner of damask, or as the spotting is practised in the lighter fabrics.

TEXTILE FIBRES CONDENSED. Mr. John Mercer's plan of transforming cotton and flax into fibres of fine silky texture, while their strength and substance are increased, excited much interest a few years since. He subjected them to the action of caustic alkaline lye, sulphuric acid, or to solution of chloride of zinc, of such strength and at such a temperature as produced certain remarkable changes in them, quite the reverse of what most people would have expected. The mode of operating according to this invention, upon cloth made wholly or partially of any vegetable-fibres and bleached, is as follows:—The cloth is passed through a padding machine charged with caustic soda or caustic potash at 60° or 70° of Twaddle's hydrometer, at the common temperature of the atmosphere (say 60° Fahr. or under); then, without being dried, it is washed in water; and, after this, it is passed through dilute sulphuric acid, and washed again. Or the cloth is conducted over and under a series of rollers in a cistern containing caustic soda or caustic potash at 40° to 50° Twaddle, at the ordinary temperature (the last two rollers being set so as to squeeze the excess of soda or potash back into the cistern); and then it is passed over and under rollers placed in a series of cisterns, which are charged at the commencement of the operation with water only; so that when the cloth arrives at the last cistern, nearly all the alkali has been washed out of it. After the cloth has either gone through the padding machine or through the cisterns, it is washed in water, passed through dilute sulphuric acid, and again washed in water.

When grey or unbleached cloth, made from the above-mentioned fibrous material, is to be treated, it is first boiled or steeped in water, so as to wet it thoroughly; then most of the water is removed by the squeezer or hydro-extractor; and, after this, it is passed through the soda- or potash-solution, &c., as before described.

Warps, either bleached or unbleached, are treated in the same manner; but, after passing through the cistern containing the alkali, they are passed through squeezers or through a hole in a metal plate, to remove the alkali; and then the warps are conducted through the water cisterns, 'soured,' and washed, as before described.

When thread or hank yarn is to be operated upon, the threads or yarns are immersed in the alkali and then wrung out (as is usually done in sizing or dyeing them); and afterwards they are subjected to the above-mentioned operations of washing, souring, and washing in water.

When any fibre in the raw state, or before it is manufactured, is to be treated, it is first boiled in water, and then freed from most of the water by the hydro-extractor or a press; after which it is immersed in the alkaline solution, and the excess of alkali is removed by the hydro-extractor or a press; then it is washed in water, soured with dilute sulphuric acid, and washed again; and, finally, the water is removed by the hydro-extractor or a press.

The following are the effects produced by the above operations upon cloth made of vegetable fibrous material, either alone or mixed with animal fibrous material:—The cloth will have shrunk in length and breadth, or have become less in its external dimensions, but thicker and closer; so that by the chemical action of caustic soda or caustic potash on cotton and other vegetable fabrics, an effect will be produced somewhat analogous to that which is produced on woollen by the process of fulling or milling; the cloth will likewise have acquired greater strength and firmness—greater force being required to break each fibre—it will be found to have become heavier than it was previously to being acted upon by the alkali, if in both cases it be weighed at the temperature of 60° Fahr., or under. It will also have acquired greatly augmented and improved powers of receiving colours in printing and dyeing.

THALLIUM. (*Symb.* Tl; *at. wt.* 204.) The existence of a new elementary substance in the deposit formed in the leaden chambers of a sulphuric-acid factory was indicated by Mr. W. Crookes as far back as March 30, 1861. Mr. Crookes announced his discovery in the following terms:—

'In the year 1850, upwards of 10 lbs. of the seleniferous deposit from the sulphuric acid manufactory at Tilkerode, in the Hartz Mountains, were placed at my disposal, for the purpose of extracting from it the selenium, which was afterwards employed in an investigation upon the selenocyanides. Some residues which were left in the purification of the crude selenium, and which from their reactions appeared to contain tellurium, were collected together and placed aside for examination at a more convenient opportunity. They remained unnoticed until the beginning of 1862, when, requiring some tellurium for experimental purposes, I attempted its extraction from these residues. Knowing that the spectra of the incandescent vapours of both selenium and tellurium were free from any strongly-marked line which might lead to the identification of either of these elements, it was not until I had in vain tried numerous chemical methods for isolating the tellurium which I supposed to be present, that the method of spectrum analysis was used. A portion of the residue, introduced into a blue gas-flame, gave abundant evidence of selenium; but as the alternate light and dark bands due to this element became fainter, and I was expecting the appearance of the somewhat similar but closer bands of tellurium, suddenly a *bright green line* flashed into view and as quickly disappeared. An isolated green line in this portion of the spectrum was new to me. I had become intimately acquainted with the appearance of most of the artificial spectra during many years' investigation, and had never before met with a similar line to this; and as from the chemical processes through which this residue had passed the elements which could possibly be present were limited to a few, it became of interest to discover which of them occasioned this green line. After numerous experiments, I have been led to the conclusion that it is caused by the presence of a new element, belonging to the sulphur group; but unfortunately the quantity of material upon which I have been able to experiment has been so small, that I hesitate to assert this very positively.'

Thallium is a soft heavy metal, resembling lead; it melts at 294° C., and is completely volatile below a red heat, both in the elementary state and in combination (except when united with a heavy fixed metal). From its hydrochloric solution it is readily precipitated by metallic zinc in the form of a heavy black powder insoluble in the acid liquid. Ammonia added very gradually, until in slight excess, to its acid solution gives no precipitate or colouration whatever, neither does the addition of carbonate or oxalate of ammonia to its alkaline solution. Dry chlorine passed over it at a dull red heat unites with it, forming a readily volatile chloride soluble in water. Sulphuretted hydrogen passed through its hydrochloric solution precipitates it incompletely, unless only a trace of free acid is present; but in an alkaline solution an immediate precipitation of a heavy black powder takes place. Fused with carbonate of soda and nitre, it becomes soluble in water.

Mr. Crookes afterwards found the new element in two or three specimens of native sulphur, and especially in some specimens from the Liparian Islands. Some samples of Spanish pyrites were likewise found to contain traces of the substance. Mr. Crookes called the new element *Thallium* (from Gr. θαλλός, *thallos*, 'budding twig'); and described a process by which it may be separated. Thallium is also found in some lithia-micas (*lepidolite*), and in the Swedish mineral called *Crookesite*, a selenide of copper and thallium, which contains as much as 19 per cent. of thallium.

On May 16, 1862, M. Lamy made known the result of his researches and experiments on a deposit formed, after the chambers had been fed for a considerable time with sulphurous acid generated by the combustion of Belgian pyrites from the mines of St. Oneux near Spa. M. Frederick Kuhlmann, jun. had extracted several specimens of selenium, one of which he placed at the disposal of M. Lamy. On submitting this specimen to spectrum analysis, M. Lamy observed (early in 1862) the same green line which had been the starting-point of Mr. Crookes' researches. It thus appears that M. Lamy was led by independent observations of his own to the detection of the green line-producing body previously observed by Mr. Crookes. M. Lamy. however; being fortunate enough to have a very considerable amount of the thalliferous deposit at his disposal, was enabled to pursue his investigation on a proportionately extensive scale. He began a series of experiments with the view of isolating the element, and soon succeeded in separating very appreciable quantities of the new body, in the form of a metallic ingot.

For the preparation of the salts of thallium, see Watts's 'Dictionary of Chemistry.'

THEBAINE. One of the numerous alkaloïds obtained from opium.

THEINE. Syn. *Caffeine.* $C^{16}H^{10}N^4O^4$ (**$C^8H^{10}N^4O^2$**). A feeble base contained in tea, coffee, and, in fact, in most of the plants used in the manner of tea; such as Paraguay and Guarana tea. See CAFFEINE and TEA.

THÉNARD'S BLUE, or *Cobalt Blue*, is prepared by digesting the oxide of cobalt with nitric acid, evaporating the nitrate of cobalt formed, almost to dryness; diluting it with water, and filtering, to separate some arsenate of iron, which usually precipitates. The clear liquor is to be poured into a solution of phosphate of soda, when an insoluble phosphate of cobalt falls. This being well washed, is to be intimately mixed in its soft state with eight times its weight of well-washed gelatinous alumina, which has been obtained by pouring a solution of alum into water of ammonia in excess. The uniformly-coloured paste is to be spread upon plates, dried in a stove, then bruised dry in a mortar, enclosed in a crucible, and subjected to a cherry-red heat for half an hour. On taking out the crucible, and letting it cool, the fine blue pigment is to be removed into a bottle, which is to be stoppered till used.

The arsenate of cobalt may be substituted, in the above process, for the phosphate, but it must be mixed with sixteen times its weight of the washed gelatinous alumina. The arsenate is procured by pouring the dilute nitrate of cobalt into a solution of arsenate of potash. If nitrate of cobalt be mixed with alumina, and the mixture be treated as above described, a blue pigment will also be obtained, but paler than the preceding, showing that the colour consists essentially of alumina stained with oxide of cobalt. See COBALT BLUE.

THEOBROMA CACAO. The Cocoa or Cacao tree: from the seeds of which both chocolate and cocoa are prepared. See COCOA.

THEOBROMINE is a chemical principle found in cocoa-beans. It is extracted by boiling with water, filtering, precipitating with acetate of lead, separating the precipitate after washing it, and then decomposing it by sulphuretted hydrogen.

THEOLINE. See ABIETENE.

THERMOGRAPHY. A term proposed by the Editor of this Dictionary, in December 1842, to express the 'Art of Copying Engravings, &c. on Metal Plates;' the effect being due in all cases to the influence of heat-radiations. The process is fully described in 'Researches on Light,' by Mr. Robert Hunt.

THERMOMETER. An instrument used, as its name signifies, as a measure of heat. A description of this valuable instrument belongs to Physics. The principle upon which it is constructed depends upon the expansion of some fluid or solid by heat. We may adopt any body as our heat-measurer, if the rate of expansion is uniform for equal increments of heat, and we determine by previous experiments the rate of expansion to which it is subject, and construct a fixed scale. Usually either mercury or spirits of wine is employed.

Thermometrical Table, by Dr. Alfred S. Taylor, F.R.S.—The accompanying thermometrical table by Dr. A. Taylor has been copied from a thermometer in his possession, graduated on the scales of Fahrenheit, Réaumur, and Celsius, or the Centigrade. It has been designed to obviate the necessity for those perplexing calculations, so often rendered necessary by the use of different methods of graduation in England and on the Continent. In most chemical works, we find, besides the rules given for the conver-

sion of the degrees of one scale into those of another, comparative tables, which however, convey no information beyond the bare fact of the correspondence of certain degrees. In this table, the attempt has been made to make it convey information on numerous interesting points, connected with temperature in relation to climatology, physical geography, chemistry, and physiology.

There is another advantage which a table of this kind must possess over those hitherto published in works on chemistry. In the latter, the degrees on one scale only run in arithmetical progression, while the corresponding degrees on the other scale are necessarily given in fractional or decimal parts, and at unequal intervals. Thus, in some of the best works on chemistry, a comparative table is printed, which is only fitted for the conversion of the Centigrade into Fahrenheit degrees, so that a person wishing to convert the Fahrenheit into Centigrade degrees, would have to revert to one of the old formulæ of conversion. This process must also be adopted whenever the Centigrade degrees are given in decimal parts, for many of the tables published in English works wrongly assume that the Centigrade degrees are always given in whole numbers. The present table renders such calculations unnecessary, since the value of any degree, or of any part of a degree on one scale, is immediately found on the other, by looking at the degree in a parallel line with it. The main divisions will, it is believed, be found perfectly accurate. In single degrees a little inequality may be occasionally detected; but the error has not been found to be such as to affect the calculated temperature.

Although the Fahrenheit and Centigrade scales are the two which are chiefly used in Europe, it has been thought advisable to carry out the parallel degrees of Réaumur's scale, by dots on the drawing of the tube. This table, therefore, comprises in itself six distinct tables, assuming the necessity for each scale to be represented in whole degrees, with the additional advantages: 1st, that the space occupied is smaller; and 2nd, the value of any fractional part of a degree on one may be at once determined on the other two scales.

It is extraordinary, considering the great advances which have been recently made in physical science, and in the manufacture of philosophical instruments, that the makers of thermometers should still adhere to the old and absurd practice of marking on the Fahrenheit scale, the unmeaning words Temperate, Summer-heat, Blood-heat, Fever-heat, Spirits boil, &c., when the instrument might be easily made to convey a large amount of information in respect to climate, as it is dependent on temperature.

It will be seen that the table here published ranges from 12° to 374° Fahrenheit., from — 11° to + 190 Centigrade, and from — 9° to + 152° Réaumur.

It will be only necessary to state generally those facts which the table is intended to illustrate. They will be fonnd arranged opposite to their respective degrees, either on the Centigrade or Fahrenheit side, according to the space afforded.

The facts connected with temperature placed on the scale may be arranged under the heads of Climatology, Physical Geography, Chemistry, and Physiology.

Climatology. 1. The mean temperatures of the principal countries, towns, and cities in the world, with the maxima and minima, as well as the mean summer and winter temperature of some of the most important localities.

2. The maximum degrees of heat and the minimum degrees of cold observed on the surface of the globe, including the accumulated temperatures of air at Edinburgh and Geneva.

Physical Geography. 1. The temperature of the atmosphere, as observed on the summits of the principal mountains of the Old and New World, with the respective elevations attached; at the sea-level in various latitudes, from the Arctic to the Antarctic Seas, as well as in deep mines and other excavations in Europe and America.

2. The temperature of the ocean at the surface, and at various depths to 12,420 feet, including the temperature of the Polar Seas, of the Mediterranean, Atlantic and Pacific, with the temperature of the Gulf Stream.

3. The temperature of the waters of lakes and rivers at various depths, with the respective fathomings attached.

4. The temperature of the strata of the earth at various depths, observed in some of the deepest mines in the Old and New World.

5. The temperature of the water raised in Artesian wells in Europe from depths varying from 250 to 1,794 feet.

6. The temperature of the principal thermal springs and baths observed in Europe, Africa, the West Indies, and South America.

7. The temperature at which water boils at all the elevated and inhabited spots in the world, including the summits of the mountains of Switzerland, South America, and Central Asia; the boiling point for all elevations up to 5,415 feet, and for 1,054 feet depression below the level of the sea.

Chemistry. 1. The evaporating, boiling, fusing, melting, subliming, and congealing points of the principal solids and liquids in chemistry, from 12° to 374° Fahrenheit, from — 11° to + 190° Centigrade and from — 9 to + 152° Réaumur, including the boiling points of the saturated solutions of numerous salts, and the melting points of a large number of alloys.

2. The temperature for fermentation of various kinds, malting, putrefaction, etherification, and other chemical processes.

3. The boiling points of alcohol and acids of various specific gravities, with the respective densities of their vapours.

4. The pressure or elastic force of the vapour of water, alcohol, oil of turpentine, and ether, at various temperatures.

5. The temperatures, with the corresponding pressures, required for the liquefaction of the gases.

6. The temperature for the explosion and ignition of fulminating and combustible substances.

Physiology. 1. The maximum degrees of natural and artificial heat, and minimum degrees of cold, borne by man and animals.

2. The temperature of the body in man, mammalia, birds, reptiles, fishes, and insects.

3. The temperature at which hybernation takes place in certain animals.

4. The temperature for the germination of seeds, incubation, the artificial hatching of the ova of birds, fishes, and insects.

5. The temperature for the growth of the sugar-cane, date, indigo, cotton-tree, and for the cultivation of the vine.

6. The temperature for warm, tepid, and vapour-baths; the vapour-baths of Russia and Finland.

Thermometer, *Self-registering, by Photography.* The first person who in this country proposed to apply photography, and actually did apply it, as a means of registering the movements of the mercury in the thermometer and barometer, and also for registering the variations in the magnetic intensity, was Mr. Thomas B. Jordan, at that time Secretary to the Royal Cornwall Polytechnic Society. The results of this gentleman's methods and the description of his plans will be found in the *Sixth Annual Report of the Royal Cornwall Polytechnic Society for* 1838.

Mr. Ronalds, of the Kew Observatory, also devised an arrangement for employing photography as the means of registering meteorological inventions, and subsequently Mr. Charles Brooke perfected a method which is now generally adopted.

THERMOSTAT is the name of an apparatus for regulating temperature, in vaporisation, distillations, heating baths or hothouses, and ventilating apartments, &c.; for which Dr. Ure obtained a patent in the year 1831. It was, in fact, a differential thermometer, similar in construction to Brady's metallic thermometer.

THIALDINE. $C^{12}H^{13}NS^4$ ($C^6H^{13}NS^2$). A curious alkaloïd, formed by the action of sulphuretted hydrogen on aldehyde ammonia.

THIEVES' VINEGAR. (*Le Vinaigre des quatre Voleurs*, Fr.) See Aromatic Vinegar.

THIMBLE. (*Dé à coudre*, Fr.; *Fingerhut* (*fingerhat*), Ger) This is a small truncated metallic cone, deviating little from a cylinder, smooth within, symmetrically pitted on the outside with numerous rows of indentations, which is put upon the tip of the middle finger of the right hand, to enable it to push the needle readily and safely through cloth or leather, in the act of sewing. This little instrument is fashioned in two ways: either with a pitted round end, or without one; the latter, called the open thimble, being employed by tailors, upholsterers, and, generally speaking, by *needle-men.* The following ingenious process for making this essential implement, the contrivance of MM. Rouy and Berthier, of Paris, has been much celebrated, and very successful. Sheet-iron, one twenty-fourth of an inch thick, is cut into strips, of dimensions suited to the size of the intended thimbles. These strips are passed under a punch-press, whereby they are cut into disks of about 2 inches diameter, tagged together by a tail. Each strip contains one dozen of these blanks. A child is employed to make them red-hot, and to lay them on a mandril nicely fitted to their size. The workman now strikes the middle of each with a round-faced punch, about the thickness of his finger, and thus sinks it into the concavity of the first mandril. He then transfers it successively to another mandril, which has five hollows of successively increasing depth; and, by striking it into them, brings it to the proper shape.

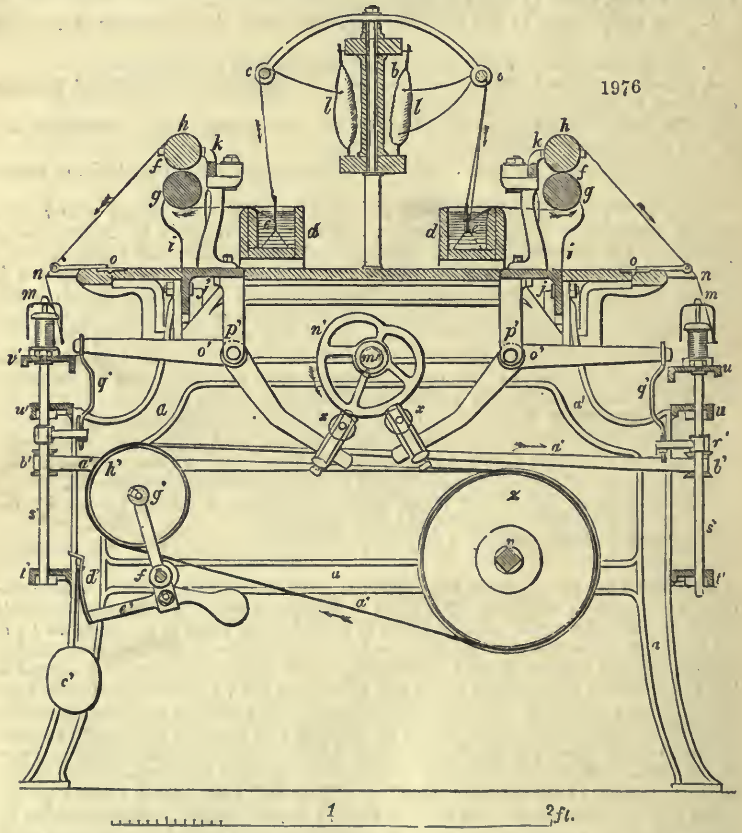
A second workman takes this rude thimble, sticks it in the chuck of his lathe, in order to polish it within, then turns it outside, marks the circles for the gold ornament, and indents the pits most cleverly with a kind of milling tool. The thimbles are next annealed, brightened, and gilt inside, with a very thin cone of gold-leaf, which is firmly united to the surface of the iron, simply by the strong pressure of a smooth steel mandril. A gold fillet is applied to the outside, in an annular space turned to receive it, being fixed by pressure at the edges, into a minute groove formed on the lathe.

Thimbles are made in this country by means of moulds in the stamping machine. See STAMPING OF METALS.

THORINUM or **THORIUM.** A rare metal, discovered in 1828 by Berzelius in the Norwegian mineral *thorite*, which contains about 57 per cent. of thorina, the oxide of this metal, and where it is associated with the oxide of iron, lead, manganese, tin, and uranium, besides earths and alkalis. None of the compounds of thorinum find any use in the arts.

THREAD MANUFACTURE. The doubling and twisting of cotton or linen yarn into a compact thread for weaving bobbin-net, or for sewing garments, is performed by a machine resembling the throstle of the cotton-spinner. *Fig.* 1976 shows the thread-frame in a transverse section, perpendicular to its length. *a*, is the strong framing of cast iron; *b*, is the *creel*, or shelf, in which the bobbins of yarn *l*, *l*, are set loosely upon their respective skewers, along the whole line of the machine,

1976



their lower ends turning in oiled steps, and their upper in wire-eyes; *c*, is a glass rod across which the yarn runs as it is unwound; *d*, *d*, are oblong narrow troughs, lined with lead and filled with water, for moistening the thread during its torsion; the threads being made to pass through eyes at the bottom of the fork *e*, which has an upright stem for lifting it out without wetting the fingers, when anything goes amiss; *f*, *f*, are the pressing rollers, the under one *g*, being of smooth iron, and the upper one *h*, of boxwood; the former extends from end to end of the frame, in lengths comprehending eighteen threads, which are joined by square pieces, as in the drawing-rollers of the mule-jenny. The necks of the under rollers are supported at the ends and the middle, by the standards *i*, secured to square bases *j*, both made of cast iron.

The upper cylinder has an iron axis, and is formed of as many rollers as there are threads; each roller being kept in its place upon the lower one by the guides *k*, whose vertical slots receive the ends of the axis.

The yarn delivered by the bobbin *l*, glides over the rod *c*, and descends into the trough *d e*, where it gets wetted; on emerging, it goes along the bottom of the roller *g*, turns up so as to pass between it and *h*, then turns round the top of *h*, and finally proceeds obliquely downwards, to be wound upon the bobbin *m*, after traversing the guide-eye *n*. These guides are fixed to the end of a plate which may be turned up by a hinge-joint at *o*, to make room for the bobbins to be changed.

There are three distinct simultaneous movements to be considered in this machine: 1, that of the rollers, or rather of the under roller, for the upper one revolves merely by friction; 2, that of the spindles *m*, *s′*; 3, the up-and-down motion of the bobbins upon the spindles.

The first of these motions is produced by means of toothed wheels, upon the right hand of the under set of rollers. The second motion, that of the spindles, is effected by the drum *z*, which extends the whole length of the frame, turning upon the shaft *v*, and communicating its rotatory movement (derived from the steam-pulley) to the whorl *b′* of the spindles, by means of the endless band or cord *a′*. Each of these cords turns four spindles, two upon each side of the frame. They are kept in a proper state of tension by the weights *e′*, which act tangentially upon the circular arc *d*, fixed to the extremity of the bell-crank lever *e′ f′ g′*, and draw in a horizontal direction the tension pulleys *h*, embraced by the cords. The third movement, or the vertical traverse of the bobbins, along the spindles *m*, takes place as follows:—

The end of one of the under rollers carries a pinion, which takes into a carrier wheel that communicates motion to a pinion upon the extremity of the shaft *m′*, of the heart-shaped pulley *n′*. As this excentric revolves, it gives a reciprocating motion to the levers *o′*, *o′*, which oscillate in a vertical plane round the points *p′*, *p′*. The extremities of these levers on either side act by means of the links *q′*, upon the arms of the sliding sockets *r′*, and cause the vertical rod *s′*, to slide up and down in guide-holes at *t′*, *u′*, along with the cast-iron step *v′*, which bears the bottom washer of the bobbins. The periphery of the heart-wheel *w′*, is seen to bear upon friction wheels *x*, *x′*, set in frames adjusted by screws upon the lower end of the bent levers, at such a distance from the point *p′*, as that the traverse of the bobbins may be equal to the length of their barrel.

By adapting change pinions and their corresponding wheels to the rollers, the delivery of the yarn may be increased or diminished in any degree, so as to vary the degree of twist put into it by the uniform rotation of the drum and spindles. The heart-motion being derived from that of the rollers, will necessarily vary with it.

Silk thread is commonly twisted in lengths of from 50 to 100 feet, with hand reels, somewhat similar to those employed for making ropes by hand.

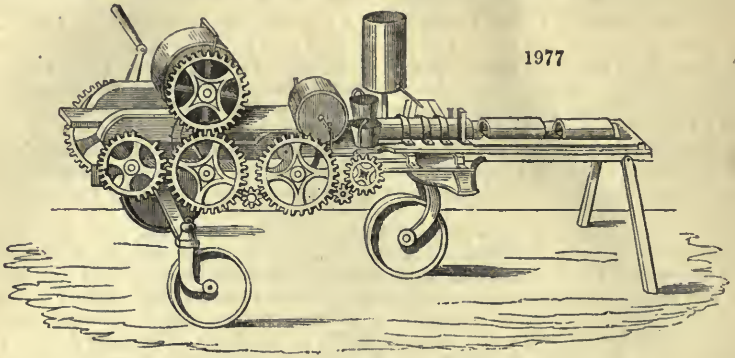
THUYA OCCIDENTALIS. A coniferous tree, from which is obtained a yellow body, *Thuyin*, which is probably identical with *Quercitrin*.

TILE ORE. (*Ziegelerz*, Ger.) An earthy variety of red oxide of copper.

TILES. Tile-manufacture is a very comprehensive term, embracing the following varieties:—Paving bricks or tiles, oven-tiles, foot tiles, plain tiles, pan tiles, hip tiles, ridge tiles, circulars, drain tiles, &c.

The clay used for making tiles is purer and stronger than that used for making bricks. When the clay is too strong, that is, too adhesive, it is mixed with sand before passing it through the pug-mill. As a usual practice the clay is *weathered*; this is effected by spreading it out in layers of about two inches in thickness during the winter, and each layer is allowed the benefit of at least one night's frost before the succeeding layer is put over it. This *weathering* is sometimes effected by exposing the layers to sunshine, which is said to answer equally well with frost. What this weathering does is by no means clear: it is said 'to open the pores of the clay.' We believe that what really takes place is, that under the influences to which it is exposed, the particles break up into smaller particles, and that we have the clay in a more finely comminuted state. The next process is that of *tempering*. After the clay has been allowed to 'mellow, or ripen,' in pits, under water, it is passed through the pug-mill and well kneaded or tempered. It is then *slung*, that is, cut into slices with a string; during which process the stones fall out, or are removed by the hand; it is then ready for the operation of moulding. This may be performed by hand, or by any one of the many machines which have been devised.

Fig. 1977 shows Mr. Hunt's machine for making tiles. It consists of two iron cylinders, round which webs or bands of cloth revolve, whereby the clay is pressed into a slab of uniform thickness, without adhering to the cylinders. It is then carried over a covered wheel, curved on the rim, which gives the tile the semi-cylindrical or other required form; after which the tiles are polished and finished by passing through three iron moulds of a horse-shoe form, as shown in the centre of the cut, while they are at the same time moistened from a water cylinder placed above them.



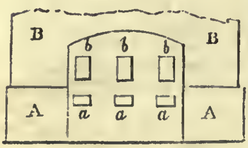
1977

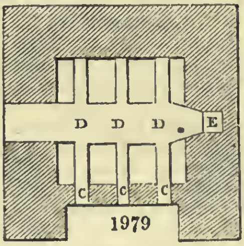
The tiles are next cut off to such lengths as are wanted, and carried away by an endless web, whence they are transferred by boys to the drying shelves.

Flat tiles, for sole pieces to draining tiles, are formed in nearly the same manner, being divided into two portions while passing through the moulds; the quantity of clay used for one draining tile being as much as for two soles.

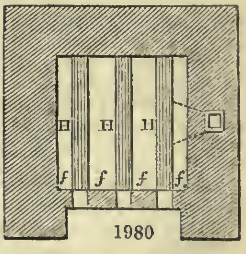
By hand, the work is divided between a moulder and a rough moulder. The latter, a boy, takes a piece of clay and squares it up, that is, beats it up into a slab nearly the shape of the mould, and about 4 inches thick, from which he cuts off a thin slice the size of a tile, and passes it to the moulder. The moulder sands his stock-board, and, regulating the thickness of the tile by four pegs, on which the mould is placed, he puts the piece of clay with which he is supplied into the mould; he then smooths

1978





1979



1980

the surface with his very wet hands, removes the superfluous clay, and moulds it into a curved shape. They are then placed to dry, with the convex side uppermost; when half-dry the tiles are taken out one by one, placed on the *thwacking* frame, and beaten with the thwacker to produce the required shape; when dry they are kilned.

The following plan of a furnace, or kiln, for burning tiles has been found very convenient:—

Fig. 1978, front view, A A, B B, the solid walls of the furnace; *a a a*, openings to the ash-pit, and the draught-hole; *b b b*, openings for the supply of fuel, furnished with a sheet-iron door. *Fig.* 1979, plan of the ash-pits and air-channels C C C. The principal branch of the ash-pit D D D, is also the opening for taking out the tiles, after removing the grate; E, the smoke-flue. *Fig.* 1980, plan of the kiln seen from above. The grates, H H H. The tiles to be fired are arranged upon the spaces *f f f f*.

Of late years the manufacture of encaustic tiles and tesseræ for tesselated pavements has been greatly improved by Messrs. Minton of Stoke-upon-Trent, and Messrs. Maw and Co. of Broseley in Shropshire. The production of such tiles by Prosser's patent is fully described under Encaustic Tiles.

TILTING OF STEEL. See Steel.

TIN. (*Étain*, Fr.; *Zinn*, Ger.) *Symb.* Sn; *At. wt.* 118. This metal, in its pure state, has nearly the colour and lustre of silver. In hardness it is intermediate between gold and lead; it is very malleable, and may be laminated into foil less than the thousandth of an inch in thickness; it has an unpleasant taste, and exhales on friction a peculiar odour; it is flexible in rods or straps of considerable strength, and emits in the act of bending a crackling sound, called the 'creaking of tin,' as if sandy particles were intermixed. A small quantity of lead, or other metal, deprives it of this characteristic quality. Tin melts at 442° Fahr., and is very fixed in the fire at higher heats. Its specific gravity is 7·29. When heated to redness with free access of air, it absorbs oxygen with rapidity, and changes first into a pulverulent grey oxide, and by longer ignition into a yellow-white powder, called '*putty* of tin.' This is the peroxide, consisting of 100 parts of metal and 27·2 of oxygen.

Tin has been known from the most remote antiquity. It is probably mentioned in the Books of Moses; and the ships of Tarshish appear to have brought this metal from islands eastward of the Persian Gulf. The Phœnicians carried on a lucrative trade in it with Spain and Cornwall.

The earliest navigators appear to have taken tin from the east and from the west to supply the wants of Egypt and of Greece. That the Phœnicians, with whom, in those days, the maritime trade of the world rested, collected tin from our own islands is certain; at the same time it is highly probable that the Indian islands were another source from which they obtained this metal in considerable quantities.

'*Kassiteros*,' says Humboldt, 'is the ancient Indian Sanskrit word *Kastira*; *Zinn* in German, *Den* in Icelandic, *Tin* in English, and *Tenn* in Swedish, is in the Malay and Javanese language *Timah*, a similarity of sound which reminds us of that of the old German word *Glessum* (the name given to transparent amber) to the modern *Glas*, glass. The names of articles of commerce pass from nation to nation, and become adopted into the most different languages. Through the intercourse which the Phœnicians, by means of their factories in the Persian Gulf, maintained with the east coast of India, the Sanskrit word *Kastira* became known to the Greeks, even before Albion and the British Cassiterides had been visited.'

The Cassiterides, or Tin Islands, have been supposed to be, by some, the Islands of Scilly. This idea has been far too hastily adopted, seeing that the Scilly Islands produce no tin. In all probability this name was given by the Phœnicians to the whole of the western promontory of Cornwall, the only part of this country with which they were acquainted, the name being without doubt derived from the *Kassiteros* of the East.

There are only two ores of tin: the peroxide, tin-stone, or *Cassiterite*; and tin pyrites, sulphide of tin, or *Stannine*: the former of which alone has been found in sufficient abundance for metallurgic purposes. The external aspect of tin-stone has nothing very remarkable. It occurs sometimes in twin crystals; its lustre is adamantine; its colours are very various, as white, grey, yellow, red, brown, black; specific gravity, 6·9 at least; which is, perhaps, its most striking feature. It does not melt by itself before the blowpipe, but is reducible in the smoky flame or on charcoal. It is insoluble in acids. It has somewhat of a greasy aspect, and strikes fire with steel.

This ore has been found in but a few countries in a workable quantity. Its principal localities are, Cornwall, Bohemia, and Saxony, in Europe; and Malacca, Banca, and Billiton, in Asia, and Australia. The tin mines of the Malay Peninsula lie between the 10th and 6th degrees of south latitude. The mines in the island of Banca, to the east of Sumatra, were discovered in 1710. Small quantities occur in Galicia in Spain, the department of Haute-Vienne in France, and in the mountain-chains of the Fichtel and Riesengebirge in Germany. The columnar pieces of pyramidal tin-ore from Mexico and Chile are found in the alluvial deposits. Vast deposits of tin-stone have recently been discovered in Queensland and New South Wales, where the stream-tin is now being actively worked. It has also been found at Mount Bischoff in Tasmania. Some tin has been recently worked in Peru (1874).

The county of Cornwall is the most important mineral district of the United Kingdom for the number of its metalliferous minerals, many of which are not found in any other part of the island. At a very early period of our history mines were worked around the sea-coasts of Cornwall: of which the evidences are still to be seen at Tol-pedden-Penwith, near the Land's End; in Gwennap, near Truro; and at Cadgwith, near the Lizard Point. The traditionary statements, that the Phœnicians traded for tin with the Britons in Cornwall, are very fairly supported by corroborative facts; and it is not improbable that the Ictes, or Iktis, of the ancients was St. Michael's Mount, near Penzance, and other similar islands on the coast.

In the reign of King John the mines of the western portion of England appear to have been principally in the hands of the Jews. The modes of working must have been very crude, and their metallurgical processes exceedingly rough. From time to time remains of furnaces, called *Jews' houses*, have been discovered, and small blocks of tin, known as *Jews' tin*, have not unfrequently been found in the mining localities.

Till a comparatively recent date, tin was the only metal which was sought for; and in many cases the mines were abandoned when the miners came to the '*yellows*,' that was the yellow sulphide of copper. A great quantity of tin has been produced by 'streaming' (as washing the *débris* in the valleys is termed); and this variety, called 'stream-tin,' produces the highest price in the market. Very little stream-tin is now obtained.

The Cornish ores occur—1, in small strata or veins, or in masses; 2, in congeries of small veins; 3, in large veins; and 4, disseminated in alluvial deposits, as described.

The stanniferous small veins, or thin flat masses, though of small extent, are sometimes very numerous, interposed between certain rocks, parallel to their beds, and are commonly called tin-floors. In the mine of Bottalack a *tin-floor* has been found in the killas (a schistose rock), thirty-six fathoms below the level of the sea; it is about a foot and a half thick, and occupies the space between a principal vein and its ramification; but there seems to be no connection between the *floor* and the great vein.

2. *Stockwerks*, as the Germans term the disseminated masses, occur in granite and in the felspar porphyry, called in Cornwall *elvan*. The most remarkable of these, in the granite, is at the tin-mine of Carclase, near St. Austell. The works are carried on in the open air, in a friable granite, containing felspar—*kaolin*, or china-clay, which is traversed by a great many small veins, composed of tourmaline, quartz, and a little tin-stone, that form black delineations on the face of the light-grey granite. The thickness of these little veins rarely exceeds 6 inches, including the adhering solidified granite, and is occasionally much less. Some of them run nearly east and west, with an almost vertical dip; others, with the same direction, incline to the south at an angle with the horizon of 70 degrees.

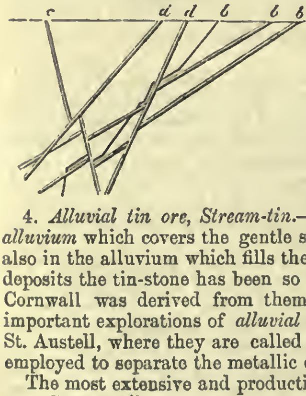
Stanniferous masses are much more frequent in the elvan (porphyry); of which the mine of Trewidden is a remarkable example. It was worked among flattened masses of elvan, separated by strata of killas, which dip to the east-north-east at a considerable angle. The tin ore occurred in small veins, varying in thickness from half an inch to 8 or 9 inches, which were irregular, and so much interrupted that it was difficult to determine either their direction or their inclination.

3. The large and proper metalliferous veins are not equally distributed over the surface of Cornwall and the adjoining part of Devonshire; but are grouped into three districts: namely, 1, In the south-west of Cornwall, beyond Truro; 2, In the neighbourhood of St. Austell; and 3, In the neighbourhood of Dartmoor in Devonshire.

The first group is by far the richest and the best explored. The great tin-veins are the most ancient metalliferous veins in Cornwall; yet they are not all of one formation, but belong to two or more different systems. Their direction is, however, nearly the same, but some of them dip towards the north, and others towards the south. It was formerly thought by the Cornish miners that tin occurred in the upper portions of the mineral lodes only, and mines were abandoned, when in sinking the miners came to the 'yellows'—*copper pyrites*, which were said 'to have cut out the tin.' Within the last few years, however, tin has been found at very great depths below the surface and beneath the copper. Dolcoath Mine is a very remarkable example of this. This mine was first worked as a tin mine for a very long period; then as a copper mine for half a century; and then, upon persevering in depth, the lode was found to become more and more rich in tin, which is now worked to great advantage. Other mines in the same locality have presented similar conditions.

At Trevaunance Mine the two systems of tin-veins are, both, intersected by the oldest of the copper-veins; indicating the prior existence of the tin-veins. In *fig.* 1981, *b* marks the first system of tin-veins; *c* the second; and *d* the east and west copper-veins. Some of these tin-veins, as at Poldice, have been traced over an extent of two miles; and they vary in thickness from a small fraction of an inch to several feet, the average width being from 2 to 4 feet; though this does not continue uniform for any length, as these veins are subject to continual narrowings and expansions. The gangue is quartz, chlorite, tourmaline, and sometimes decomposed granite and fluor-spar.

1981

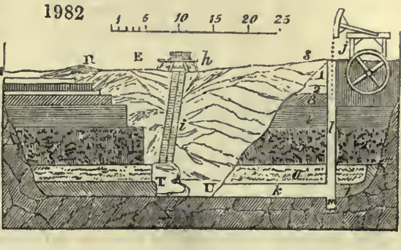


4. *Alluvial tin ore, Stream-tin.*—Peroxide of tin occurs disseminated both in the *alluvium* which covers the gentle slopes of the hills adjoining the rich tin mines, and also in the alluvium which fills the valleys that wind round their base; and in these deposits the tin-stone has been so abundant that for centuries the whole of the tin of Cornwall was derived from them; and it is still so to some extent. The most important explorations of *alluvial tin ore* are grouped in the environs of St. Just and St. Austell, where they are called *stream-works*, because water is the principal agent employed to separate the metallic oxide from the sand and gravel.

The most extensive and productive stream-works were formerly those of Pentewan, near St. Austell.

Fig. 1982 represents a vertical section of the Pentewan deposit, taken from the stream-work *Happy Union*, long since abandoned. A vast excavation, R, T, U, *s*, has been hollowed out in the open air, in quest of the alluvial tin ore T, which occurs here at an unusual depth, below the level of the strata R, *s*. Before getting at this deposit, several successive layers had to be sunk through, namely, 1, 2, 3, the gravel, containing in its middle a band of ochreous earth, 2, or ferruginous clay; 4, a black peat, perfectly combustible, of a coarse texture, composed of reeds and woody fibres, cemented into a mass by a fine loam; 5, coarse sea-sand, mingled with marine shells; 6, a blackish marine mud, filled with shells. Below these the deposit of tin-stone occurs, including fragments of various size, of clay-slate, flinty slate, quartz, iron ore, jasper; in a word, of all the rocks and gangues to be met with in the surrounding territory, with the exception of granite. Among these fragments there occurred, in rounded particles, a coarse quartzose sand, and the tin-stone, commonly in small grains and crystals. Beneath the bed T, is the clay-slate called *killas* (A, X, Y), which supports all the deposits of more recent formation.

1982



The system of mining employed in stream-works is very simple. The successive beds, whose thickness is shown in the figure, are visibly cut out into steps or platforms. By a level or gallery of efflux *k*, the waters flow into the bottom of the well *l*, *m*, which contains the drainage pumps; and these are put in action by a machine *j*, moved by a water-wheel. The extraction of the ore is effected by an inclined plane *i*, cut out of one of the sides of the excavation, at an angle of about 45 degrees. At the lower end of this sloping pathway there is a place of loading; and at its upper end *h*, a horse-gin, for alternately raising and lowering the two baskets of extraction on the pathway *i*.

Mine-tin—as distinguished from *Stream-tin*, the former being worked by the miner out of the lode—requires peculiar care in its mechanical preparation or dressing, on account of the presence of foreign metals, from which, as we have stated, stream-tin is free.

Tin ore, therefore, should be first of all pounded very fine in the stamp-mill, then subjected to reiterated washings, and afterwards calcined. The order of proceeding in Cornwall and other parts is fully described in the article DRESSING OF ORES. See also ROASTING, for a description of the roasting processes.

The tin ores of Cornwall and Devonshire are all smelted within the counties where they are mined: the vessels which bring the fuel from Wales, for smelting these ores, return to Swansea and Neath loaded with copper ores.

Australian Tin.—As far back as 1849 the Rev. W. B. Clarke, from the character of certain granites, predicted the occurrence of tin in New South Wales; and in 1853 he reported the actual discovery of tin ore near the Severn River. It was not, however, until recently that the tin ore of New South Wales and Queensland has been found in sufficient abundance to attract general attention. In New South Wales the tin-yielding district forms an elevated plateau of granitic rocks, associated with metamorphic slates and sandstones. The granite is, in places, traversed by veins of quartz, rich in tin-stone, and is capped by a deposit of tin-bearing detritus of variable thickness. The stanniferous district extends into the adjacent colony of Queensland, the ore having been traced over an area of about 550 square miles in the neighbourhood of the head-waters of the Severn River and its tributaries. The Queensland tin occurs partly in lodes associated with granitic rocks, and partly as stream-tin in beds of the rivers and in the alluvial flats on their banks.

From these new districts the following quantities have been obtained:—

In Victoria.—Tin has been found in the districts of Beechworth, Koetong, Upper Murray, Burrawa Creek, Yackandandah, Cudgewa Creek, La Trobe River, Corner Inlet, Chiltern, Mansfield, Foster, and Omea. In all cases the black tin has been obtained from alluvial deposits—generally termed 'black sand.' The quantity of tin produced in Victoria up to the end of 1873 has been as follows:—

	Tin Ore Tons	Tin Ore Cwts.	Tin lbs.
Previously up to December 31, 1872	3,831	16	139,648
From January 1 to December 31, 1873	174	16	109,312
Total . . .	4,006	12	248,960

The Tin district of *New South Wales* from the commencement of the workings for tin unto the present time :—

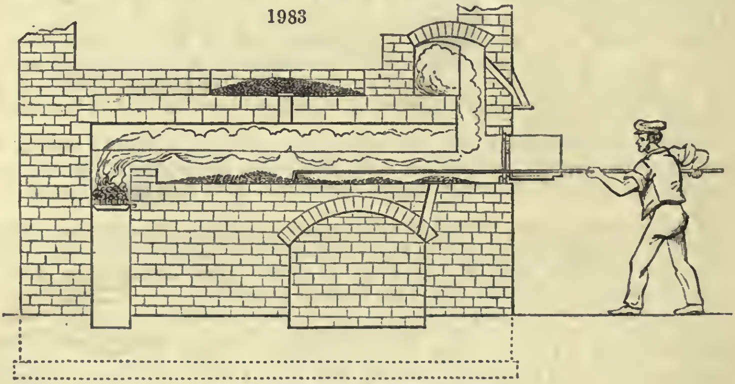
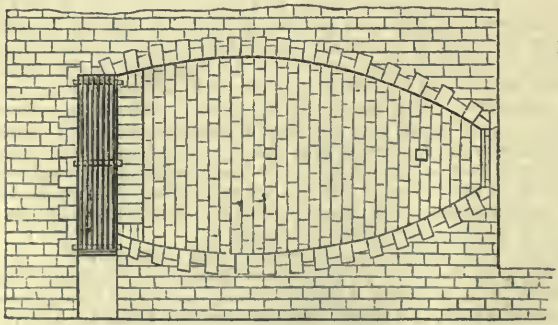
„	1,760	16 „ Sydney

Tasmania.—Tin ore has also been recently discovered at Mount Bischoff, in the north-western part of Tasmania. The ore is not only found as an alluvial deposit, but occurs in a porphyritic rock, resembling some of the Cornish elvans, and is in many places intimately associated with a gossany oxide of iron. It will be seen from the general statement of imports that a small quantity was sent from this colony. Large masses of tin have been found in the alluvial deposits, evidently derived from lodes ; and we understand some lodes have been discovered.

Tin Dressing.—Most of the tin ores in Cornwall have to be roasted, or calcined, before they are fit for the smelting-house, although in some mines the admixture with

1983



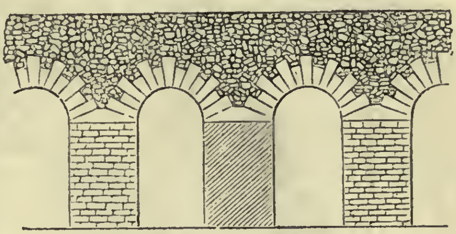


1984

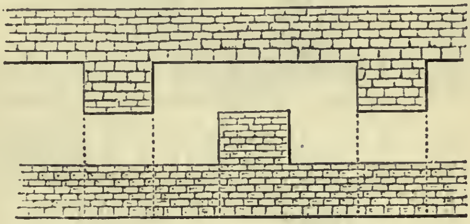
other minerals is so trifling that this operation is considered unnecessary. The furnace (*figs.* 1983, 1984) in which the roasting is carried on, is about 10 feet long, 5 feet 6 inches wide in the middle, and 3 feet wide near the mouth. The fireplace, it will be observed, is situated at the back, the flames playing through the oven and ascending the chimney, which is above the furnace-door. The man is represented in *fig.* 1983, as stirring the ore with a long iron rake. The ore, before it is submitted to the action of the fire, is thoroughly dried in a circular pit, placed immediately above the oven, into which it is let down through the opening, when it is considered to be ready for calcining. Beneath the oven and connected with it by an opening through which the ore when sufficiently roasted is made to pass, is an arched opening about 4 feet wide, termed the 'wrinkle.' Here the ore is collected, whilst another charge is being placed in the furnace. About 7 cwts. or 8 cwts. of ore is the quantity usually roasted at one time. Whilst undergoing this operation, dense fumes of arsenic and sulphur escape with the smoke from the fire, and pass through large flues, divided into several chambers (*figs.* 1985 to 1987) where the former is collected. The flue is often 70 yards long, and the greatest deposit of arsenic takes place at about 15 yards from the oven or furnace. Instead of being at once completely roasted, the 'whits' from the stamps are sometimes first 'rag' (or partially) burnt, for about six or eight hours. The object of this partial burning is to save time and expense, nearly three-fourths of it being thrown away after dressing it from the first burning.

1985

1986



1987



The machine called originally 'Brunton's Patent Calciner' (*fig.* 1988), for calcining tin ore, is gradually coming into use in Cornwall, and is adopted in many of the larger mines. Its operation may be thus briefly described :—A revolving circular table, usually 8 feet or 10 feet in diameter, turned by a water-wheel, receives through the hopper the tin-stuff to be roasted or calcined. The frame of the table is made of cast iron, with bands, or rings, of wrought iron, on which rests the fire-bricks composing the surface of the table. The flames from each of the two fireplaces pass over the ore as it lies on the table, which slowly revolves at the rate of about once in every quarter of an hour. In the top of the dome, over the table, are fixed three cast-iron frames, called the 'spider,' from which depend numerous iron coulters, or teeth, which stir up the tin-stuff, as it is carried round under them. The coulters on one of the arms of the 'spider' are fixed obliquely, so as to turn the ore downwards from one to the other—the last one at the circumference of the table, projecting the ore (by this time fully calcined) over the edge, into one of the two 'wrinkles' beneath. A simple apparatus called the 'butterfly,' moved by a handle outside the building, diverts the stream of roasted tin-stuff, as it falls from the table, either into one or the other as may be required. Unlike the operation of roasting in the oven previously described, the calciner requires little or no attention ; the only care requisite being to see that the hopper is fully supplied, and the roasted ore removed when necessary from the wrinkles.

For this description of the burning-house and of the calciner, we are indebted to Mr. James Henderson's communication to the Institution of Civil Engineers.

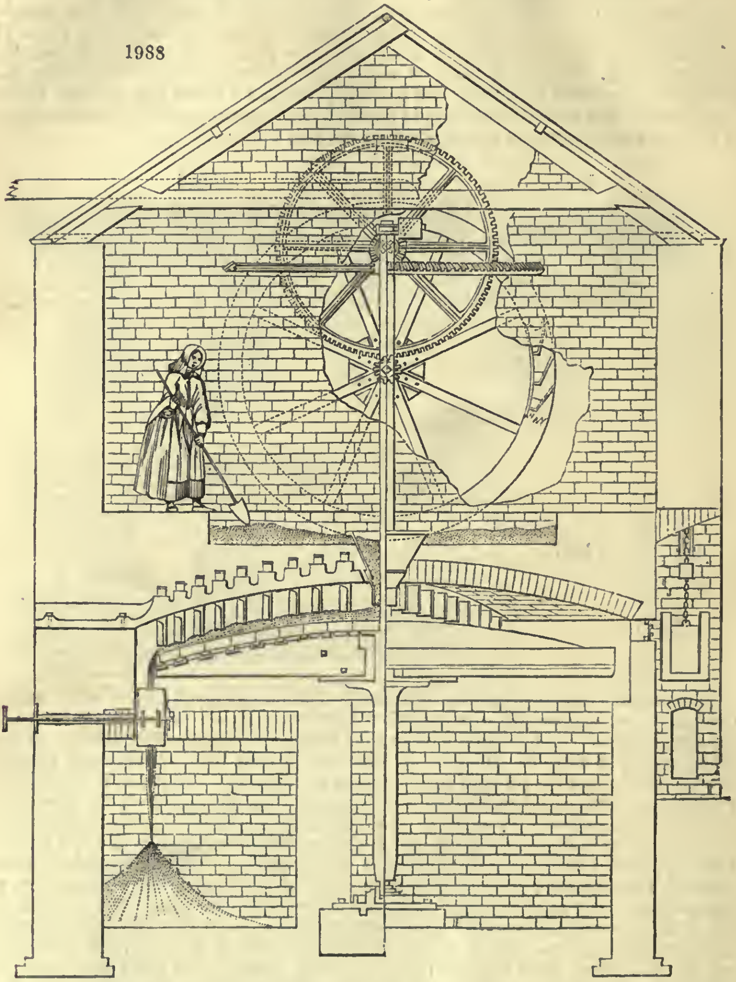
We have been favoured with the following notes on the action of Brunton's calciners, employed at Fabrica la Constanto, Spain, which are of great value, as are also the additional suggestions.

Diameter of revolving bed, 14 feet.

Revolution of bed per hour from 3 to 4, or about 1 foot of the circumference per minute.

Ores introduced by hopper, at the rate of 1 quintal to every revolution of table.
Quantity of ore calcined per day of 10 hours, 30 to 35 quintals.
Salt consumed, generally six per cent. of weight of ore.
Fuel consumed per 10 hours, 1,200 to 1,400 lbs. of pine-wood.
Power employed to revolve table, half horse.

1988



Remarks.—The furnace is charged with ore and salt by means of iron hoppers placed immediately over the centre of each of the hearths. For the supply of each hopper, a heap of about 14 quintals of ore, with 5 or 6 per cent. of salt, is prepared from time to time upon a small platform on the top of the furnaces, and a few shovelsful thrown in occasionally as required, taking care, however, always to have enough ore in the hopper to prevent the ascension of acid vapours, &c., from the furnace. The time the mineral remains in the furnace, and the quantity calcined per hour, must depend on the rapidity of motion of the revolving hearth, and the angle at which the iron stirrers are fixed.

The average amount passed through each furnace in 24 hours is about 84 quintals or 3½ quintals per hour. For every revolution of the bed, nearly 1 quintal is discharged from the furnace.

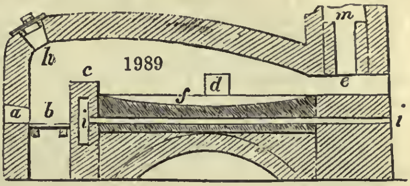
The smelting of tin ores has been effected by two different methods :—

In the first a mixture of the ore with anthracite was exposed to heat on the hearth of a reverberatory furnace fired with coal.

In the second, the tin ore was fused in a blast-furnace, called a blowing-house, supplied with wood-charcoal. This method is not now practised in England.

In the *smelting-houses*, where the tin is worked in reverberatories, two kinds of furnaces are employed; the reduction and the refining furnaces.

Figs. 1989 and 1990 represent the furnaces for smelting tin at Truro, in Cornwall: the former being a longitudinal section, the latter a ground plan. *a* is the fire-door, through which pitcoal is laid upon the grate *b*; *c* is the fire-bridge; *d*, the door for introducing the ore; *e*, the door through which the ore is worked upon the hearth *f*; *g*, the stoke-hole; *h*, an aperture in the vault or roof, which is opened at the discharge of the waste schlich, to secure the free escape of the fumes up the chimney; *i*, *i*, air-channels, for admitting cold air under the fire-bridge and the sole of the hearth, with the view of protecting them from injury by the intensity of the heat above. *k*, *k*, are basins into which the melted tin is drawn off; *l*, the flue; *m*, the chimney, from 35 to 50 feet high. The roasted and washed schlich is mixed with small coal or culm, along with a little slaked lime, or fluor-spar, as a flux; each charge of ore amounts to from 15 to 24 cwts., and contains from 60 to 70 per cent. of metal.



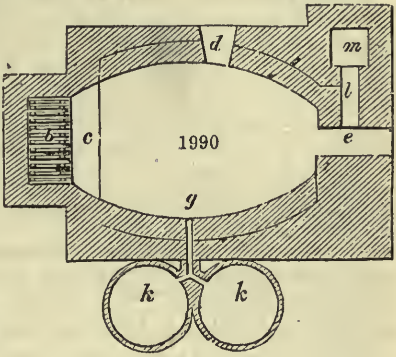


Fig. 1991 represents in a vertical section through the tuyère, and *fig.* 1992, in a horizontal section, in the dotted line *x*, *x*, of *fig.* 1991, the furnace employed for smelting tin at the Erzegebirge mines in Saxony. *a*, are the furnace-pillars, of gneiss; *b*, *b*, are shrouding or casing walls; *c*, the tuyère wall; *d*, front wall, both of granite; as also the tuyère *e*. *f*, the sole stone, of granite, hewn out basin-shaped; *g*, the *eye*, through which the tin and slag are drawn off into the fore-hearth *h*; *i*, the stoke-hearth; *k*, *k*, the light ash-chambers; *l*, the arch of the tuyère; *m*, *m*, the common flue, which is placed under the furnace and the hearths, and has its outlet under the vault of the tuyère.

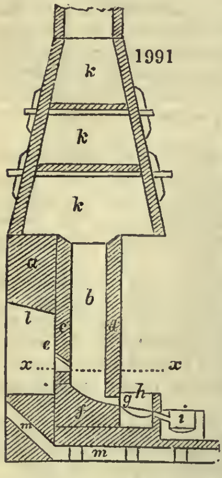
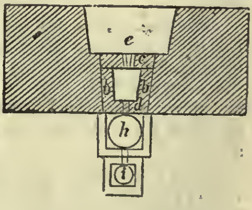


In the smelting-furnaces at Geyer the following dimensions are preferred: length of the tuyère wall, 11 inches; of the breast wall, 11 inches; depth of the furnace 17 inches. High chimney-stalks are advantageous where a great quantity of ores is to be reduced, but not otherwise.

The *refining furnaces* are similar to those which serve for reducing the ore; only, instead of a basin of reception, they have a refining basin placed alongside into which the tin is run. This basin is about 4 feet in diameter, and 32 inches deep; it consists of an iron pan, placed over a grate, in which a fire may be kindled. Above this pan there is a turning gib, by means of which a billet of wood may be thrust down into the bath of metal, and kept there by wheeling the gibbet over it, lowering a rod, and fixing it in that position.

1992



Formerly in Cornwall nearly all the tin was smelted in blast-furnaces; these works were called *blowing-houses.* The smelting-furnaces were 6 feet high from the bottom of the crucible (concave hearth) to the throat, which is placed at the origin of a long and narrow chimney, interrupted by a chamber, where the metallic dust carried off by the blast was deposited. This chamber was not placed vertically over the furnace; but the lower portion of the chimney had an oblique direction from it. The furnace was lined with an upright cylinder of cast iron, coated internally with loam, with an opening in it for the blast. This opening, which corresponds to the lateral face opposite to the charging side, receives a tuyère, in which the nozzles of two cylinder single bellows, driven by a water-wheel, were planted. The tuyère opens at a small height above the sole of the furnace. On a level with the sole, the iron cylinder presents a slope, below which was the hemispherical basin of reception, set partly beneath the interior space of the furnace, and partly without. Near the corner of the building there was a second basin of reception, larger than the first, which could discharge itself into the former, by a sloping gutter. Near this basin there was another, for the refining operation. These were all made either of brick or cast iron. Such blast-furnaces are now entirely superseded in this country by the reverberatory furnace.

The quality of the average ground tin ore prepared for smelting is such that 20 parts of it yield from 12½ to 13 of metallic tin (62½ to 65 per cent.) The treatment consists of two operations, *smelting* and *refining*.

First operation; deoxidisation of the ore, and fusion of the tin.—Before throwing the ore into the smelting furnace, it is mixed with from one-fifth to one-eighth of its weight of *blind coal*, in powder, called *culm*; and a little slaked lime is sometimes added, to render the ore more fusible. These matters are carefully blended, and damped with water to render the charging easier, and to prevent the draught from sweeping any of it away at the commencement. From 20 to 25 cwts. are introduced at a charge; and the doors are immediately closed and luted, while the heat is progressively raised. Were the fire too strong at first, the tin oxide would unite with the quartz of the gangue, and form an enamel. The heat is applied for 6 or 8 hours, during which the doors are not opened; of course the materials are not stirred. By this time the reduction is in general finished; the door of the furnace is removed, and the melted mass is worked up to complete the separation of the tin from the scoriæ, and to ascertain if the operation be in sufficient forwardness. When the reduction seems to be finished, the scoriæ are taken out at the same door, with an iron rake, and divided into three sorts: those of the first class A, which constitute at least three-fourths of the whole, are as poor as possible, and may be thrown away; the scoriæ of the second class B, which contain some small grains of tin, are sent to the stamps; those of the third class C, which are last removed from the surface of the bath of tin, are set apart, and re-smelted, as containing a considerable quantity of metal in the form of globules. These scoriæ are in small quantity. The stamp-slag contains fully 5 per cent. of metallic tin.

As soon as the scoriæ are cleared away, the channel is opened which leads to the basin of reception, into which the tin consequently flows out. Here it is left for some time, that the scoriæ which may be still mixed with the metal may separate, in virtue of the difference of their specific gravities. When the tin has sufficiently settled, it is lifted out with ladles, and poured into cast-iron moulds, in each of which a bit of wood is fixed, to form a hole in the ingot, for the purpose of drawing i out when it becomes cold.

Refining of Tin.—The object of this operation is to separate from the tin, as completely as possible, the metals reduced and alloyed along with it. These are, principally, iron, copper, arsenic, and tungsten; to which are joined, in small quantities, some sulphides and arsenides that have escaped decomposition, a little unreduced oxide of tin, and also some earthy matters which have not passed off with the scoriæ.

Liquation.—The refining of tin consists of two operations; the first being a liquation, which, in the interior, is effected in a reverberatory furnace similar to that employed in smelting the ore (*figs.* 1989, 1990). The blocks being arranged on the hearth of the furnace, near the bridge, are moderately heated; the tin melts, and flows away into the refining-basin; but, after a certain time, the blocks cease to afford tin, and leave on the hearth a residuum, consisting of a very ferruginous alloy.

Fresh tin-blocks are now arranged on the remains of the first; and thus the liquation is continued till the refining-basin be sufficiently full, when it contains about 5 tons. The residuums are set aside, to be treated as shall be presently pointed out.

Refining proper.—Now begins the second part of the process. Into the tin-bath billets of green wood are plunged, by the aid of the gibbet above described. The disengagement of gas from the green wood produces a constant ebullition in the tin; bringing up to its surface a species of froth, and causing the impurest and densest parts to fall to the bottom. That froth, composed almost wholly of the oxides of tin and foreign metals, is successively skimmed off, and thrown back into the furnace. When it is judged that the tin has boiled long enough, the green wood is lifted out, and the bath is allowed to settle. It separates into different zones, the upper being the purest; those of the middle are charged with a little of the foreign metals; and the lower are much contaminated with them. When the tin begins to cool, and when a more complete separation of its different qualities cannot be looked for, it is lifted out in ladles, and poured into cast-iron moulds. It is obvious that the order in which the successive blocks are obtained is that of their purity; those formed from the bottom of the basin being usually so impure that they must be subjected anew to the refining process, as if they had been directly smelted from the ore.

The refining operation takes five or six hours; namely, an hour to fill the basin, three hours to boil the tin with the green wood, and from one to two hours for the subsidence.

Sometimes a simpler operation, called *tossing*, is substituted for the above artificial ebullition. To effect it a workman lifts some tin in a ladle, and lets it fall back into the boiler from a considerable height, so as to agitate the whole mass. He continues this manipulation for a certain time; after which, he skims with care the surface of the bath. The tin is afterwards poured into moulds, unless it be still impure. In this case the separation of the metals is completed by keeping the tin in a fused state in the boiler for a certain period, without agitation; whereby the upper portion of the bath (at least one-half) is pure enough for the market.

The moulds into which the tin-blocks are cast are usually made of granite. Their capacity is such, that each block shall weigh a little more than 3 cwts. This metal is called 'block tin.' The law requires them to be stamped or *coined* by public officers, before being exposed to sale. The purest block tin is called 'refined tin.'

The treatment just detailed gives rise to two stanniferous residuums, which have to be smelted again. These are—

1. The scoriæ B and C, which contain some granulated particles of tin.
2. The dross found on the bottom of the reverberatory furnace, after re-melting the tin to refine it.

The scoriæ C are smelted without any preparation; but those marked B are stamped in the mill, and washed, to concentrate the tin-grains; and from this rich mixture, called *prillion*, smelted by itself a tin is procured of very inferior quality. This may be readily imagined, since the metal which forms these granulations is what, being less fusible than the pure tin, solidified quickly, and could not flow off into the metallic bath.

Whenever all the tin-blocks have thoroughly undergone the process of liquation, the fire is increased, to melt the less fusible residuary alloy of tin with iron and some other metals, and this is run out into a small basin, totally distinct from the refining-basin. After this alloy has reposed for some time, the upper portion is lifted out into block-moulds, as impure tin, which needs to be refined anew. On the bottom and sides of the basin there is deposited a white, brittle alloy, with a crystalline fracture, which contains so great a proportion of foreign metals that little use can be made of it. About 3½ tons of coal are consumed in producing 2 of tin.

Summary of Produce of Tin in Cornwall and Devon for each of the ten years ending 1873.

Year	No. of mines	Tin ore		Metallic tin	
		Quantity	Value	Quantity	Value
		Tons	£	Tons	£
1864	174	13,985	881,031	9,295	995,029
1865	156	14,122	782,284	9,038	873,659

To test the quality of tin, dissolve a certain weight of it with heat in hydrochloric acid; should it contain arsenic, brown-black flocks will be separated during the solution, and arseniuretted hydrogen gas will be disengaged, which, on being burned at a jet, will deposit the usual grey film of metallic arsenic upon a white saucer held a little way above the flame. Other metals present in the tin are to be sought for by treating the above solution with nitric acid of spec. grav. 1·16, first in the cold, and at last with heat and a small excess of acid. When the action is over, the supernatant liquid is to be decanted off the peroxidised tin, which is to be washed with very dilute nitric acid, and both liquors are to be evaporated to dissipate the acid excess. If, on the addition of water to the concentrated liquor, a white powder falls, it is a proof that the tin contains bismuth; if, on adding sulphate of ammonia, a white precipitate appears, the tin contains lead; water of ammonia added to supersaturation will occasion reddish-brown flocks, if iron is present; and on evaporating the supernatant liquid to dryness, the copper will be obtained.

[1] 1,000 Banca slabs weigh about 22 tons; the average weight of 1,000 slabs Straits tin being from 35 to 40 tons. The weight of the Billiton slabs is the same as the Banca.

Tin in Ingots, blocks, bars, slabs or regulus, *Imported* in 1874, 184,377 cwts.; value 904,488*l.*

Tin unwrought *Exported* in 1874, 155,068 cwts.; value 813,305*l.*

For the purification of tin from tungsten, see TUNGSTEN.

The uses of tin are very numerous. Combined with copper, in different proportions, it forms Bronze, and a series of other useful alloys; for an account of which, see COPPER. With iron, it forms Tin-plate; with lead, it constitutes Pewter, and Solder of various kinds. (See LEAD.) Tin-foil coated with quicksilver makes the reflecting surface of glass mirrors. (See GLASS.) Nitrate of tin affords the basis of the scarlet dye on wool, and of many bright colours to the calico-printer and the cotton-dyer. (See SCARLET and TIN-MORDANTS.) A compound of tin with gold gives the fine crimson and purple colours to stained glass and artificial gems. (See PURPLE OF CASSIUS.) Enamel is made by fusing oxide of tin with the materials of flint glass. This oxide is also an ingredient in the white and yellow glazes of pottery-ware. See PUTTY POWDER.

TIN ASSAYING. The ore of tin submitted to assay is Cassiterite, peroxide of tin or black tin. When the ore is poor it must be submitted to a washing, vanning, or other concentration process, to separate the peroxide of tin from vein-stuff before submitting it to the assay. If the ore is associated with iron pyrites, copper pyrites, or other foreign metalliferous matters, it must be calcined or treated with acids, before submitting it to the final washing process. The assays are made by the dry method.

a. Cornish method. This process is conducted in black-lead crucibles in an air-furnace similar to that described in COPPER (*Fig.* 533). Two ounces (960 grs.) of the ore are mixed with about one-fifth of its weight of culm or anthracite powder, or charcoal, and heated for about twenty minutes at a high temperature; the reduced metal is now poured out into a long flat ingot-mould. The slaggy residue is then scraped out from the pot, and any shots of metal separated by pounding and washing, and the total weight of metal ascertained. A small quantity of borax or fluor-spar is added when necessary to render the slag fluid. The assay may also be made in earthen crucibles.

b. By Fusion with Cyanide of Potassium. This process is conducted in earthen or porcelain crucibles: 100 grs. of the black tin is a convenient quantity to operate on. The ore is mixed with from four to six times its weight of cyanide of potassium, and the crucible and its contents exposed to a low red heat for about 20 minutes. The contents are poured out into the iron mould (*fig.* 534, see COPPER), and when cold the button of tin is detached from the slag, cleaned and weighed.

TINCAL. The Oriental name for crude borax. Under this name considerable quantities are brought from the East Indies. But the largest quantities are obtained from the lagoons near Monte Cerbole in Tuscany. Recently, tincal of a very fine quality has been discovered in California. A lake in Colorado Territory contained so much of the bi-borate of soda that it was found crystallised out around the edges, but was soon exhausted. See BORAX.

TINCTORIAL MATTER. The colouring-matter employed in dyeing. See DYEING; MADDER; TURKEY RED, &c.

TINCTURE is a title used by apothecaries to designate alcohol, in a somewhat dilute state, impregnated with the active principles of either vegetable or animal substances.

TINDER ORE. (*Zundererz*, Ger.) An impure arsenical sulphide of antimony. It is found at Andreasberg in the Hartz, in soft flexible flakes resembling tinder, of a dirty reddish colour and with little lustre.

TINE, *in metallurgy*, a modification of the *Trompe* adopted by the French.

TIN GLANCE is an old name of bismuth. See BISMUTH.

TIN-MORDANTS for dyeing scarlet. See MORDANT.

Mordant A, as commonly made by the dyers, is composed of 3 parts of nitric acid, 1 part of common salt or of sal-ammoniac, and 1 of granulated tin. This preparation is very uncertain.

Mordant B. Pour into a glass globe with a long neck, 3 parts of pure nitric acid at 30° B., and 1 part of muriatic acid at 17°; shake the globe gently, avoiding the corrosive vapours, and put a loose stopper in its mouth. Throw into this nitro-muriatic acid, one-eighth of its weight of pure tin, in small bits at a time. When the solution is complete, and settled, decant it into bottles, and close them with ground stoppers. It should be diluted only when about to be used.

Mordant C, by Dambourney.—In 2 drams (Fr., 144 grs.), of pure muriatic acid, dissolve 18 grains of Malacca tin. This is reckoned a good mordant for brightening or fixing the colour of peachwood.

Mordant D, by Hellot.—Take 8 ounces of nitric acid, diluted with as much water; dissolve in it half an ounce of sal-ammoniac, and 2 drams of nitre. In this acid solution dissolve 1 ounce of granulated tin of Cornwall, observing not to put in a fresh piece till the preceding be dissolved.

Mordant E, by Scheffer.—Dissolve 1 part of tin in 4 of nitro-muriatic acid, prepared with nitric acid diluted with its own weight of water, and one thirty-secondth of sal-ammoniac.

Mordant F, by Poerner.—Mix 1 pound of nitric acid with 1 pound of water, and dissolve it in an ounce and a half of sal-ammoniac. Stir it well, and add, by very slow degrees, 2 ounces of tin turned into thin ribbons upon the lathe.

Mordant F, by Berthollet.—Dissolve in nitric acid of 30° B., one-eighth of its weight of sal-ammoniac, then add by degrees one-eighth of its weight of tin, and dilute the solution with one-fourth of its weight of water.

Mordant K, by Dambourney.—In 1 dram (72 grs.) of muriatic acid at 17°, one of nitric acid at 30°, and 18 grains of water, dissolve slowly, and with some heat, 18 grains of fine Malacca tin.

Mordant L, is the birch-bark prescribed by Dambourney. This bark, dried, and ground, is said to be a very valuable substance for fixing the otherwise fugitive colours produced by woods, roots, archil, &c.

TIN-PLATES. The art of coating copper with tin seems to have been known at an early period. Pliny refers to this, and from his description it is probable the vessels to be covered were dipped into melted tin, and the '*vasa stannea*' of the Romans were copper vessels covered with tin. The difficulty of coating iron with tin was, however, much greater; and the process of hammering the iron into sheets sufficiently thin, and cleaning the surface, which latter work had often to be done by filing, were serious hindrances to the extensive use of the invention.

The art of tinning iron appears to have been first practised in Bohemia, and about the year 1620 to have been introduced into Saxony.

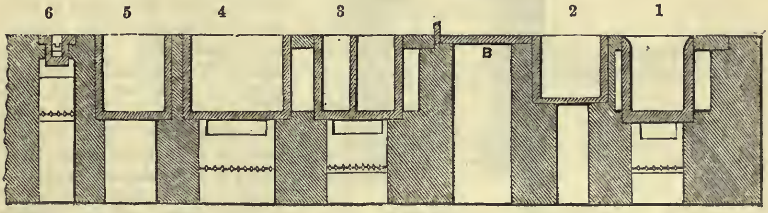
Beckmann states that, 'in the year 1670, a company sent to Saxony, at their expense, an ingenious man named Andrew Yarrenton, in order to learn the process of tinning. Having acquired the necessary knowledge, he returned to England with some German workmen, and manufactured tin-plate which met with general approbation. Before the company could carry on business on an extensive scale, a man of some distinction, having made himself acquainted with Yarrenton's process, obtained a patent for his art, and the first undertakers were obliged to give up their enterprise, which had cost them a great deal of money, and yet no use whatever was made of the patent which had been obtained.' About the year 1720 works for the manufacture of tin-plates were established at Pontypool, and these seem to be the earliest of such works in England which were permanently successful.

In 1728, John Payne invented a process for rolling iron. This seems to have at once led to the use of the flat or sheet rolls for the manufacture of iron for tin-plates; but it is very remarkable that no further progress was made in this discovery of rolling iron until 1783, when Henry Cort invented the grooved rolls. This discovery was not appreciated for some years. Mr. Reynolds, of Ketley, erected Cort's rolls in 1785. In 1790 Henry Cort was engaged by Mr. Richard Crawshay to erect the mills at Cyfarthfa, and, soon after, this important improvement in the iron manufacture was generally adopted. The writer proposes to give in this paper a short *résumé*, first, of the process for cleaning and tinning the iron-plate, and after, of the methods of preparing the iron for this purpose.

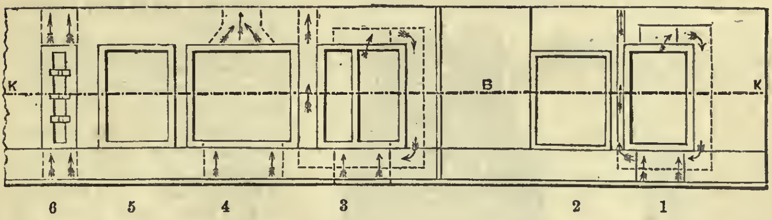
The affinity of iron for tin is much greater than is generally supposed. The point at which the metals cohere is no doubt an *actual alloy;* and advantage is taken of this by the manufacturers of articles for domestic use, made in iron—as bridle-bits, common stirrups, small nails, &c. When the iron, whether wrought or cast, *is perfectly clean and free from rust*, and brought in contact with melted tin, at a high temperature, an alloy seems to be at once formed, protecting the iron from oxidisation whilst the tin lasts. Many plans are used for tinning iron articles, of small size, by the manufacturers. One of the common methods of the manufacturers of bridle-bits and small ware, in South Staffordshire, is to clean the surface of the articles to be tinned, by steeping them for sufficient time in a mixture of sulphuric and hydrochloric acids, diluted with water, then washing them well with water, but taking great care they do not rust, at once placing them in a partially closed stoneware vessel (such as a common bottle), which contains a mixture of tin and sal-ammoniac. This vessel is then placed on a smith's hearth, duly heated, and frequently agitated to secure the complete distribution of the tin over the iron. The articles, when thus tinned, are thrown into water to wash away all remains of the sal-ammoniac; and lastly, cleaned in hot bran, or sawdust, to improve the appearance for sale.

The plans of cleaning and preparing the iron for tinning have undergone many changes in the past century. About 1720 the plan of cleaning was to scour the plates with sand and water, and file off the rough parts, then cover with resin, and dip them in the melted tin. About 1747 the plates were, after being cold-rolled, soaked for a week in the lees of bran, which had been allowed to stand in water about ten days, to become, by fermentation sufficiently acid, and then scoured with sand and water. In 1760 the plates were pickled in dilute hydrochloric acid before annealing, and cleaned with dilute sulphuric acid after being taken out of the bran lees. An improvement of great importance in this process was made about 1745; the inventor seems to have been Mr. Mosely, who carried on tin-plate works in South Staffordshire. This invention was the use of the grease-pot, and in this department little, if any, improvement has since been made. The plan was introduced into South Wales in 1747 by Mr. John Jenkins, and his descendants are still amongst the principal manufacturers in the trade. The process of cleaning and tinning at some of the best works now is as follows:—When the sheet iron leaves the plate-mill, and after separating the plates, and sprinkling between each plate a little sawdust, the effect of which is to keep them separate, they are then immersed, or as technically termed 'pickled,' in dilute sulphuric acid, and after this placed in the annealing-pot, and left in the furnace about 24 hours; on coming out, the plates are passed through the cold rolls; after passing the cold rolls, the plates seem to have too much the character of steel, and are not sufficiently ductile: to remedy this they are again annealed at a low heat, washed in dilute sulphuric acid, to remove any scale of oxide of iron, and scoured with sand and water; the plates in this state require to be perfectly clean and bright, and may be left for months immersed in pure water without rust or injury; but a few minutes' exposure to the air rusts them. With great care to have them perfectly clean, they are taken to the stow, *fig.* 1993, being a section through the line K K of the plan *fig.* 1994. Taken from right to left, 1 represents the tinman's pan; 2, the tin-pot; 3, the washing or dipping pot; 4, the grease-pot; 5, the cold pot; 6, the list pot.

1993

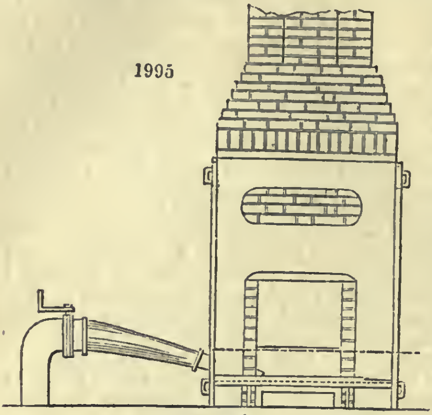


1994

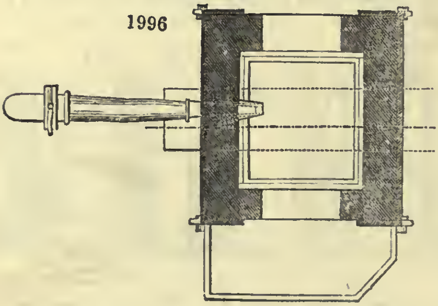


The tinman's pan is full of melted grease: in this the plates are immersed, and left there until all aqueous moisture upon them is evaporated, and they are completely covered with the grease; from this they are taken to the tin-pot, and there plunged into a bath of melted tin, which is covered with grease; but as in this first dipping the alloy is imperfect, and the surface not uniformly covered, the plates are removed to the dipping or wash pot; this contains a bath of melted tin covered with grease, and is divided into two compartments. In the larger compartment the plates are plunged, and left sufficiently long to make the alloy complete, and to separate any superfluous tin which may have adhered to the surface; the workman takes the plate and places it on the table marked B on the plan and wipes it on both sides with a brush of hemp; then to take away the marks of the brush, and give a polish to the surface, he dips it in the second compartment of the washing pot. This last always contains the purest tin, and as it becomes alloyed with the iron it is removed on to the first compartment, and after to the tin-pot. The plate is now removed to the grease-pot (No. 4); this is filled with melted grease, and requires very skilful management as to the temperature it is to be kept at. The true object is to allow any superfluous tin to run off, and to prevent the alloy on the surface of the iron plate cooling quicker than the iron. If this were neglected the face of the plate would be cracked. The plate is removed to the cold pot (No. 5): this is filled with tallow, heated to a comparatively low temperature. The use of the grease-pots, Nos. 4 and 5 is the process adopted in practice for annealing the alloyed plates. The list pot (No. 6) is used for the purpose of removing a small wire of tin, which adheres to the lower edge of the plate in all the foregoing processes. It is a small cast-iron bath, kept at a sufficiently high temperature, and covered with tin about one-fourth of an inch deep. In this the edges of the plates are dipped, and left until the wire of tin is melted, and then detached by a quick blow on the plate with a stick. The plates are now carefully cleaned with bran to free them from grease. Lastly, they are taken to the sorting-room, where every plate is separately examined and classed, and packed in boxes for market as hereafter described.

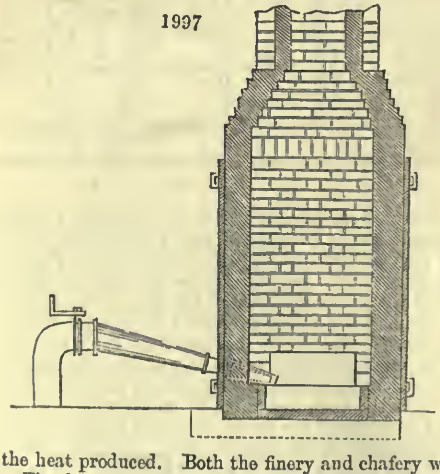
1995



1996



1997



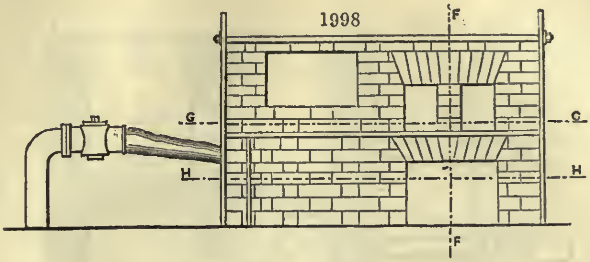
The tests of quality for tin-plates are—ductility, strength, and colour. To obtain these, the iron must be of the best quality, and the manufacture must be conducted with proportionate skill. This necessity will explain to some extent the cause why nearly all the improvements in working iron during the past century have been either originated or first adopted by the tin-plate makers, and a sketch of the processes used at different times, in working iron for tin-plates, will be, in fact, a history of the trade.

The process of preparing the best or charcoal iron seems to have undergone but little change from 1720 to 1807. The finery, the chafery, and the hammer, were the modes of bringing the iron from the pig to the state of finished bars. The finery was of the exact form of the *figs.* 1995, 1996, 1997, but less in size than those now used. The chafery or hollow fire was, in fact, the same as the present smiths' forge fire, but on a larger scale; and the '*hollow*,' or chamber, in which the bloom was heated, was made by coking the coal in the centre with the blast, and taking care not to disturb the mass of coal above, which was used to reverberate the heat produced. Both the finery and chafery were worked by blast.

The hammers were of two descriptions: the forge hammer, a heavy mass for shaping the blooms, and the tilt hammer, much lighter and driven quicker, for shaping the bars.

The charge for the finery was about 1½ cwt. of pig-iron; this, under the first process, was reduced to $1\frac{1}{4}$ cwt. It was, when ready, put under the forge hammer, and shaped into a 'bloom,' about 2 feet long and 5 inches thick; this was then heated

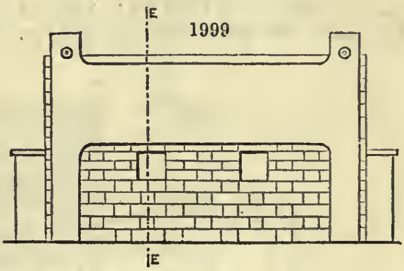
1998



in the chafery, and under the tilt hammer drawn out to a 'bar,' 3 to 4 inches wide, and half an inch thick.

The manufacture up to this point was formerly carried on by the iron-masters, and the iron in this state was sold under the name of 'tin bars' to the plate-makers. The average price for these bars, from 1780 to 1810, was 21*l.* per ton. The sheet and cold rolls were then in use nearly as at the present time.

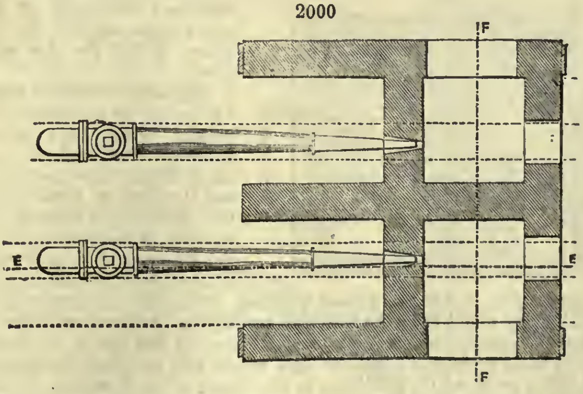
1999



In 1807, Mr. Watkin George, whose position had been established as one of the first engineers of his time, by the erection of the great water-wheel and works at Cyfarthfa, removed to Pontypool, and undertook the remodelling of the old works there. He clearly saw that the secret of the manufacture was to produce the largest possible quantity with least possible machinery and labour. His inventions, to this end, worked a complete change in the trade. His plans were: to first reduce the pig-iron in a finery under coke, and then bring this 'refiners' metal' (so termed) into the charcoal finery. The charcoal finery was built as shown in *figs.* 1995, 1996, and 1997: *fig.* 1995 being a front elevation, *fig.* 1996 a horizontal, and *fig.* 1997 a vertical section.

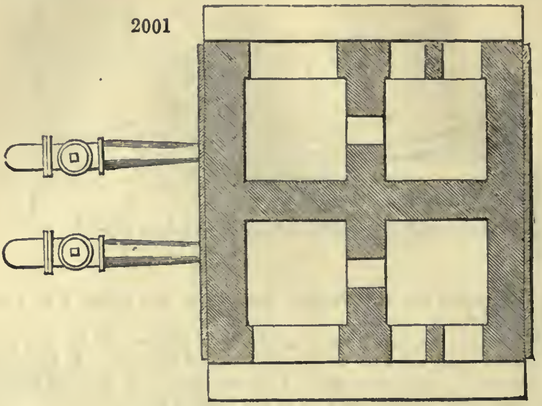
A charge of 3 cwts. of iron was used in this, and as it became malleable it was reduced under the hammer to what he termed a 'stamp:' this was a piece of iron

2000



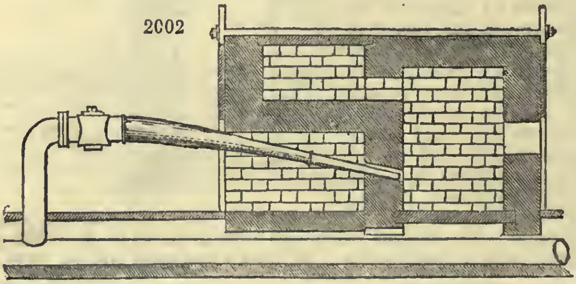
about 1 inch thick, and of any shape horizontally. It was next broken in pieces of a convenient size, and about 84 lbs. were 'piled' on a flat piece of tilted iron, with a handle about 4 feet long. This rough shovel, or holder, was called the 'portal,' or the 'staff.' To re-heat this 'pile' in the chafery would be a work of great

2001



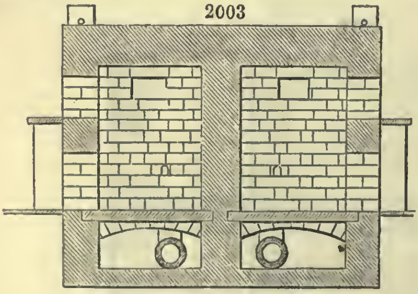
cost and difficulty, and the brick hollow fire (as shown in *figs.* 1998 to 2003; *figs.* 1998 and 1999 being elevations, and *figs.* 2000, 2001, 2002, and 2003 sections)

2002



was invented. This is, the writer believes, one of the inventions which, although in work during the past fifty years, still points to very great improvements in the manufacture of iron. It is in substance the plan of using the gases produced by the decomposition of fuel for the working of iron.

2003



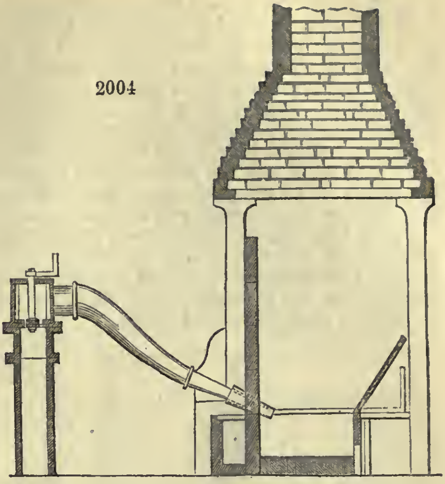
The *charcoal finery* is also worked by the use of the gases to a much greater extent than is generally known. The workman sends his blast directly into the mass of iron, and the charcoal seems to be simply the means by which he is better enabled to manipulate the iron in the finery, and keep it covered, so as to revive the oxidised metal, and thus prevent waste. A few hours spent with any intelligent workman at the side of his charcoal finery would show the wasteful and expensive character of the so-called *new* schemes for converting cast- into wrought-iron by the use of air alone. The late belief in these schemes, by men of high repute and practical knowledge in the trade is a direct proof of the deficiency in knowledge of exact science as at present applied to the manufacture of iron.

The pile was now placed in the hollow fire, and brought to a soft welding or washing heat; again hammered out to 'slabs,' 6 inches wide and three-quarters of an inch thick; these were re-heated, cut up, and afterwards passed through rolls, reducing them to 'bars,' 6 inches by half an inch. These were known in the trade as 'hollow fire iron,' or 'tin-bars.' The result of Mr. Watkin George's improvements was, to reduce the cost and double the production with the same outlay in machinery. All the tin-plates made at this time had the great defect of a rough and smooth side. In the year 1820, Mr. Wm. Daniell found a mode to remedy this defect. Himself a maker of tin-bars and plates, he had observed that the smooth side of the plate was always that corresponding to the flat part of the 'portal,' or 'staff;' he at once, having ascertained this cause, remedied the defect by hammering out the pile, notching it, and doubling it over, so that the tilted blade of the 'staff' was on the top as well as the bottom of the pile. This was the invention of 'tops and bottoms,' and the writer need not remind practical men of the immense sums made by this discovery during the past fifty years.

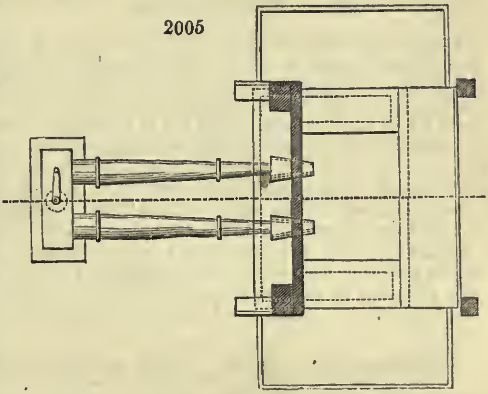
Another improvement since 1807, is the use of the running-out fire; it is still adopted in only a few works. This is represented by *figs.* 2004, 2005, and 2006. *Fig.* 2004 is a vertical section; *fig.* 2005 a horizontal section; and *fig.* 2006 a front elevation. This process saves waste of heat and labour, by running the refined metal at once into the charcoal-finery.

The 'tin-bars' before referred to, 6 inches by half an inch, are heated and run through rollers until they form a sheet of sufficient width; this sheet is then doubled and passed through the rolls, and this repeated until this sheet is quadrupled,—the laminæ are then cut to size, and separated as before described. The writer asks careful attention to the fact, that the last part of the rolling is done when the iron

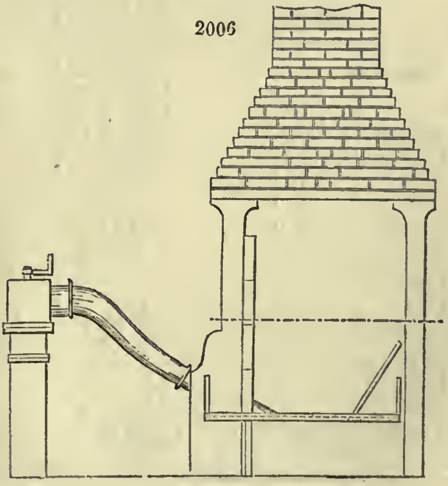
2004



2005



2006

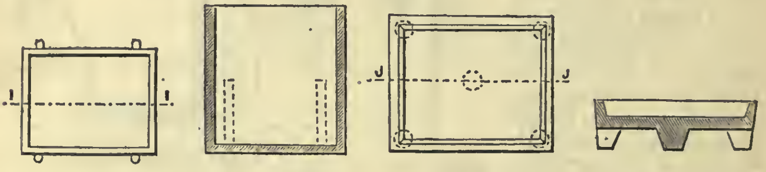


is nearly cold. These sheets are next annealed, and were formerly bent separately by hand, into a saddle, forming two sides of a triangle, thus Λ, and placed in a reverberatory furnace, so that the flame should play amongst them, and heat them to redness; they were then plunged into a bath of muriatic acid, or sulphuric acid and water, for a few minutes, taken out, and drained on the floor, and again heated in a furnace; after which, a scale of oxide of iron separates from the plate during the work of bending them again straight, on a cast-iron block.

The plates should be now free from rust or scale, and are then passed cold through the chilled rolls: this last process is most important, as the ductility and the strength and colour of the tin-plate depend upon this; at this point bad iron will crack or split, and any want of quality in the iron, or skill in the manufacture, will be shown.

A great improvement in the process of annealing was made in 1829 by Mr. Thomas Morgan: the plates were piled on a stand, and covered with a cast-iron box, now termed an 'annealing pot;' in this they were exposed to a dull red heat in a reverberatory furnace for 24 hours. This annealing pot with its stand is represented by *fig.* 2007, in plan and vertical section.

2007



A very important invention in the manufacture of iron for tin-plates, was made by Mr. William Daniell in 1845. About 2½ cwts. of refined metal is placed in the charcoal-finery; this is taken out in one lump, put under the hammer and 'nobbled,' then passed at once through the balling rolls, and reduced to a bar 6 inches square and about 2 feet 6 inches long. This bar is either cut or sawed off in pieces 6 inches long, and these rolled endways to give a bar about 6 inches wide, 2½ inches thick, and 12 inches long, and in this state the inventor calls it 'a billet.' This is heated in a small balling furnace and rolled down to a bar one-quarter inch thick and eleven inches wide, and will be about six feet long. This is taken at once to the tin-plate mill, and the process saves great expense in fuel and machinery.

By the old method of annealing, a box of tin-plates required about 13 lbs. of tin. This is now done with about 9 lbs. for charcoal and 8 lbs. for coke plates.

In referring to tin-plates the standard for quotation is always taken as 1 C. (Common, No. 1.) This is a box containing 225 plates, which should weigh exactly 112 lbs.

The following are the Marks, Weights, and Measurement of the Tin Plates now in common use:—

One of the great items of expense in the manufacture of best iron, as before described, is the cost of charcoal for the fineries. About 1850 the attention of Mr. Rogers was directed to the use of a substitute for charcoal in the finery. Careful thought and experiment led him to the conclusion that some coals could be charred in such a way as to produce a mechanical structure analogous to charcoal, and at the same time when deprived of sulphur might be used in the finery. These experiments resulted in the manufacture of '*charred coal.*' This material has been worked at several of the principal manufactories in South Wales, and declared equal in every respect to charcoal.

The preparation of the '*charred coal*' is very simple. The coal is first reduced to small, and washed by any of the ordinary means: it is then spread over the bottom of a reverberatory furnace to a depth of about 4 inches; the bottom of a furnace is first raised to a red heat. When the small coal is thrown over the bottom a great volume of gases is given off, and much ebullition takes place: this ends in the production of a light spongy mass which is turned over in the furnace, and drawn in about one hour and a half. To completely clear off the sulphur, water is now freely sprinkled over the mass until all smell of the sulphuretted hydrogen gas produced ceases. The result is 'charred coal.' The quantities of 'charred coal' hitherto produced have been made on the floor of an ordinary coke oven, whilst red hot after drawing the charge of coke.

Tin Coating of Iron and Zinc, by Mr. Morries Stirling's patent process. For this purpose the sheet, plate, or other form of iron, previously coated with zinc, either by dipping or depositing from solutions of zinc, is taken; and, after cleaning the surface by washing in acid or otherwise, so as to remove any oxide or foreign matter which would interfere with the perfect and equal adhesion of the more fusible metal or alloy with which it is to be coated, it is dipped into melted tin, or any suitable alloy thereof, in a perfectly fluid state, the surface of which is covered with any suitable material, such as fatty or oily matters, or the chloride of tin, so as to keep the surface of the metal free from oxidation; and such dipping is to be conducted in a like manner to the process of making tin-plate or of coating iron with zinc. When a fine surface is required, the plates or sheets of iron coated with zinc may be passed between polished rolls (as already described) before and after, or either before or after they are coated with tin or other alloy thereof. It is preferred in all cases to use for the coating pure tin of the description known as 'grain tin.'

Another part of the invention consists in covering, either wholly or in part, zinc and its alloys with tin, and such of its alloys as are sufficiently fusible. To effect this, the following is the process adopted:—A sheet or plate of zinc (by preference such as has been previously rolled, both on account of its ductility and smoothness) is taken, and after cleaning its surface by hydrochloric or other acid, or otherwise, it is dried, and then dipped or passed in any convenient manner through the melted tin, or fusible alloy of tin. It is found desirable to heat the zinc, as nearly as may be, to the temperature of the melted metal, previous to dipping it, and to conduct the dipping, or passing-through, as rapidly as is consistent with thorough coating of the zinc, to prevent as much as possible the zinc becoming alloyed with the tin. It is recommended also that the tin, or alloy of tin, should not be heated to a higher temperature than is necessary for its proper fluidity. The metal thus coated, if in the form of sheet, plate, or cake, can then be rolled down to the required thickness; and should the coating of tin or alloy be found insufficient or imperfect, the dipping is to be repeated as above described, and the rolling also, if desired, either for smoothing the surface or further reducing the thickness.

Another part of the invention consists in coating lead or its alloys with tin or alloys thereof. The process is to be conducted as before described for the coating of zinc, and the surface of lead is to be perfectly clean. The lead may, like the zinc, be dipped more than once, either before or after being reduced in thickness by rolling.

Lead and its alloys may also be coated with tin or its alloys of greater fusibility than the lead to be coated.

Crystallised Tin-plate. See MOIRÉE MÉTALLIQUE. It would seem that the acid merely lays bare the crystalline structure really present on every sheet, but marked by a film of redundant tin. Though this showy article has become of late years vulgarised by its cheapness, it is still interesting in the eyes of the practical chemist. The English plates marked F, answer well for producing the *Moirée*, by the following process:—Place the tin-plate, slightly heated, over a tub of water, and rub its surface with a sponge dipped in a liquor composed of four parts of aquafortis and two of distilled water, holding one part of common salt or sal-ammoniac in solution. Whenever the crystalline spangles seem to be thoroughly brought out, the plate must be immersed in water, washed either with a feather or a little cotton (taking care not to rub off the film of tin that forms the feathering), forthwith dried with a low heat, and coated with a lacquer-varnish, otherwise it loses its lustre in the air. If the whole surface is not plunged at once in cold water, but if it be partially cooled by sprinkling water on it, the crystallisation will be finely variegated with large and small figures. Similar results will be obtained by blowing cold air through a pipe on the tinned surface, while it is just passing from the fused to the solid state; or a variety of delineations may be traced by playing over the surface of the plate with the pointed flame of a blowpipe.

Export of Tin Plates in the Year ending 1872 *and the two previous years.*

TITANIUM (*Sym.* Ti; *At. wt.* 25) is a rare metal, discovered by Klaproth, in Menaccanite, in 1794. Small cubes of a copper-red colour, and so hard as to scratch quartz, which have been found in some of the blast-furnaces in Yorkshire, Wales, and Cumberland, were thought to be titanium; they have recently been shown to be a cyano-nitride of that metal, represented by $TiCy,3Ti^3N$ ($\mathbf{TiCy^2.3Ti^3N^2}$). This metal is very brittle, so hard as to scratch steel, and very light, having a specific gravity of only 5·3. It will not melt in heat of any furnace, nor dissolve, when crystallised, even in nitro-muriatic acid; but only when in fine powder. According to Hassenfratz, it presence in small quantity does not impair the malleability of iron. By calcination with nitre, it becomes oxygenated, and forms titanate of potash. Traces of this metal may be detected in many irons, both wrought and cast. The principal minerals containing titanium, are *sphene, brookite, anatase, rutile, iserine* and *menaccanite.* Rutile has been used, with doubtful advantage, in the preparation of steel.

TOAD'S-EYE TIN. A pale hair-brown variety of wood-tin, found near Tregarthy Moor in Cornwall.

TOAST. When bread in thin slices is held in front of a bright fire it is converted into 'toast,' and acquires a characteristic flavour. This appears, according to the experiments of Piesse, to be a product of the destructive distillation of diastase, which all bread contains. When diastase is obtained from bread by alcoholic infusion and precipitation with water, and then heated to 330°, an intense odour of 'toast' is produced.

TOBACCO. It is said that the name 'tobacco' was given by the Spaniards to the plant, because it was first observed by them at Tabasco, or Tabaco, a province of Yucatan in Mexico. Others derive the name from Tabac, an instrument used by the natives of America in smoking this herb. In 1560, Nicot, the French ambassador to Portugal, having received some tobacco from a Flemish merchant, showed it, on his arrival in Lisbon, to the grand prior, and on his return to France, to Catherine of Medicis, whence it has been called Nicotiana by the botanists. Admiral Sir Francis Drake, having on his way home from the Spanish Main, in 1586, touched at Virginia, and brought away some forlorn colonists, is reported to have first imported tobacco into England. But, according to Lobel, this plant was cultivated in Britain before the year 1570; and was consumed by smoking in pipes by Sir Walter Raleigh and companions, so early as the year 1584.

Tobacco is prepared as follows:—The plants are hung up to dry during four or five weeks; taken down out of the sheds in damp weather, for in dry they would be apt to crumble into pieces; stratified in heaps, covered up, and left to sweat for a week or two, according to their quality and the state of the season; during which time they must be examined frequently, opened up, and turned over, lest they become too hot, take fire, or run into putrefactive fermentation.

Respectable tobacconists are very careful to separate all the damaged leaves before they proceed to their preparation, which they do by spreading them in a heap upon a stone pavement, watering each layer in succession with a solution of sea-salt, of spec. grav. 1·107, called *sauce*, till a ton or more be laid; and leaving their principles to react on each other for three or four days, according to the temperature and the nature of the tobacco. It is highly probable that ammonia is the volatilising agent of many odours, and especially of tobacco. If a fresh green leaf of tobacco be crushed between the fingers, it emits merely the herbaceous smell common to many plants; but if it be triturated in a mortar along with a little quick-lime or caustic potash, it will immediately exhale the peculiar odour of snuff. Analysis shows the presence of ammonia in this plant, and fermentation serves further to generate free ammonia in it.

Tobacco contains a great quantity of an azotised principle, which by fermentation produces abundance of ammonia; the first portions of which saturate the acid juices of the plant, and the rest serve to volatilise its odorous principles. The salt water is useful chiefly in moderating the fermentation, and preventing it from passing into the putrefactive stage; just as salt is sometimes added to saccharine worts in tropical countries, to temper the fermentative action. The sea-salt, which contains some muriate of lime, tends to keep the tobacco moist, and is therefore preferable to pure chloride of sodium for this purpose. Some tobacconists mix molasses with the salt *sauce*, and ascribe to this addition the violet colour of the *macouba* snuff of Martinique; and others add a solution of extract of liquorice.

The fermented leaves, being next stripped of their middle ribs by the hands of children, are sorted anew, and the large ones are set apart for making cigars. Most of the tobaccos on sale in our shops are mixtures of different growths: one kind of smoking tobacco, for example, consists of 70 parts of Maryland and 30 of meagre Virginia; and one kind of snuff consists of 80 parts of Virginia and 30 parts of either Mumesfort or Warwick. The Maryland is a very light tobacco, in thin yellow leaves; that of Virginia is in large brown leaves, unctuous or somewhat gluey on the surface, having a smell somewhat like the figs of Malaga; that of Havannah is in brownish light leaves, of an agreeable and rather spicy smell; it forms the best cigars. The Carolina tobacco is less unctuous than the Virginian; but in the United States it ranks next the Maryland. The shag tobacco is dried to the proper point upon sheets of copper.

Tobacco is cut into what is called 'shag tobacco' by knife-edged chopping stamps. For grinding the tobacco-leaves into snuff, conical mortars are employed, somewhat like that used by the Hindoos for grinding sugar-canes; but the sides of the snuff-mill have sharp ridges from the top to near the bottom.

Mr. L. W. Wright introduced a tobacco-cutting machine, which bears a close resemblance to the well-known machines with revolving knives for cutting straw into chaff. The tobacco, after being squeezed into cakes, is placed upon a smooth bed within a horizontal trough, and pressed by a follower and screws to keep it compact. These cakes are progressively advanced upon the bed, or fed in, to meet the revolving blades. The speed of the feeding-screw determines the degree of fineness of the sections or particles into which the tobacco is cut.

Snuff is sometimes largely drugged with pearlashes, and thereby rendered pungent, and absorbent of moisture.

Refuse leaves and roots, such as those of senna, rhubarb, and the like, after their medicinal properties have been extracted in the manufacture of infusions, extracts, and tinctures, by the druggists, were formerly ground, coloured with burnt sienna or yellow ochre, made pungent with ammonia, and then sold in large quantities to the snuff-manufacturers. We have reasons for believing that this fraud is but rarely practised now.

According to the analysis of Posset and Reimann, 10,000 parts of tobacco-leaves contain 6 of the peculiar chemical principle *nicotine*; 1 of *nicotianine*; 287 of slightly bitter extractive; 174 of gum, mixed with a little malic acid; 26·7 of a green resin; 26 of vegetable albumen; 104·8 of a substance analogous to gluten; 51 of malic acid; 12 of malate of ammonia; 4·8 of sulphate of potass; 6·3 of chloride of potassium; 9·5 of potassa, which has been combined with malic and nitric acids; 16·6 of phosphate of lime; 24·2 of lime, which had been combined with malic acid; 8·8 of silica; 496·9 of fibrous or ligneous matter; traces of starch; and 88·28 of water.

In 'Silliman's Journal,' vol. vii. p. 2, a chemical examination of tobacco is given by Dr. Covell, which shows its components to have been but imperfectly represented in the above German analysis. He found, 1, gum; 2, a viscid slime, equally soluble in water and alcohol, and precipitable from both by subacetate of lead; 3, tannin; 4, gallic acid; 5, chlorophyll (leaf-green); 6, a green pulverulent matter, which dissolves in boiling water, but falls down again when the water cools; 7, a yellow oil, possessing the smell, taste, and poisonous qualities of tobacco; 8, a large quantity of a pale yellow resin; 9, nicotine; 10, a white substance, analogous to morphia, soluble in hot, but hardly in cold, alcohol; 11, a beautiful orange-red dye-stuff, soluble only in acids: it deflagrates in the fire, and seems to possess neutral properties; 12, nicotinine.

A strict royal monopoly exists, or existed, in Austria Proper, France, Sardinia, the Duchies of Parma and Lucca, and the Grand-Duchy of Tuscany, and in Portugal, Spain, Naples, and the States of the Church; the license to manufacture is periodically sold to companies, which regulate the prices of tobacco as they please. It will be found that the situation of all these countries where the monopolies and high prices are kept up, is nearly the same, as to illicit trade in tobacco, as in England.

Tobacco *Imported* in 1873:—

	lbs.	Value.
Unmanufactured	81,382,733	2,618,799*l.*
		lbs.
Entered for Home consumption		44,719,756
Deduct Exported on drawback, &c.		535,146
Total		44,184,610*l.*

Duty: containing 10 lbs. or more of moisture in every 100 lbs. 3*s.* $1\frac{8}{10}$*d.* per lb.

Containing less than 10 lbs. of moisture in every 100 lbs. 3*s.* 6*d.* per lb. This was fixed March 27, 1863. The gross amount received in 1873 was 6,949,836*l.*

The total quantities of tobacco retained for home consumption in 1842 amounted to nearly 17,000,000 lbs. Professor Schleiden gives a singular illustration of the quantity of tobacco consumed. North America alone produces annually upwards of 200,000,000 lbs. of tobacco. The combustion of this mass of vegetable material would yield about 340,000,000 lbs. of carbonic acid gas, so that the yearly produce of carbonic acid gas, from tobacco-smoking alone, cannot be estimated at less than 1,000,000,000 lbs.: a large contribution to the annual demand for this gas made upon the atmosphere by the vegetation of the world.

It has been observed by Lane, the learned annotator of the 'Arabian Nights,' (and the observation was confirmed by the experience of Mr. Layard, M.P., the explorer of Assyria), that the growth and use of tobacco amongst Oriental nations has gradually reduced the resort to intoxicating beverages; and Mr. Crawford, in a paper 'On the History and Consumption of Tobacco,' in the Journal of the Statistical Society for March 1853, remarked, that simultaneously with the decline in the use of spirits in Great Britain, there had been a corresponding increase in the use of tobacco.

Year	Population	Quantity of Tobacco consumed	Consumption per head
1821 . .	21,282,960 . .	15,598,152 . .	11·71 oz.
1831 . .	24,410,439 . .	19,533,841 . .	12·80 „
1841 . .	27,016,972 . .	22,309,360 . .	13·21 „
1851 . .	27,452,262 . .	28,062,978 . .	16·86 „

The actual quantity now consumed is not easily obtainable. It has certainly greatly increased, and all medical evidence goes to show that it acts injuriously on the health of the people.

TOBACCO-PIPES are made of a fine-grained plastic white clay, to which they have given the name. It is worked with water into a thin paste, which is allowed to settle in pits, or it may be passed through a sieve, to separate the siliceous or other stony impurities; the water is afterwards evaporated till the clay becomes of a doughy consistency, when it must be well kneaded to make it uniform. Pipe-clay is found chiefly in the Isle of Purbeck, in Dorsetshire, and at Newton Abbot, in Devonshire. It is distinguished by its perfectly white colour, and its great adhesion to the tongue after it is baked, owing to the large proportion of alumina which it contains. See Clay,

A child fashions a ball of clay from the heap, rolls it out into a slender cylinder upon a plank, with the palms of his hands, in order to form the stem of the pipe. He sticks a small lump to the end of the cylinder for forming the bowl; which having done, he lays the pieces aside for a day or two, to get more consistency. In proportion as he makes these rough figures, he arranges them by dozens on a board, and hands them to the pipemaker.

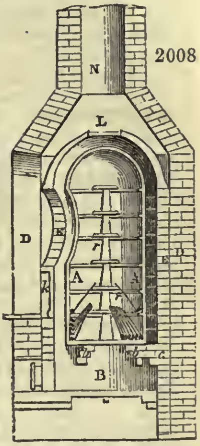
The pipe is finished by means of a folding brass or iron mould, channelled inside, of the shape of the stem of the bowl, and capable of being opened at the two ends. It is formed of two pieces, each hollowed out like a half-pipe, cut as it were lengthwise; and these two jaws, when brought together, constitute the exact space for making one pipe. There are small pins in one side of the mould, corresponding to holes in the other, which serve as guides for applying the two together with precision.

The workman takes a long iron wire, with its end oiled, and pushes it through the soft clay in the direction of the stem, to form the bore, and he directs the wire by feeling with his left hand the progress of its point. He lays the pipe in the groove of one of the jaws of the mould, with the wire sticking in it; applies the other jaw, brings them smartly together, and unites them by a clamp or vice, which produces the external form. A lever is now brought down, which presses an oiled stopper into the bowl of the pipe while it is in the mould, forcing it sufficiently down to form the cavity; the wire being meanwhile thrust backwards and forwards so as to pierce the tube completely through. The wire must become visible at the bottom of the bowl, otherwise the pipe will be imperfect. The wire is now withdrawn, the jaws of the mould opened, the pipe taken out, and the redundant clay removed with a knife. After drying for a day or two, the pipes are scraped, polished with a piece of hard wood, and the stems being bent into the desired form, they are carried to the baking kiln, which is capable of firing 50 gross in from 8 to 12 hours. A workman and a child can easily make 5 gross of pipes in a day.

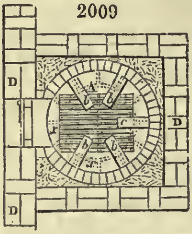
No tobacco-pipes are so highly prized as those made at Natolia, in Turkey, out of meerschaum, a hydrous silicate of magnesia, of a soft greasy feel, which is formed into pipes after having been softened with water. It becomes white and hard in the kiln. See MEERSCHAUM.

A tobacco-pipe kiln should diffuse an equal heat to every part of its interior, while it excludes the smoke of the fire. The crucible, or large sagger, A, A, *figs.* 2008 and 2009, is a cylinder, covered in with a dome L. It is placed over the fireplace B, and enclosed within a furnace of ordinary brickwork D D, lined with fire-bricks E, E. Between this lining and the cylinder, a space of about 4 inches all round is left for the circulation of the flame. There are 12 supports or ribs between the cylinder and the furnace lining, which form so many flues, indicated by the dotted lines *x*, in *fig.* 2009 (the dotted circle representing the cylinder). These ribs are perforated with occasional apertures as shown in *fig.* 2008, for the purpose of connecting the adjoining flues; but the main bearing of the hollow cylinder is given by five piers, *b*, *b*, *c*, formed of bricks projecting over and beyond each other. One of these piers, *c*, is placed at the back of the fireplace, and the other four at the sides *b*, *b*. These project nearly into the centre, in order to support and strengthen the bottom; while the flues pass up between them, unite at the top of the cylinder in the dome L, and discharge the smoke by the chimney N.

2008



2009



The lining E, E, of the chimney is open on one side to form the door, by which the cylinder is charged and discharged. The opening is permanently closed as high as *k*, *fig.* 2008, by an iron plate plastered over with fire-clay; above this it is left open, and shut merely with temporary brickwork while the furnace is going. When this is removed, the furnace can be filled or emptied through the opening, the cylindric crucible having a correspondent aperture in its side, which is closed in the following ingenious way, while the furnace is in action. The workman first spreads a layer of clay round the edge of the opening: he then sticks the stems of broken pipes across from one side to the other, and plasters up the interstices with clay, exactly like the lath-and-plaster work of a ceiling. The whole of the cylinder, indeed, is constructed in this manner, the bottom being composed of a great many fragments of pipe-stems, radiating to the centre; these are coated at the circumference with a layer of clay. A number of bowls of broken pipes are inserted in the clay; in these other fragments are placed upright to form the sides of the cylinder. The ribs round the outside, which form the flues, are made in the same way, as well as the dome L; by which means the cylindric case may be made very strong, and yet so thin as to require little clay in the building, a moderate fire to heat it, while it is not apt to split asunder. The pipes are arranged within, as shown in the figure, with their bowls resting against the circumference, and their ends supported on circular pieces of clay, *r*, which are set up in the centre for that purpose. Six small ribs are made to project inwards all round the crucible, at the proper heights to support the different ranges of pipes, without having so many resting on each other as to endanger their being crushed by the weight. By this mode of distribution, the furnace may contain 50 gross, or 7,200 pipes, all baked within eight or nine hours; the fire being gradually raised, or damped if occasion be, by a plate partially slid over the chimney-top.

TODDY, *Sura*, *Mee-ra*, 'sweet juice.' The proprietors of cocoa-nut plantations in the peninsula of India, and in the Island of Ceylon, instead of collecting a crop of nuts, frequently reap the produce of the trees by extracting sweet juice from the flower-stalk. When the flowering branch is half shot, the toddy-drawers bind the stock round with a young cocoa-nut-leaf in several places, and beat the *spadix* with a short baton of ebony. This beating is repeated daily for ten or twelve days, and about the end of that period a portion of the flower-stalk is cut off. The stump then begins to bleed, and an earthy vessel (chatty) or a calabash is suspended under it, to receive the juice, which is by the Europeans called *toddy*.

A thin slice is taken from the stump daily, and the toddy is removed twice a day. A cocoa-nut frequently pushes out a new spadix once a month; and after each spadix begins to bleed, it continues to produce freely for a month, by which time another is ready to supply its place. The old spadix continues to give a little juice for another month, after which it withers; so that there are sometimes two pots attached to a tree at one time, but never more. Each of these spadices, if allowed to grow, would produce a bunch of nuts from two to twenty. Trees in a good soil produce twelve bunches in the year; but when less favourably situated, they often do not give more than six bunches. The quantity of six English pints of toddy is sometimes yielded by a tree daily.

Toddy is much in demand as a beverage in the neighbourhood of villages, especially where European troops are stationed. When it is drunk before sunrise, it is a cool, delicious, and particularly wholesome beverage; but by eight or nine o'clock fermentation has made some progress, and it is then highly intoxicating.[1]

TOLU is a brownish-red balsam, extracted from the stem of the *Myroxylon toluiferum*, a tree which grows in South America. It is composed of resin, oil, and benzoic acid. Having an agreeable odour, it is sometimes used in perfumery. It has a place in the Materia Medica.

TOLUIDINE. $C^{14}H^{9}N$ (**$C^{7}H^{9}N$**). A volatile base isomeric with lutidine, formed from toluole, by processes analogous in all respects to those by which aniline is produced from benzole.

TOLUOLE. $C^{14}H^{8}$ (**$C^{7}H^{8}$**). Syn. *Hydruret of toluenyle.* A hydrocarbon produced in the destructive distillation of the resin of tolu. It is also produced by the decomposition of toluylic acid by baryta at a high temperature. Coal-naphtha contains it in large quantity. For its physical properties, see CARBO-HYDRIDES.

TOMBAC, or *White Copper.* An alloy of copper and zinc, containing 85 per cent. of the former and 15 of the latter.

TON. An English weight of 20 cwts., according to the statute, or 2,240 lbs. It varies in different districts:—

South Wales, from 2,400 lbs. to 2,618 lbs.
Ayrshire, from 2,464 lbs. to 2,520 lbs.
North Staffordshire, coal, 2,400 lbs.
 Do. do. stone, 2,520 lbs.

Copper ores are sold by the ton of 21 cwts. of 112 lbs. or 2,352 lbs.

In Newcastle the leases are by the ton of 440 bolls of 36 gallons each = 48 tons, 11 cwts. 2 qrs. 17 lbs. statute.

TONKA or **TONQUIN BEAN.** The fruit of the *Dipteryx odorata* affords a concrete crystalline volatile oil (*stearoptene*), called *Coumarine* by the French. It is extracted by digestion with alcohol, which dissolves the stearoptene and leaves a fat oil. It has an agreeable smell, and a warm taste. It is fusible at 122° Fahr., and volatile at higher heats.

TOOTH, ARTIFICIAL MANUFACTURE. Teeth should be made of the best ivory. The following, however, is one of the processes adopted for the artificial manufacture of teeth. Pure quartz is calcined by a moderate heat. When taken from the fire it is thrown into cold water, which breaks it into numberless pieces. The pieces of calcined quartz are ground into fine powder. Next fluor-spar, free from all impurities, is ground up in like manner into a fine powder.

The next step is to mix together nearly equal parts, by weight, of the powdered spar and quartz. This mixture is again ground to a greater fineness. Oxide of tin is now added to it, for the purpose of producing an appropriate colour, and water and china clay to make it plastic and give it consistency. This mixture resembles soft paste, which is transferred to the hands of females, who are engaged in filling moulds with it. After the paste has been moulded into proper shape, two small platina rivets are inserted near the base of each tooth, for the purpose of fastening it (by the dentist), to a plate in the mouth. They are now transferred to a furnace, where they are 'cured,' as it is technically called; that is, half-baked or hardened. The teeth are now ready to receive the enamel, which is applied by women; it consists of spar and quartz which has been ground, pulverised, and reduced to the state of a soft paste, which is evenly spread over the half-baked body of the tooth, by means of a delicate brush. The teeth must be next subjected to an intense heat. They are put into ovens, lined with platina and heated by a furnace, in which the necessary heat is obtained. The baking process is superintended by a workman, who occasionally removes a tooth to ascertain whether those within have been sufficiently baked. This is indicated by the appearance of the tooth.

[1] Contributions to the History of the Cocoa-nut Tree. By Henry Marshall, Esq., Deputy Inspector of Hospitals.

TOPAZ. The fundamental form is a scalene 4-sided pyramid; but the secondary forms have a prismatic character, and are frequently observed in 4-sided prisms, terminated by 4 planes. The lateral planes of the prism are longitudinally striated. Fracture conchoïdal, uneven; lustre vitreous; colours, white, yellow, green, blue, generally of pale shades. Hardness, 8; spec. grav. 3·5. Prismatic topaz consists, according to Berzelius, of alumina, 57·45; silica, 34·24; fluoric acid, 7·75. In a strong heat the faces of crystallisation, but not those of cleavage, are covered with small blisters, which however immediately crack. With borax, it melts slowly into a transparent glass. Its powder colours the tincture of violets green. Those crystals which possess different faces of crystallisation on opposite ends acquire the opposite electricities on being heated. By friction it acquires positive electricity.

Most perfect crystals of topaz have been found in Siberia, of green, blue, and white colours, along with beryl, in the Uralian and Altai mountains, as also in Kamtschatka; in Brazil, where they generally occur in loose crystals, and pebble-forms of bright yellow colours; and in Mucla in Asia Minor, in pale straw-yellow regular crystals. They are also met with in the granitic detritus of Cairngorm in Aberdeenshire. The blue varieties are absurdly called *oriental aquamarine* by lapidaries. If exposed to heat, the Saxon topaz loses its colour and becomes white; the deep yellow Brazilian varieties assume a pale pink hue, and are then sometimes mistaken for spinelle, to which, however, they are somewhat inferior in hardness. Topaz is also distinguishable by its double refractive property. Tavernier mentions a topaz, in the possession of the Great Mogul, which weighed 157 carats, and cost 20,000*l.* sterling. There is a specimen in the Museum of Natural History at Paris which weighs 4 ounces 2 gros. Topazes are not scarce enough to be very highly valued. See GEMS.

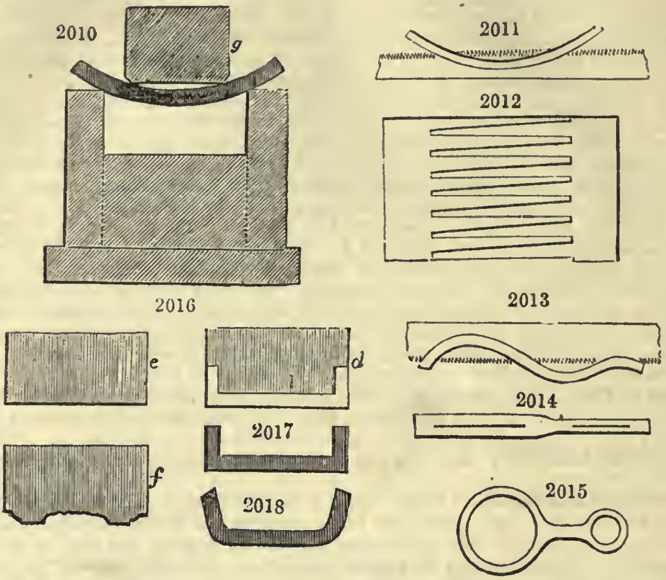
TORBANITE, or *Torbane-Hill mineral.* See BOGHEAD COAL.

TORBITE. A preparation of Peat, for which works were established at Horwich, in Lancashire. It does not appear that this manufacture was attended with success.

TORREFACTION. Roasting ores to deprive them of sulphur, arsenic, or other volatile substances.

TORTOISE-SHELL, or rather *scale*; a horny substance that covers the hard strong covering of a bony contexture, which encloses the *Testudo imbricata*, Linn. The lamellæ or plates of this tortoise are thirteen in number, and may be readily separated from the bony parts by placing fire beneath the shell, whereby they start asunder. They vary in thickness from one-eighth to one-quarter of an inch, according to the age and size of the animal, and weigh from 5 to 25 lbs. The larger the animal, the better is the shell. This substance may be softened by the heat of boiling water; and if compressed in this state by screws in iron or brass moulds, it may be bent into any shape. The moulds being then plunged in cold water, the shell becomes fixed in the form imparted by the mould. If the turnings or filings of tortoise-shell be subjected skilfully to gradually increased compression between moulds immersed in boiling water, compact objects of any desired ornamental figure or device may be produced. The soldering of two pieces of scale is easily effected, by placing their edges together, after they are nicely filed to one bevel, and then squeezing them strongly between the long flat jaws of hot iron pincers, made somewhat like a hairdresser's curling tongs. The pincers should be strong, thick, and just hot enough to brown paper slightly without burning it. They may be soldered also by the heat of boiling water, applied along with skilful pressure. But in whatever way this process is attempted, the surfaces to be united should be made very smooth, level, and clean: the least foulness, even the touch of a finger, or breathing upon them, would prevent their coalescence. See HORN.

Tortoise-shell is manufactured into various objects, partly by cutting out the shapes and partly by agglutinating portions of the shell by heat. When the shell has become soft by dipping it in hot water, and the edges are in the cleanest possible state without grease, they are pressed together with hot flat tongs, and then plunged into cold water, to fix them in their position. The teeth of the larger combs are parted in their heated state, or cut out with a thin frame saw, while the shell, equal in size to two combs with their teeth interlaced, as in *fig.* 2010, is bent like an arch in the direction of the length of the teeth, as in *fig.* 2011. The shell is then flattened, the points are separated with a narrow chisel or *pricker*, and the two combs are finished, while flat, with coarse single-cut files and triangular scrapers. They are finally warmed, and bent on the knee over a wooden mould, by means of a strap passed round the foot, just as a shoemaker fixes his last. Smaller combs of horn and tortoise-shell are parted while flat, by an ingenious machine, with two chisel-formed cutters placed obliquely, so that each cut produces one tooth. See Rogers's Comb-cutting Machine, 'Trans. Soc. Arts,' vol. xlix. part 2, since improved by Mr. Kelly. In making the frames for eye-glasses, spectacles, &c., the apertures for the glasses were formerly cut out to the circular form with a tool something like a carpenter's centre-bit, or with a crown saw in the lathe. The disks so cut out were used for inlaying in the tops of boxes, &c. This required a piece of shell as large as the front of the spectacle; but a piece one-third of the size will now suffice, as the eyes are *strained* or *pulled*. A long narrow piece is cut out, and two slits are made in it with a saw. The shell is then warmed, the apertures are pulled open, and fastened upon a taper triblet of the



appropriate shape; as illustrated by *figs.* 2013, 2014, and 2015. The groove for the edge of the glass is cut with a small circular cutter, or sharp-edged saw, about three-eighths or half an inch in diameter; and the glass is sprung in when the frame is expanded by heat.

In making tortoise-shell boxes, the round plate of shell is first placed centrally over the edge of the ring, as in *fig.* 2010; it is slightly squeezed with the small round edgeblock *g*, and the whole press is then lowered into the boiling water; after immersion for about half an hour, it is transferred to the bench, and *g* is pressed entirely down, so as to bend the shell into the shape of a saucer, as at *fig.* 2018, without cutting or injuring the material; and the press is then cooled in a water-trough. The same processes are repeated with the die *d*, which has a rebate turned away to the thickness of the shell, and completes the angle of the box to the section, *fig.* 2017, ready for finishing in the lathe. It is always safer to perform each of these processes at two successive boilings and coolings. Two thin pieces are cemented together by pressure with the die *e*, and a device may be given by the engraved die *f* (*fig.* 2016).

TOSSING or **TOZING.** A process in dressing ores, by which they are kept suspended in water by agitation. See DRESSING OF ORES.

TOUCH-NEEDLES and **TOUCH-STONE** are means of ascertaining the quality of gold trinkets. The touch-needles are bars of known composition, and the touch-stone is black basalt; according to the streak made by the article to be tested, as compared with that made by the needles, its quality is inferred.

TOURMALINE. A silico-borate of alumina and several other bases, usually with fluorine. This mineral is used in the construction of polariscopes. The black varieties are known as *Schorl*, the red as *Rubellite*, and the blue as *Indicolite*.

TOUS-LES-MOIS. A name given to a kind of starch obtained from the *Canna edulis*, one of the *Marantaceæ*, or Arrowroot order.

TOW. See FLAX.

TRAGACANTH, GUM, (*Gomme adracante*, Fr.; *Traganth*, Ger.) See GUM.

TRASS or **TARRAS.** A German term for a tertiary earth, probably volcanic, which occupies wide areas in the Eifel district of the Rhine. Its basis appears to be pumice-stone, mixed with fragments of basalt and calcined slate. When powdered it is used, like the *pozzolano* of Italy, as an hydraulic cement.

TRAVERTIN. A white concretionary limestone deposited from springs holding carbonate of lime in solution. Travertin is compact; tufa is a porous body.

TREACLE is the viscid brown uncrystallisable syrup which drains from the sugar-refining moulds. Its spec. grav. is generally 1·4, and it contains upon an average 75 per cent. of solid matter. See SUGAR.

TREFOIL, BITTER. One of the clovers which possesses a bitter taste.

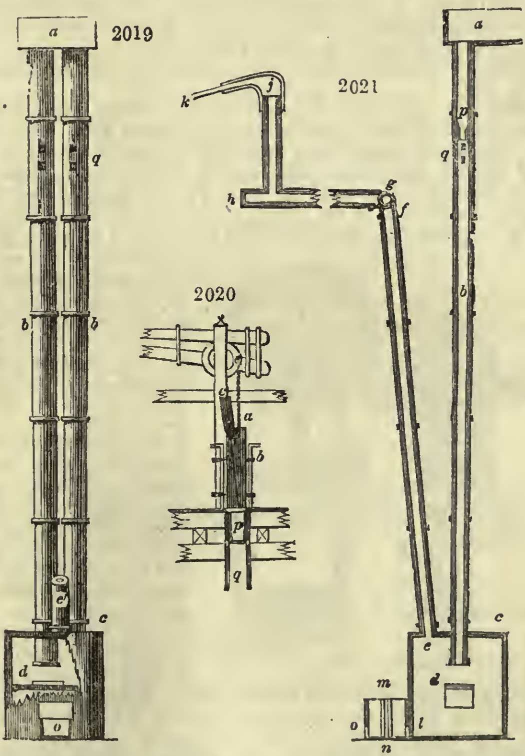
TRENT SAND or **WHARPE.** A river sand found in some parts of the Trent, and also in the Severn, and some other places; used for polishing German silver.

TRIPOLI (*Terre pourrie*, Fr.; *Tripel*, Ger.) is a mineral of an earthy fracture, a yellowish-grey or white colour, composition impalpably fine, meagre to the touch, does not adhere to the tongue, and burns white.

M. Ehrenberg has shown that those friable homogeneous rocks, which consist almost entirely of silica, are actually composed of the exuviæ or rather the skeletons of Infusoria (*animalculæ*), of the family of *Barcellariæ*, and the genera *Cocconema*, *Gonphonema*, &c. They are recognised with such distinctness in the microscope, that their analogies with living species may be readily traced, and in many cases there is no appreciable difference between the living and the fossil forms. The species are distinguished by the number of partitions or transverse lines upon their bodies. The length is about $\frac{1}{288}$th of a line. M. Ehrenberg made his observations upon the tripolis of Billen in Bohemia, of Santafiora in Tuscany, of the Isle of France, and of Francisbad, near Eger.

Tripoli is said by Brooke and Miller to be found near Prague in Saxony, in France, Tripoli, Corfu. Tripoli has been confounded by many writers with the English Rottenstone. Mr. Kirwan, in his 'Elements of Mineralogy,' says, 'Mr. Haase who has lately analysed it found 100 parts of it to contain 90 of silicious earth, 7 of argill, and 3 of iron; but the red sort probably contains more iron.'

TROMPE, THE. The *trompe*, or water-blowing engine, *figs.* 2019, 2020, 2021, is employed in some of the great metallurgical works of the Continent. *Fig.* 2019 is



the elevation; *fig.* 2020 is a vertical section, made at right angles to the elevation. The machine is formed of two cylindrical pipes; the bodies of the *trompe*, *b b*, set upright, called the funnel, which terminate above in a water-cistern *a*, and below in a close basin under *c*, called the *tub* or *drum*. The conical part *p* of the funnel has been called *étranguillon*, being *strangled*, as it were, in order that the water discharged into the body of the trompe shall not fill the pipe in falling, but be divided into many streamlets. Below this *narrow part*, holes, *q q*, are perforated obliquely through the substance of the trompe, called the vent-holes or nostrils, for admitting the air, which the water carries with it in its descent. The air afterwards parts from the water, by dashing upon a cast-iron slab, placed in the *drum* upon the pedestal *d*. An aperture, at the bottom of the drum, allows the water to flow away after its fall; but to prevent the air from escaping along with it, the water as it issues is received in a chest, *l m o n*, divided into two parts by a vertical side-plate between *m n*. By raising or lowering this plate, the water may be maintained at any desired level within the drum, so as to give the included air any determinate degree of pressure. The superfluous water then flows off by the hole *o*. See ASPIRATOR.

The air-pipe *e f*, *fig.* 2021, is fitted to the upper part of the *drum*: it is divided, by the point *f*, into three tubes, of which the principal one is destined for the furnace of cupellation, whilst the other two, *g g*, serve for different melting furnaces. Each of these tubes ends in a leathern pocket, and an iron nose-pipe, *k*, adjusted in the tuyère of the furnace. At Pesy, and in the whole of Savoy, a floodgate is fitted into the upper cistern, *a*, to regulate the admission of water into the trompe; but in Carniola the funnel is closed with a wooden plug, suspended to a cord, which goes round a pulley mounted upon a horizontal axis, as shown in *fig.* 2020. By the plug *a* being raised more or less, merely the quantity of water required for the operation is admitted. The plug is pierced lengthwise with an oblique hole, *c c*, in which the small tube *c* is inserted, with its top some way above the water level, through which air may be admitted into the heart of the column descending into the trompe *p q*.

The ordinary height of the trompe apparatus is about 26 or 27 feet to the upper level of the water-cistern; its total length is 11 meters (36½ feet), and its width 2 feet, to give room for the drums. It is situated 10 meters (33⅓ feet) from the melting furnace. This is the case at the smelting works of Jauerberg, in Upper Carniola.

TRONA. A name given by the Africans to NATRON.

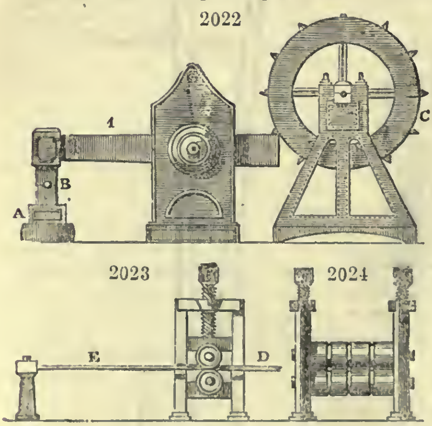
TROUBLES. Disturbances in the strata, interfering with the progress of work in a coal mine.

TRUFFLES. A mushroom-like vegetable production, found underground in Northamptonshire and elsewhere, but imported as a luxury from Italy.

TUBES. The manufacture of iron tubes for gas, water, and other purposes has become one of extreme importance. Mr. Russell, of Wednesbury, patented a process which has been carried out on a very large scale. In this process plate-iron, previously rolled to a proper thickness, is cut into such strips or lengths as may be desirable, and in breadth corresponding with the width of the tube intended to be formed.

2022

2023 2024



The sides of the metal are then bent up with swages in the usual way, so as to bring the two edges as close as possible together. The iron thus bent is then placed in an air or blast furnace, and brought to a welding heat, in which state it is withdrawn and placed under the hammer. *Fig.* 2022, A, is the anvil having a block or bolster, with a groove suited to and corresponding with a similar groove B, in the face of the block, C is a wheel with projecting knobs, which, striking in succession upon the iron-shod end of the hammer-shaft, causes it to strike rapidly on the tube. In this process the tube is repeatedly heated and hammered, until the welding is complete from end to end. A mandril may be inserted or not during the operation. When the edges of iron have been thus thoroughly united, the tube is again heated in a furnace, and then passed through a pair of grooved rollers similar to those used in the production of rods. *fig.* 2022. Suppose a tube D, to be passing through these rollers, of which *fig.* 2023 represents a cross-section, immediately upon its being delivered from the groove it receives an egg-shaped core of metal fixed upon the extremity of the rod E, over which the tube sliding on its progress, the inside and outside are perfected together. Mr. Cort patented a similar process for the manufacture of gun-barrels.

Brass or copper tubes are formed of rolled metal, which is cut to the required breadth by means of revolving disks: in the large sizes of tubes the metal is partially curved in its length by means of a pair of rolls; when in this condition it is passed through a steel hole or a die, a plug being held in such a position as allows the metal to pass between it and the interior of the hole. Oil is used to lubricate the metal; the motion is communicated by power, the drawing apparatus being a pair of huge nippers, which holds the brass, and is attached to a chain and revolves round a windlass or cylinder. The tube in its unsoldered state is annealed, bound round at intervals of a few inches with iron wire, and solder and borax applied along the seam. The operation of soldering is completed by passing the tube through an air-stove, heated with 'cokes' or 'breezes', which melts the solder, and unites the two edges of the metal, and forms a perfect tube; it is then immersed in a solution of sulphuric acid, to remove scaly deposits on its surface, the wire and extra solder having been previously removed: it is then drawn through a 'finishing hole plate,' when the tube is completed.

Mandril-drawn tubes, as the name indicates, are drawn upon a very accurately turned steel mandril; by this means the internal diameter is rendered smooth; the tube formed by this process is well fitted for telescopes, syringes, small pump-cylinders, &c.

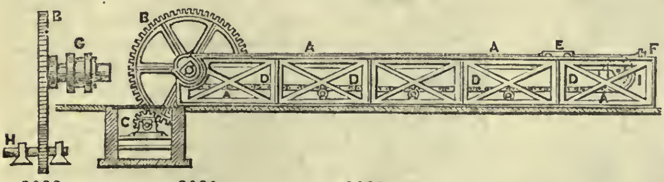
The manufacture in all its details is described by Mr. W. C. Aitken, of Birmingham, in the following article:—

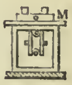
Manufacture of Tubes in Lead, Tin, Iron, Steel and Brass, whether soldered, plain, taper, ornamental, solid, or seamless.

The introduction of water into public and private establishments as provision for heating and ventilating, the use of tubes for the conveyance of gas, the large demands for tubes also required in the construction of locomotive and marine engine-boilers, have been the means of developing what is now an important branch of national industry. Tubes or pipes are essential requisites of the day, and may be said to have originated in the practical application of science to the wants of the present and coming generations: as pipes to let pure water in and carry foul water out, pipes for warming, ventilating, and drainage, pipes to bring in gas, and to carry away the results of its combustion, pipes for the rich man's marble or earthenware bath, pipes for the poor man's brick kitchen, pipes for fountains and cesspools, for arresting conflagration and pestilence, for the locomotive on the iron road, and the steamboat as it cleaves the ocean-wave. This brief allusion to the multifarious uses to which pipes or tubes are applied may be accepted either as introductory to the *modus operandi* or means by which tubes are produced from various metals. There is every reason to believe that in the early stages of tube-manufacture tubes generally were formed by casting, the aperture being produced by means of a core of sand laid in a print in a mould. They were cast in short lengths, and soldered together, or they were turned up from flat sheet-metal and the edges united by means of soldering if lead or brass; or if of iron, they were welded; the methods of manipulation now adopted arising from the increasing demand for such forms of metal.

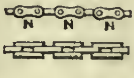
Lead-pipes were formerly produced by being cast in sand-moulds, a cylinder or 'core' of sand being laid in corresponding to the internal diameter of the aperture. These

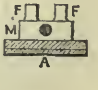
2029 2025 2026





2032 2030 2028 2031 2027

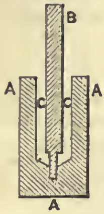




were cast in short lengths and soldered together, or they were produced from milled or rolled sheet lead and soldered together with soft or plumber's solder at the seam or junction of the two edges of the sheet lead: then followed the process by which the tube was elongated from a thick cylinder, or billet of lead, by means of the drawbench, the billet in its interior being supported by a mandril of steel; and in that condition it was drawn through a succession of wortles or tools which diminished the external diameter of the billet until the desired external diameter of the tube was arrived at. As, however, the drawbench is an important machine in the production of tube formed of every kind of metal, a cut is here introduced to show its construction.

In *fig.* 2025, an elevation of drawbench, A A A A represents the frame of the drawbench; C the pinion connected with the driving shaft of the engine; B the toothed wheel; D D D D, the endless chain; E the clip to which the plyers are attached; F the two snags or standards against which the die M is held in the process of drawing. *Fig.* 2026, represents an end section of the drawbench at F; *fig.* 2028, representation of a section of endless chain; *fig.* 2029, section of wheel and pinion. H represents the driving shaft, and G the pulley or sheaf in which the chain moves. *Fig.* 2030, K shows hook which is inserted into interstices of endless chain at N, into which the plyers or nippers are attached in which the spit, mandril, or metal is placed and held in the process of drawing the tube. *Fig.* 2027 represents the 'snags' or standards against which the tool M is held. *Fig.* 2031 represents section of tool M; *fig.* 2032 section through G showing projections which catch the interstices or apertures in chain, *fig.* 2028, and drag it along; a corresponding pulley or sheaf is placed at I, *fig.* 2025.

2033

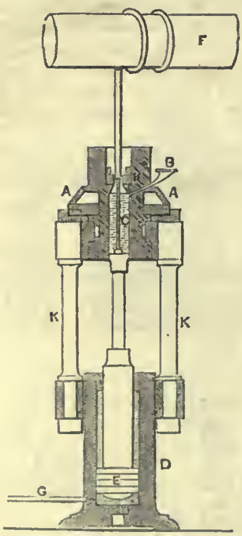


2034

2035

Reverting to the manufacture of lead-tube, the billet was cast in metal moulds or chills, thus, *fig.* 2033, A A A represents metal mould and B the steel mandril; into the space C C, the lead was poured; the result was a casting or 'billet,' when the mould was opened, and the mandril B withdrawn. The result was a hollow cylinder, *fig.* 2034, in section. Into the space B B a mandril was introduced, *fig.* 2035, in form corresponding to its internal diameter, the parallel part of mandril D D being of the length of the intended tube. The 'billet' alluded to was passed on to the mandril D D; and held by the shoulder of the diminishing part thereof in front of the nose of the billet, and on the reduced portion of the mandril a series of 'wortles' or 'dies' were placed, diminishing in diameter to the required external size of the tube; in this condition the mandril and billet was taken to the drawbench, the largest die placed against the snags or rest for the die, and the billet drawn through and thereby reduced in diameter and elongated: then followed drawing through the other and smaller or diminishing dies in succession as described; the last operation consisted in withdrawing the spit or mandril: an easy operation, and simply effected by reversing the billet and using a die, the full size of the mandril to be withdrawn, the drawbench assisting in the operation. By a similar process, BLOCK TIN tube, now so largely used in gas-fitting, for liquor-fountains, and other purposes, is still made; its brightness being produced in the process of drawing by a cutting-die, which shaves off a thin portion of the metal and exposes its brilliancy: the polish is given by the dies which follow in succession. It will, however, be evident that the process alluded to is a slow one, and but imperfectly adapted to supply the great demand for lead-pipes now existing. An exceeding rapid process for its production is now adopted, in which an hydraulic press, operating on a molten mass of lead, forces it in its melted state through a suitably-formed annular space, and produces lengths of tube limited only in their length by the quantity of liquid lead operated upon. The process will be best understood by reference to the cut, *fig.* 2036, which consists of a double-ended piston, operated upon by a hydraulic apparatus, a lead furnace, and a nosel or exit from which issues the pipe

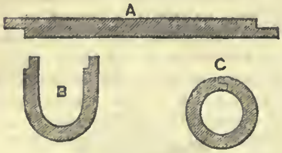
2036



made. Supported on pillars K K stands an arrangement of metal in which is inclosed an annular furnace under C, represented by A A, with provision for introducing fire. In centre, marked C, is the melted lead contained in a cylinder fitted with piston, connected with that of the hydraulic press, D; the lead is introduced at the spout or feeder, B; on the cylinder, C, being filled, the feeder, B, is unscrewed, and a solid plug introduced. The white line ascending through the space, C, is a mandril, which is the size of the interior of the intended tube. K represents suitably-formed dies, the size of the external diameter of the tube required; the space between the interior of the die and the exterior of the mandril is that through which the melted lead is forced which forms the tube, it being formed, congealed, or solidified at the point where it comes in contact with the external atmosphere, the forcing up of the lead being produced by the water in gate-pipe G being connected with the pump which, set in motion, forces the water under the packing of the piston E; this raises it, and it in turn, operating on the piston, which works up in the interior of the cylinder containing the fluid, or melted lead, presses it out from the space between the die and the mandril. As the tube is made it is wound into coils on a revolving drum F, which is placed over the press; the size of the mandril and the die may be changed, and tubes of lead of any size and length can be produced by this ingenious process, alike simple and speedy in its operation.

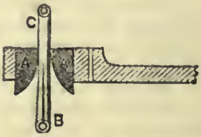
The Manufacture of Wrought-iron Tube. There is an immense demand for wrought-iron welded tube now universally used in conducting gas for lighting, water, steam for heating, or for boilers for locomotive- and marine-engine purposes (though there are reasons for believing that for the last two purposes the application of good brass tubes as a substitute is on the increase). The first impetus given to the manufacture of welded iron tube arose immediately after the practical demonstration of William Murdock as to the possibility of lighting public establishments by means of gas, consequent on the experiments made by him at Redruth in Cornwall in the year 1792, the facility afforded by iron of being united by welding naturally suggested iron tubes as a means of conveying the new lighting agent. No doubt the idea of applying iron-pipe for the purpose arose from the very great quantity of gun-barrels made for the construction of the 'Brown Bess' guns used in the continental wars terminating in the year 1815. Great quantities of barrels, incapable of standing the necessary charges in proving, were thrown on one side, and when the introduction of gas began to be favourably entertained, these waste barrels were united together by means of screwing the ends of the barrels, and connecting them by means of ferrules of iron screwed internally; they were thus converted or made into long lengths; the ordinary length of gun-barrels permitted of their being readily welded up the joint or seam, when the two edges of the 'skelp,' as the piece of iron was called from which the barrels were made, were brought in contact. Of course the kind of gun-barrels referred to were not of the first class; but for ordinary use, simply a skelp of iron beaten in a groove, or partially turned up by a hammer in a grooved tool placed on the anvil until they formed a half-closed tube of iron, and they were finally lap-joint-welded, *i.e.* the two edges of the skelp, when in a position that they overlapped each other, such operation being performed entirely by manual labour. The next step consisted in application of the tilt-hammer or hammer worked by power, see *fig.* 2022, and eventually the welding and reduction of the billet or turned-up skelp was effected by rolls, see *figs.* 2023, and 2024. However much and numerous the various patents for the manufacture of iron-tube may have operated in improving the production of iron tubing, it is very evident, that of the number many have been abandoned as worthless or too complicated and expensive in their operation. Thus Cook in 1808 suggested three several processes for the making of barrels or tubes: *i.e.* to drill a hole through a solid cylinder of iron, introduce a mandril and then reduce the external surface by drawing down by grooved rolls; to weld up a strip or skelp as already described; or to force a flat disk of iron into a cup-like form, and elongate the same by drawing down or rolling out. In 1811 a patent was taken out in which the turned-up skelp was welded on a grooved anvil or swage, the hammer being moved by power, an internal support being used. Osborne in 1817 used grooved rolls for 'turning up': the mandril was stationary, and held by means of a shield. Russell in 1824 welded by means of a hollow-faced hammer and a tool; the latter held the tube while the operation of welding was being proceeded with: this patent was unsuccessful, and was abandoned. Whitehouse in 1825 suggested the idea that an internal support might be got rid of altogether, and the weld effected in a 'butt' jointed tube by external pressure only; this is the method now generally adopted as being the simplest and best for the production of iron-tubes for purposes of gas-fittings. In 1831, Royl attempted to evade Whitehouse's patents of welding without internal support by using rolls instead of bell-mouth plyers, or compressible tools or dies. In 1826, Harvey and Brown used a long-ended mandril with bit attached thereto, corresponding to the internal diameter of the iron tube which was to be welded. Russell in 1836 attempted to expedite the production of iron tube by turning up the end of the skelp to a tube-like form, and when the iron was at welding heat, on being drawn through the tool, the entire length of the skelp was turned up, and welded by one operation or heating, either by means of rollers or bell-mouthed plyers, as already described. Prosser in 1840 followed in intention the last-described process, using, however, a tool composed of four pulleys, operated upon by pinions, and a long-shanked mandril with a thick end: the end of the skelp was in this process turned up to enter the combined roller die; it was heated and welded, passing over the thick part of the mandril when being welded. A united patent of Russell and Whitehouse, taken out in 1842, and specially adapted for the production of locomotive- and marine-engine boiler tubes, consisted in introducing a mandril of smaller diameter into the turned-up tube, the edges of which were thinned; the mandril lay immediately under the overlapping edges of the joint: the tube being heated, was then passed under rollers, which pressed the laps or edges of the skelp together on the internal support and produced a firm, strong, and substantial joint or weld. In 1844-5, Russell, instead of passing the tube through the tools, used a moveable bed on which the tube to be welded was laid; the mandril in this process was either placed in the interior of the tube, or was held stationary at the point of welding, or immediately at the point of contact or pressure of the rolls, and the tube passing under it was welded: the tube in this process required two heatings to weld it into its entire length. It will be evident that the majority of these patents ring the changes on the roller alternating with the 'plyer' mode of welding; the former method having been used by Mr. Bush in 1780, not for welding purposes as regards tubes, but for the production of lead-tube, being used by him for rolling down the thick billet of lead in order to elongate and reduce it in its external diameter. Of the patents noticed, the majority depend on the use of rollers as a means of welding in connection with an internal mandril, pointing to the conclusion that, previous to the introduction of the amended Patent Law in 1852, such arrangement of tools or welding machines included therein must have formed, as they did, fertile sources of litigation. A somewhat ingenious process for making tubes to be applied for locomotive and marine-engine boiler purposes was carried into execution by the late Mr. Richard Prosser in the years 1852–3. In this process the welding of the tubes was attempted to be got rid of altogether by a process dependent entirely on the accuracy of the preparation of the skelp, and the closing of its edges; the skelp, being placed on the bed of a planing machine, had its two outer edges planed down to half the thickness on the opposite sides of the sheet, thus; see A, *fig.* 2037, a stationary

2037



2038

2039

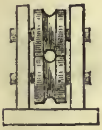


cast-iron grooved bed die, the entire length of the intended tube, with corresponding convex tool, which descended and converted the flat metal into the form represented at B, *fig.* 2037. In this condition a concave die, descending in a similar manner, turned over the edges of the metal, which was eventually forced down, and assumed the cylindrical form as represented at C, as the tightness of the tube was dependent on the accuracy of the planing of the edges of the skelp and the closeness with which these edges were brought together, the only means of retaining these firmly being the cohesion of the joints arising from the pressure of the water in the interior of the boiler. Perfect as these joints were made, the vibration of the engine speedily opened them, and the tube, it is almost unnecessary to add, was not a success.

The manufacture of welded 'edge and edge' or 'butt' and 'lap' jointed iron tube is practised as follows:—The iron of which the tube is made is received from the manufacturer of iron in the form, thickness, and breadth required for the tubes of the various diameters and thicknesses of metal necessary for the purposes intended: it is cut into lengths, and then heated to a red heat in a reverberatory furnace of sufficient length to heat the iron at one operation. This furnace is similar in construction to a soldering stove, shown at *fig.* 2047; the heat is also regulated by dampers; it can, however, be raised to a higher temperature. When heated the 'skelp' at its end is beaten into a semi-tubular form, and after passing it through the tool, it is taken hold of with the plyers of the drawbench and drawn through its entire length, the tool either being a pair of rolls, as in *fig.* 2040, or a two-part conical pair of dies united together as a pair of plyers; see *fig.* 2038. In *fig.* 2039 the operation of the die, &c., is shown in welding, after a second heating: A A is section of bell-mouthed tool; B the unwelded tube; C, the portion drawn through the tool or die, and welded in passing through; this completes the manufacture of a 'butt or jump-joint welded tube for gas or the transmission of a fluid in which the pressure is not great.'

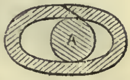
In the manufacture of a 'lap' welded tube, the manipulation is more complicated, as the edges of the iron to be welded require to be thinned preparatory to welding, and this is effected by drawing the edge of the sheet against a suitably-formed cutter, which cuts away the desired metal from the opposite sides of the metal, which come together, and form the 'lap' to be welded; see *fig.* 2041. The flat strip is then worked into an oval form in its entire length, the lap being in the centre of the longest diameter of the oval in a transverse section; see *fig.* 2042. Down the centre of this oval-formed tube or unwelded cylinder, a mandril is introduced, A, which forms an internal support: the tube being heated, and the mandril inserted, the tube is passed through rolls to effect and complete the weld. The tube is brought into a cylindrical form by passing through rolls, the reverse or largest diameter being compressed or converted thereby into a cylindrical tube; the rolls are operated upon by screws which permit of their being pressed down into closer contact, and to convert an oval opening in the rolls when asunder or not screwed down into a circular opening, when the rolls are brought into closer contact.

2040



2041

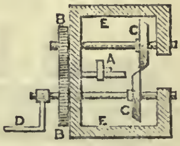
2042



The Manufacture of Steel Tubes for Ordnance, Gun-barrels, and other purposes, has recently been carried into practical usefulness, and more particularly so since the extensive application of the Bessemer process. Ingots of iron produced by the process named are reheated, and hammered in every direction, so as to ensure perfect homogeneity of substance and material, and the ingot reduced in thickness and increased in breadth. To form a cylinder for a heavy gun or rifle, the centre of the blank of steel is operated upon by a punch moved by machinery, which not only condenses the metal operated upon, but in moving radially forms or raises the disk-like mass into a partially-formed solid-ended crude cup, eventually into a steel billet: into the centre of the billet a mandril is inserted, and it is elongated and compressed until the desired length and dimensions of the tube required are arrived at. The lightness and strength of steel in a tubular form suggests its applicability to large-sized shafting hitherto made of solid iron, and to other purposes where great masses of steel were forged solid and bored out. When this process of manufacture is perfected, and consequently cheapened by being more generally applied, steel tubes, cylinders, and hollow shafts will supersede the use of tubes, large solid shaftings, and many tubular articles now made of iron.

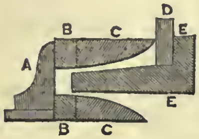
The Manufacture of Brass Tube of the ordinary kind, known as Soldered.—This variety of brass tube, so largely used in the manufacture of gas-fittings, cornice-poles, and other articles in which brass tube is employed in the construction, is made from brass cast in thick strips, and rolled out into sheets of the thickness required. These sheets are cut into ribbons in breadth corresponding to that necessary to produce, when turned up, tubes of the various diameters required. This is done by means of revolving disks of steel, or cutters fitted into a frame, and operated upon by a winch-handle when worked by hand, or attached to a shaft in connection with an engine when moved by power, see *fig.* 2043: E E, represents a cast-iron frame; C C, the revolving disks of steel, or cutters; A, a moveable gauge, in order to determine the breadth and guide the edge of the sheet brass to be cut; B B are pinions which are attached to the spindles which carry the cutters, and D the winch-handle to move the cutters when worked by hand.

2043

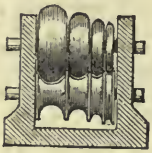


When the metal of which the tube is made is thin, and the tube is small in diameter, it is readily formed into a cylinder by simply converting the end of the ribbon into a tange by hammering together the metal which forms the end of the ribbon, in order to allow it to enter the drawing tool, using also an additional funnel-shaped tool to gather up or concave the ribbon in its width. This is assisted by a tapering iron plug held in the funnel-shaped gathering-up tool already alluded to. This arrangement is represented in *fig.* 2044: A representing the snag of drawbench against which the tool rests; B, the tool or die; C, the trumpet-shaped or 'gathering-up' die; E, an iron tapering plug; D, a wedge, in order to prevent E from being drawn in and stopping the metal being turned up in its passage through the 'gathering-up' tool and die, thus converting the ribbon of brass into a tubular form, the edges of the ribbon forming a longitudinal opening down the entire length of the partially-formed tube: this longitudinal opening or slit and the edges of the metal are brought closer together by removing the wedge D, and checking the passage of the ribbon, when the pull of the drawbench brings the two edges of the partially-formed tube closer together. Tubes of larger diameter and of thicker metal, however, require the breadth of metal necessary for their construction to be rendered concave in their entire length, to facilitate the operation of turning the metal up; and this is done by means of a pair of rolls, one of which has on it a series of projecting beads of varying diameters in convexity; the corresponding roll has corresponding concave grooves, as shown in *fig.* 2045. The

2044



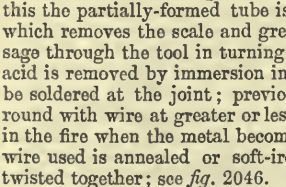
2045

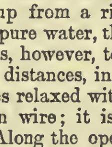


2046

width of metal is presented to that portion of the roll which will impart the necessary degree of concavity to the strip in its entire length. It is then passed through the rolls, and in passing through is converted into a concave trough-like piece of sheet metal. As in former descriptions in reference to thin metal, the end of the metal is beaten into a tange to be caught by the plyers of the drawbench. This tange is passed through the drawing tool, laid hold of by the plyers, and drawn through the tool; its edges are drawn together by a final pinch or pull of the drawbench. The next operation is that of soldering or uniting the two edges of the metal together: previous to this the partially-formed tube is annealed, and immersed in a solution of weak acid, which removes the scale and grease used in lubricating the metal to facilitate its passage through the tool in turning up from a ribbon to its tube-like form. After the acid is removed by immersion in pure water, the open-jointed tube is in a condition to be soldered at the joint; previous, however, to this it is necessary to bind the tube round with wire at greater or less distances, in order to prevent the seam from opening in the fire when the metal becomes relaxed with the heat of the soldering stove. The wire used is annealed or soft-iron wire; it is passed round the tube, and its ends twisted together; see *fig.* 2046. Along the open joint is laid granulated brass solder, mixed with borax, the latter acting as a flux, at the same time keeping the edges of the joint clean. The solder fuses at a lower temperature than the tube to be soldered. When the solder has been distributed along the seam of the tube (this and the preceding operation usually being performed by women and girls), the tube is in a condition to be passed into the hands of the solderer. The soldering furnace or stove has a provision for a fire 6 or 7 feet long, which burns in a firebrick square tunnel, open at both ends for the introduction of the unsoldered tube at one end, and when soldered to remove it at the opposite end. The fuel used is small coke or 'breezes;' coal until reduced to coke would prevent by its smoke and consequent low heat the fusion of the solder. *Fig.* 2047 shows a section through length of a soldering stove, and *fig.* 2048 a perpendicular section of the same. A A A A A, *fig.* 2047, is brickwork; D D, dampers, to regulate the draught of fire and increase or diminish its intensity;

2047 2048





C C are iron bars, on which those rest on which the fire is placed; and B B, the tube which is to undergo the soldering process. The pipe is inserted at one end; the fire playing under and over it, speedily heats the tube; the necessary heat to fuse the solder arrived at, it fuses and unites the two edges of the metal, and the operation of soldering is completed. If the tube has been bound round with wires, these are untwisted and taken off, and in order to get rid of the borax, the tubes are immersed in long troughs of wood, lined with lead and filled with a 'pickle,' composed of a solution of oil of vitriol and water. After remaining in this bath for a limited period, and being rinsed out in water, the superfluous solder is filed off, and the tube is in a condition to receive its final finish in the drawbench, which is effected by placing a drawing-tool so formed that its internal diameter has more friction on the tube than the one used for 'turning up' the tube from the ribbon, the tange of the tube is passed through the tool, and laid hold of by the plyers attached to the chain of the bench, the wheels are thrown into gear, and the tube is drawn through and receives in the operation the fine smooth surface apparent on well and carefully drawn brass tubes.

The Ornamentation of Tubes in Brass, &c.—The action of the drawbench being, as its name indicates, to draw or pull a partially-formed cylinder through a steel tool or die, the tool or die being placed at right angles, the aperture in the centre of the tool being placed parallel to the surface of the top of the drawbench, suggests that if the tube is cylindrical, reeded, fluted, square, oval, hexagonal, polygonal, or angular in its entire length, any of these forms may readily be produced, by simply substituting a draw-plate, the aperture of which corresponds to the external configuration of the desired form of the tube. Tubes which have spiral, concave, or convex twists or threads, traversing their entire length, however, require peculiarly formed tools or dies, and an arrangement in their use to meet the requirements of the desired style of ornamentation.

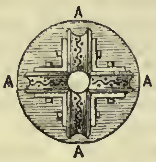
2049

A B C

Tubes shown in *fig.* 2049, A B C, are produced from metal, first ornamented by the introduction of perforated sheet zinc between two sheets of metal, and in that position the three sheets are passed through a pair of rolls, the perforated zinc, by the pressure in rolling, being forced into the surface of the brass to be ornamented; the raised portions of ornament in relief; as the quatrefoils, disks, and diamonds, corresponding to the perforations in the zinc introduced between the two sheets of brass to be ornamented. This style of ornamentation of flat metal was introduced by R. F. Sturges, of Birmingham, in the year 1852, and is identical with the process employed in the production of the plates used to produce impressions from natural objects, and known as Nature-Printing. The same effect would be produced by steel rolls cut with ornamental devices on their outer circumference, but the expense of such rolls being very great, the perforated zinc, considering the limited character of the demand for such tubes, is more economical. The ornamental metal being cut up into the breadth required, is made into tube by the process already described as that by which ordinary soldered cylindrical brass tube is made.

Another variety of ornamental tube is produced by a very ingenious process introduced also in the year 1852, by Mr. Fearn. In this process the ornament is impressed on the surface of the tube after it is made: the tool used is formed by a construction of rolls as shown at *fig.* 2050, the internal or hollow surface of the rollers which press

2050



2051

A B C

2052

A B C

upon the tube being cut with the necessary design, the cylindrical or other tube to be ornamented is supported internally by a mandril, and in passing it through the combined tool or die, the rollers, A A A A, revolve and indent the design cut on their circumference into the surface of the plain tube to be ornamented. *Fig.* 2051 shows the style of ornament produced by this process: A being produced on a steel mandril as an internal support; in B and C the convexity or relief of the ornamental beads being greater, it is produced by substituting for the incompressible steel mandril a filling of pitch and resin; the number of rolls may be diminished, or the designs on the concave surface of the rollers may be varied according to the style of ornament desired. It is unnecessary to state that the rollers are formed of the best steel, and are carefully tempered after the die-sinker has cut the design thereon.

When the ornamentation desired consists of series of reeds or flutes traversing spirally and screw-like, familiarly known as 'twisted tube,' and largely used in the construction of mediæval and other gas-fittings, &c., the tool represents a screw-nut, which is made to revolve by attachment to a hollow spindle; the cylindrical tube is firmly held by the artizan when passing through the tool, and the thread is impressed into the tube, or rather is indented in its passage through the tool or die, the tube being lubricated with oil or tallow to aid the indentation and prevent the projecting thread in the die from cutting or tearing the metal of the tube subjected to its operation. These tools or dies are not made of steel, but of chilled cast iron, their production by the process of casting being more easily effected than by their being cut in cast steel; the friction being reduced to a minimum by the hollow tube yielding readily to the pressure of the convex threads of metal in the die: the characters of such tubes are represented in *fig.* 2052. A and B are the result of once passing the tube through the tool; C showing a diamond raised in centre, is produced by first passing the tube through a tool with the thread right-handed, and then through a tool in which the thread is left-handed, or in the reverse direction or inclination to that through which it was previously passed.

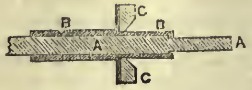
2053

A B

The tubes, *fig.* 2053, are formed of three separate tubes united together, each component tube being first drawn as a separate tube: A being composed of three six-fluted tubes, produced by being drawn through a correspondingly shaped die; B by ordinary separately drawn plain tubes; and in C the three tubes, in addition to the ordinary process of drawing, are subjected to the operation of twisting as already described in the last paragraph (under the head of twisted tubes); the three tubes, eventually forming one united tube, are then arranged parallel to each other and the rope-like appearance of the tube, when finished, is produced by uniting them together by twisting, as strands in an ordinary rope, each tube being filled with pitch and resin to preserve its primitive tube-like form, and prevent its collapsing in the process of uniting the three tubes into the rope-like appearance when finished.

The Manufacture of Mandril-drawn Tubes, or Tubes perfectly cylindrical in their internal and external diameters.—This variety of tube, is chiefly made in brass or copper: in the former material principally used in the manufacture of optical instruments, more particularly telescopes, dependent for their perfection in working on tubes of the utmost degree of accuracy and perfectly cylindrical form, to ensure steadiness when in work; large quantities of mandril-drawn tubes are also used for the barrels of garden and other syringes, telescopic hearth-brushes and toasting-forks, &c.; while ordinary soldered jointed brass tube could not be successfully used, or if used, would require an amount of labour to fit it for the purpose, obviously out of place with the expeditious modes of working now in existence. The elasticity resulting from the process of mandril-drawing, is another advantage in connection with this process, arising from the condensation of the particles of the brass of which the tube is made, these being forced down or compressed by the action of the unyielding steel tool, and the equally unyielding mandril or spit, which internally supports the ordinary brass tube subjected to the process. An ordinary brass tube is unequal in thickness internally throughout its entire length; the two edges of the strip from which it is made and where it is soldered, are clearly seen; and it is evident that anything working piston-like therein, would do so only imperfectly. The manufacture of light brass mandril-drawn tube is practised as follows: A carefully selected and well-forged cylinder of steel is turned to a perfect cylinder by means of a slide rest, and carefully polished; the brass tube made in the way already described, is slipped on the mandril: in this position the mandril and sheath of brass is presented to the die in the drawbench, and is drawn through the tool which forms the outside surface of the tube, compressing the metal, reducing the thickness, and compelling it to embrace the steel mandril or internal support. The result is an elastic brass tube, suitable for the purposes already enumerated. The air being expelled between the tube and the mandril, considerable difficulty arises in releasing the tube from the mandril, and this is effected by means of a collet or collar a little larger than the steel mandril, but less in aperture than the tube: the collet is placed in position of the drawing tool, the reverse end of the mandril being operated upon, as in drawing the tube, the result is that the tube is withdrawn from its internal support, and if the mandril has been correctly turned, a perfectly cylindrical tube is the result of the preceding operations. In *fig.* 2054 the arrangement of mandril and tube to be drawn, and tool, are shown: A A, represents the mandril; B B, the brass to be operated upon; C C, section of the tool; the thickness of line to the left of the tool C C indicates that part of the brass which has not been subjected to the operation of the drawing tool. The release of the drawn tube is shown in *fig.* 2055; the collar or collet C is substituted in the drawbench for the tool shown in the preceding *fig.*; the thick end of mandril A, passed through this, is taken hold of by the plyers of the drawbench;

2054



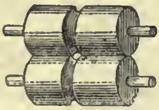
2055

the end of the metal of the tube presents a resistance, while the force of the drawbench drags out or releases the mandril from the drawn tube. Mandril, or drawn 'inside' and 'out' tubes, as they are familiarly called by the 'users,' may be made of any form or size. When of extra thick metal, very powerful, slowly moving drawbenches are required.

The Manufacture of Patent Brass-cased Tube, or iron tube, cased with brass.—This variety of tube—largely used in the construction of articles in which the external appearance of brass is desired with the strength of iron, as in balustrades for stairs, railings of various kinds, picture-rods, window and other rods, and bedsteads, chairs, and other articles of furniture made in metal of a portable character, and otherwise—was introduced to the brass-foundry trade of Birmingham in the year 1803, and is stated to have originated in the observation of the difficulty of removing a mandril-drawn brass tube from the steel mandril on which it was drawn. The inventor, Sir Edward Thomason, was largely engaged in the silver and plated ware manufactures in Birmingham. As a manufacturer of sliding hearth-brushes, toasting-forks, and other articles telescopically formed, he used large quantities of mandril-drawn tubes, and in the production of such tubes, and the difficulty of getting these off the internal support, the manufacture of patent tube originated. Thomason first also originated the idea of covering solid iron rods with copper and brass, with the intention of their being used instead of solid copper bolts for ship-building purposes. Though unsuccessful as regards the application of iron-cased bolts for the purpose, solid iron rods cased with brass became, and have become, an article of large consumption in the form of the rods which retain the carpetings on stairs. Eventually an iron tube took the place of the solid iron rod, and the manufacture of cased tube took its place as an article of extensive demand for the purposes already named. The manufacture of patent cased brass or iron tube is thus practised:—Sheet iron of good quality, if for articles which do not require to be bent in manufacture, as in rods for pictures, straight railings, &c.; but if the tube is to be bent, charcoal-iron is selected; the sheets of iron are cut up with circular cutters, as shown at *fig.* 2043; and the ribbon arising from the cutting or slitting of sheet iron is concaved in its entire length by passing it through rolls, as shown in *fig.* 2044. It is drawn into tube at the drawbench, in this state: if the tube is intended for articles which are to remain straight, the iron tube is in a condition to allow of its receiving its case of brass; if it is intended that the tube should be bent, the iron tube is soldered together at the seam, as already described in the manufacture of soldered brass tube, the brass sheath intended to cover the iron tube or to case it with, is made of such an internal diameter as will slide over the iron tube it is intended to 'case' or cover, the brass case being turned up, made, and soldered, as already described in the manufacture of soldered brass tube. The brass sheath is then slid over the iron tube, and in this position the end of the two united tubes of iron and brass is passed through the drawing tool: the pressure resulting from the action of the drawbench causes the external brass sheath or tube to embrace firmly the iron tube in its interior, and an externally brass and internally iron tube is produced thereby. During the many years this branch of tube manufacture has been practised, no change or improvement has been made in its manipulation—if we except that, within the last few years, hoop-iron has been substituted in the manufacture of second-rate cased tube, instead of cutting up the broad sheet-iron as formerly.

Taper Tubes of Brass or Iron.—This form of tube, formerly made entirely by hand, is now drawn with ease and facility. The old method of production consisted of cutting out the metal from the sheet requisite to produce the desired taper tube. It was then malleted into a taper tubular form, and the metal soldered together at the junction; then, after the extra solder was removed, it was hammered on a taper mandril or stake, as in use among tinmen. Many ingenious drawing tools were made for the purpose of producing taper tubes. These consisted of dies made in sections, or various pieces; they were united in frames, and when used in the drawbench the parts of the die were operated upon by springs, which permitted of their expansion as the taper increased in the tube and mandril intended to be drawn. Such tools, however, never produced good taper tubes. An after invention consisted in using a pair of rolls with diminishing grooves on their diameter or circumference, and presenting the taper mandril with its sheath of metal at its smallest diameter to the narrowest part of the groove; the revolution or partial revolution of the rolls compressed the metal sheath to the mandril and produced a taper, but still irregular taper tube. This method was patented by Henry Osburn so far back as the year 1813. It, however, seems to have been lost sight of, from the limited demand for taper tubes at the period, and the same process was revived by Church and Harlow in 1841. Though great numbers of taper tubes so made are still produced, it is obvious that, from the very nature of the action of the rolls, the production of taper tubes is limited to those of a purely tapering, externally smooth cylinder; and it would be impossible to produce either reeded, fluted, or twisted tapering tubes by the rolling process. The means, however, by which nearly every variety of tapering tubes can be produced, was effected in 1850 by John Ward, who in that year suggested, instead of an expanding tool made up of a complication of segments of steel, operated upon by springs, or that of the rolling process as already described (see *fig.* 2056), the production of a tool, draw-plate, or die formed in one piece, and of block tin cast in a metal mould. This tool, placed in the position of a 'die' in the drawbench, by the expanding yet compressing property of the metal of which it is made, forces the metal of the sheath to be converted into a taper tube, and into every groove or reed in the internal mandril or support on which the sheath or case to form the taper tube is placed. By the same process, also, tapering tubes with convex or concave twistings, threads, or reeds on the outer diameter can also be produced by the application of a swivel on the drawbench chain, which permits the mandril and its case of metal to revolve in its passage through the tool, the tool remaining stationary.

2056



The process may be described as follows:—The die or mould to produce the block-tin tool is formed of metal; the aperture in its centre is tapering—cylindrical if for a plain round taper tube—or if reeded, fluted, or twisted, a metal core with its requisite reeds, flutes, threads, or twists is introduced into the centre of the mould, and the tin poured in: the result is a cast, the interior of which is a copy of the mandril, and also of the external contour of the desired tube. *Fig.* 2057 shows external appearance of the tool when cast, and *fig.* 2058 its internal configuration, depending on the plain or ornamental character of the tube.

2057

2058

2059

The sheet brass or iron, being cut to the required diminishing breadth, is turned up and soldered at the joint, after the removal of the wires which held the edges of the partially-formed tube together, and the extra solder, the case to form the intended taper tube, &c., is placed on the mandril. In *Fig.* 2059, A A represents the sheath of brass to form the taper tube; B B, the mandril; the tool is then placed in the proper position in the drawbench, the end of the mandril forced through it, and taken hold of by the plyers attached to the chain; the tool expands and compresses the sheath against the internal mandril, clinging, yet expanding with the increased diameter of the taper of the tube and mandril it is drawn through. The result is a perfectly-formed taper tube, a perfect copy externally of the mandril on which the tube is placed. If the mandril is of an ornamental spiral construction, provision is made, as has been already stated, to admit of a screw-like revolution to indent the metal case into the concavities or threads cut on it externally, *i.e.*, the tool representing a stationary nut, and the mandril and its covering a screw in motion.

Finish of Cased and other Brass Tubes.—As regards the mode of finish adopted for tubes of which immense quantities are sent out in long lengths, especially of the iron cased with brass variety, it has been the custom of the trade to finish such by means of hand-labour only; the artizan engaged in the process using 'floats,' or files cut in one direction only, for the purpose of the removal of the external skin preparatory to polishing. One house only has applied or substituted a machine for the purpose of finishing tube. *i.e.* that of W. Tonks and Sons, Birmingham. Their machine is self-acting. The tube to be floated is attached to a horizontal bed: the floats, five in number, move parallel, and in a longitudinal direction. Each in its operation passes a little into the space previously floated; the tube is turned by the machine, and a new surface is exposed to be operated upon. The next operation after 'floating' is polishing, which is either effected by hand with list passed round the tube, the tube being lubricated with rotten-stone and oil, or (in the finish of large-sized tubes) an internal buff or hole lined with list or felt, revolves by machinery: the tube being passed in, is polished by the revolution of the buff; the final polish is given by dry list, with powdered dry rotten-stone. Brass tube when finished by burnishing is floated, then scoured with wet pounded clay crucible; then burnished by steel burnishers, gall being applied to hinder their scratching. The last method gives the most brilliant style of finish; by either mode of finish, they are protected from oxidation by a lacquer applied with a camel's-hair brush when the tube is heated, which is done either by laying the tube to be lacquered on a hot iron plate, or by passing through its interior a jet of steam. On cooling, the protection is perfect and the finish completed.

Solid Brass Tube, i.e. brass tube drawn without seam, as used for locomotive- and marine-boiler purposes, &c.

In 1780, Matthew Bolton suggested the introduction of tubes into steam-engine stationary boilers. Trevithick in 1815, in his experiments on engines for locomotive purposes, suggested and applied pipes or tubes, but placed them perpendicularly. Gurney, Summers, and Ogle, in their experiments used also tubes; and George Stephenson in his 'rocket' engine, adopted the almost present arrangement of the tubular boiler. By the ordinary, or soldered brass-tube process, the tubes so produced not unfrequently leaked at the joint or seam from imperfect running of the solder, and the production of a 'solid' or seamless tube became a desideratum. Iron tubes speedily become corroded by the surrounding water in the boiler, and the necessity for finding a substitute in a tube of a material not liable to oxidise and of sufficient strength to resist the exigencies of wear and tear, became a desideratum. Economically, also, the brass tube is in the end cheaper, as the old tubes are taken back by the manufacturers in exchange for the new at a trifling advance in order to cover expense of re-manufacture. Up to the year 1838, tubes for locomotive- and marine-engines were either formed of welded iron, or of brass tube produced by soldering at the joints. In that year, however, Mr. Green of Birmingham conceived and carried into practice the production of seamless brass tubes, in a manner akin or similar to that already described in the production or manufacture of lead and block-iron tube; *i.e.* he cast the brass or copper 'billet,' from which the future tube was to be made in moulds, inserted a mandril into the aperture produced by the sand 'core,' made an alteration in the drawbench, increasing its strength, and operated on its motion by reducing the speed, thereby increasing its power, in order to overcome the stubborn nature of the brass or copper billet operated upon. By reference to cut of drawbench, *fig.* 2025, the large wheel is not operated upon in the manufacture of solid brass tube, by a pinion as shown, but by an endless screw which worked into corresponding threads on the outer surface of the large wheel, and the die was formed not of one, but four parts, *i.e.* as four revolving pulleys placed at an angle to each other, forming a round hole or die in the centre; the brass billet or copper with its mandril similar in form to that already shown. It was then subjected to the action of the drawbench, and gradually reduced by the action of the four-roll tool to the desired external size and the strength of metal desired. Repeated annealings are required in the process of drawing, in order to restore the ductility of the metal of the partially-drawn billet, which is eventually converted into the finished locomotive tube. The metal or brass of which these tubes are composed is made from the best copper and zinc or spelter, as such tubes are replaced every three years; when worn out they are sold to manufacturers for reconversion into similar tubes, or command good prices for raw material, to be used for other purposes in the brass foundry trade.

Another method or process for the manufacture of solid brass tube is also in use, which was introduced in 1852 by G. F. Muntz, junior, and made from the metal familiarly known as 'Muntz's' metal, which possesses the property of being worked, rolled, or manipulated at a low red heat. (See MUNTZ METAL and SHEATHING.) In this, as in Green's process, the raw material is presented in 'billet' form for manufacture into finished tube. This process may be described as follows:—

The 'billet' out of which the future tube is intended to be made is cast in an iron mould with a sand-core: the billet is oval in form, the metal being thickest on the two largest surfaces of the oval. The billet being cast, and the sand removed from its interior, the interior is coated with a wash of lime-water and salt. This prevents the adhesion of the interior surfaces of the metal together in the process of rolling the billet to the length of the intended tube. This is effected by means of rolls grooved in their circumference. In the ordinary process of rolling metal, it will be observed that it is simply elongated by the thickness being reduced, but its breadth is not increased; the thickness of the metal of the 'billet' in the upper and under side therefore provides for this, and the result of the first rollings is to reduce the metal on the upper or under side to the same thickness as the sides. The oval billet being rolled into a flat strip or bar, has then one end opened to the length sufficient to admit of the introduction of a thick-ended mandril. With this introduced, the opened end of the tube is presented to the rolls; the thick part of the mandril retained in the tube at the point of pressure; the tube is drawn on and opened throughout its entire length. The position of the tube in the opening-up of the bar is the reverse of the previous operation, being presented in its largest diameter to the action of the rolls, or at right angles to the preceding operation. The adhering webs or fins consequent on this mode of production being removed, the tube is again passed through rolls, to produce it in form perfectly cylindrical, a mandril in the interior assisting the operation. All the operations in this variety of solid tube are conducted when the metal is at a low red heat, the metal of which these tubes are made, or Muntz's metal, consisting of copper, with a large percentage of zinc or spelter, imparting to it the property of being rolled at the temperature named, much facilitating the rapidity of production.

It may not be uninteresting to know that nearly all the locomotive-engines in use on the railroads of the United Kingdom are fitted up with seamless brass tubes. If to these are added the quantity of seamless brass tubes in use in the steamboats of the United Kingdom also, the united weights of these tubes gives a total of upwards of 20,000 tons of solid or seamless brass tubes in use by the various railway companies, steam-boat proprietors, &c., of this country. The production of solid brass tube in Birmingham, for these purposes alone, amounts to upwards of 8,000 tons annually.

A very admirable variety of solid or seamless *copper* tube is now produced from the worn-out copper rollers used by calico-printers for printing cotton fabrics. The old roller, with the rib which holds the roller on the printing spindle, in the operation of printing, taken out forms the billet; it is reduced in outer diameter, its internal diameter depending on the size of the internal mandril used, the reduction being effected as in the manufacture of Green's tube by powerful draw-benches. As in Green's tube, also, repeated annealings are required in the operation of reduction or drawing down to the size of tube required. This method of producing seamless copper tube from previously waste material was introduced in 1850, by the late Thomas Attwood: the density of the material of which the tube is formed, good at first, as being formed of wrought copper, is further solidified by the *modus operandi* in converting the worn-out roller into a tube for steam purposes. When subjected to great pressure it is unequalled in service.

In conclusion, as regards the manufacture of brass and copper tube but little remains to be stated. Messrs. Alexander and Henry Parkes patented the addition of phosphorus and manganese to the alloy of brass and zinc, out of which locomotive and marine boiler-tubes are made, which they state improves the metal, imparting to it superior cohesive properties, and also solidity. The direction recently given for locomotive and marine engine-tubes is towards tubes containing a larger proportion of copper than even in those of 'Green's' mixture. It is stated, if the percentage of copper is increased, the tubes may be made lighter in material, and will be less likely to be operated upon by the sulphates in the fuel. Finally, if certain preliminary details as to the casting of the 'billets,' from which the solid or seamless tubes are drawn, or in raising the 'billets' up from thick disks of rolled metal, but little remains to be recorded as respects the improved manipulatory operations in the manufacture of brass or copper tubes.

TUBULAR BRIDGES. In the fourth edition—the last published during the lifetime of Dr. Ure—there was a long article bearing the heading of FAIRBAIRN'S TUBULAR BRIDGES. This article no longer appears. In the first place, it ought never to have found a place in a work which has nothing whatever to do with Engineering Science. Such was the introduction to the article as it appeared in the fifth and sixth editions of this Dictionary. The article, which was written with great care by the Editor himself, after several interviews with both Mr. Robert Stephenson and Mr. Fairbairn, was acknowledged by both these eminent engineers to give the most correct account of the merits of each of them, in the construction of these remarkable works. Those who may be interested in this question are referred to the last edition of the Dictionary: the article having been withdrawn from this edition to make room for matter which belongs more especially to Art, Manufactures, or Mines.

TUE-IRON, also *Tuiron* and *Tuarn.* The old name for the blast-hole, or twyer, or tuyère of a blast-furnace.

TUFA. A deposit of calcareous carbonate from springs and streams. Also, a volcanic product. See MORTAR, HYDRAULIC.

TUGMUTTON. A wood resembling box, which was imported and used for making ladies' fans. It does not appear to be now known in the trade.

TULA METAL is an alloy of silver, copper, and lead; made at Tula in Russia.

TUNGSTEN or **WOLFRAM.** (*Tungstène*, Fr.; *Wolframium*, Ger.) *Symbol* Ts or W; *at. wt.* 92. Its name is derived from the principal mineral from which it is obtainable—*Tungsten* (Swedish *tung*, 'heavy,' *sten*, 'stone,') or *Wolfram.* This metal was discovered by the Brothers De Luyart, about 1784, shortly after the discovery of tungstic acid by Scheele, from whom it has been sometimes called *Scheelium.* It is never found in the native state, but is produced by a variety of processes. First, and most easily, by mixing the dried and finely-powdered tungstate or bitungstate of soda with finely-divided charcoal, such as lamp-black; placing the mixture in a crucible lined with charcoal, covering it with charcoal in powder, and then exposing the whole to a steady red heat for two or three hours. On removal of the crucible and cooling it, a porous mass is found, from which the soda is removed by solution in water, and the unconsumed carbon is separated by washing it off, the metal being left as a bright, glistening blackish-grey metallic powder. It may also be obtained by treating tungstic acid in a similar manner, or by exposing the acid at a bright red heat, in an iron or glass tube, to a current of hydrogen gas. Tungsten is one of the heaviest metals known, its specific gravity being 17·22 to 17·6. It requires such a very high temperature for fusion that it has never yet been obtained in mass, more commonly as a fine powder, but sometimes in small grains. It is not magnetic. It is very hard and brittle. Alone it has not been rendered available for any useful purpose, but it has lately been employed for the manufacture of certain alloys. Tungsten is comparatively a rare substance, and is remarkable for the very limited extent to which in nature it is found to have been mineralised by combination with other substances. In none of these does it exist as a salifiable base, but as an acid, as in wolfram, Scheelite, yttrotantalite, and the tungstate of lead.

The most common ore of this metal is *wolfram*, known also to the Cornish miner as 'cal' or 'callen.' It is most commonly found associated with tin ores, which contain besides the black oxide of tin or cassiterite, the metallic minerals, arsenical iron, copper, lead, and zinc sulphides: but its peculiarly characteristic associate is the metal molybdenum, for the most part mineralised as a sulphide. This metal is remarkable in connection with tungsten as producing isomeric compounds, and as having both its equivalent and its specific gravity equal to about one-half that of tungsten, they being, respectively, as follow: equivalents, W 92, Mo 49; sp. gr. W 16·22, Mo 8·615.

Amongst miners wolfram has the reputation of being an abundant mineral, but it is comparatively rare, schorl, specular and other iron ores, and gossan being often mistaken for it. From its association with tin ores, it has been until lately the source of great loss to the miner, as it was found quite impossible to separate it from the ore in consequence of its specific gravity, 7·1 to 7·4, being so near to that of black tin, 6·3 to 7·0.

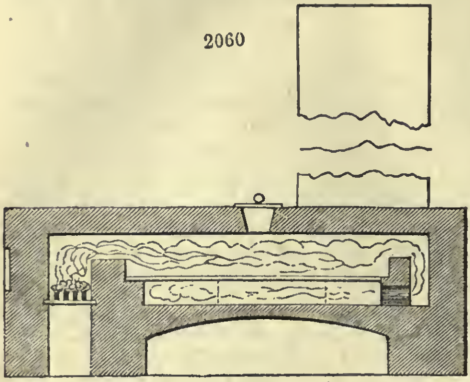
Pryce, in his 'Mineralogia Cornubiensis, 1778,' says: 'After the tin is separated from all other impurities by repeated ablutions, there remains a quantity of this mineral substance (gal), which being of equal gravity cannot be separated from the tin ore by water, therefore it impoverishes the metal and reduces its value down to 8 or 9 parts of metal for twenty of mineral, which without its brood, so called, might fetch twelve for twenty.' This description of tin ores containing wolfram was still applicable until a very recent period, who a new process was invented by Mr. Robert Oxland, of Plymouth, and by him successfully introduced at the Drake Walls Tin Mine, at Gunnis Lake, on the banks of the Tamar, where it was continued in operation until the mine was closed. At this mine, although the tin ore raised was of excellent quality, it was left associated with so much wolfram that the ore fetched the lowest price of any mine in Cornwall. By Oxland's process, it was brought up to the price of the best black tin. The process is now employed at East Huel Rose, near Camborne.

At the time of the introduction of the process the greater portion of the ore was sold for 42*l.* per ton. The improvement effected by it was so great that the same sort of ore fetched the price of the best black tin.

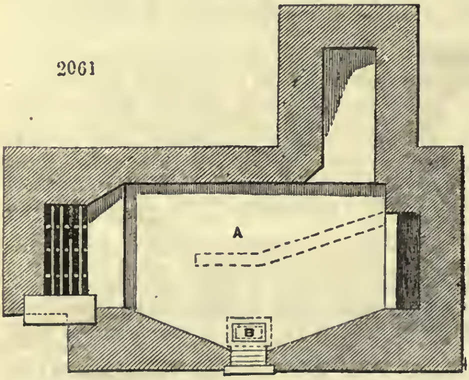
The process consists in taking tin ores mixed with wolfram, dressed as completely as possible by the old process, and having ascertained by analysis the quantity of wolfram contained therein, then mixing therewith such a quantity of soda-ash of known value as shall afford an equivalent of soda for combination with the tungstic acid of the wolfram, which is the tungstate of iron and manganese; the object of the process being by calcination to convert the insoluble tungstate of iron and manganese into the soluble tungstate of soda, leaving the oxides of iron and manganese in a very finely-divided state of low specific gravities, so that they can be easily washed off with water.

The mixture, in charges of five to ten cwts., is roasted in a reverberatory furnace on a cast-iron bed of the construction shown in the annexed engraving. The use of the cast-iron bed is attended with considerable economy in the consumption of fuel, and it is admirably well adapted for the calcination of the raw ores, for the evolution of the sulphur and arsenic contained in them, but it is especially necessary, instead of fire-brick or tile, to avoid the loss which would accrue from the reaction of the soda-ash on the silica of the brick, and the formation of soda silicate of tin which would consequently take place. The mixture is introduced to the bed through a hole in the crown of the furnace; from a side door it is equally distributed over the bed, and from time to time it is turned over by the furnace-man until the whole mass is of a dull red heat, emitting a slight hissing sound, and in an incipient pasty condition. In successive quantities the charge is then drawn through a hole in the bed of the furnace into the *wrinkle* or arch beneath, whence it is removed to cisterns, in which it is lixiviated with water, and the tungstate of soda is drawn off in solution. The residuary mass left in the cisterns,—the whole of the soluble matter having been washed out,—is removed to the burning-house floors, and is there dressed over again in the usual manner, the final product of the operations being very nearly pure black oxide of tin. The liquid obtained is either evaporated sufficiently for crystallisation when set aside to cool, or is at once dried down to powder. The crystals of tungstate of soda thus obtained are colourless, translucent, of a beautiful pearly lustre, having the form of rhombic prisms or of four-sided laminæ.

2060



2061



It has been proposed to use this substance as a mordant for dyeing purposes, as a source of supply of metallic tungsten for the manufacture of alloys, for the manufacture of the tungstates of lime, baryta, and of lead to be used as pigments; and still more recently it has been found to be preferable to any other substance, for rendering fabrics non-inflammable, so as to prevent the terrible accidents constantly occurring from the burning of ladies' dresses. For this purpose a patent was obtained by Messrs. Versmann and Oppenheim.

For the manufacture of metallic alloys a patent has been obtained by Mr. R. Oxland, as a communication from Messrs. Jacob and Koeller. It is prepared by simply melting with cast steel, or even with iron only, either metallic tungsten, or preferably, what has been termed the 'native alloy,' of tungsten, in the proportion of two to five per cent. The steel obtained works exceedingly well under the hammer. It is very hard and fine grained, and for tenacity and density is superior to any other steel made. The 'native alloy,' is obtained by exposing to strong heat in a charcoal-lined crucible a mixture of clean powdered wolfram with fine carbonaceous matter. A black steel-grey metallic spongy mass is obtained resembling metallic tungsten.

The tungstate of soda is used in dyeing. Metallic tungsten is also used for the manufacture of packfong or Britannia metal, by alloying with copper and tin.

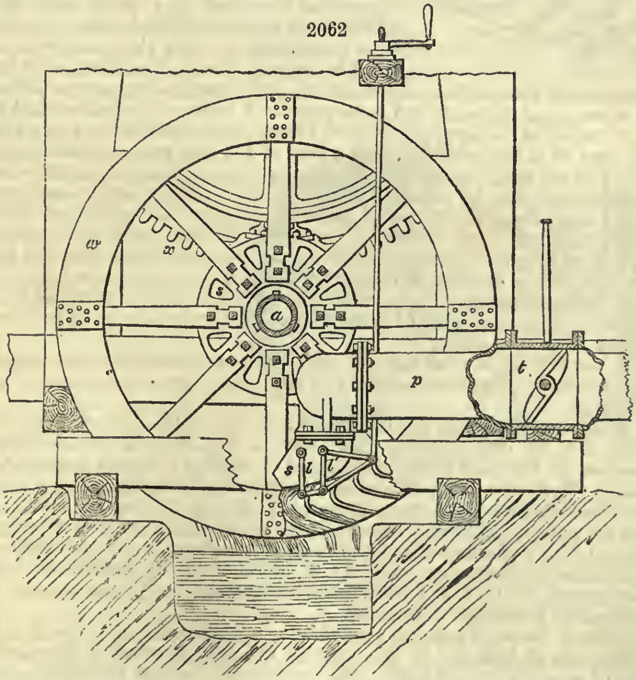
TURBA. This is a mere local word used in the want of knowledge of a more precise designation. *Turba,* in Portuguese and Spanish (like *Tourbe* in French), is

Tourbe in French), is a general term signifying any peat-like or earthy deposit formed in swamps and afterwards dried, and is also applied to peat itself.

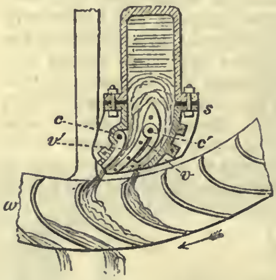
TURBINE. Numberless are the varieties, both of principle and of construction, to be met with in the mechanisms by which motive power may be obtained from falls of water. The chief modes of action of the water are, however, reducible to three, as follow:—First: The water may act directly, by its weight, on a part of the mechanism which descends while loaded with water, and ascends while free from load. The most prominent example of the application of this mode is afforded by the ordinary bucket water-wheel. Second: The water may act by fluid pressure, and drive before in some part of the vessel, by which it is confined. This is the mode in which the water acts in the water-pressure-engine, analogous to the ordinary high-pressure steam-engine. Third: The water, having been brought to its place of action, subject to the pressure due to the height of its fall, may be allowed to issue through small orifices with a high velocity, its inertia being one of the forces essentially involved in the communication of the power to the mechanism. Throughout the general class of wheels called Turbines, which is of wide extent, the water acts according to some of the variations of which this third mode is susceptible. The name Turbine is derived from the Latin word *turbo*, 'a top,' because the wheels to which it is applied almost all spin round a vertical axis, and so bear some considerable resemblance to the top. In our own country, and more especially on the Continent, turbines have attracted much attention, and many forms of them have been made known by published descriptions.

Turbines for Mining Purposes.—Although the horizontal water-wheel has been known and employed under various forms from the highest antiquity, and has latterly been improved by Fourneyron, Fontaine, Jouval, and others, so as to rank among the most perfect of hydraulic motors, it has only recently been applied to mining uses (pumping, loading, &c.), and where so employed its success can scarcely be said to be yet decided. The failures may be attributed to the following causes:—First: The plan of causing the water to flow simultaneously through all the buckets necessitates the use of wheels of small dimensions, making a very great number of revolutions per minute, and thus requiring a considerable train of intermediate gear to reduce the speed to the working rate. Second: The complex nature of the ring sluices

2062



employed between the guide curves and the mouths of the buckets, renders them uncertain in action, and from their small dimensions liable to be easily choked by any mechanical impurities in the water; and lastly, the lubrication of the foot spindle of the vertical wheel, revolving at very great velocity, is attended with considerable difficulty and inconvenience, especially where the engine-room is at a considerable distance below the surface of the earth, and it is requisite, as in the case of pumping wheels, to keep the machinery in action continuously for long periods of time. The form of wheel of which a notice is here appended, was introduced into the Saxon mines about the year 1849 by Herr Schwamkrug, inspector of machinery at the Royal Mines and Smelting Works at Freiberg, and since that time several have been introduced for pumping, winding, driving stamp-heads, &c. The example selected for illustration was built to take the place of two overshot water-wheels, employed in pumping water at the mine 'Churprinz Friedrich August': it differs from the usual form of turbine in having the wheel placed vertically, and in having the water supplied through a small number of guide-curves near the lowest part. In this latter respect it resembles the tangential turbine of General Poncelet, with this difference that the water flows from the inner to the outer circumference, instead of the reverse way, as is the case in Poncelet's wheel. The construction of the wheel is as follows:—*a*, *fig.* 2062, is the tubular axle of cast iron which carries the seating for the arms, *s*, which is similar to that usually used for large water-wheels; to the ends of the arms is attached the wheel *w*, which is formed of two brags or shroudings of sheet iron, each 13 inches deep, measured radially, and of a total height of 10 feet 2 inches; these two rings are maintained at a distance of 6 inches apart, by means of 44 sheet-iron buckets of the form shown in the smaller detailed figure, *fig.* 2063; the driving water is admitted



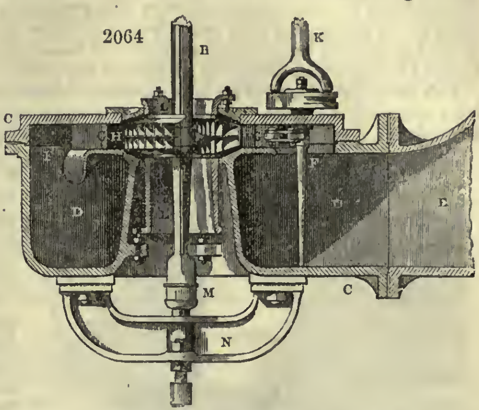
through the pressure pipe, *p*, in which is placed the admission throttle, *t*, and turned through a pipe of rectangular section (shown in the smaller figure) into the sluice box, *s*, which contains the two guide-curves, *v*, *v'*, which are moveable about the centres, *c*, *c'*, by means of the levers, *l*, *l'*; by means of these guide-curves when fully opened, as shown in the figure, the water is admitted into the buckets in two parallel streams or jets of $5\frac{3}{4}$ inches in breadth, and $1\frac{3}{10}$ths in. in thickness; the power is transmitted from the axle of the wheel by a pinion with 28 teeth, which draws the large toothed wheel, *x*, which acts on a third shaft carrying the pump-cranks. The wheel is constructed to work under a head of 147 feet, and makes about 130 revolutions per minute, with a maximum quantity of 550 cubic feet of water, equal to nearly 175 horse-power. A series of dynamometrical experiments on a wheel of similar construction of 7 feet 9 inches in diameter, with a discharge varying from 39 to 134 cubic feet, with a head of 103 feet, gave an available duty of from 58 to 70 per cent., the number of revolutions varying from 112 to 148 per minute.

In conclusion, it may be remarked that the vertical turbine may be employed with advantage where the available fall of water is too great to be employed on a single overshot water-wheel; and although a less perfect machine than the water-pressure engine, it is of simpler construction, and may be preferred where, from the hardness or yielding nature of the rock, it becomes difficult to construct large machine-rooms or wheel-pits underground. In practice it is found necessary to surround the wheel with a casing of wood, in order to prevent the affluent water from being projected to a distance by centrifugal action.

A fine model of one of these turbines, with two sets of buckets, constructed for the purpose of winding (*Turbinengöpel*), may be seen at the Museum of Practical Geology, Jermyn Street.

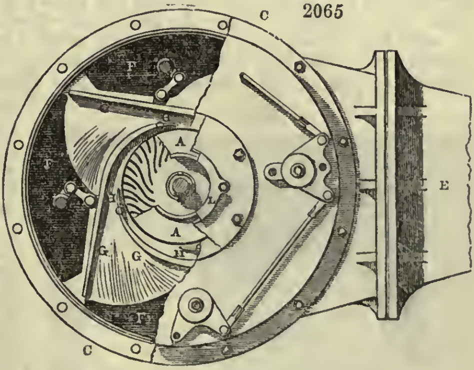
For further information on this subject, we may refer to the *Polytechnisches Centralblatt*, Nos. 8, 9, for 1845, and No. 3 for 1850; to the *Jahrbuch für den Berg- und Hüttenmann*, for 1850 and 1853. The subject of turbines is treated in great detail in Weisbach's 'Mechanics of Machinery and Engineering.' Redlenbache's *Theorie und Bau der Turbinen und Ventilatoren*, Mannheim, 1844, is the best and most complete work on the subject. Notices of Fourneyron's, Jouval's, and Fontaine's turbines are to be found in Glyn's 'Rudimentary Treatise on Water-Power,' in Weale's Series. The original notice of Fourneyron's turbine is published in the *Bulletin de la Société d'Encouragement*, for 1834, and several new forms are noticed in the various volumes of Armengaud's *Publication Industrielle.*

The name of Vortex Wheel has been given to a modification of the turbine by Mr. James Thomson of Belfast. In this machine the moving wheel is placed within a chamber of a nearly circular form. The water is injected into the chamber tangentially at the circumference, and thus it receives a rapid motion of rotation. Retaining this motion, it passes towards the centre, where alone it is free to make its exit. The wheel, which is placed within the chamber, and which almost entirely fills it, is divided by thin partitions into a great number of radiating passages. Through these passages the water must flow in its course towards the centre; and, in doing so, it imparts its own rotatory motion to the wheel. The whirlpool of water, acting within the wheel-chamber, being one principal feature of this turbine, leads to the name *Vortex*, as a suitable designation for the machine as a whole.



The vortex admits of several modes of construction; but the two principal forms are the one adapted for high falls, and the one for low falls. The former may be called the high-pressure vortex, and the latter the low-pressure vortex. An example of each of these two kinds is delineated in the accompanying figures.

Figs. 2064 and 2065 are respectively a vertical section and a plan of a vortex constructed for employing a very high fall near Belfast to drive a flax-mill.[1] A A is the water-wheel. It is fixed on the upright shaft B, which conveys away the power to the machinery to be driven. The water-wheel occupies the central part of the upper division of a strong cast-iron case C C. This part of the case is called the *wheel-chamber*. D D is the lower division of the case, and is called the *supply-chamber*. It receives the water directly from the supply pipe, of which the lower extremity is shown at E, and delivers it into the outer part of the upper division by four large openings F, in the partition between the two divisions. This outer part of the upper division is called the *guide-blade chamber*, from its containing four guide-blades, G, which direct the water tangentially into the wheel-chamber. Immediately after being injected into the wheel-chamber, the water is received by the curved radiating passages of the wheel, which are partly to be seen in *fig.* 2065, at a place where both the cover of the wheel-chamber and the upper plate of the wheel are broken away for the purpose of exposing the interior to view. The water on reaching the inner ends of these curved passages, having already done its work, is allowed to make its exit by two large central orifices, shown distinctly on the figures at or adjacent to the letters L L, the one leading upwards and the other downwards. Close joints between the case and the wheel, to hinder the escape of water otherwise than through the radiating passages, are made by means of two annular pieces L, L, called *joint-rings*, fitting to the central orifices of the case, and capable of being adjusted, by means of studs and nuts, so as to come close to the wheel without impeding its motion by friction. The four openings H, H, *fig.* 2065, through which the water flows into the wheel-chamber, each situated between the point or edge of one guide-blade and the middle of the next, determine, by their width, the quantity of water admitted, and consequently the power of the wheel. To render this power capable of being varied at pleasure, the guide-blades are made moveable round gudgeons or centres near their points; and a spindle K, worked by a handle in any convenient position, is connected

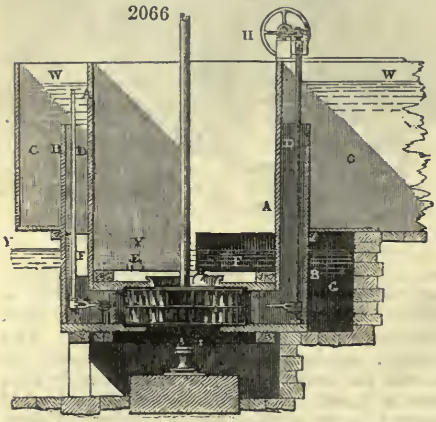


[1] In these figures, as also in *figs.* 2066, 2067, some unimportant modifications are made for the purpose of simplifying the drawings, and rendering them more easily understood than they would otherwise be.

with the guide-blades by means of links, cranks, &c. (see the figures), in such a way that when the handle is moved, the four entrance orifices are all enlarged or contracted alike. The gudgeons of the guide-blades, seen in *fig.* 2064, as small circles near the points, are sunk in sockets in the floor and roof of the guide-blade chamber, and so they do not in any way obstruct the flow of the water. M is the pivot-box of the upright shaft, and is constructed with peculiar provisions for oiling the pivot, which, by reason of its being under water, does not admit of being oiled by ordinary means. N is a hanging bridge which forms the mixture of the pivot.

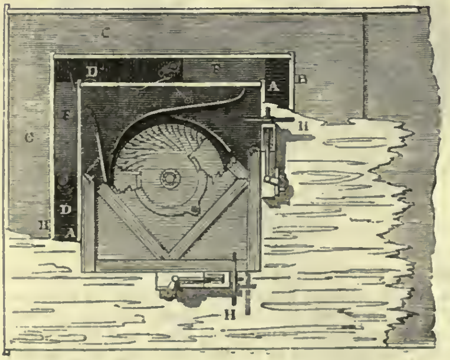
This vortex is calculated for 50 horse-power, with a fall varying from 90 to 100 feet. On account of the great height of the fall, the machine comes to be of very small dimensions; the diameter of the water-wheel itself being only about 15 inches, and he extreme diameter of the case 3 feet 9 inches. The speed for which the wheel is calculated, in accordance with its diameter and the velocity of the water entering its chamber, is 768 revolutions per minute.

2066



A low-pressure vortex constructed for another mill near Belfast, is represented, in vertical section and plan, in *figs.* 2066 and 2067. This is essentially the same in principle as the vortex already described, but it differs in the material of which the case is constructed, and in the manner in which the water is led to the guide-blade chamber. In this the case is almost entirely composed of wood. The water flows with a free upper surface W W, into this wooden case, which consists chiefly of two tanks A A, and B B, one within the other. The water-wheel chamber, and the guide-blade chamber, are situated in the open space between the bottom of the outer and that of the inner tank, and will be readily distinguished by reference to the figures. The water of the head race having been led all round the outer tank in the space, C C, flows inwards over its edge, and passes downwards by the space D D, between the sides of the two tanks. It then passes through the guide-blade chamber and the water-wheel, just in the same way as was explained in respect to the high-pressure vortex already described; and in this one likewise it makes its exit by two central orifices, the one discharging upwards and the other downwards. The part of the water which passes downwards flows away at once to the tail race, and that which passes upwards into the space E, within the innermost tank, finds a free escape to the tail race through boxes and other channels, F and G, provided for that purpose. The wheel is completely submerged under the surface of the water in the tail race, which is represented at its ordinary level at Y Y, *fig.* 2066, although in floods it may rise to a much greater height. The power of the wheel is regulated in a similar manner to that already described, in reference to the high-pressure vortex. In this case, however, as will be seen by the figures, the guide-blades are not linked together, but each is provided with a hand-wheel H, by which motion is communicated to itself alone.

2067



The foregoing descriptions are sufficient to explain the principal points in the structural arrangements of these water-wheels.

And now a few words more in respect to their principles may be added. In these machines the velocity of the circumference of the wheel is made the same as the velocity of the entering water, and thus there is no impact between the water and the wheel; but, on the contrary, the water enters the radiating conduits of the wheel gently, that is to say, with scarcely any motion in relation to their mouths. In order to attain the equalisation of these velocities, it is necessary that the circumference of the wheel should move with the velocity which a heavy body would attain in falling through a vertical space equal to half the vertical fall of the water, or, in other words, with the velocity *due* to half the fall; and that the orifices through which the water is injected into the wheel-chamber should be conjointly of such an area, that, when all the water required is flowing through them, it also may have the velocity due to half the fall.

Thus one half only of the fall is employed in producing velocity in the water; and, therefore, the other half still remains, acting on the water within the wheel-chamber at the circumference of the wheel, in the condition of fluid pressure. Now, with the velocity already assigned to the wheel, it is found that this fluid pressure is exactly that which is requisite to overcome the centrifugal force of the water in the wheel, and to bring the water to a state of rest at its exit, the mechanical work due to both halves of the fall being transferred to the wheel during the combined action of the moving water and the moving wheel. In the foregoing statements, the effects of fluid friction, and of some other modifying influences, are, for simplicity, left out of consideration.

TURBITH'S MINERAL or **TURPETH MINERAL.** The yellow sub-sulphate of mercury, called Queen's Yellow.

TURF (*Peat*, Scotch; *Tourbe*, Fr.; *Torf*, Ger.) consists of vegetable-matter, chiefly of the Moss family, in a state of partial decomposition by the action of water. Cut, during summer, into brick-shaped pieces, and dried, it is extensively used as fuel by the peasantry in every region where it abounds. The dense black turf, which forms the lower stratum of a peat moss, is much contaminated with iron, sulphur, sand, &c., while the lighter turf of the upper strata, though nearly pure vegetable-matter, is too bulky for transportation, and too porous for factory fuel. These defects have been removed, several processes having been patented for converting the lightest and poorest beds of peat-moss, or bog, into the four following products: 1. A brown combustible solid, denser than oak; 2. A charcoal, twice as compact as that of hard wood; 3. A factitious coal; and 4. A factitious coke: each of which possesses very valuable properties.

Mr. D'Ernst, artificer of fireworks to Vauxhall, proved, by the severe test of coloured fires, that turf-charcoal is 20 per cent. more combustible than that of oak. Mr. Oldham, engineer of the Bank of England, applied it in softening his steel plates and dies, with remarkable success. A prospect was thus opened up of turning to admirable account the unprofitable bogs of Ireland; and of producing, from their inexhaustible stores, a superior fuel for every purpose of arts and engineering.

The turf is treated as follows:—Immediately after being dug, it is triturated under revolving edge-wheels, faced with iron plates perforated all over their surface, and is forced by the pressure through these apertures, till it becomes a species of pap, which is freed from the greater part of its moisture by squeezing in a hydraulic press between layers of caya-cloth; then dried, and coked in suitable ovens. (See CHARCOAL, and COKE.) Mr. Williams, by his patent, makes his factitious coal by incorporating with pitch or resin, melted in a cauldron, as much of the above charcoal, ground to powder, as will form a doughy mass, which is moulded into bricks in its hot and plastic state. It has been found preferable to all other fuel for case-hardening iron, tempering steel, forging horse-shoes, and welding gun-barrels. Since turf is partially carbonised in its native state, when it is condensed by the hydraulic press, and fully charred, it affords a charcoal superior in calorific power to the porous substance obtained from wood. For recent modes of utilising peat, see PEAT.

TURKEY RED is the name given to one of the most beautiful and durable of known dyes. The art of dyeing cotton with this colour seems to have originated in India. In his 'Philosophy of Permanent Colours,' Bancroft has given a detailed account of the process as practised in that country; and this process will be found to agree in all essential particulars with that pursued by the Turkey-red dyers of Europe, except that in India the chaya-root is employed as the dyeing material in the place of madder. In the middle ages the art was practised in various parts of Turkey and Greece, especially in the neighbourhood of Adrianople, and hence this colour is often called *Adrianople Red*. Even as late as the end of last century the manufacture of Turkey-red yarn seems to have been extensively carried on at Ambelakia and other places in the neighbourhood of Larissa. An interesting account of the manufactures and trade of this then flourishing district, by Felix, will be found in the *Annales de Chimie*, t. xxi. 1799. About the middle of last century the art of Turkey-red dyeing was introduced into France by means of dyers brought over from Greece. The

French were also the first to dye pieces with this colour, the art having previously been applied merely to the dyeing of yarn. The first establishments for dyeing this colour in Great Britain were founded and conducted by Frenchmen. At the present day Turkey-red dyeing is carried on in various parts of France and Switzerland, at Elberfeld in Germany, in Lancashire, and at Glasgow.

Turkey-red dyeing is essentially distinguished from other dyeing processes by the application previous to dyeing of a peculiar preparation consisting of fatty matter combined with other materials. Without the use of oil or some fatty matter it would be impossible to produce this colour, of which indeed it seems to form an essential constituent. If the colour of a piece of Turkey-red cloth be examined in the manner described under MADDER, it will be found to consist of red colouring-matter and fat-acid, combined with alumina and a little lime. The colouring-matter thus obtained is so little contaminated with impurities as to appear on evaporating its alcoholic solution in yellowish-red crystalline needles. What part the fat-acid plays, whether it merely serves to give to the compound of colouring-matter and alumina the power of resisting the action of the powerful agents used after the operation of dyeing, or whether it also modifies and imparts additional lustre to the colour itself, is quite unknown. The formation of this triple compound of colouring-matter, fat-acid, and alumina, seems at all events to be the final result which is attained. Nevertheless, this apparently simple result can only be arrived at by means of a long and complicated process, each step of which seems to be essential for its final success. The details of the process vary considerably both in their nature and number, in different countries and different dyeing establishments. They may, however, be described in general terms as follow:—

The goods, after being passed through a soap-bath or weak alkaline lye, are oiled. For this purpose a mere impregnation with oil would not be sufficient. The oil must be mixed with a solution of carbonate of potash or soda, to which there is often added a quantity of sheep- or cow-dung, the ingredients being well mingled, so as to form a milky liquid or emulsion. Olive or Gallipoli oil is the kind generally used, and an impure, mucilaginous oil is preferred to one of a finer quality. Drying oils are not adapted for the purpose. In this liquid the goods are steeped for a short time, so as to become thoroughly impregnated with it. In the case of pieces the liquid is generally applied by means of a padding machine. After being taken out of this liquid the goods are often left to lie for some days in heaps, and if the weather is fine, they are then exposed on the grass to the action of the air; otherwise, they must be hung up in a hot stove. This process of steeping and exposing to the air is repeated a number of times, until the fabric is thoroughly impregnated with fatty matter. During this part of the process there can be no doubt that the oil undergoes a partial decomposition and oxidation, so as to become capable of uniting, on the one hand, with the vegetable fibre, and, on the other hand, with the colouring-matter, with which it is subsequently brought into contact. The dung, by inducing a state of fermentation among the ingredients probably promotes the decomposition of the oil into fatty acid and glycerine, and the alkali serves to convey the fatty acid into every part of the fabric, and to assist in its oxidation on exposure to the air. The process of oxidation which takes place is sometimes so active as to produce spontaneous combustion of the goods in the stove. It might be supposed that by previously saponifying the oil, impregnating the goods with the soap, and after sufficient exposure, decomposing the latter by means of an acid, the same object might be more easily attained than by the long process usually employed. This is, however, not the case, which proves that we are still ignorant of the exact chemical nature of the change which takes place during the oiling process. The supposition formerly entertained, that the effect of the oiling consisted in a so-called *animalisation* of the vegetable fibre, is quite untenable. In some establishments, the goods, after being oiled and stoved, are passed through a bath of very dilute nitric acid, and then exposed to the air before being oiled again, the process being repeated after every oiling. The nitric acid is supposed to contribute to the oxidation of the oil. Several years ago a patent was taken out by Messrs. Mercer and Greenwood for preparing the oil, previous to its being applied to the cotton, by treating it with sulphuric acid, and then with chloride of soda, but their invention, though apparently of some importance, has not generally been adopted by Turkey-red dyers.

After being oiled, the goods are steeped for some hours in a weak tepid solution of carbonate of potash or soda. This operation, which is called by the French *dégraissage*, serves to remove the excess of fatty acid, or that portion which has not thoroughly combined with the vegetable fibre. The liquid thus obtained is carefully preserved for the purpose of being mixed with the liquid used for the oiling of fresh goods, the quality of which it serves to improve.

To this operation succeeds that of galling and mordanting. The goods, after being washed, are passed through a warm solution of tannin, prepared by extracting galls or sumac with boiling water and straining, after which they are impregnated with a solution of alum, to which sometimes a little chalk or carbonate of potash is added, or with a solution of acetate of alumina, prepared by double decomposition from alum and acetate of lead. Sometimes the alum is dissolved in the decoction of galls, and thus the two operations are combined into one. The goods, after being dried in the stove, passed through hot water containing chalk, and rinsed, are now ready to be dyed. It has been asserted that the galling is not an essential part of the process, that it merely serves to fix the alumina of the mordant, and may be dispensed with when acetate of alumina is used instead of alum. It is certainly difficult to conceive how it can permanently affect the appearance of the colour, since the tannin of the galls is undoubtedly removed from the fibre during the subsequent stages of the process.

The dyeing is performed in the usual manner. (See MADDER and CALICO-PRINTING.) The materials employed are madder, chalk, sumac, and blood, in various relative proportions. The heat of the dye-bath is gradually raised to the boiling point, and the boiling is continued for some time. The part played by the chalk in dyeing with madder has been explained elsewhere. (See MADDER.) It was formerly supposed that the red colouring-matter of the blood contributed in producing the desired effect in Turkey-red dyeing; but to the modern chemist this supposition does not appear probable. Nevertheless, it is certain that the addition of blood is of some benefit, though it is uncertain in what the precise effect consists. Glue is occasionally employed in the place of blood. Sometimes a second mordanting with galls and alum, and a second dyeing, is allowed to succeed the first mordanting and dyeing.

After being dyed the goods appear of a dull brownish-red colour, and they must therefore be subjected to the brightening process, in order to make them assume the bright red tint required. For this purpose they are first treated with a boiling solution of soap and carbonate of potash or carbonate of soda, and then with a mixture of soap and muriate-of-tin crystals. This operation is usually performed in a close vessel under pressure. The alkalis remove the brown colouring-matters and the excess of fat-acid contained in the colour, and the tin salt probably acts by extracting a portion of the alumina of the mordant, and substituting in its place a quantity of oxide of tin, which has the effect of giving the colour a more fiery tint. The last finish is given to the colour by treating the goods with bran or with chloride of soda.

The chief objects which the Turkey-red dyer seeks to attain are, 1st, to obtain the desired effect with the least possible expenditure of time and material; 2nd, to produce a perfect uniformity of tint in the same series of dyeings; and 3rd, to impart to his goods a colour which, though perfectly durable, shall be fixed as much as possible on the surface of the fabric. The last point is one of importance in the case of calicoes dyed of this colour, since this kind of goods is much employed for the production of a peculiar style of prints, in which portions of the colour are discharged, in order either to remain white or to be covered with other colours. (See CALICO-PRINTING.) And if the red dye is too firmly fixed, or too deeply seated, it becomes more difficult to discharge it. In this respect the art has in modern times attained to such a degree of perfection, that the interior of each thread of Turkey-red cotton will be found on examination to be perfectly white. This is particularly the case with the Turkey-reds from the establishment of Mr. Steiner, Accrington, Lancashire, whose productions in this branch of the art of dyeing are also unrivalled for the brilliancy and purity of their colour.—E. S.

TURMERIC (*Curcuma*, *Terra merita*, *Souchet* or *Safran des Indes*, Fr.; *Gelbwurzel*, Ger.) is the rhizome of the *Curcuma longa* and *C. rotunda*, a plant which grows in the East Indies, where it is much employed in dyeing yellow, as also as a condiment in curry sauce or powder. The root is knotty, tubercular, oblong, and wrinkled; pale-yellow without, and brown-yellow within; of a peculiar smell, a taste bitterish and somewhat spicy. It contains a peculiar yellow principle, called *Curcumine*, a brown colouring-matter, a volatile oil, starch, &c. The yellow tint of turmeric is changed to brown-red by alkalis, alkaline earths, subacetate of lead, and several metallic oxides; for which reason, paper stained with it is employed as a chemical test.

Turmeric is employed by the wool-dyers for compound colours which require an admixture of yellow, as for cheap browns and olives. As a yellow dye it is employed only upon silk. It is a very fugitive colour. A yellow-lake may be made by boiling turmeric-powder with a solution of alum, and pouring the filtered decoction upon pounded chalk.

TURNBULL'S BLUE. Ferricyanide of iron, obtained by precipitating a solution of a salt of protoxide of iron with ferricyanide of potassium. See BLUE PIGMENTS and PRUSSIAN BLUE.

TURNER'S YELLOW. An oxychloride of lead. See Patent Yellow.

TURNSOLE. See Archil and Litmus.

TURPENTINE. (*Térébenthine*, Fr.; *Terpentin*, Ger.) The term *Turpentine* is applied to a liquid or soft solid product of certain coniferous plants, and of the *Pistachia Terebinthus*.

The following varieties are those which are usually found in the market:—American or White Turpentine; Bordeaux Turpentine; Venice Turpentine; Strasburg Turpentine; Canadian Turpentine, or Canada Balsam; Chio Turpentine; Frankincense.

In nearly all cases the processes of collecting are similar. A hollow is cut in the tree yielding the turpentine, a few inches from the ground, and the bark removed for the space of about 18 inches above it. The turpentine runs into this hollow for several months, especially during the summer months. In general character these turpentines have much in common; being oleo-resins, varying slightly in colour, consistency, and smell. They enter into the composition of many varnishes.

TURPENTINE, OIL OF. This is obtained by distilling American turpentine (which has been melted and strained) with water in an ordinary copper still. The distilled product is colourless, limpid, very fluid, and possessed of a peculiar smell. Its specific gravity, when pure, is 0·870; that of the oil commonly sold in London is 0·875. It always reddens litmus-paper, from containing a little succinic acid. According to Oppermann, the oil which has been repeatedly rectified over chloride of calcium, consists of 84·60 carbon, 11·735 hydrogen, and 3·67 oxygen. Rectified oil of turpentine is known as spirits or essence of turpentine. When oil of turpentine contains a little alcohol, it burns with a clear flame; but otherwise it affords a very smoky flame. (See Camphine.) Chlorine inflames this oil; and hydrochloric acid converts it into a crystalline substance, like camphor. It is employed extensively in varnishes, paints, &c., as also in medicine.

TURQUOISE. This gem is a compound of phosphate of alumina, with oxide of copper. The Silesian turquoise, according to John, consists of:—alumina, 44·50; phosphoric acid, 30·90; water, 19·00; oxide of copper, 3·75; oxide of iron, 1·80: while the blue Oriental turquoise was found by Hermann to consist of alumina, 47·45; phosphoric acid, 27·34; water, 18·18; oxide of copper, 2·02; oxide of iron, 1·10; manganese, 0·50; and phosphate of lime, 3·41.

Turquoise occurs in the mountainous ranges of Persia, and when finely coloured it is highly esteemed as a gem. The Shah of Persia is said to retain for his own use all the more remarkable specimens. It is also found in Thibet.

Major Macdonald discovered a new locality for the turquoise in Arabia Petræa. Of the discovery of these, he gives the following account:—

'In the year 1849, during my travels in Arabia in search of antiquities, I was led to examine a very lofty range of mountains composed of iron sandstone, many days' journey in the desert, and whilst descending a mountain of about 6,000 feet high by a deep and precipitate gorge, which in the winter time served to carry off the water, I found a bed of gravel, where I perceived a great many small blue objects mixed with the other stones; on collecting them I found they were turquoises of the finest colour and quality. On continuing my researches through the entire range of mountains, I discovered many valuable deposits of the same stones, some quite pure, like pebbles, and others in the matrix. Sometimes they are found in nodules varying in size from a pin's head to a hazel-nut; and when in this formation they are usually of the finest quality and colour. The action of the weather gradually loosens them from the rock, and they are rolled into the ravines, and, in the winter season, mixed up by the torrents with beds of gravel, where they are found. Another formation is, where they appear in veins, and sometimes of such a size as to be of immense value. They also occur in a soft yellow sandstone, enclosed in the centre, and of a surpassing brilliancy of colour. Another very curious formation is where they are combined with innumerable small coloured quartz crystals, and which has the appearance of a mass of sand, small pebbles, and turquoise, all firmly cemented together. This formation is one of the most peculiar in the whole collection.'

Mr. Harry Emanuel, speaking of the Persian turquoise, says that, 'small clear stones bring from 6*d.* to 20*s.* each, whilst fine ring-stones will realise from 10*l.* to 40*l.*' . . . 'A perfect stone of the size of a shilling, and of good depth, was sold not long ago for 400*l.*' 'A good turquoise, sky blue and oval cut, five lines long and four and a half lines broad, was sold in France for 241 francs; and a light blue, greenish lustre, and oval cut, five and a half lines long and five broad, was sold for 500 francs; whereas an occidental turquoise, four lines long and three and a half broad, brought only 121 francs.'—*Feuchtwanger.*

The occidental turquoise, frequently called the 'bone turquoise,' or *Odontolite*, is said to be fossil bone, ivory, or teeth, coloured with phosphate of iron.

Turquoise is imitated by adding to the ammonia sulphate of copper, or oxide of copper dissolved in ammonia, finely-powdered calcined ivory. They are allowed to remain together for about a week, at a moderate heat. The coherent mass is dried and exposed to a gentle heat.

TUSSILAGO. The herb Coltsfoot (*Tussilago farfara*).

TUTENAG or **TUTENAGUE,** sometimes called *Chinese silver*. It is the *Packfong* of the East Indies. A white metal of the Chinese, frequently stated to be an alloy of copper and zinc. It is, in fact, a compound resembling German silver: nickel, in combination with zinc and copper, is found in most specimens

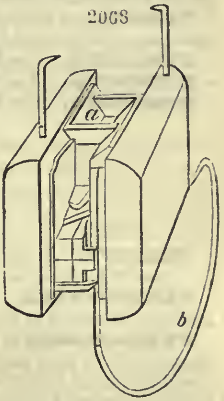
TUTONITE. See Explosive Agents.

TYMP, in *metallurgy*, a rectangular casting of iron, placed upon the tymp-arch at the top of the hearth of a blast-furnace. When it has a wrought-iron tube in its interior through which cold water circulates, it is then called a 'water-tymp.'

TYPE. (*Caractère*, Fr.; *Druckbuchstabe*, Ger.) The first care of the letter-cutter is to prepare well-tempered steel punches, upon which he draws or marks the exact shape of the letter, with pen and ink if it be large, but with a smooth blunted point of a needle if it be small; and then, with a proper sized and shaped graver and sculpter, he digs or scoops out the metal between the strokes upon the face of the punch, leaving the marks untouched and prominent. He next works the outside with files, till it be fit for the matrix. Punches are also made by hammering down the hollows, filing up the edges, and then hardening the soft steel. Before he proceeds to sink and justify the matrix, he provides a mould to justify them by.

A matrix is a piece of brass or copper, about an inch and a half long, and thick in proportion to the size of the letter which it is to contain. In this metal the face of the letter intended to be cast is sunk, by striking it with the punch to a depth of about one-eighth of an inch. The mould, *fig.* 2068, in which the types are cast, is composed of two parts. The outer part is made of wood, the inner of steel. At the top it has a hopper-mouth, *a*, into which the fused type-metal is poured. The interior cavity is as uniform as if it had been hollowed out of a single piece of steel; because each half, which forms two of the four sides of the letter, is exactly fitted to the other. The matrix is placed at the bottom of the mould, directly under the centre of the orifice, and is held in its position by a spring, *b*. Every letter that is cast can be loosened from the matrix only by removing the pressure on the spring.

2068



A good type-foundry is always provided with several furnaces, each surmounted with an iron pot containing the melted alloy, of 3 parts of lead and 1 of antimony. Into this pot the founder dips the very small iron ladle, to lift merely as much metal as will cast a single letter at a time. Having poured in the metal with his right hand, and returned the ladle to the melting-pot, the founder throws up his left hand, which holds the mould, above his head, with a sudden jerk, supporting it with his right hand. It is this movement which forces the metal into all the interstices of the matrix; for without it, the metal, especially in the smaller moulds, would not be able to expel the air and reach the bottom. The pouring in the metal, the throwing up the mould, the unclosing it, removing the pressure of the spring, picking out the cast letter, closing the mould again, and reapplying the spring to be ready for a new operation, are all performed with such astonishing rapidityand precision, that a skilful workman will turn out 500 good letters in an hour, being at the rate of one every eighth part of a minute. A considerable piece of metal remains attached to the end of the type as it quits the mould. There are nicks upon the lower edge of the types, to enable the compositor to place them upright without looking at them.

From the table of the *caster* the heap of types turned out of his mould is transferred from time to time to another table, by a boy, whose business it is to break off the superfluous metal, and this he does so rapidly as to clear from 2,000 to 5 000 types in an hour; a very remarkable despatch, since he must seize them by their edges, and not by their feeble flat sides. From the breaking-off boy the types are taken to the *rubber*, a man who sits in the centre of the workshop with a grit-stone slab on a table before him, and having on the fore and middle finger of his right hand a piece of tarred leather, passes each broad side of the type smartly over the stone, turning it in the movement, and that so dexterously as to be able to rub 2,000 types in an hour.

From the rubber the types are conveyed to a boy, who with equal rapidity sets them up in lines, in a long shallow frame, with their faces uppermost and nicks outwards. This frame containing a full line is put into the dresser's hands, who polishes them on each side, and turning them with their faces downwards, cuts a groove or channel in their bottom, to make them stand steadily on end. It is essential that each letter be perfectly symmetrical and square: the least inequality of their length would prevent them from making a fair impression; and were there the least obliquity in their sides, it would be quite impossible, when 200,000 single letters are combined, as in one side of *The Times* newspaper, that they could hold together as they require to do, when wedged up in the chases, as securely as if that side of the type formed a solid plate of metal. Each letter is finally tied up in lines of convenient length, the proportionate numbers of each variety, small letters, points, large capitals, small capitals, and figures, being selected, when the fount of type is ready for delivery to the printer.

The sizes of types cast in this country vary, from the smallest, called Diamond, of which 205 lines are contained in a foot length, to those letters employed in placards, of which a single letter may be several inches high. The names of the different letters and their dimensions, or the number of lines which each occupies in a foot, are stated in the following table:—

Double Pica	41½	Small Pica	83	Minion	128
Paragon	44½	Long Primer	89	Nonpareil	143
Great Primer	51¼	Bourgeois	102¼	Pearl	178
English	64	Brevier	112½	Diamond	205

TYPE METAL. An alloy of 3 parts of lead and 1 of antimony. Small type, however, usually contains tin, in proportions varying from 1½ to 20 per cent.

TYRIAN PURPLE. A costly dye obtained from a mollusc, which was employed by the Tyrians in dyeing wool. See Crookes's 'Handbook of Dyeing.'

TYRITE. A Norwegian mineral, containing columbic acid and yttria, discovered and analysed by David Forbes.

TYROLINE. See ANILINE VIOLET.

TYROLITE. An arsenate of copper found in the Tyrol.

TYROSINE. See ANILINE.

U

ULEXITE. A native borate of lime and soda, known also as *Boronatrocalcite*. It occurs at Iquique, in Peru; and in the Province of Tarapaca. See BORON.

ULLMANNITE. An antimonio-sulphide of nickel, occasionally containing arsenic. It occurs at Freusberg, in Nassau.

ULTRAMARINE (*Outremer*, Fr.; *Ultramarin*, Ger.), is a beautiful blue pigment, obtained from the blue mineral called *lapis-lazuli*, by the following process:— Grind the stone to fragments, rejecting all the colourless bits, calcine at a red heat, quench in water, and then grind to an impalpable powder along with water, in a mill, or with a porphyry slab and muller. The paste being dried, is to be rubbed to powder, and passed through a silk sieve. 100 parts of it are to be mixed with 40 of resin, 20 of white wax, 25 of linseed oil, and 15 of Burgundy pitch, previously melted together. This resinous compound is to be poured hot into cold water; kneaded well first with two spatulas, then with the hands, and then formed into one or more small rolls. Some persons prescribe leaving these pieces in the water during fifteen days, and then kneading them in it, whereby they give out the blue pigment, apparently because the ultramarine matter adheres less strongly than the *gangue*, or merely siliceous matter of the mineral, to the resinous paste. MM. Clément and Desormes, who were the first to divine the true nature of this pigment, thought that the soda contained in the lapis-lazuli, uniting with the oil and the resin, forms a species of soap, which serves to wash out the colouring-matter. If it should not separate readily, water heated to about 150° Fahr. should be had recourse to. When the water is sufficiently charged with blue colour, it is poured off and replaced by fresh water; and the kneading and change of water are repeated till the whole of the colour is extracted. Others knead the mixed resinous mass under a slender stream of water, which runs off with the colour into a large earthen pan. The first waters afford, by rest, a deposit of the finest ultramarine; the second a somewhat inferior article, and so on. Each must be washed afterwards with several more waters before they acquire the highest quality of tone; then dried separately, and freed from any adhering particles of the pitchy compound by digestion in alcohol. The remainder of the mass being melted with oil and kneaded in water containing a little soda or potash, yields an inferior pigment, called *ultramarine ashes.* The best *ultramarine* is a splendid blue pigment, which works well with oil, and is not liable to change by time.

Analyses of lapis-lazuli ultramarine will be found in the following article.

ULTRAMARINE, ARTIFICIAL. For many years every attempt failed to make ultramarine artificially. At length, in 1828, M. Guimet resolved the problem, guided by the analysis of MM. Clément and Desormes, and by an observation of M. Tassaert, that a blue substance, like ultramarine was occasionally produced on the sandstone hearths of his reverberatory soda-furnaces. M. Gmelin, of Tübingen, published a prescription for making it; which consisted in enclosing carefully in a Hessian crucible a mixture of 2 parts of sulphur and 1 of dry carbonate of soda, heating them gradually to redness until the mass fuses, and then sprinkling into it by degrees another mixture, of silicate of soda and aluminate of soda; the first containing 72 parts of silica, and the second 70 parts of alumina. The crucible must be exposed after this for an hour to the fire. The ultramarine will be formed by this time; only it contains a little sulphur, which can be separated by means of water M. Persoz likewise succeeded in making an ultramarine, of perhaps still better quality than that of M. Guimet. Lastly, M. Robiquet has announced, that it is easy to form ultramarine by heating to redness a proper mixture of kaolin (China clay), sulphur, and carbonate of soda. It would therefore appear, from the preceding details, that ultramarine may be regarded as a compound of silicate of alumina, and silicate of soda, with sulphide of sodium, and that to the reaction of the last constituent upon the former its colour is due.

The constituents used in the different methods of making ultramarine vary in character and in quantity. It is said that a good mixture may consist of:—dried kaolin, 100; calcined Glauber salt, or sulphate of soda, 41; calcined soda, 41; pulverised charcoal or coal, 17; and sulphur, 13. When such a mixture is heated without access of air it yields a product from which a white substance may be obtained, known as *white ultramarine.* Calcined in crucibles at a high temperature, with a very limited supply of air, the mixture affords a semi-fused greenish mass termed *green ultramarine.* By carefully roasting this with sulphur at a low temperature, with free access of air, the ordinary *blue ultramarine* is obtained; and this when powdered, lixiviated, and dried, is ready for the market.

It appears that potash-salts cannot be substituted for soda-salts in the manufacture of ultramarine, but it is said that those of baryta may be so employed. In some cases, silica is added to the ultramarine mixture in the proportion of from 5 to 10 per cent.

Both native and artificial ultramarine have been examined very carefully by several eminent chemists. The following are a few specimens of these analyses:—

Analysis of Ultramarine, by Warrentrap.

	Lapis-lazuli.	Artificial from Meissen.	Blue.	Green.
Potash		1·75		
Soda	9·09	21·47	40·0	25·5
Alumina	31·07	23·30	29·5	30·0
Silica	42·50	45·00	40·0	39·9
Sulphur	0·95	1·68	4·0	4·6
Lime	3·52	0·02		
Iron	0·86	1·06	1·0	0·9
Chlorine	0·42			
Sulphuric acid	5·89	3·83	3·4	0·4
Water	0·12			

	Parisian artificial ultramarine, *by C. G. Gmelin.*
Soda and potash	12·863
Lime	1·546
Alumina	22·000
Silica	47·306
Sulphuric acid	4·679
Resin, sulphur, and loss	12·218

Notwithstanding the many investigations which have been made of ultramarine, its chemical composition is by no means thoroughly understood; and the German Association of Ultramarine Makers have recently (1874) offered a prize for the best essay on this subject, from which, it may be hoped, more light will be thrown upon the constitution of this compound.

ULVA. A seaweed used in the preparation of Green Laver. See ALGÆ.

UMBER. A mechanical mixture of limonite (brown hæmatite) and hydrated oxide of manganese and clay. It occurs in beds with brown jasper in the island of Cyprus. It is used by painters as a brown colour, raw or burnt.

UNGUENTS. The name given by engineers to the greases applied to the bearing parts of machinery. Unguents should be thick for heavy pressures, that they may resist being forced out; and thin for light pressures, that their viscidity may not add to the resistance to motion.—*Rankine.*

UNION GOODS. Cloths of a mixed character, as of flax and jute, or cotton and jute.

UPAS TREE. The *Antiaris toxicaria*, one of the order to which the bread-fruit tree belongs. Fabulous tales have been told of its poisonous nature; if wounded, a juice exudes which, when introduced into the human system, produces vomiting, purging, and finally death.

URANITE. Two varieties of this mineral are known: the one is *Copper-uranite*, or *Torbernite*, a phosphate of uranium and copper; and the other, *Lime-uranite*, or *Autunite*, a phosphate of uranium and lime.

URANIUM is one of the rare metals, and was first discovered by Klaproth in 1786 in the mineral called *pechblende*, which was, previously to this, mistaken for an ore of zinc. He called it Uranium after the planet discovered by Herschel about the same time. The ores of uranium are few; the principal being, *Pechblende* (*pitchblende*), a brownish or velvet-black mineral, which is essentially a proto-peroxide of uranium. It occurs in veins with ores of lead and silver in Saxony, and with tin in Cornwall. *Uranite*, a phosphate of copper and uranium, occurs in France; and is found of great beauty near Callington and near Redruth in Cornwall. *Samarskite* and *urano-tantalite* contain oxide of uranium with yttria and niobic acid. *Johannite*, uran-vitriol, or sulphate of uranium. *Zippeite*, sulphate of sesquioxide of uranium. *Uranochre*, an earthy yellow impure oxide of uranium.

The metal itself can only be obtained by the intervention of potassium or sodium, in the same manner as magnesium. It is a black coherent powder, or a white malleable metal, according to the state of aggregation. It is not oxidised by air or water, but very combustible when exposed to heat. It unites also with great violence with chlorine and with sulphur. M. Peligot admits three distinct oxides of uranium, and two other compounds of the metal and oxygen, which he designates as suboxides.

Protoxide, UO.—This is a brown powder, sometimes highly crystalline.

Proto-sesquioxide; black oxide; U^4O^5, or $2UO + U^2O^3$.—This oxide was formerly considered as the protoxide, and is produced whenever either of the other oxides are strongly heated in the air.

Sesquioxide, U^2O^3.—This is the best known and most important of the oxides. It forms a number of beautiful yellow salts; its colour, when prepared by heating the nitrate to 480° in an oil-bath till no more nitrous fumes are disengaged, is a chamois yellow. It may be obtained from *pitchblende*.

The only application of uranium is to enamel-painting and glass-staining; the protoxide giving a fine black colour, probably by absorbing oxygen and becoming black oxide, and the sesquioxide a delicate yellow.

Uranium has been found in a German blue pigment used by paper-hanging manufacturers: it contained both copper and uranium.

URANIUM YELLOW. Uranate of soda, used as a yellow colour for porcelain painting.

URAO. See Natron.

UREA. This is one of the principal constituents of urine, being always present in it, but in variable quantities; the average quantity in healthy urine is about 14 or 15 parts in 1,000 of urine, but of course this varies from several circumstances, as in disease, drinking a large quantity of liquid, &c. The urine passed the first in the morning gives a fair estimate of the quantity of urea yielded by the urine of an individual. It seems to be the principal form in which the waste nitrogenous compounds of the body are eliminated from the system. As this animal product has no direct use in the arts, the reader may be referred to Watts's 'Dictionary of Chemistry,' or to any modern treatise on Animal Chemistry.

USQUEBAUGH (*Irish*). A name given to whisky occasionally, but usually applied to a liqueur prepared from whisky, or some other ardent corn-spirit. The following liqueurs, as being of a similar character, are named here. *Kirschwasser* is obtained in Switzerland and in some parts of France, from bruised black cherries fermented and distilled. *Maraschino* is a similar liqueur, prepared also from a peculiar kind of cherry growing in Dalmatia. *Noyau* and several analogous liqueurs are flavoured with an essential oil, containing more or less hydrocyanic acid and often with that derived from bitter almonds, the kernels of peaches, apricots, &c., or from the leaves of laurels. Some of these compounds come under the denomination of *tinctures*; such, for instance, as *Curaçoa*, which is prepared by digesting orange-berries (the immature fruit) and bitter orange-peal, with cloves and cinnamon, in brandy. When this tincture is distilled and afterwards sweetened, it constitutes *White Curaçoa.* The compounds are frequently called *Ratafias*: a term derived, like the word 'ratify,' from *ratum* and *fio*, 'to make firm,' 'or confirm.' By Ratafia, therefore, was originally meant a liquid drank at the *ratification* of an agreement.

V

VAALITE. A name recently given by Prof. Maskelyne to a variety of vermiculite, occurring in the diamond-bearing rocks of South Africa. It takes its name from the Vaal River.

VACUUM PAN. For a description of it, see SUGAR.

VALONIA is a kind of acorn, imported from the Levant and the Morea, for the use of tanners, as the husk or cup contains abundance of tannin. See LEATHER.

Valonia *Imported* in 1873:—

	Tons	Value
From Austrian Territories	1,141	£20,793
,, Greece	3,598	58,699
,, Turkey	24,233	443,899
,, Other countries	5	99
Total	28,977	524,490

Valonia *Exported* in 1873:—

	Tons	Value
To Germany	196	£3,848
,, Belgium	202	3,927
,, Other countries	208	4,034
Total	606	11,809

VALUE. Two methods have been adopted for ascertaining the value of our exports; one by means of the *official* value, the other according to the *declared* value. In Lowe's 'Present State of England' (1822), there is a very succinct and clear account of these methods, which is here extracted:—

'The *official* value of goods means a computation of value formed with reference, not to the prices of the current year, but to a standard, fixed so long ago as 1696, the time when the office of Inspector-General of the Imports and Exports was established, and a Custom-house ledger opened to record the weight, dimensions, and value of the merchandise that passed through the hands of the officers. One uniform rule is followed, year by year, in the valuation, some goods being estimated by weight, others by the dimensions, the whole without reference to the market price. This course has the advantage of exhibiting, with strict accuracy, every increase or decrease in the quantity of our exports.

Next as to the value of these exports in the market:—In 1798 there was imposed a duty of 2 per cent. on our exports, the value of which was taken, not by the official standard, but by the declaration of the exporting merchants. Such a declaration may be assumed as a representation of, or at least an approximation to, the market price of merchandise, there being on the one hand no reason to apprehend that merchants would pay a percentage on an amount beyond the market value, while on the other the liability to seizure afforded a security against under valuation.' See IMPORTS and EXPORTS.

VANADINITE. A vanadate of lead, with chloride of lead, occurring at Wanlock Head, in Dumfriesshire, and in Siberia and Mexico.

VANADIUM is a metal discovered by Sefström, in 1830, in a Swedish iron extracted from the iron ores of Taberg, not far from Jönköping. Its name is derived from Vanadis, a Scandinavian idol. This metal has been found as vanadate of lead, in the mineral *Vanadinite*, and it has been detected in the copper-bearing sandstone of Alderley Edge, in Cheshire. Vanadium is white, and when its surface is polished it resembles silver or molybdenum more than any other metal. It combines with oxygen to form four oxides. The compounds of vanadium have recently been studied by Prof. Roscoe.

The vanadate of ammonia, mixed with infusion of nutgalls, forms a black liquid, which is a very excellent writing-ink.

VANADIUM BRONZE. See BRONZE POWDERS.

VANILLA, or **VANILLE,** is the oblong narrow pod of various species of *Vanilla* (as *V. aromatica* and *V. planifolia*), of the natural family *Orchideæ*, which grows in Mexico, Columbia, Peru, and on the banks of the Oronoco.

The best comes from the forests round the village of Zentila, in the Intendancy of Oaxaca. The vanilla plant is cultivated in Brazil, in the West Indies, and some other tropical countries, but does not produce fruit of such a delicious aroma as in Mexico. It clings like a parasite to the trunks of old trees, and sucks the moisture which their bark derives from the lichens, and other cryptogams, but without drawing the nourishment from the tree itself. The fruit is subcylindric, about 8 inches long, one-celled, siliquose, and pulpy within. It should be gathered before it is fully ripe.

When about 12,000 of these pods are collected, they are strung like a garland by their lower end, as near as possible to the foot-stalk; the whole are plunged for an instant in boiling water to blanch them; they are then hung up in the open air, and exposed to the sun for a few hours. Next day they are lightly smeared with oil, by means of a feather, or the fingers; and are surrounded with oiled cotton, to prevent the valves from opening. As they become dry, on inverting their upper end they discharge a viscid liquid from it, and they are pressed at several times with oiled fingers, to promote its flow. The dried pods lose their appearance, grow brown, wrinkled, soft, and shrink into one-fourth of their original size. In this state they are touched a second time with oil, but very sparingly; because, with too much oil, they would lose much of their delicious perfume. They are then packed for the market, in small bundles of 50 to 100 in each, enclosed in lead-foil, or tight metallic cases. As it comes to us, vanilla is a capsular fruit, of the thickness of a swan's quill, strait, cylindrical, but somewhat flattened, truncated at the top, thinned off at the ends, glistening, wrinkled, furrowed lengthwise, flexible, from 5 to 10 inches long, and of a reddish-brown colour. It contains a pulpy parenchyma, soft, unctuous, very brown, in which are embedded black, brilliant, very small seeds. Its smells ambrosial and aromatic; its taste is hot, and rather sweetish. These properties seem to depend upon an essential oil, and also upon benzoic acid, which forms efflorescences upon the surface of the fruit. The pulpy part possesses alone the aromatic quality.

The kind most esteemed in France is called *leq* vanilla: it is about six inches long, from $\frac{1}{4}$ to $\frac{1}{3}$ of an inch broad, narrowed at the two ends, and curved at the base, somewhat soft and viscid, of a dark-reddish colour, and of a most delicious flavour, like that of balsam of Peru. It is called vanilla *givrées*, when it is covered with efflorescences of benzoic acid, after having been kept in a dry place, and in vessels not hermetically closed.

The second sort, called *vanilla simarona*, or bastard, is a little smaller than the preceding, of a less deep brown hue, drier, less aromatic, destitute of efflorescence. It is said to be the produce of the wild plant, and is brought from St. Domingo.

A third sort, which comes from Brazil, is the *vanillon*, or large vanilla of the French market; the *vanilla pamprona* or *bova* of the Spaniards. Its length is from 5 to 6 inches; its breadth from $\frac{1}{2}$ to $\frac{3}{4}$ of an inch. It is brown, soft, viscid, almost always open, of a strong smell, but less agreeable than the *leq*. It is sometimes a little spoiled by an incipient fermentation. It is cured with sugar, and enclosed in tin-plate boxes, which contain from 20 to 60 pods.

Vanilla, as an aromatic, is much sought after by makers of chocolate, ices, and creams; by confectioners, perfumers, and liquorists, or distillers. It is difficultly reduced to fine particles; but it may be sufficiently attenuated by cutting it into small bits, and grinding these along with sugar. The odorous principle can, for some purposes, be extracted by alcohol.

Some researches recently conducted in Dr. Hofmann's laboratory at Berlin, by MM. Tiemann and Haarmann, have led to the successful preparation of a substance which appears to be identical in chemical and physical properties with *vanillin* or the aromatic principle of vanilla. The cambium of coniferous trees contains a crystallisable glucoside called *coniferin*; submitted to the action of ferments, coniferin is resolved into glucose and a crystalline product, which, under the influence of oxidising agents, such as a mixture of bichromate of potash and sulphuric acid, gives rise to the formation of *vanillin*, or the aromatic principle of vanilla. The manufacture of artificial vanillin on a commercial scale is about to be commenced (1874).

VAPOUR (*Vapeur*, Fr.; *Dampf*, Ger.) is the state of elastic or aëriform fluidity into which any substance, naturally solid or liquid at ordinary temperatures, may be converted by the agency of heat. A *visible* fluid floating in the atmosphere, as distinguished from a gas which is ordinarily, unless it be coloured as chlorine gas, invisible. The vapour of water is STEAM.

VAREC. The name of kelp made on the coast of Normandy. See KELP and VRIAC.

VARNISH (*Vernis*, Fr.; *Firniss*, Ger.) is a solution of resinous matter, which is spread over the surface of any body, in order to give it a shining, transparent, and hard coat, capable of resisting, in a greater or less degree, the influences of air and moisture. Such a coat consists of the resinous parts of the solution, which remain in a thin layer upon the surface after the liquid solvent has either evaporated away, or has dried up. When large quantities of spirit-varnish are to be made, a common still, mounted with its capital and worm, is the vessel employed for containing the materials, and it is placed in a steam- or water-bath. The capital should be provided with a stuffing-box, through which a stirring-rod may pass down to the bottom of the still, with a cross-piece to its lower end, and a handle or winch at its top. After heating the bath till the alcohol boils and begins to distil, the heat ought to be lowered, that the solution may continue to proceed in an equable manner, with as little evaporation of spirit as possible. The operation may be supposed to be complete when the rod can be easily turned round. The varnish must be passed through a silk sieve of proper fineness; then filtered through porous paper, or allowed to clear leisurely in stone jars. The alcohol which has come over should be added to the varnish, if the just proportions of the resins have been introduced at first.

The building or shed wherein varnish is made, ought to be quite detached from any buildings whatever, to avoid accidents by fire. For general purposes, a building about 18 feet by 16 is sufficiently large for manufacturing 4,000 gallons and upwards annually, provided there are other convenient buildings for the purpose of holding the utensils, and warehousing the necessary stock.

Procure a copper pan made like a common washing-copper, which will contain from 50 to 80 gallons, as occasion may require; when wanted, set it upon the boiling furnace, and fill it up with linseed oil within 5 inches of the brim. Kindle a fire in the furnace underneath, and manage the fire so that the oil shall gradually, but slowly, increase in heat for the first two hours; then increase the heat to a gentle simmer; and if there is any scum on the surface, skim it off with a copper ladle, and put the skimming away. Let the oil boil gently for three hours longer; then introduce, by a little at a time, one quarter of an ounce of the best calcined magnesia for every gallon of oil, occasionally stirring the oil from the bottom. When the magnesia is all in, let the oil boil rather smartly for one hour; it will then be sufficient. Lay a cover over the oil, to keep out the dust while the fire is withdrawn and extinguished by water; next uncover the oil, and leave it till next morning; and then while it is yet hot, ladle it into the carrying-jack, or let it out through the pipe and cock; carry it away, and deposit it in either a tin or leaden cistern, for wooden vessels will not hold it; let it remain to settle for at least three months. The magnesia will absorb all the acid and mucilage from the oil, and fall to the bottom of the cistern, leaving the oil clear and transparent, and fit for use. Recollect when the oil is taken out not to disturb the bottoms, which are only fit for black paint.

General Observations and Precautions to be observed in making Varnishes.—Set on the boiling-pot with 8 gallons of oil; kindle the fire; then lay the fire in the gum-furnace; have as many 8lb.-bags of gum copal all ready weighed up as will be wanted; put one 8lb. into the pot, put fire to the furnace, set on the gum-pot: in three minutes (if the fire is brisk) the gum will begin to fuse and give out its gas, steam, and acid; stir and divide the gum, and attend to the rising of it, as before directed. 8 lbs. of copal take in general from sixteen to twenty minutes in fusing, from the beginning till it gets clear like oil, but the time depends very much on the heat of the fire and the attention of the operator. During the first twelve minutes while the gum is fusing, the assistant must look to the oil, and bring it to a smart simmer; for it ought to be neither too hot nor too cold, but in appearance beginning to boil, which he is strictly to observe, and when ready to call out, 'Bear a hand!' Then immediately both lay hold of a handle of the boiling-pot, lift it right up so as to clear the plate, carry it out and place it on the ash-bed, the maker instantly returning to the gum-pot, while the assistant puts three copper ladlefuls of oil into the copper pouring-jack, bringing it in, and placing it on the iron plate at the back of the gum-pot to keep hot until wanted. When the maker finds the gum is nearly all completely fused, and that it will in a few minutes be ready for the oil, let him call out, 'Ready oil!' The assistant is then to lift up the oil-jack with both hands, one under the bottom and the other on the handle, laying the spout over the edge of the pot, and wait until the maker calls out 'Oil!' The assistant is then to pour in the oil as before directed, and the boiling to be continued until the oil and gum become concentrated, and the mixture looks clear on the glass; the gum-pot is now to be set upon the brick-stand until the assistant puts three more ladlefuls of hot oil into the pouring-jack, and three more into a spare tin for the third run of gum. There will remain in the boiling-pot still 3½ gallons of oil. Let the maker put his right hand down the handle of the gum-pot near to the side, with his left hand near the end of the handle, and with a firm grip lift the gum-pot, and deliberately lay the edge of the gum-pot over the edge of the boiling-pot, until all its contents run into the boiling-pot. Let the gum-pot be held, with its bottom turned upwards for a minute, right over the boiling-pot. Observe, that whenever the maker is beginning to pour, the assistant stands ready with a thick piece of old carpet without holes, and sufficiently large to cover the mouth of the boiling-pot should it catch fire during the pouring, which will sometimes happen if the gum-pot is very hot; should the gum-pot fire, it has only to be kept bottom upwards, and it will go out of itself; but if the boiling-pot should catch fire during the pouring, let the assistant throw the piece of carpet quickly over the blazing pot, holding it down all round the edges; in a few minutes it will be smothered. The moment the maker has emptied the gum-pot, he throws into it half-a-gallon of turpentine, and with the *swish* immediately washes it from top to bottom, and instantly empties it into the flat tin jack: he wipes the pot dry, and puts in 8 lbs. more gum, and sets it upon the turnace; proceeding with this run exactly as with the last, and afterwards with the third run. There will then be 8 gallons of oil, and 24 lbs. of gum in the boiling-pot, under which keep up a brisk strong fire until a scum or froth rises and covers all the surface of the contents, when it will begin to rise rapidly. Observe, when it rises near the rivets of the handles, carry it from the fire and set it on the ash-bed, stir it down again, and scatter in the driers by a little at a time; keep stirring, and if the frothy head goes down put it upon the furnace, and introduce *gradually* the remainder of the driers, always carrying out the pot when the froth rises near the rivets. In general, if the fire be good, all the time a pot requires to boil from the time of the last gum being poured in, is about three and a half or four hours: but *time* is no criterion for a beginner to judge by, as it may vary according to the weather, the quality of the oil, the quality of the gum, the driers, or the heat of the fire, &c.; therefore, about the third hour of boiling, try it on a bit of glass, and keep it boiling, until it feels strong and stringy between the fingers; it is then boiled sufficiently to carry it on the ash-bed, and to be stirred down until it is cold enough to mix, which will depend much on the weather, varying from half an hour in dry frosty weather to one hour in warm summer weather. Previous to beginning to mix, have a sufficient quantity of turpentine ready, fill the pot, and pour in, stirring all the time at the top or surface, as before directed, until there are 15 gallons, or five tins of oil of turpentine introduced, which will leave it quite thick enough if the gum is good, and has been well run; but if the gum was of a weak quality, and has not been well fused, there ought to be no more than 12 gallons of turpentine mixed, and even that may be too much. Therefore, when 12 gallons of turpentine have been introduced, have a flat saucer at hand, and pour into it a portion of the varnish, and in two or three minutes it will show whether it is too thick; if not sufficiently thin, add a little more turpentine, and strain it off quickly. As soon as the whole is stored away, pour in the turpentine washings with which the gum-pots have been washed, into the boiling-pot, and with the swish quickly wash down all the varnish from the pot sides; afterwards, with a large piece of woollen rag dipped in pumice-powder, wash and polish every part of the inside of the boiling-pot, performing the same operation on the ladle and stirrers; rinse them with the turpentine washings, and at last rinse them altogether in clean turpentine, which also put to the washings; wipe dry with a clean soft rag the pot, ladle, stirrer, and funnels, and lay the sieve so as to be completely covered with turpentine, which will always keep it from gumming up. The foregoing directions concerning running the gum and pouring in the oil, and also boiling off and mixing, are, with very little difference, to be observed in the making of all sorts of copal varnishes, except the differences of the quantities of oil, gum, &c., which will be found under the various descriptions by name, which will be hereafter described.

The choice of linseed oil is of peculiar consequence to the varnish-maker. Oil from fine full-grown ripe seed, when viewed in a phial, will appear limpid, pale, and brilliant; it is mellow and sweet to the taste, has very little smell, is specifically lighter than impure oil, and, when clarified, dries quickly and firmly, and does not materially change the colour of the varnish when made, but appears limpid and brilliant.

Copal Varnishes for fine paintings, &c.—Fuse 8 lbs. of the very cleanest pale African gum copal, and, when completely run fluid, pour in two gallons of hot oil, old measure; let it boil until it will string very strong; and in about fifteen minutes, or while it is yet very hot, pour in three gallons of turpentine, old measure, and got from the top of a cistern. Perhaps during the mixing a considerable quantity of the turpentine will escape; but the varnish will be so much the brighter, transparent, and fluid; and will work freer, dry more quickly, and be very solid and durable when dry. After the varnish has been strained, if it is found too thick, before it is quite cold, heat as much turpentine, and mix with it, as will bring it to a proper consistency.

Cabinet Varnish.—Fuse 7 lbs. of very fine African gum copal, and pour in half a gallon of pale clarified oil; in three or four minutes after, if it feel stringy, take it out of doors, or into another building where there is no fire, and mix with it three gallons of turpentine; afterwards strain it, and put it aside for use. This, if properly boiled, will dry in ten minutes; but if too strongly boiled, will not mix at all with the turpentine; and *sometimes*, when boiled with the turpentine, will mix, and yet refuse to incorporate with any other varnish less boiled than itself: therefore it requires a nicety which is only to be learned from practice. This varnish is chiefly intended for the use of japanners, cabinet-painters, coach-painters, &c.

Best-body Copal Varnish, for coach-makers, &c.—This is intended for the body parts of coaches and other similar vehicles, intended for polishing.

Fuse 8 lbs. of fine African gum copal; add two gallons of clarified oil (old measure); boil it very slowly for four or five hours, until quite stringy; mix with three gallons and a half of turpentine; strain off, and pour it into a cistern. As they are too slow in drying, coach-makers, painters, and varnish-makers have introduced to two pots of the preceding varnish one made as follows:—

8 lbs. of fine pale gum animé;	$3\frac{1}{2}$ gallons of turpentine.
2 gallons of clarified oil;	To be boiled four hours.

The more minutely the gum copal is run, or fused, the greater the quantity, and the stronger the produce. The more regular and longer the boiling of the oil and gum together is continued, the more fluid or free the varnish will extend on whatever it is applied to. When the mixture of oil and gum is too suddenly brought to string by too strong a heat, the varnish requires more than its just proportion of turpentine to thin it, whereby its oily and gummy quality is reduced, which renders it less durable; neither will it flow so well in laying on. The greater proportion of oil there is used in varnishes, the less they are liable to crack, because the tougher and softer they are. By increasing the proportion of gum in varnishes, the thicker will be the stratum, the firmer they will set solid, and the quicker they will dry. When varnishes are quite new made, and must be sent out for use before they are of sufficient age, they must always be left thicker than if they were to be kept the proper time. Varnish made from African copal alone possesses the most elasticity and transparency. Too much drier in varnish renders it opaque and unfit for delicate colours. Copperas does not combine with varnish, but only hardens it. Sugar of lead does combine with varnish. Turpentine improves by age; and varnish by being kept in a warm place. All copal- or oil-varnishes require age before they are used.

All body-varnishes are intended and ought to have $1\frac{1}{2}$ lb. of gum to each gallon of varnish, when the varnish is strained off and cold; but as the *thinning up*, or quantity of turpentine required to bring it to its proper consistency, depends very much upon the degree of boiling the varnish has undergone, therefore, when the gum and oil have not been strongly boiled, it requires less turpentine for that purpose; whereas, when the gum and oil are very strongly boiled together, a pot of 20 gallons will require perhaps 3 gallons above the regular proportionate quantity; and if mixing the turpentine be commenced too soon, and the pot be not sufficiently cool, there will be frequently above a gallon and a half of turpentine lost by evaporation.

Pale Amber Varnish.—Fuse 6 lbs. of fine picked very pale transparent amber in the gum-pot, and pour in 2 gallons of hot clarified oil. Boil it until it strings very strong. Mix with 4 gallons of turpentine. This will be as fine as body-copal, will work very free, and flow well upon any work it is applied to: it becomes very hard, and is the most durable of all varnishes.

Fine Mastic, or Picture Varnish.—Put 5 lbs. of fine picked gum mastic into a new 4-gallon tin bottle; get ready 2 lbs. of glass, bruised as small as barley; and put it into the bottle with 2 gallons of turpentine that has settled some time; put a piece of soft leather under the bung; lay the tin on a sack upon the counter, table, or anything that stands solid; begin to agitate the tin, smartly rolling it backward and forward, causing the gum, glass, and turpentine, to work as if in a barrel-churn for at least 4 hours, when the varnish may be emptied out. If the gum is not all dissolved, return the whole into the bottle, and agitate as before, until all the gum is dissolved; then strain it through fine thin muslin into a clean tin bottle: leave it uncorked, so that the air can get in, but no dust; let it stand for nine months at least before it is used, for the longer it is kept the tougher it will be, and less liable to chill or bloom.

Common Mastic Varnish.—Put as much gum mastic, unpicked, into the gum-pot as may be required, and to every $2\frac{3}{4}$ lbs. of gum pour in 1 gallon of cold turpentine; set the pot over a very moderate fire, and stir it with the stirrer; be careful, when the steam of the turpentine rises near the mouth of the pot, to cover it with the carpet, and carry it out of doors, as the vapour is very apt to catch fire. A few minutes' low heat will perfectly dissolve 8 lbs. of gum, which will, with 4 gallons of turpentine, produce, when strained, $4\frac{1}{2}$ gallons of varnish; to which add, while yet hot, 5 pints of pale turpentine varnish, which improves the body and hardness of the mastic varnish.

Crystal Varnish.—Procure a bottle of Canada balsam, and set the bottle of balsam at a little distance from the fire, turning it round several times, until the heat has thinned it; then have something that will hold as much as double the quantity of balsam; carry the balsam from the fire, and, while fluid, mix it with the same quantity of good turpentine, and shake them together until they are well incorporated: in a few days the varnish is fit for use. This varnish is used for maps, prints, charts, drawings, paper-ornaments, &c.; and when made upon a larger scale, requires only warming the balsam to mix with the turpentine.

White Hard Spirit of Wine Varnish.—Put 5 lbs. of gum sandarac into a 4-gallon tin bottle, with 2 gallons of spirits of wine, 60 over proof, and agitate it until dissolved, exactly as directed for the best mastic varnish, recollecting if glass is used that it is convenient to dip the bottle containing the gum and spirits into a copperful of hot water every 10 minutes—the bottle to be immersed only 2 minutes at a time—which will greatly assist the dissolving of the gum; but, above all, be careful to keep a firm hold over the cork of the bottle, otherwise the vapour will drive it out. The bottle, every time it is heated, ought to be carried away from the fire; the cork should be eased a little, to allow the rarefied air to escape; then driven tight, and the agitation continued in this manner until all the gum is properly dissolved. After it is strained off, put into the varnish 1 quart of very pale turpentine varnish, and shake and mix the two well together. Spirit varnishes should be kept well corked: they are fit to use the day after being made.

Brown Hard Spirit Varnish is made by putting into a bottle 3 lbs. of gum sandarac, with 2 lbs. of shellac, add 2 gallons of spirits of wine, 60 over proof; proceeding exactly as before directed for the white hard varnish, and agitating it when cold, which requires about four hours' time, without any danger of fire; whereas, making any spirit varnish by heat is always attended with danger. No spirit varnish ought to be made either near a fire or by candle-light. When this brown hard is strained, add 1 quart of turpentine varnish, and shake and mix it well: next day it is fit for use.

The *Chinese Varnish* comes from a tree which grows in Cochin-China, China, and Siam. It forms the best of all varnishes.

Gold Lacker.—Put into a clean 4-gallon tin, 1 lb. of ground turmeric, 1½ ounce of powdered gamboge, 3½ lbs. of powdered gum sandarac, ¾ of a pound of shellac, and 2 gallons of spirits of wine. After being agitated, dissolved, and strained, add 1 pint of turpentine varnish, well mixed.

Red Spirit Lacker.

2 gallons of spirits of wine;
1 lb. of dragon's blood;
3 lbs. of Spanish annotto;
3¼ lbs. of gum sandarac;
2 pints of turpentine.

Made exactly as the yellow gold lacker.

Pale Brass Lacker.

2 gallons of spirits of wine;
3 ounces of Cape aloes, cut small;
1 lb. of fine pale shellac;
1 ounce gamboge, cut small.

No turpentine varnish. Made exactly as before.

White Spirit Varnish.—Sandarac, 250 parts; mastic in tears, 64; elemi resin, 32; turpentine (Venice), 64; alcohol, of 85 per cent., 1,000 parts by measure.

The turpentine is to be added after the resins are dissolved. This is a brilliant varnish, but not so hard as to bear polishing.

Varnish for the Wood Toys of Spa.—Tender copal, 75 parts; mastic, 12·5; Venice turpentine, 6·5; alcohol, of 95 per cent., 100 parts by measure; water ounces, for example, if the other parts be taken in ounces.

The alcohol must be first made to act upon the copal, with the aid of a little oil of lavender or camphor, and the solution being passed through a linen cloth, the mastic must be introduced. After it is dissolved, the Venice turpentine, previously melted in a water-bath, should be added; the lower the temperature at which these operations are carried on, the more beautiful will the varnish be. This varnish ought to be very white, very drying, and capable of being smoothed with pumice-stone and polished.

The Varnish of Watin, for Gilded Articles.—Gum lac, in grain, 125 parts; gamboge, 125; dragon's blood, 125; annotto, 125; saffron, 32. Each resin must be dissolved in 1,060 parts by measure of alcohol of 90 per cent.; two separate tinctures must be made with the dragon's blood and annotto, in 1,000 parts of such alcohol; and a proper proportion of each should be added to the varnish, according to the shade of golden colour wanted.

For fixing engravings or lithographs upon wood, a varnish called *mordant* is used in France, which differs from others chiefly in containing more Venice turpentine, to make it sticky; it consists of—sandarac, 250 parts; mastic, in tears, 64; resin, 125; Venice turpentine, 250; alcohol, 1,000 parts by measure.

Milk of Wax is a valuable varnish, which may be prepared as follows:—Melt in a porcelain capsule a certain quantity of white wax, and add to it, while in fusion, an equal quantity of spirit of wine, of sp. gr. 0·830; stir the mixture, and pour it upon a large porphyry slab. The granular mass is to be converted into a paste by the muller, with the addition, from time to time, of a little alcohol; and as soon as it appears to be smooth and homogeneous, water is to be introduced in small quantities successively, to the amount of four times the weight of the wax. This emulsion is to be then passed through canvas, in order to separate such particles as may be imperfectly incorporated. The *milk of wax*, thus prepared, may be spread with a smooth brush upon the surface of a painting, allowed to dry, and then fused by passing a hot iron (salamander) over its surface. When cold, it is to be rubbed with a linen cloth to bring out the lustre.

Black Japan is made by putting into the set-pot 48 lbs. of Naples or any other of the foreign asphaltums (except the Egyptian). As soon as it is melted, pour in 10 gallons of raw linseed oil; keep a moderate fire, and fuse 8 lbs. of dark gum animé in the gum-pot; mix it with 2 gallons of hot oil, and pour it into the set-pot. Afterwards fuse 10 lbs. of dark or sea amber in the 10-gallon iron-pot; keep stirring it while fusing; and whenever it appears to be overheated, and rising too high in the pot, lift it from the fire for a few minutes. When it appears completely fused, mix in 2 gallons of hot oil, and pour the mixture into the set-pot; continue the boiling for 3 hours longer, and during that time introduce the same quantity of driers as before directed: draw out the fire, and let it remain until morning; then boil it until it rolls hard, as before directed: leave it to cool, and afterwards mix with turpentine.

Best Brunswick Black.—In an iron pot, over a slow fire, boil 45 lbs. of foreign asphaltum for at least 6 hours; and during the same time boil in another iron pot 6 gallons of oil which has been previously boiled. During the boiling of the 6 gallons introduce 6 lbs. of litharge gradually, and boil until it feels stringy between the fingers; then ladle or pour it into the pot containing the boiling asphaltum. Let the mixture boil until, upon trial, it will roll into hard pills; then let it cool, and mix it with 25 gallons of turpentine, or until it is of a proper consistency.

Iron-work Black.—Put 48 lbs. of foreign asphaltum into an iron pot, and boil for 4 hours. During the first 2 hours introduce 7 lbs. of red lead, 7 lbs. of litharge, 3 lbs. of dried copperas, and 10 gallons of boiled oil; add 1 eight-pound run of dark gum, with 2 gallons of hot oil. After pouring the oil and gum, continue the boiling 2 hours, or until it will roll into hard pills like japan. When cool, thin it off with 30 gallons of turpentine, or until it is of a proper consistency. This varnish is intended for blacking the iron-work of coaches and other carriages, &c.

A cheap Brunswick Black.—Put 28 lbs. of common black pitch, and 28 lbs. of common asphaltum made from gas-tar, into an iron pot; boil both for 8 or 10 hours, which will evaporate the gas and moisture; let it stand all night, and early next morning, as soon as it boils, put in 8 gallons of boiled oil; then introduce, gradually, 10 lbs. of red lead and 10 lbs. of litharge, and boil for 3 hours, or until it will roll very hard. When ready for mixing, introduce 20 gallons of turpentine, or more, until of a proper consistency. This is intended for engineers, founders, ironmongers, &c. It will dry in half an hour, or less, if properly boiled.

VEGETABLE BUTTER. A fatty substance expressed from the seeds of an Indian tree, the *Bassia butyracea*, Roxb. It is said to make good soap.

VEGETABLE ETHIOPS. A charcoal prepared by the incineration in a covered crucible of the *Fucus vesiculosus*, or common sea-wrack.

VEGETABLE FIBRE. Most of the useful vegetable fibres are described under their proper heads, as FLAX, HEMP, &c. See also FIBRES, and FIBRE, VEGETABLE.

VEGETABLE IVORY. See COROSA NUTS, and IVORY, VEGETABLE.

VEGETABLE PARCHMENT. See PARCHMENT, VEGETABLE.

VEINS (*Filons*, Fr.; *Gänge*, Ger.) are the fissures or rents in rocks, which are filled with peculiar mineral substances, most commonly metallic ores. See MINES, MINING, &c.

VEIN-STONES are the mineral substances which accompany, and frequently enclose, the metallic ores. See MINES, MINING, &c.

VELLUM is a fine sort of parchment. See PARCHMENT.

VELVET (*Vélours*, Fr.; *Sammet*, Ger.). A peculiar stuff, the nature of which is explained under FUSTIAN and TEXTILE FABRICS.

VENETIAN CHALK is STEATITE.

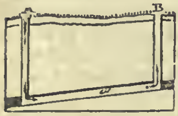
VENETIAN WHITE. A carefully-prepared carbonate of lead. See WHITE LEAD.

VENICE TURPENTINE. A turpentine obtained from the larch (*Larix Europœa*).

VENTILATION OF MINES. In our subterranean operations, especially where quantities of carbonic acid are constantly being produced by respiration and combustion, and where, as especially in our coal-mines, the workmen are constantly exposed to the efflux of a gas—light carburetted hydrogen, which, when mixed with air, becomes explosive, it is necessary to adopt the means of removing, as rapidly as possible, the atmosphere by which the miner is surrounded.

The production of noxious gases renders ventilation a primary object in the system of mining. If an air-pipe has been carried down the engine pit for the purpose of ventilation in the sinking, other pipes are connected with it, and laid along the pavement, or are attached to an angle of the mine next the roof. These pipes are prolonged with the galleries, by which means the air at the forehead is drawn up the pipes and replaced by atmospheric air, which descends by the shaft in an equable current, regulated by the draught of the furnace at the pit-mouth. This circulation is continued till the miners cut through upon the second shaft, when the air-pipes become superfluous; for it is well known that the instant such communication is made, as is represented in *fig.* 2068 *a*, the air spontaneously descends in the engine-pit A, and passing along the gallery *a*, ascends in a steady current in the second pit B. The air, in sinking through A, has at first the atmospheric temperature, which in winter may be at or under the freezing-point of water; but its temperature increases in passing down through the relatively warmer earth, and ascends in the shaft B, warmer than the atmosphere. When shafts are of unequal depths, as represented in the figure, the current of air flows pretty uniformly in one direction. If the second shaft has the same depth with the first, and the bottom and mouth of both be in the same horizontal plane, the air would sometimes remain at rest, as water would do in an inverted syphon, and at other times would circulate down one pit and up another, not always in the same direction, but sometimes up the one and sometimes up the other, according to the variations of temperature at the surface, and the barometrical pressures, as modified by winds. There is in mines a proper heat, proportional to their depth, increasing about one degree of Fahrenheit's scale for every 50 feet of descent.

2068 *a*



There is a simple mode of conducting air from the pit-bottom to the forehead of the mine, by cutting a *ragglin*, or *trumpeting*, as it is termed, in the side of the gallery, as represented in *fig.* 2069, where A exhibits the gallery in the coal, and B the ragglin, which is from 15 to 18 inches square. The coal itself forms three sides of the air-pipe, and the fourth is composed of thin deals applied air-tight, and nailed to small props of wood fixed between the top and bottom of the lips of the ragglin. This mode is very generally adopted in running galleries of communication, and dip-head level galleries, where carbonic acid abounds, or when from the stagnation of the air the miners' lights burn dimly.

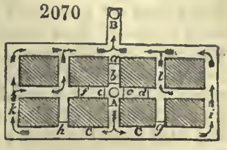
2069

When the ragglin or air-pipes are not made spontaneously active, the air is sometimes impelled through them by means of ventilating-fanners, having their tube placed at the pit-bottom, while the vanes are driven with great velocity by a wheel and pinion worked with the hand. In other cases, large bellows like those of the blacksmith, furnished with a wide nozzle, are made to act in a similar way with the fanners. But these are merely temporary expedients for small mines.

Ventilation of mines and collieries has been likewise effected on a small scale, by attaching a horizontal funnel to the top of air-pipes elevated a considerable height above the pit-mouth. The funnel revolves on a pivot, and by its tail-piece places its mouth so as to receive the wind. At other times, a circulation of air is produced by placing coal-fires in iron grates, either at the bottom of an upcast pit, or suspended by a chain a few fathoms down.

In all great coal-mines the aërial circulation is regulated and directed by double doors, called main or bearing doors. These are true air-valves, which prevent the current of air moving in one direction from mixing with another moving in a different direction. Such valves are placed on the main roads and passages. Their functions are represented in the annexed *fig.* 2070: where A shows the downcast shaft, in which the aërial current is made to descend; B is the upcast shaft, sunk towards the rise of the coal; and C the dip-head level. Were the mine here figured to be worked without any attention to the circulation, the air would flow down the pit A, and proceed in a direct line up the rise mine to the shaft B, in which it would ascend. The consequence would therefore be, that all the galleries and boards to the dip of the pit A, and those lying on each side of the pits, would have no circulation of air; or, in the language of the collier, would be laid dead. To obviate this result, double doors are placed in three of the galleries adjoining the pit; viz. at *a* and *b*, *c* and *d*, *e* and *f*; all of which open inwards to the shaft A. By this plan, as the air is not suffered to pass directly from the shaft A to the shaft B, through the doors *a* and *b*, it would have taken the next shortest direction by *c d* and *e f*; but the doors in these galleries prevent this course, and compel it to proceed downwards to the dip-head level C, where it will spread or divide, one portion pursuing a route to the right, another to the left. On arriving at the boards *g* and *h*, it would have naturally ascended by them; but this it cannot do by reason of the building or stopping placed at *g* and *h*. By means of such stoppings placed in the boards next the dip-head level, the air can be transported to the right hand or to the left for many miles, if necessary, provided there be a train or circle of aërial communication from the pit A to the pit B. If the boards *i* and *k* are open, the air will ascend in them, as traced out by the arrows; and after being diffused through the workings, will again meet in a body at *a*, and mount the gallery to the pit B, sweeping away with it the deleterious air which it meets in its path. Without double doors on each main passage, the regular circulation of the air would be constantly liable to interruptions and derangements; thus, suppose the door *c* to be removed, and only *d* to remain in the left-hand gallery, all the other doors being as represented, it is obvious, that whenever the door *d* is opened, the air, finding a more direct passage in that direction, would mount by the nearest channel *l*, to the shaft B, and lay dead all the other parts of the work, stopping all circulation. As the passages on which the doors are placed constitute the main roads by which the miners go to and from their work, and as the corves are also constantly wheeling along, were a single door, such as *d*, so often opened, the ventilation would be rendered precarious or languid. But the double doors obviate this inconvenience; for both men and horses, with the corves, in going to or from the pit-bottom A, no sooner enter the door *d*, than it shuts behind them, and encloses them in the still air contained between the doors *d* and *c*; *c* having prevented the air from changing its proper course while *d* was open. When *d* is again shut, the door *c* may be opened without inconvenience, to allow the men and horses to pass on to the pit-bottom at A: the door *d* preventing any change in the aërial circulation while the door *c* is open. In returning from the pit, the same rule is observed of shutting one of the double doors before the other is opened.

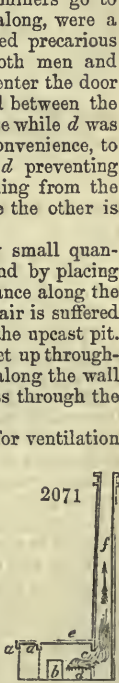
2070



When carbonic acid gas abounds, or when the fire-damp is in very small quantity, the air may be conducted from the shaft to the dip-head level, and by placing stoppings of each room next the level, it may be carried to any distance along the dip-head levels; and the farthest room on each side being left open, the air is suffered to diffuse itself through the wastes, along the wall faces, and mount in the upcast pit. But should the air become stagnant along the wall faces, stoppings are set up throughout the galleries, in such a way as to direct the main body of fresh air along the wall faces for the workmen, while a partial stream of air is allowed to pass through the stoppings, to prevent any accumulation of foul air in the wastes.

In very deep and extensive collieries more elaborate arrangements for ventilation are introduced. The circulation is made active by rarefying the air at the upcast shaft, by means of a large furnace placed either at the bottom or top of the shaft. The former position is generally preferred. *Fig.* 2071 exhibits a furnace placed at the top of the pit. A little way below the scaffold, a passage is previously cut, either in a sloping direction, to connect the current of air with the furnace, or it is laid horizontally, and then communicates with the furnace by a vertical opening. If any obstacle prevent the scaffold from being erected within the pit, this can be made air-tight at top, and a brick flue carried thence along the surface to the furnace.

2071

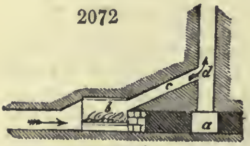


The furnace has a size proportional to the magnitude of the ventilation, and the chimneys are either round or square, being from 50 to 100 feet high, with an inside diameter of from 5 to 9 feet at bottom, tapering upwards to a diameter of from $2\frac{1}{2}$ feet to 5 feet. Such stalks are made 9 inches thick in the body of the building, and a little thicker at bottom, where they are lined with fire-bricks.

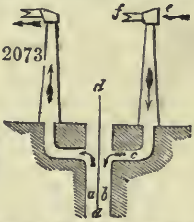
The plan of placing the furnace at the bottom of the pit is, however, more advantageous, because the shaft through which the air ascends to the furnace at the pit-mouth, is always at the ordinary temperature; whereas, when the furnace is situated at the bottom of the shaft, its sides get heated, like those of a chimney, through its total length, so that, though the heat of the furnace be accidentally allowed to decline or become extinct for a little, the circulation will still go on, the air of the upcast pit being rarefied by the heat remaining in the sides of the shaft.

To prevent the annoyance to the onsetters at the bottom from the hot smoke, the plan has been adopted, as shown in the wood-cut, *fig.* 2072, where *a* represents the lower part of the upcast shaft; *b*, the furnace, built of brick, arched at top, with its sides insulated from the solid mass of coal which surrounds it. Between the furnace wall and the coal-beds a current of air constantly passes towards the shaft, in order to prevent the coal catching fire. From the end of the furnace a gallery is cut in a rising direction at *c*, which communicates with the shaft at *d*, about 7 or 8 fathoms from the bottom of the pit. Thus the furnace and the furnace-keeper are completely disjoined from the shaft; and the pit-bottom is not only free from all incumbrances, but remains comfortably cool. To obviate the inconveniences from the smoke to the banksmen in landing the coals at the pit-mouth, the following plan has been contrived for the Newcastle collieries. *Fig.* 2073 represents the mouth of the pit: *a* is the upcast shaft, provided with a furnace at bottom; *b*, the downcast shaft, by which the supply of atmospheric air descends; and *d*, the brattice carried above the pit-mouth. A little way below the settle-boards, a gallery, *c*, is pushed, in communication with the surface from the downcast shaft, over which a brick tube or chimney is built from 60 to 80 feet high, 7 or 8 feet diameter at bottom, and 4 or 5 feet diameter at top. On the top of this chimney a deal funnel is suspended horizontally on a pivot, like a turn-cap. The vane *f*, made also of deal, keeps the mouth of the funnel always in the same direction with the wind. The same mechanism is mounted at the upcast shaft *a*, only here the funnel is made to present its mouth in the wind's eye. It is obvious

2072



2073



2074

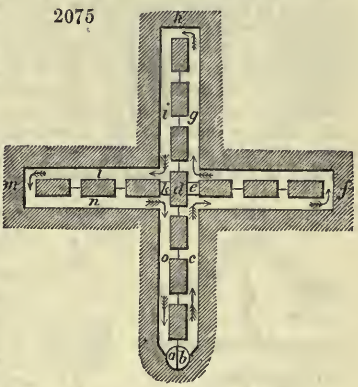
from the figure, that a high wind will rather aid than check the ventilation by this plan.

The principle of ventilation being established, the next object in opening up a colliery, and in driving galleries, is the *double mine* or double *headways course*; on the simple but ingenious distribution of which, the circulation of air depends at the commencement of the excavations.

The double headways course is represented in *fig.* 2074, where *a* is the one heading or gallery, and *b* the other; the former being immediately connected with the upcast side of the pit *c*, and the latter with the downcast side of the pit *d*. The pit itself is made completely air-tight by its division of deals from top to bottom, called 'the brattice wall'; so that no air can pass through the brattice from *d* to *c*, and the intercourse betwixt the two currents of air is completely intercepted by a stopping betwixt the pit-bottom and the end of the first pillar of coal; the pillars or walls of coal, marked *e*, are called 'stenting walls;' and the openings betwixt them, 'walls' or 'thirlings.' The arrows show the direction of the air. The headings *a* and *b* are generally made about 9 feet wide, the stenting-walls 6 or 8 yards thick, and are holed or thirled at such a distance as may be most suitable for the state of the air. The thirlings are 5 feet wide.

When the headings are set off from the pit-bottom, an aperture is left in the brattice at the end of the pillar next the pit, through which the circulation betwixt the upcast and downcast pits is carried on; but whenever the workmen cut through the first thirling No. 1, the aperture in the brattice at the pit-bottom is shut; in consequence of which the air is immediately drawn by the power of the upcast shaft through that thirling as represented by the dotted arrow. Thus a direct stream of fresh air is obviously brought close to the forehead where the mines are at work. The two headings *a* and *b* are then advanced, and as soon as the thirling No. 2 is cut through, a wall of brick and mortar, 4½ inches thick, is built across the thirling No. 1. This wall is termed 'a stopping;' and being air-tight, it forces the whole circulation through the thirling No. 2. In this manner the air is always led forward, and caused to circulate always by the last-made thirling next the forehead; care being had, that whenever a new thirling is made, the last thirling through which the air was circulated be secured with an air-tight stopping. In the woodcut, the stoppings are placed in the thirlings numbered 1, 2, 3, 4, 5, 6, and of consequence the whole circulation passes through the thirling No. 7, which lies nearest the foreheads of the headings, *a*, *b*. By inspecting the figure, we observe that on this very simple plan a stream of air may be circulated to any required distance, and in any direction, however tortuous. Thus, for example, if while the double headways course *a*, *b*, is pushed forward, other double headways courses are required to be carried on at the same time on both sides of the first headway, the same general principles have only to be attended to as shown in *fig.* 2075, where *a* is the upcast and *b* the downcast shaft. The air advances along the heading *c*, but cannot proceed farther in that direction than the pillar *d*, being obstructed by the double doors at *e*. It therefore advances in the direction of the arrows to the foreheads at *f*, and passing through the last thirling made there, returns to the opposite side of the double doors, ascends now the heading *g* to the foreheads at *h*, passes through the last-made thirling at that point, and descends, in the heading *i*, till it is interrupted by the double doors at *k*. The aërial current now moves along the heading *l*, to the foreheads at *m*, returns by the last-made thirling there, along the heading *n*, and finally goes down the heading *o*, and mounts by the upcast shaft *a*, carrying with it all the noxious gases which it encountered during its circuitous journey. This woodcut is a faithful representation of the system by which collieries of the greatest extent are worked and ventilated. In some of these the air courses are from 30 to 40 miles long. Thus the air conducted by the medium of a shaft divided by a brattice-wall only a few inches thick, after descending in the downcast in one compartment of the pit at 6 o'clock in the morning, must thence travel through a circuit of nearly 30 miles, and cannot arrive at its reascending compartment on the other side of the brattice, or pit partition, till 6 o'clock in the evening, supposing it to move all the time at the rate of 2½ miles per hour. Hence we see that the *primum mobile* of this mighty circulation, the furnace, must be carefully looked after, since its irregularities may affect the comfort, or even the existence of hundreds of miners spread over these vast subterraneous labyrinths. On the principles just laid down, it appears, that if any number of boards be set off from any side of these galleries, either in a level, dip, or rise direction, the circulation of air may be advanced to each forehead by an ingoing and returning current.

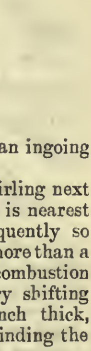
2075



Yet while the circulation of fresh air is thus advanced to the last-made thirling next the foreheads *f*, *h*, and *m*, *fig.* 2075, and moves through the thirling which is nearest to the face of every board and room, the emission of fire-damp is frequently so abundant from the coaly strata, that the miners dare not proceed forwards more than a few feet from that aërial circulation, without hazard of being burned by the combustion of the gas at their candles. To guard against this accident, temporary shifting brattices are employed. These are formed of deal, about ¾ of an inch thick, 3 or 4 feet broad, and 10 feet long; and are furnished with cross-bars for binding the deals together, and a few finger-loops cut through them, for lifting them more expeditiously, in order to place them in a proper position.

The mode of applying these temporary brattices, or deal partitions, is shown in the accompanying figure (2076), which shows how the air circulates freely through the thirling *d*, *d*, before the brattices are placed. At *b* and *c*, we see two heading boards or rooms, which are so full of inflammable air as to be unworkable. Props are now erected near the upper end of the pillar *e*, betwixt the roof and pavement, about 2 feet clear of the sides of the next pillar, leaving room for the miner to pass along between the pillar side and the brattice. The brattices are then fastened with nails to the props, the lower edge of the under brattice resting on the pavement, while the upper edge of the upper is in contact with the roof. By this means any variation of the height in the bed of coal is compensated by the overlap of the brattice boards; and as these are advanced, shifting brattices are laid close to and alongside of the first set. The miner next sets up additional props in the same parallel line with the former, and slides the brattices forwards to make the air circulate close to the forehead where he is working; and he regulates the distance betwixt the brattice and the forehead by the disengagement of fire-damp and the velocity of the aërial circulation. The props are shown at *d d*, and the brattices at *f f*. By this arrangement the air is pre-

2076

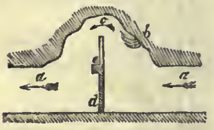


vented from passing directly through the thirling *a*, and is forced along the right-hand side of the brattice, and, sweeping over the wall face or forehead, returns by the back of the brattice, and passes through the thirling *a*. It is prevented, however, from returning in its former direction by the brattice planted in the forehead *c*, whereby it mounts up and accomplishes its return close to that forehead. Thus headways and boards are ventilated till another thirling is made at the upper part of the pillar. The thirling *a* is then closed by a brick stopping, and the brattice-boards removed forward for a similar operation.

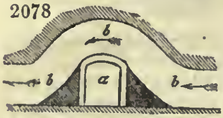
When blowers occur in the roof, and force the strata down, so as to produce a large vaulted excavation, the accumulated gas must be swept away; because, after filling that space, it would descend in an unmixed state under the common roof of the coal. The manner of removing it is represented in *fig.* 2077, where *a* is the bed of coal, *b* the blower, *c* the excavation left by the downfall of the roof, *d* is a passing door, and *e* a brattice. By this arrangement the aërial current is carried close to the roof, and constantly sweeps off or dilutes the inflammable gas of the blower, as fast as it issues. The arrows show the direction of the current; but for which, the accumulating gas would be mixed in explosive proportions with the atmospheric air, and destroy the miners.

There is another modification of the ventilating system, where the air-courses are traversed across; that is, when one air-course is advanced at right angles to another, and must pass it in order to ventilate the workings on the farther side. This is accomplished on the plan shown in *fig.* 2078, where *a* is a main road with an air-course, over which the other air-course *b*, has to pass. The sides of this air-channel are built of bricks arched over, so as to be air-tight, and a gallery is driven in the roof strata as shown in the figure. If an air-course, as *a*, be laid over with planks made air-tight, crossing and recrossing may be effected with facility. The general velocity of the air in these ventilating channels is from 3 to 4 feet per second, or about 2½ miles per hour, and their internal dimensions vary from 5 to 6 feet square, affording an area of from 25 to 36 square feet.

2077



2078



2079

The hydraulic air-pump deserves to be noticed among the various ingenious contrivances for ventilating mines, particularly when they are of moderate extent. *a* is a large wooden tub, nearly filled with water, through whose bottom the ventilating pipe *b* passes down into the recesses of the mine. Upon the top of *b* there is a valve *e*, opening upwards. Over *b*, the gasometer vessel is inverted in *a*, having a valve also opening outwards at *d*. When this vessel is depressed by any moving force the air contained within it is expelled through *d*; and when it is raised, it diminishes the atmospherical pressure in the pipe *b*, and thus draws air out of the mine into the gasometer; which cannot return on account of the valve at *e*, but is thrown out into the atmosphere through *d* at the next descent.

Struve's Mine Ventilator.—This ventilator has been constructed in some of the mines of South Wales upon a very large scale. Although in principle a pump of the simplest form, some of the pistons have been made 20 feet in diameter, and two pumps were constructed 21 feet in diameter. See *fig.* 2080.

In some mines to which the machine has been applied, the rarefaction and ventilation has proved so strong as to prevent single doors being opened, unless protected by supplemental doors. The circumstance of the air not being compressed in the machine admits of large valve spaces, so that there is scarcely any appreciable resistance to the passage of the air through the machine.

The annexed drawing, *fig.* 2080, represents the machine in operation at the Governor and Company's large collieries at Cwm Avon, Glamorganshire.

The sectional view explains the internal construction, the darts showing the air-currents ascending the upcast pit A, from the interior of the mine into the machine.

The general plan of distributing the air in all cases is to send the first of the current that descends in the downcast shaft among the horses in the stables, next among the workmen in the foreheads, after which the air, loaded with whatever mixtures it may have received, is made to traverse the old wastes. It then passes through the furnace with all the inflammable gas it has collected, ascends the upcast shaft, and is dispersed into the atmosphere. This system, styled *coursing the air*, was invented by Mr. Spedding of Cumberland.

The piston B, is shown immersed in water, which forms an air-tight packing.

The front or outlet valves E, are shown in the external view of the ventilator. The end of the machine is represented open in the drawing, for the convenience of showing the inlet valves E, and of explaining the internal construction.

A. The upcast pit.
B. Hollow pistons, made of wrought iron.
C. Wrought-iron tanks, resting on two blocks of masonry, and on six iron pillars.
D. Beam work, resting on three blocks of masonry.
E. The valve work and framing, fastened to sixteen upright pieces of timber, 9 inches square.
F. Crank-wheel of steam-engine.
G. Piston-rods.

In ventilating the very thick coal of Staffordshire, though there is much inflammable gas, less care is needed than in the North-of England collieries, as the workings are very roomy, and the air-courses of comparatively small extent. The air is conducted down one shaft, carried along the main roads, and distributed into the sides of work. A narrow gallery, termed 'the air-head,' is carried in the upper part of the coal, in the rib walls, along one or more of the sides. Lateral openings, named 'spouts,' are led from the air-head gallery into the side of the work; and the circulating stream, mixed with the gas in the workings, enters by these spouts, and returns by the air-head to the upcast pit.

The means adopted in the South Staffordshire coal-mines, which have seams varying from 25 to 30 feet in thickness, are well worthy of consideration; since a solid mass of that magnitude must be peculiarly difficult to drain of its imprisoned gas. In excavating such coal large masses must be detached, and pockets or hollows must be formed, which are immediately filled with carburetted hydrogen; whilst a thin vein, for which a level roof can be generally secured, can be kept tolerably free from such accumulations.

According to the ordinary system adopted in the collieries of the South Staffordshire district, two shafts are sunk, near together, about 7 to 7½ feet in diameter, each to the bottom of the coal, say about 180 yards depth, the two shafts commencing at the same level, and terminating at the same level. One of these becomes the 'downcast pit' down which the air descends, and the other the 'upcast pit' up which the air ascends, when a communication is made between them at the bottom; but the only determining causes for the motion of the air being accidental, it is unknown beforehand what direction the current will take, and which will become the downcast pit. It is always found that a current of air does take place without any other means being employed; but the determining power is so faint, that, issuing from the upcast pit with such trifling velocity, it is liable to be deranged by the action of the wind, or by atmospheric changes; and it sometimes happens that the air becomes quiescent, or an unsteady column, alternately ascending and descending the same shaft; and then, in miner's language, the pits 'fight,' and the air will neither ascend nor descend with regularity in one direction.

When the two pits are sunk down through the stratum of coal 30 ft. in thickness, a 'gate-road' or horse-way is next driven in the bottom of the coal, from 8 to 9 ft. high, and about the same width, commencing from the bottom of the downcast pit.

At the same time an air-head is driven about the middle of the coal, or 15 feet high from the 'floor' or the bottom of the coal, commencing from the downcast pit. The gate-road and air-head are then driven in parallel lines, at the same level upon which they commence, for the distance of 100 to 500 yards, or more, according to the quantity of coal intended to be cleared by the pits.

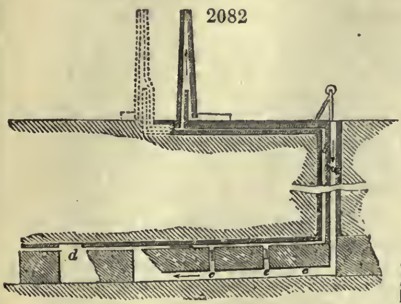
A series of 'spouts' or openings are driven upwards from the gate-road into the air-head, at intervals of 10 or 15 yards to carry off the gas formed, and produce a current of air for the workmen,—each spout being closed up when a new one is made in advance. The excavation of the whole thickness of the stratum of coal, 30 feet thick, is then proceeded with, by opening right and left from the end of the gate-road, and excavating a 'side of work,' which forms a rectangular cavity, say about 90 yards long by 50 yards wide, or about an acre, the whole of the coal being taken away as far as practicable, excepting the pillars of coal (generally 10 yards square and 10 yards distant from each other) which are left to support the superincumbent strata.

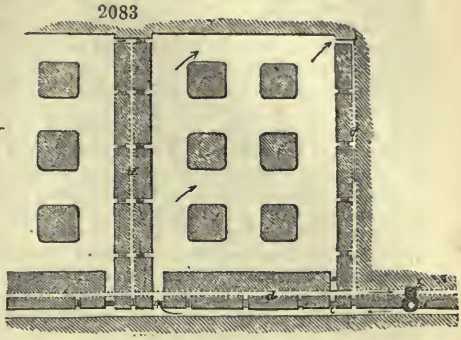
The air descending the downcast pit, and travelling along the gate-road into the workings, ascends to the air-head, and traversing that, ascends the upcast pit, carrying with it the gas and impure vapours, as far as such imperfect and interrupted means will effect, and delivering them into the open air.

By this plan the mine is ventilated, until the lower 15 feet of the coal is excavated; but where the whole thickness of the coal above the air-head has been removed, by undergoing the coal from the bottom, and dropping it down in large masses, the upper portion of the cavity, being above the level of the air-head, forms a reservoir for gas, which gradually accumulates, and has no means of escape,—a reservoir of the capacity of some hundred thousand of cubic feet, which may be wholly or in part occupied by gas. An accidental change in the direction of the current of air would turn the course of the air along the air-head into this reservoir of gas, and from thence into the gate-road, and render an explosion very probable. After the coal is extracted, a solid wall or 'rib' of coal, from 6 to 10 yards thick, which is commonly termed a 'fire-rib,' is left all round the chamber, separating it from the next workings; and the entrance from the gate-road is securely walled up, to exclude the air, and prevent spontaneous combustion, which would otherwise, in a short period, take place. When an explosion occurs, it is generally followed by a second, or more, as portions of the gas become successively charged with the due proportions of air; and the liability to these terrible explosions will always remain in mines thus worked, till, by some efficient means, the gas can be allowed a continuous escape, and a current of air can be ensured to move always in one direction, with sufficient power to overcome all extraneous disturbing forces, either of the wind or any atmospheric changes.

In *fig.* 2082 the system adopted and carried into operation by the late Benjamin Gibbons is shown. One pit *a*, is sunk, instead of two; and in the side of the shaft a smaller shaft *b* is cut, to form an 'air-chimney,' and is afterwards separated from the main shaft; this air-chimney is circular, and may be made about three feet diameter inside, or more, as may be required. The air-chimney is bricked at the same time with the shaft,—the circular brickwork of each forming a partition of double thickness and secure strength, from the two arches abutting against each other.

The gate-road *c*, is driven from the shaft at the bottom of the coal, as in the ordinary





plan; but the air-head *d* is driven from the air-chimney within 2 feet of the top of the coal, or higher, if practicable, and runs into the vertical air-chimney. The gate-road and air-head are carried forward in a parallel direction to the extent of the work, as before described in the ordinary system; and 'spouts' or openings, *e*, are driven upwards to connect them, at about every 15 yards—every spout being bricked up close, in succession, when a fresh one is made in advance, so as to make the current of air traverse the whole extent of the gate-road before it rises up to the air-head and passes away to the air-chimney.

In the ordinary system of ventilation, it is manifest that only a very slight determining power compels the air to travel constantly in the same direction. Its current is, at all times, weak and insufficient, and liable to be deranged by the action of the wind, or atmospheric changes; and it is under no command whatever. To ensure safety a constant current of air is indispensably necessary; it should be a current, too, maintained by natural causes, as far as possible, and never interrupted, for the reasons already assigned; and should be one that would not vary or fail.

To effect this, the ascending column of air must be rendered specifically lighter than the air of the descending column, which circulates through the workings; and this difference of specific gravity must be maintained constantly free from disturbance by accidental causes, and to such an extent as to produce under all circumstances a total amount of propelling power that is found sufficient for the complete ventilation of the mine. This is accomplished by conducting the whole of the gas in a continuous ascending column, free from interruption or disturbance, up the separate air-chimney; and this ascending power is further increased by erecting a ventilating chimney (shown by dots in the vertical section), of a sufficient height, on the surface of the ground, into the base of the air-chimney is continued so as to form one uninterrupted air-flue, from the top of the ventilating chimney down to the air-head in the seam of coal.

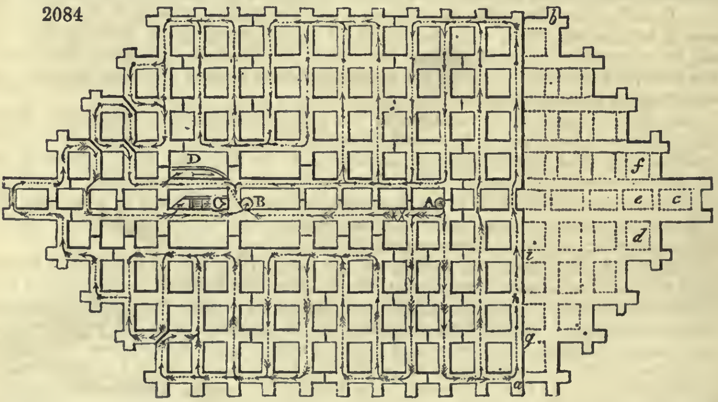
Ventilation is nowhere exhibited to such advantage as in the coal-mines of Northumberland and Durham, where they have carried well nigh to systematic perfection the plan of coursing the air through the winding galleries.

In Mr. Spedding's system the whole of the return air came in one current to his rarefying furnace (see letter C, *fig.* 2084), whether it was at the explosive point or not. This distribution was often fraught with such danger, that a torrent of water had to be kept in readiness, under the name of 'the waterfall,' to be let down to extinguish the fire in a moment. Many explosions at that time occurred, from the furnaces below, and also down through tubes from the furnaces above ground.

About the year 1807 Mr. Buddle had his attention intensely occupied with this most important object, and then devised his plan of a divided current, carrying that portion of the air which, descending in the downcast pit A, coursed through the *clean* workings, through the active furnace C, *fig.* 2084, and the portion of the air from the *foul* workings up the dumb furnace D, till it reached a certain elevation in B, the upcast pit, above the fireplace. The pitmen had a great aversion, however, at first to adopt this plan, as they thought that the current of air by being split would lose its ventilating power; but they were ere long convinced by Mr. Buddle to the contrary. He divided the main current into two separate streams, at the bottom of the pit A, as shown by darts in the figure; the feathered ones representing that part of the pit in which the course of the current of air is free from explosive mixture, or does not contain above one-thirtieth of carburetted hydrogen, as indicated by its effect upon the flame of a candle. The naked darts denote the portions of the mine where the air, being charged to the firing-point, is led off towards D, the dumb furnace, which communicates with the hot upcast shaft, out of reach of the flame, and thence derives its power of draught. By suitable alterations in the stoppings (see the various transverse lines, and the crosses) any portion of the workings may, by the agency of the furnace, be laid out of, or brought within, the course of the vitiated current, at the pleasure of the skilful mine-viewer; so that, if he found it necessary, he could confine, by proper arrangements of his furnace, all the vitiated currents to a mere gas-pipe or drift, and direct it wholly through the dumb furnace. During a practice of twenty years Mr. Buddle had not met with any accident in consequence of a defect in the stoppings preventing the complete division of the air. The engineer has it thus within his power to detach or insulate those portions of the mine in which there is a great exudation of gas, from the rest; and, indeed, he is continually making changes, borrowing and lending currents, so to speak; sometimes laying one division or panel upon the one air-course, and sometimes upon the other, just to suit the immediate emergency. As soon as any district has ceased to be dangerous, by the exhaustion of the gas-blowers, it is transferred from the foul to the pure air-course, where gunpowder may be safely used, as also candles, instead of Davy's lamps, which give less light.

Till the cutting out of the pillars commences (see the right end of the diagram), the ventilation of the several passages, boards, &c., may be kept perfect, supposing

2084



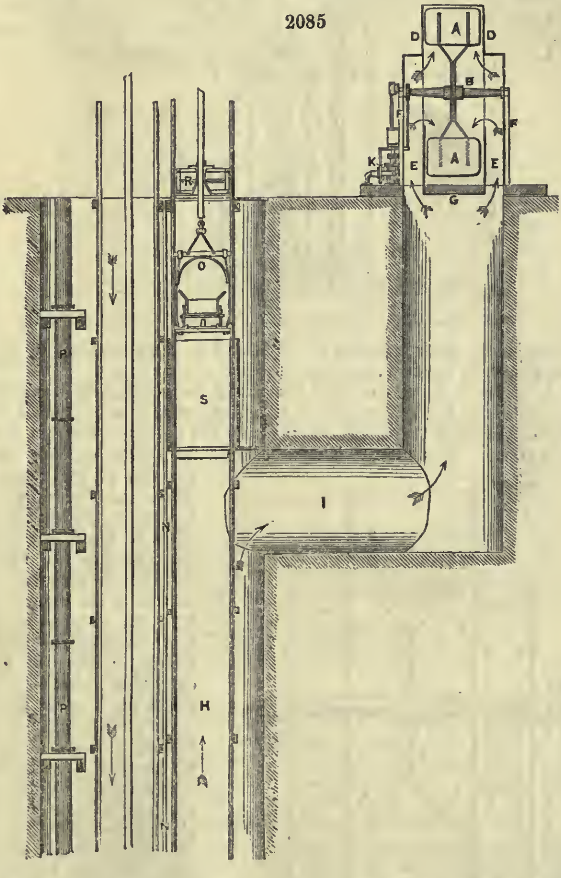
the working, extending no farther than *a* or *b*; because, as long as there are pillars standing, every passage may be converted into an air-conduit, for leading a current of air in any direction, either to C, the burning, or D, the dumb furnace. But the first pillar that is removed deranges the ventilation at that spot, and takes away the means of carrying the air in the further recess towards *c*. In taking out the pillars, the miners always work to windward, that is to say, against the stream of air; so that whatever gas may be evolved shall be immediately carried off from the people at work. When a range of pillars has been removed, as at *d, e, f*, no power remains of dislodging the gas from the section of the mine beyond *a, b*; and as the pillars are successively cut away to the left hand of the line *ab, b*, the size of the *goaf*, or void, is increased. This vacuity, or goaf, is a true gas-holder, or reservoir, continually discharging itself at the points *g, h, i*, into the circulating current, to be carried off by the gas-pipe drift at the dumb furnace, but not to be suffered ever to come in contact with flame of any description. The next range of working is the line of pillars to the left of *a, b*; the coal having been entirely cleared out of the space to the right, where the place of the pillars is marked by dotted lines. The roof in the waste soon falls down, and gets fractured up to the next seam of coal, which, abounding in gas, sends it down in large quantities, and keeps the goaf below continually replenished.

Description of the Ventilating Fan at the Abercarn Collieries.—The late Mr. E. Rogers having occasion to ventilate the workings in some extensive and very fiery coal-seams won at Abercarn in South Wales, under circumstances where the furnace-ventilation could not be applied, came to the conclusion that a plan of machine proposed for the purpose by Mr. James Nasmyth would be the most suitable and effective. After consultation with Mr. Nasmyth, it was resolved to test the principle and plan by actual practice; and the ventilating fan described was erected at the Abercarn Collieries.

The general arrangements of the top of the shaft and the ventilating fan are shown in *figs.* 2085 and 2086. *Fig.* 2087 is a side elevation of the fan and engine, to a larger scale; and *fig.* 2086 a vertical section of the fan.

The fan A A, *fig.* 2087, is 13½ feet diameter, with 8 vanes, each 3 feet 6 inches wide and 3 feet long. It is fixed on a horizontal shaft B, 8 feet 7 inches in length from centre to centre of its bearings, which are nine inches long by 4½ inches diameter. The vanes are of thin-plate iron, and carried by forked wrought-iron arms secured to a centre disk C, fixed upon the shaft B. The fan works within a casing, D D, consisting of two fixed sides of thin wrought plate, entirely open round the circumference and connected together by stay-rods; the sides are 3 inches clear from the edges of the vanes, and have a circular opening 6 feet diameter in the centre of each, from which rectangular wrought-iron trunks, E E, are carried down for the entrance of the air, the bearings

2085



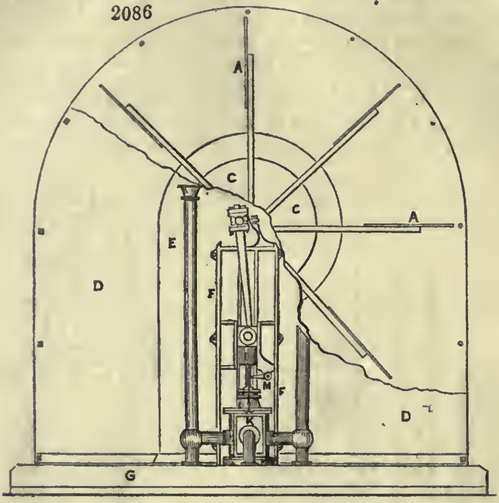
for the fan-shaft B being fixed in the outer side of these trunks, which are strengthened for the purpose by vertical cast-iron standards F bolted to them, and resting upon the bottom foundation-stone G.

The two air-trunks E E join together below the fan, as shown in *fig.* 2085, and communicate with the pit H by means of a horizontal tunnel I, which enters the pit at 21 feet depth from the top.

The fan is driven by a small direct-acting non-condensing engine K, which is fixed upon the face of one of the vertical cast-iron standards F, and is connected to a crank on the end of the fan-shaft B. The steam-cylinder is 12 inches diameter and 12 inches stroke, and is worked by steam from the boilers of the winding engine of the pit, at a pressure of about 13 lbs. per square inch. The excentric L for the slide valve is placed just inside the air-trunk E, and works the valve through a short-weight shaft M, with a lever on the outside.

The pit H, *fig.* 2085, is of an oval form, 10 feet by 18 feet, and divided near the centre by a timber brattice N, the one side forming the upcast shaft and the other the downcast. Both of these are used for winding, and the cages O, in which the trucks,

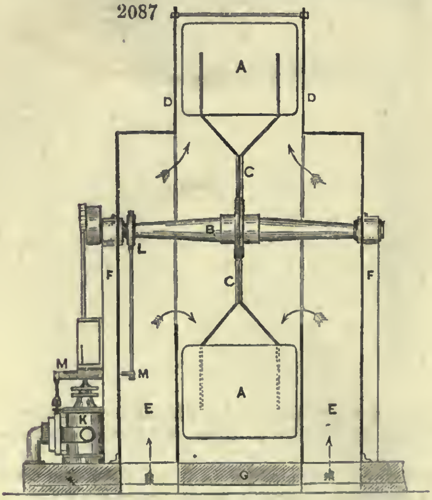
2086



&c., are brought up, work between guides fixed to the timbering of the pit. The pumps P are placed in the downcast shaft.

In order to allow of the upcast shaft being used for winding, the top is closed by an air-valve R, which is formed by simply boarding up the underside of the ordinary guard upon the mouth of the shaft, leaving only the hole in the centre through which the chain works. This air-valve R is carried up by the cage O on arriving at the top of the shaft, as in *fig.* 2085, and then drops down again flat upon the opening when the cage is again lowered. During the time that the valve is lifted, its place is occupied by the close bottom of the cage O, which nearly fills the rectangular opening left at the top of the shaft. By this simple means it is found practically that a complete provision is made for keeping the top of the upcast shaft closed, and maintaining a uniform current of air up the shaft; for the leakage of air downwards through the top whilst the cage is in the act of opening or closing the air-valve, and through the small area that always remains open, is found to be quite immaterial, and the surplus ventilating power of the fan is amply sufficient to provide against it.

2087



In the original construction a more perfect air-valve was supposed to be requisite, and was provided by the inclined flaps S S, which are fixed just above the horizontal tunnel I. These are fitted closely together, leaving only a small opening in the centre for the chain to pass through, and were intended to be opened by the ascending cage coming in contact with them, closing again directly by means of balance weights before the air-valve R at the top of the shaft was opened, so as to preserve a thorough closing of the top of the shaft. The flaps were to be opened again by a lever from the top to allow the cage to descend. However, it was found on trial that the valve R at the top was amply sufficient; and consequently, although the other valves were also provided, they were never put into use.

The total depth of the pit is nearly 300 yards, and at a depth of 120 yards a split of air is taken off, and coursed through workings from which coal and fire-clay are got; the larger portion of the air descends to the bottom of the pit, and is there split into many courses, to work two separate seams of coal and a vein of ironstone. The total length of road laid with plates or rails in the workings is about 7 miles, and the working faces amount to nearly double that distance. The longest distance that is traversed by any single course or split of air in passing from the downcast to the upcast shaft is nearly 2 miles. The quantity of materials raised from the pit is about 500 tons daily.

The following Table gives the results of a series of experiments made with this ventilating fan by Mr. R. S. Roper, showing that the quantity of air delivered at the velocities of 60 and 80 revolutions of the fan per minute is 45,000 and 56,000 cubic feet per minute, with a velocity of current of 782 and 1,037 lineal feet per minute respectively, or about 9 and 12 miles per hour; and the degree of vacuum or exhaustion in the upcast shaft is ·5 and ·9 inch of water respectively.

Synopsis of Experiments on Fan Ventilation.

	Height of barometer		Temperature by Fahrenheit's thermometer				Revolutions of fan per minute	Water-gauge	Velocity of air in feet per minute	Cubic feet of air per minute	Steam-gauge on fan	Theoretical consumption of coal per hour
	At the surface	At the bottom	Top of downcast	Bottom of downcast	Bottom of upcast	10 yards from top of upcast

The speed at which the ventilating fan is usually worked is about 60 revolutions per minute, giving a velocity at the circumference of the fan of 2,545 feet per minute; 45,000 cubic feet of air per minute are then drawn through the mine, nearly one-third of which ventilates the upper workings, and the rest passes through the lower workings.

The Guibal fan especially has been used in several collieries.

Several modified forms of fan ventilation have been introduced, but the principle involved is essentially the same in all.

VERANTINE. See MADDER.

VERATRINE. $C^{64}H^{52}N^{2}O^{16}$ ($\mathbf{C^{32}H^{52}N^{2}O^{6}}$). An alkaloïd contained in white hellebore (*Veratrum album*), and in cevadilla (*V. Sabadilla*). It is exceedingly poisonous, and if introduced into the nostrils excites violent and prolonged sneezing. In the form of ointment it has been found a valuable remedy in neuralgic disorders.

VERDIGRIS. (*Vert-de-gris*, Fr.; *Grünspan*, Ger.) The copper used in this manufacture is formed into round sheets, from 20 to 25 inches diameter, by one-twenty-fourth of an inch in thickness. Each sheet is then divided into oblong squares, from 4 to 6 inches in length, by 3 broad; and weighing about 4 ounces. They are separately beaten upon an anvil, to smooth their surfaces, to consolidate the metal, and to free it from scales. The refuse of the grapes, after the extraction of their juice, formerly thrown on to the dunghill, is now preserved for the purpose of making verdigris. It is put loosely into earthen vessels, which are usually 16 inches high, 14 in diameter at the widest part, and about 12 at the mouth. The vessels are then covered with lids, which are surrounded by straw mats. In this situation the materials soon become heated, and exhale an acid odour; the fermentation beginning at the bottom of the cask, and gradually rising till it actuates the whole mass. At the end of two or three days the manufacturer removes the fermenting materials into other vessels, in order to check the process, lest putrefaction should ensue. The copper-plates, if new, are now prepared, by rubbing them over with a linen cloth, dipped in a solution of verdigris; and they are laid up alongside of one another to dry If the plates are not subjected to this kind of preparation they will become black, instead of green, by the first operation. When the plates are ready, and the materials in a fermenting state, one of them is put into the earthen vessel for 24 hours, in order to ascertain whether it be a proper period to proceed to the remaining part of the process. If, at the end of this period, the plate be covered with an uniform green layer, concealing the whole copper, everything is right; but if, on the contrary, liquid drops hang on the surface of the metal, the workmen say the plates are *sweating*, and conclude that the heat of the fermented mass has been inadequate; on which account another day is allowed to pass before making a similar trial. When the materials are finally found to be ready, the strata are formed in the following manner:—The plates are laid on a horizontal wooden grating, fixed in the middle of a vat, on whose bottom a pan full of burning charcoal is placed, which heats them to such a degree that the women who manage this work are obliged to lay hold of them frequently with a cloth when they lift them out. They are in this state put into earthen vessels, in alternate strata with the fermented materials, the uppermost and undermost layers being composed of the expressed grapes. The vessels are covered with their straw mats, and left at rest. From 30 to 40 lbs. of copper are put into one vessel.

At the end of 10, 12, 15, or 20 days the vessels are opened to ascertain, by the materials having become white, if the operation be completed.

Detached glossy crystals will be perceived on the surface of the plates; in which case the grapes are thrown away, and the plates are placed upright in a corner of the verdigris cellar, one against the other, upon pieces of wood laid on the ground. At the end of two or three days they are moistened by dipping in a vessel of water, after which they are replaced in their former situation, where they remain seven or eight days, and are then subjected to momentary immersion, as before. This alternate moistening and exposure to air is performed six or eight times, at regular intervals of about a week. As these plates are sometimes dipped into damaged wine, the workmen term these immersions *one wine, two wines*, &c.

By this treatment the plates swell, become green, and covered with a stratum of verdigris, which is readily scraped off with a knife. At each operation every vessel yields from 5 to 6 lbs. of verdigris, in a *fresh* or *humid* state; which is sold to wholesale dealers, who dry it for exportation. For this purpose they knead the paste in wooden troughs, and then transfer it to leathern bags, a foot and a half long and ten inches in diameter. These bags are exposed to the sun and air till the verdigris has attained a sufficient degree of hardness. It loses about half its weight in this operation; and it is said to be knife-proof when this instrument, plunged through the leathern bag, cannot penetrate the loaf of verdigris.

Verdigris is a mixture of the crystallised acetate of copper and the subacetate, in varying proportions. According to Vauquelin's researches, there are three compounds of oxide of copper and acetic acid: 1, a subacetate, insoluble in water, but decomposing in that fluid, at common temperatures changing into peroxide and acetate; 2, a neutral acetate, the solution of which is not altered at common temperatures, but is decomposed by ebullition, becoming peroxide and superacetate; and 3, superacetate, which in solution is not decomposed, either at common temperatures or at the boiling point; and which cannot be obtained in crystals, except by slow spontaneous evaporation, in air or *in vacuo*. The first salt, in the dry state, contains 66·51 of oxide; the second, 44·44; and the third, 33·34.

Distilled Verdigris, as it was long erroneously called, is merely a *binacetate* or superacetate of copper, made by dissolving, in a copper kettle, one part of verdigris in two of distilled vinegar; aiding the mutual action by slight heat and agitation with a wooden spàtula. When the liquor has taken its utmost depth of colour, it is allowed to settle, and the clear portion is decanted off into well-glazed earthen vessels. Fresh vinegar is poured on the residuum, and if its colour does not become deep enough, more verdigris is added. The clear and saturated solution is then slowly evaporated, in a vessel kept uniformly filled, till it acquires the consistency of syrup, and shows a pellicle on its surface; when it is transferred into glazed earthen pans, called *oulas* in the country. In each of these dishes two or three sticks are placed, about a foot long, cleft till within two inches of their upper end, and having the base of the cleft kept asunder by a bit of wood. This kind of pyramid is suspended by its summit in the liquid. All these vessels are transported into crystallising rooms, moderately heated with a stove, and left in the same state for 15 days, taking care to maintain an uniform temperature. Thus are obtained very fine groups of crystals of acetate of copper, clustered round the wooden rods; on which they are dried, taken off, and sent into the market. They are distinctly rhomboïdal in form, and of a lively deep blue colour.

Each cluster of crystals weighs from five to six pounds; and, in general, their total weight is equal to about one-third of the verdigris employed.

VERDINE. One of the aniline colours, prepared by M. Eusebi.

VERDITER, or *Bremen Green.* This pigment is a light powder, having a blue or bluish-green colour. The first is most esteemed. When worked up with oil or glue, it resists the air very well.

The following is, according to M. J. G. Gentele, the process of fabrication in Bremen, Cassel, Eisenach, Minden, &c.:—225 lbs. of sea salt, and 222 lbs. of blue vitriol, both free from iron, are mixed in the dry state, and then reduced between mill-stones with water to a thick homogeneous paste. 225 lbs. of plates of old copper are cut by scissors into bits of an inch square, then thrown and agitated in a wooden tub containing 2 lbs. of sulphuric acid, diluted with a sufficient quantity of water, for the purpose of separating the impurities; they are afterwards washed with pure water in casks made to revolve upon their axes. The bits of copper being placed in oxidation-chests, along with the magma of common salt and blue vitriol previously prepared in strata of half an inch thick, they are left for some time to their mutual reaction. The above chests are made of oaken planks joined without iron nails, and set aside in a cellar, or other place of moderate temperature. The saline mixture, which is partially converted into sulphate of soda and chloride of copper, absorbs oxygen from the air, whereby the metallic copper passes into a hydrated oxide, with a rapidity proportioned to the extent of the surfaces exposed to the atmosphere. During the three months that the process requires, the whole mass must be turned over once every week, with a copper shovel, transferring it into an empty chest alongside, and then back into the former one. At the end of three months the corroded copper scales must be picked out, and the saline particles separated from the slimy oxide with the help of as little water as possible. This oxidised *Schalmm* or mud is filtered, then thrown by means of a bucket containing 30 lbs., in a tub, where it is carefully divided or comminuted. For every six pailfuls of *schalmm* thus thrown into the large tub, 12 lbs. of muriatic acid, at 15° Beaumé, are to be added; the mixture is to be stirred, and then left at rest for twenty-four or thirty-six hours. Into another tub, called the 'blue black,' there is to be introduced, in like manner, for every six pailfuls of the acidified *schalmm,* fifteen similar pailfuls of a solution of colourless clear caustic alkali, at 19° Beaumé. When the back has remained long enough at rest, there is to be poured into it a pailful of pure water for every pailful of *schalmm.* When all is thus prepared, the set of workmen who are to empty the back, and those who are to stir, must be placed alongside of each. The first set transfer the *schalmm* rapidly into the latter back, where the second set mix and agitate it all the time requisite to convert the mass into a consistent state, and then leave it at rest from thirty-six to forty-eight hours. The whole mass is to be now washed; with which view it is to be stirred about with the affusion of water, allowed to settle, and the supernatant liquor is drawn off. This process is to be repeated till no more traces of potash remain among the blue. The deposit must be then thrown upon a filter, where it is to be kept moist, and exposed freely to the air. The pigment is now squeezed in the filter-bags, cut into bits, and dried in the atmosphere, or at a temperature not exceeding 78° Fahr. It is only after the most complete desiccation that the colour acquires its greatest lustre.

VERDITER, BLUE. This is a precipitate of oxide of copper with lime, made by adding that earth, in its purest state, to the solution of nitrate of copper, obtained in quantities by the refiners, in parting gold and silver from copper by nitric acid. The cupreous precipitate must be triturated with lime, after it is nearly dry, to bring out the fine velvety blue colour. The process is delicate.

The *Cendres bleues en pâte* of the French, though analogous, are in some respects a different preparation. To make it, dissolve sulphate of copper in hot water, in such proportions that the liquid may have a density of 1·3. Take 240 pound measures of this solution, and divide it equally into four open-headed casks; add to each of these 45 pound measures of a boiling-hot solution of muriate of lime, of spec. grav. 1·317, whereby a double decomposition will ensue, with the formation of muriate of copper and sulphate of lime, which precipitates. It is of consequence to work the materials well together at the moment of mixture, to prevent the precipitate agglomerating in unequal masses. After leaving it to settle for 12 hours, a small quantity of the clear liquor may be examined, to see whether the just proportions of the two salts have been employed, which is done by adding either sulphate of copper or muriate of lime. Should either cause much precipitation, some of the other must be poured in till the equivalent decomposition be accomplished; though less harm results from an excess of sulphate of copper than of muriate of lime.

The muriate of copper is to be decanted from the subsided gypsum, which must be drained and washed in a filter; and these blue liquors are to be added to the stronger; and the whole distributed as before, into four casks; composing in all 670 pound measures of a green liquor, of 1·151 spec. grav.

Meanwhile, a magma of lime is to be prepared as follows:—100 lbs. of quicklime are to be mixed up with 300 lbs. of water, and the mixture is to be passed through a wire-gauze sieve, to separate the stony and sandy particles, and then to be ground in a proper mill to an impalpable paste. About 70 or 80 lbs. of this mixture (the beauty of the colour is inversely as the quantity of lime) are to be distributed in equal portions between the four casks, strongly stirring all the time with a wooden spatula. It is then left to settle, and the limpid liquor is tested by ammonia, which ought to occasion only a faint blue tinge: but if the colour be deep blue, more of the lime-paste must be added. The precipitate is now to be washed by decantation, employing for this purpose the weak washings of a former operation; and it is lastly to be drained and washed on a cloth filter. The proportions of material prescribed above furnish from 500 to 540 lbs. of green paste.

Before making further use of this paste, the quantity of water present in it must be determined by drying 100 or 200 grains. If it contain 27 per cent. of dry matter, 12 lbs. of it may be put into a wooden bucket (and more or less in the ratio of 12 to 27 per cent.) capable of containing 17½ pints; a pound (measure) of the lime-paste is then to be rapidly mixed into it; immediately afterwards, 1¼ pint of a watery solution of the pearlash of commerce, of spec. grav. 1·114, previously prepared; and the whole mixture is to be well stirred, and immediately transferred to a colour-mill. The quicker this is done, the more beautiful is the shade.

VERJUICE. (*Verjus*, Fr.; *Agrest*, Ger.) A harsh kind of vinegar, containing much malic acid, made from the expressed juice of the wild crab apple.

VERMICELLI, a paste of wheat-flour, drawn out and dried in slender cylinders, more or less tortuous, like worms—whence the Italian name. The flour of Southern countries is best suited for its manufacture.

It may be made economically by the following prescription:—

Vermicelli, or Naples flour	21 lbs.
White potato-flour	14
Boiling-water	12
Total	47 lbs.

Affording 45 lbs. of dough and 30 of dry vermicelli.

VERMICULITES. A group of minerals resembling the chlorites, remarkable for their exfoliation before the blowpipe.

VERMILION, or *Cinnabar*, is a compound of mercury and sulphur in the proportion of 100 parts of the former to 16 of the latter, which occurs in nature as a common ore of quicksilver, and is prepared by the chemist as a pigment, under the name of Vermilion. It is, properly speaking, a bisulphide of mercury. This artificial compound being extensively employed, on account of the beauty of its colour, in painting, for making red sealing-wax, and other purposes, is the object of an important manufacture. When vermilion is prepared by means of sublimation, it concretes in masses of considerable thickness, concave on one side, convex on the other, of a needle-form texture; brownish-red in the lump, but when reduced to powder it is of a lively red colour. On exposure to a moderate heat, it evaporates without leaving a residuum, if it be not contaminated with red lead; and at a higher heat, it takes fire, and burns entirely away, with a blue flame.

The English vermilion is now most highly prized by the French manufacturers of sealing-wax.

The humid process of Kirchhoff has of late years been so much improved, as to furnish a vermilion quite equal in brilliancy to the Chinese. The following process has been recommended:—Mercury is triturated for several hours with sulphur, in the cold, till a perfect ethiops is formed; potash-lye is then added, and the trituration is continued for some time. The mixture is now heated in iron vessels, with constant stirring at first, but afterwards only from time to time. The temperature must be kept up as steadily as possible at 130° Fahr., adding fresh supplies of water as it evaporates. When the mixture, which was black, becomes, at the end of some hours, brown-red, the greatest caution is requisite to prevent the temperature from being raised above 114°, and to preserve the mixture quite liquid, while the compound of sulphur and mercury should always be pulverulent. The colour becomes red, and brightens in its hue, often with surprising rapidity. When the tint is nearly fine, the process should be continued at a gentler heat, during some hours. Finally, the vermilion is to be elutriated, in order to separate any particles of running mercury.

The three ingredients should be very pure. The proportion of product varies with that of the constituents, as we see from the following results of experiments, in which 300 parts of mercury were always employed, and from 400 to 450 of water:—

Sulphur	Potash	Vermilion obtained	Sulphur	Potash	Vermilion obtained
114	75	330	120	180	245
115	75	331	100	180	244
120	120	321	60	180	142
150	152	382			

VERT DE GUIGNET. See MITTLER'S GREEN.

VICUNA or **VICUGNA.** *Llama vicugna.* A variety of the Llama of South America.

VINE BLACK. A black procured by charring the tendrils of the vine and levigating them.

VINE DISEASE. *Oïdium Tuckeri.* The disease which has recently ravished the vines of the South of France is attributed to the *Phylloxera vastatrix.* See WINES.

VINEGAR. All liquids which are susceptible of the vinous fermentation are capable of yielding vinegar. A solution of sugar is the essential ingredient, which is converted first into alcohol, and subsequently into acetic acid. The liquids employed vary according to circumstances. In this country the vinegar of commerce is obtained from an infusion of malt, and in wine countries from inferior wines.

The oxidation of alcohol is remarkably facilitated by the presence of nitrogenised organic bodies in a state of change, called *ferments*; hence the process is frequently termed *acetous fermentation.* Now, although in most cases the presence of these ferments curiously promotes the process, yet they have no specific action of this kind; for we have already seen that, by exposure to air in a condensed state, alcohol, even when pure, is converted into acetic acid; and, moreover, the action of oxidising agents, such as chromic and nitric acid, &c., is capable of effecting this change.

However, in the presence of a ferment, with a free supply of air, and at a temperature of from 60° to 90° Fahr., alcohol is abundantly converted into acetic acid.

At the same time that the alcohol is converted into acetic acid, the nitrogenised and other organic matters undergo peculiar changes, and often a white gelatinous mass is deposited,—which contains *vibriones* and other of the lower forms of organised beings,—and which has received the name of *mother of vinegar*,[1] from the supposition that the formation and development of this body, instead of being a secondary result of the process, was really its exciting cause.

1. WINE VINEGAR. (*Vinaigre*, Fr.; *Weinessig*, Ger.) Wine vinegar is made of the best quality, and on the greatest scale, at Orléans in France, out of wines which have become more or less acidulous, and are, therefore, of inferior value. When the vinegar is made from well-flavoured wines, it is preferable to every other for the use of the table. The old method pursued in the *vinaigreries* consists merely in partially filling a series of large casks placed in three or four ranges over each other, in a cellar warmed with a stove to the temperature of 85° Fahr., with the wine mixed with a certain proportion of ready-made vinegar as a ferment. Low-roofed apartments are the most suitable; when there is a high ceiling it is necessary to elevate the 'mothers,' in order that they may occupy the higher strata of warm air. This trouble is dispensed with when the roofs are low. Experience has proved that in high-roofed apartments, where the tuns are placed at different levels, the uppermost work off quicker and better than the others. More wine is added, in successive small portions, as fast as the first has become acetified, taking care that a free ventilation be maintained, in order to replace the carbonic acid produced by fresh atmospheric oxygen. In summer, under a favourable exposure of the windows and walls of the fermenting room to the sun, artificial heat is not needed. Each cask is of about 60 gallons' capacity, and into each cask of the set is poured $\frac{1}{3}$rd its capacity of vinegar, to which 2 galls. of wine are added, and weekly, afterwards, 2 galls. more. About 8 galls. are drawn off at the end of four weeks as vinegar, and then successive additions of wine are made as before to the casks. These are laid horizontally in rows upon their gawntrees, and are pierced at the upper surface of the front end with two holes: one, called the *eye*, is two inches in diameter, and serves for pouring in the charges through a funnel; the other is a small air-hole alongside. The casks should never be more than $\frac{2}{3}$rds full, otherwise a sufficient body of air is not present in them for favouring rapid acetification. At the end of a certain period, the deposit of tartar and lees becomes so great that the

[1] This substance has been supposed by some to be a fungus, and has been described by Mulder under the name of *Mycoderma aceti*, or *vini*.

casks must be cleared out. This renovation usually takes place every 10 years; but the casks, when made of well-seasoned oak and bound with iron hoops, will last 25 years. The wine, as well the vinegar produced, should be clarified by being slowly filtered through beech-chips, closely packed in a large open tun. When wines are new, and somewhat saccharine or too alcoholic, they acetify reluctantly, and need the addition of a little yeast, or even water, to the mixture; and when they are too weak, they should be enriched by the addition of some sugar or stronger wine, so as to bring them to a uniform state for producing vinegar of normal strength. To favour the renewal of fresh air into the upper part of the hogsheads, it would be advisable to pierce a two-inch hole near to the upper level of the liquid when the cask is fullest, by which means the heavy carbonic acid would fall out, and be replaced by the atmospheric air at the superior apertures.

Wine vinegar is of two kinds, *white* and *red*, according as it is prepared from white or red wine. *White wine vinegar* is usually preferred, and that made at Orléans is regarded as the best.

Dr. Ure found its average specific gravity to be 1·019, and to contain from 6½ to 7 per cent. of real acid; according to the Edinburgh Pharmacopæia, its specific gravity varies from 1·014 to 1·022.

2. Malt Vinegar. (*British Vinegar*; in Germany called *Malz-Getreide-* or *Bier-essig.*) In England vinegar is chiefly made from an infusion of malt, by first exciting in it the alcoholic fermentation, and subsequently inducing the oxidation of the alcohol into acetic acid.

For details of the processes of *malting* and *brewing* the alcoholic liquor, we must refer to the special articles on these subjects, confining our attention here more especially to the latter stages of the operation.

From 6 bushels of malt, properly crushed, 100 gallons of wort may be extracted by due mashing, the first water of infusion being of the temperature of 160° Fahr., and the next two progressively hotter, for exhausting the soluble saccharine matter. When the wort is cooled to 75°, from 3 to 4 gallons of good yeast are stirred into it in the fermenting tun, and when it has been in brisk fermentation for about 40 hours, it is ready for transference into the vessels in which the acetification is to be accomplished.

The transformation of the fermented wort into vinegar was formerly effected in two ways, which were entirely opposite in their manner of operation. In one case the casks containing the fermented malt infusion (or *gyle*) were placed in close rooms, maintained at a uniform temperature, as already described in the preparation of wine vinegar; in the other, they were arranged in rows in an open field, where they remained many months. As regards the convenience and interests of the manufacturer, it appears that each method had its respective advantages, but both are now almost entirely abandoned for the more modern processes to be described: a short notice of the fielding process is, however, retained.

When *fielding* is resorted to, it must be commenced in the spring months, and then left to complete itself during the warm season. The *fielding* method requires a much larger extent of space and utensils than the stoving process. The casks are placed in several parallel tiers, with their bung-side upwards and left open. Beneath some of the paths which separate the rows of casks are pipes communicating with the '*back*' at the top of the brewhouse; and in the centre of each is a valve, opening into a concealed pipe. When the casks are about to be filled, a flexible hose is screwed on to this opening, the other end being inserted into the bung-hole of the cask, and the liquor in the '*gyle back*' at the brewhouse, by its hydrostatic pressure flows through the underlying pipe and hose into the cask. The hose is so long as to admit of reaching all the casks in the same row, and is guided by a workman.

After some months the vinegar is made, and is drawn off by the following operation:—A long trough or sluice is laid by the side of one of the rows of casks, into which the vinegar is transferred by means of a syphon, whose shorter limb is inserted into the bung-hole of the cask. The trough inclines a little from one end to the other, and its lower end rests on a kind of travelling tank or cistern, wherein the vinegar from several casks is collected. A hose descends from the tank to the open valve of the underground pipe, which terminates in one of the buildings or stores, and, by the agency of a steam-boiler and machinery, the pipe is exhausted of its air, and this causes the vinegar to flow through the hose into the valve of the pipe, and thence into the factory buildings. By this arrangement the whole of the vinegar is speedily drawn off. From the storehouse, where the vinegar is received, it is pumped into the *refining* or *rape* vessels.

These rape vessels are generally filled with the stalks and skins of grapes or raisins (the refuse of the British wine manufacture is generally used), and the liquor being admitted at the top, is allowed slowly to filter through them; after passing through, it is pumped up again to the top, and this process is repeated until the acetification is complete. Sometimes wood-shavings, straw, or spent tan, are substituted for the grapes refuse, but the latter is generally preferred.

By this process, not only is the oxidation of the alcohol completed, but coagulable nitrogenous and mucilaginous matter is separated, and thus the vinegar rendered *bright*. It is finally pumped into store vats, where it is kept until put into casks for sale.

3. Sugar, Cider, Fruit, and Beet Vinegars. An excellent vinegar may be made for domestic purposes by adding, to a syrup consisting of one pound and a quarter of sugar for every gallon of water, a quarter of a pint of good yeast. The liquor being maintained at a heat of from 75° to 80° Fahr., acetification will proceed so well that in 2 or 3 days it may be racked off from the sediment into the ripening cask, where it is to be mixed with 1 oz. of cream of tartar and 1 oz. of crushed raisins. When completely freed from the sweet taste, it should be drawn off clear into bottles, and closely corked up. The juices of currants, gooseberries, and many other indigenous fruits, may be acetified either alone or in combination with syrup. Vinegar made by the above process from sugar should have fully the Revenue strength. It will keep much better than malt vinegar, on account of the absence of gluten, and at the present low price of sugar will not cost more, when fined upon beech-chips, than 1*s*. per gallon.

The sugar-solution may likewise be replaced by honey, cider, or any other alcoholic or saccharine liquid. An endless number of prescriptions exist, of which the following example may suffice:—100 parts of water to 13 of brandy, 4 of honey, and 1 of tartar.

Messrs. Neale and Duyck, of London, patented a process, in 1841, for the manufacture of vinegar from *beet-root*.

The saccharine juice is pressed out of the beet, previously rasped to a pulp, then mixed with water and boiled; this solution is fermented with yeast, and finally acetified in the usual way, the process being accelerated by blowing air up through the liquid, which is placed in a cylindrical vessel with fine holes at the bottom.

In some factories large quantities of sour ale and beer are converted into vinegar; but it is usually of an inferior quantity, in consequence of being liable to further fermentation.

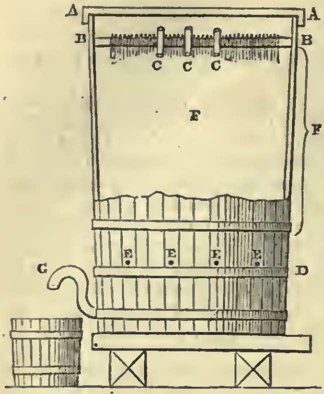
Dr. Stenhouse has shown that when *sea-weed* is subjected to fermentation, at a temperature of 96° Fahr., in the presence of lime, acetate of lime is formed, from which acetic acid may be liberated by the processes described under the head of Pyroligneous Acid. Although such large quantities of sea-weed are found on all our coasts, it does not yet appear that it has hitherto been utilised in this way, although it would still be, to a certain extent, valuable as manure after having been subjected to this process.

4. The German or Quick-Vinegar Process. (*Schnellessigbereitung*, Ger.)—In the manufacture of vinegar it is highly important that as free a supply of air should be admitted to the liquid as possible, since if the oxidation take place but slowly, a considerable loss may be sustained from much of the alcohol, instead of being completely oxidised to acetic acid, being only converted into aldehyde, which, on account of its volatility passes off in the state of vapour. This is secured in the German process by greatly enlarging the surface exposed to the air; which, however, not only diminishes or prevents the formation of aldehyde, but also greatly curtails the time necessary for the whole process. In fact, when this method was first introduced, from the supply of air being insufficient, very great loss was sustained from this cause, which was, however, easily remedied by increasing the number of air-holes in the apparatus.

This *quick-vinegar process* consists in passing the fermented liquor (which generally contains about 50 gallons of brandy of 60 per cent., and 37 gallons of beer or malt-wort, with $\frac{1}{1000}$th of ferment), two or three times through an apparatus called the Vinegar Generator (*Essigbilder*).

This apparatus consists of an oaken tub (*fig.* 2088), narrower at the bottom than at the top, furnished with a loose lid A, with a funnel, through which the liquids for charging the graduator are supplied; below this is a perforated shelf, B, having a number of small holes, loosely filled with packthread, about six inches long, and prevented from falling through by a knot at the upper end. Through this lid there likewise pass some glass tubes, open at both ends, C, which, having their apertures above and below the shelf, act as air-vents. At a distance of about eighteen inches from the bottom is placed another perforated diaphragm, at D; and two inches above this the tub is perforated with eight or ten equidistant holes, E E, an inch to an inch and a half in diameter, which serve to admit atmospheric air. The space F, between the diaphragm and the perforated lid, is filled with shavings of beechwood; by percolating through which, the solution is exposed, over a very considerable surface, to the oxidising influence of the air, which passes in a current upwards through the apparatus. One inch above the bottom is a syphon-shaped discharge pipe G, the upper curvature of which stands one inch below the air-holes in the side of the tub; so that when the liquid in the bottom of the generator, which has passed through the shavings, collects up to this level, it runs off into any vessel placed beneath to receive it.

2088



The analogy between acetification and ordinary processes of decay, and even combustion, is well seen in this process; for, as the oxidation proceeds, the temperature of the liquid rises to 100° or even 104° Fahr.; but if the temperature generated by the process itself be not sufficient, the temperature of the rooms in which the tuns are placed should be artificially raised.

By this method 150 gallons of vinegar can be manufactured daily in ten tuns, which one man can superintend; and the vinegar, in purity and clearness, resembles distilled vinegar.

It is better to avoid using liquors containing much suspended mucilaginous matter, which, collecting on the chips, quickly chokes up the apparatus, and not only impedes the process, but contaminates the product.

The chips and shavings may with advantage be replaced by charcoal in fragments, which, by the oxygen it contains condensed in its pores, still further accelerates the process. The charcoal would of course require re-igniting from time to time.

Processes for the rapid formation of vinegar have likewise been adopted in this country. So long ago as the year 1824, Mr. Ham obtained a patent for the following method, which is still in operation at several works:—

The apparatus consists of a large vat, in the centre of which is placed a revolving pump, having two or more shoots pierced with holes, so as to cause a constant shower of wash—fermented wort—to descend. The lower part of the vat is charged with wash, the upper part with birch-twigs, piled as high as possible, but without interfering with the revolution of the shoots. Between the surface of the wash and the joist which supports the birch-twigs, a space of three or four inches is unoccupied, and holes are perforated in it, to admit a current of air, either from the atmosphere or from a blowing apparatus.

If the wash be maintained at a temperature of from 90 to 100° Fahr., and the supply of liquid duly proportioned to the mass of the twigs, a charge is generally acetified in about a fortnight. The acetification can of course be arrested at any moment, and the current of air increased or diminished at will.

Generally in England much larger tuns are used than in Germany, the larger mass of matter thus undergoing oxidation generating so much heat that no artificial elevation of temperature is required; and in consequence of the promotion of the process in this way, one of these large tuns, fifteen feet wide at the bottom, fourteen at the top, and thirteen high, turns out as much vinegar as in Germany is obtained from six tubs eighteen feet high and four feet wide.

By the quick process of Ham, when the fermentation is finished, the greatest care ought to be taken that all access of air is excluded from the wash, and that its temperature be reduced to, and maintained at, a heat below the point where acetification commences. Those who, like Messrs. Hill, Evans, and Co., of Worcester, attach great importance to the fabrication of the best-keeping vinegars, are in the habit of filtering the fermented wash, and also of storing it away for many months in a cool situation ere it is passed through the acetifier; and there cannot be a moment's doubt concerning the great value of this practice, not only as regards the appearance and flavour of the resulting vinegar, but also in respect to its dietetic and sanitary properties.

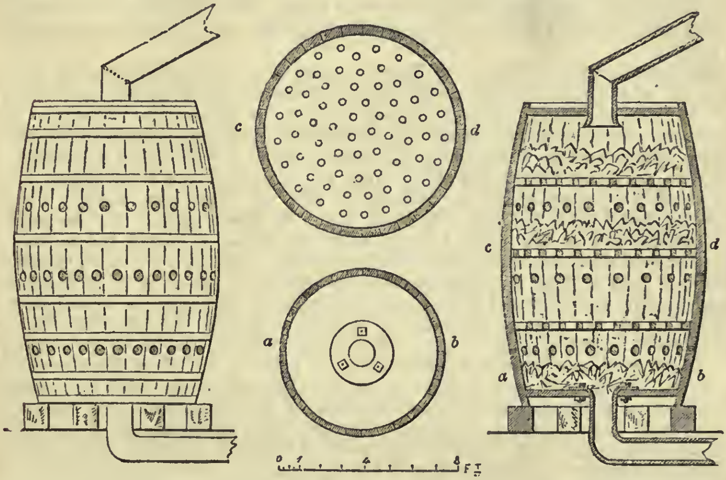
All recently-fermented wash contains a quantity of partially-decomposed gluten, some of which is mechanically suspended merely, but by far the larger portion exists in a state of solution through the agency of carbonic acid gas.

A filter will remove the former, but time alone can dissipate the carbonic acid, and lead to the deposition of the soluble gluten. At all events, time is the only available remedy, for though heat would expel the carbonic acid, yet it would at the same time drive off the alcohol; and agitation in contact with air, though it removed the carbonic acid, would tend to the formation of acetic acid, by which the gluten would be kept in solution more decidedly than before, and thus lead to the production of a turbid, ropy, and impure vinegar, extremely liable to decompose and undergo the putrefactive fermentation. It is obvious, therefore, that the theoretical conditions needed in the treatment of fermented wort by the vinegar-maker are precisely those which we have shown to be in use at Worcester. That is to say, the gluten, when insoluble, should be removed by a filter, and when held in solution by carbonic acid gas, this must be slowly expelled by keeping at a temperature too low for acetification to take place, and which may be assumed at less than 55° Fahr. Fermented wort stored away at this temperature for six months will flow to the acetifier perfectly limpid and bright; it will cause no deposition of gluten upon the birch-twigs, and thus secure complete oxidation; it will rapidly take on the grateful flavour of acetic ether, and never become tainted by the formation of that noxious product aldehyde, which so frequently contaminates ill-made vinegar.

Presuming, however, that all the necessary precautions with respect to care in washing, fermenting, and keeping the wort, have been attended to, we may now pass on to the acetifier, that is to say, Ham's acetifier.

This is a wooden vat or vessel (*figs.* 2089, 2090) about 12 feet in height and from

2089 2090



7 to 8 feet in diameter, closed at top and bottom, except at the opening for the introduction of the wash and the exit of the vinegar. The sides are perforated by a few small holes for the admission of air, and within are three floors or partitions perforated with numerous holes for the passage of the wash through them. Upon these floors are laid bundles of birch-twigs, to favour the dispersion and division of the fluid which passes through the acetifier, and is thus brought into the most immediate contact with the oxygen contained in the vessel, or admitted through the openings in its sides. The fluid or wash is admitted at the top of the acetifier, and suffered to trickle slowly through the masses of birch-twigs and through the partitions, thus causing a rapid absorption of oxygen, and consequent production of vinegar, which with any undecomposed wash flows out at the bottom of the vessel, and is again pumped up to the top, and so on until the process is finished. If we examine the circumstances connected with the formation of vinegar in this way, we shall perceive that it is a case of partial combustion, or, in other words, an example in which an organic compound undergoes oxidation at a temperature and under conditions which prevent the completion of the change.

Every one must have observed that when common coals are thrown upon a fire, a volatile portion immediately bursts into flame, while copious particles of soot or carbon are thrown off unburnt; though of the other constituent of the coal, that is to say, the hydrogen gas, no particle escapes unoxidised. This arises from the fact, that, except at very high temperatures, hydrogen has a greater affinity for oxygen than carbon has; consequently, as the supply of oxygen from atmospheric air in the immediate neighbourhood is limited, the hydrogen seizes upon its equivalent to the exclusion of the carbon, which, therefore, remains, and constitutes soot. Exactly in the same way the hydrogen of the alcohol in the wash oxidises to the exclusion of the carbon, and vinegar is formed from the remaining or carbonaceous element, which becomes itself slightly oxidised.

From this explanation it follows that, as the oxidation of the hydrogen generates heat, there ought to be a very appreciable rise in the temperature during the passage of the wort through the acetifier. And, in practice, this is found to be the case; so that precautions are needed to prevent the heat from rising so high as to vaporise the remaining alcohol of the wash. The temperature sought to be obtained is about 90° to 92° Fahr., at which oxidation goes on freely, and the loss of alcohol is moderate. In using the word 'moderate,' we speak practically rather than chemically: for, in reality, the loss is very serious with strong worts. From practical results, conducted with more than ordinary care, it has been ascertained that about one-third of all the extractive matter of the malt and grain is lost or dissipated during the processes of fermentation and acetification. Thus, a wort having a specific gravity of 1·072, or, in technical language, weighing about 26 lbs. per barrel, affords vinegar containing 5·4 per cent. of pure acetic acid, and a residuary extract of 10 lbs. from 36 gallons. The former of these would indicate 35 lbs. of sugar or 13·7 lbs. per barrel of gravity; whilst the latter shows 3·8 lbs. per barrel; the two united being only 17·5 lbs. instead of 26, the original weight. The loss, therefore, has been 8·5 lbs., or from a specific gravity of 1·072 to less than 1·050. This prodigious destruction of extract seems to imply that great improvements may yet take place in the manufacture of vinegar.

The manufacture of vinegar, by Ham's process, is an extremely interesting operation, and, when conducted with proper care, furnishes results of the most satisfactory and uniform character. These, however, are not to be obtained without a vast amount of experience and the most vigilant attention on the part of the manufacturer. Thus a difference in the water, in the malt, in the mode of washing, in the cooling of the wort, or in the fermentation of the wort, will each give rise to modifications in the acetifying process which no subsequent skill or labour can rectify. There seems no doubt that the most important points in Ham's method are the cooling and fermentation of the wort; though, where perfection is sought for, no one of the other conditions can be omitted or neglected with impunity. We shall, therefore, proceed to treat of these conditions *seriatim*, rather than in the order of their importance. At first sight it might be supposed that the purer the water the better; that is to say, the less the amount of earthy or saline constituents, the more valuable the water would be for making vinegar. Experience, however, teaches us the contrary; and science confirms the truth of this teaching, by pointing out the real nature of the operation. When pure water is made to act at a high temperature upon the ordinary ingredients of a vinegar-maker's mash-tun, it is not alone the sugar, gum, and starch of the grain which enters into solution, for, under such circumstances, the gluten is also dissolved; but this gluten is composed of vegetable albumen and vegetable gelatine, the former of which, as is well known, is capable of being decomposed and precipitated by many earthy and metallic salts, of which the sulphate of lime is one. If, therefore, this salt exists in the water employed for the fabrication of vinegar, or of ale or beer, the wort will contain little or no vegetable albumen; consequently, the vinegar or beer made with such water never becomes cloudy or ropy, as happens when pure water is used, for these defects arise from an excess of albuminous matter. The water used for making the celebrated Burton ale contains a great deal of sulphate of lime; and the spring-water of Worcester, which is employed by the extensive firm of Hill, Evans, and Co., in that city, vinegar-makers, contains also a very large amount of sulphate of lime, and no doubt contributes much towards maintaining the well-established reputation of that firm. Whenever, therefore, much sulphate of lime exists in water, without the presence of any noxious ingredient, such water may always be relied upon as favourable for the production of good beer and vinegar.

As regards the malt, or rather the mixture of malt and grain, employed for the production of wort, the common Scotch distillers' formula is the best, containing, as it always does, a considerable percentage of oats, for the long husk of the oat greatly facilitates the operation of draining, and thus secures the thorough separation of the wort from the spent grains.

In practice it is found necessary to ferment only two gravities, a high and a low, all the other qualities of vinegar being made by mixing or diluting these after acetification. The most common, and unquestionably the best, gravity for fermentation is that which in technical language weighs about 20 lbs., or has a specific gravity of 1·056; the other, or that intended for strong or proof vinegar, being of specific gravity 1·072: this latter affords a vinegar containing about 5½ per cent. of anhydrous acetic acid.

In every instance the fermentation must be carried to its utmost limit, or to zero at least; and in cooling the wort prior to fermentation, great care must be used to prevent the accession of the acetous fermentation before the yeast is added; for if this happens to any considerable extent, the nitrogenised matter of the yeast is then permanently retained in solution by the acetic acid, and this may give rise to the inconvenience called the 'mother.' To secure a perfect vinegar by Ham's process, as much attention is required during the cooling and fermentation as for the finest ale; and this axiom cannot be too strongly inculcated into the minds of vinegar-makers. The heat of the fermenting tun should not exceed 76° Fahr., as the alcohol formed by the process is apt at a higher temperature to pass off in considerable quantity with the carbonic acid, and thus give rise to a loss of vinegar. Presuming that the fermentation has been well conducted, and that the specific gravity of the wash is as low as water, or 1·000, the next step is to pass it through that apparatus which constitutes the great peculiarity of Ham's process. This process is called 'the acetifier.'—*Ure.*

Impurities and Adulterations.

In order to prevent the putrefactive change which often takes place in vinegar, when carelessly prepared by the fermentation of malt-wine, &c., it was at one time supposed to be necessary to add a small quantity of sulphuric acid. This notion has long since been shown to be false; nevertheless, since the addition of 1 part of sulphuric acid to 1,000 of vinegar was permitted by an Excise regulation, and thus the practice has received legal sanction, it is still continued by many manufacturers. So long as the quantity is retained within these limits, and if pure sulphuric acid be used (great care being taken that there is no arsenic present in such oil of vitriol, as is not unfrequently the case in inferior varieties), no danger can ensue from the habit; but occasionally the quantity is much overpassed by dishonest dealers.

Dr. Ure mentions having found by analysis in a sample of vinegar, made by one of the most eminent London manufacturers, with which he supplied the public, no less than 175 grains of the strongest oil of vitriol per gallon, added to vinegar containing only $3\frac{6}{10}$ths per cent. of real acetic acid, giving it an apparent strength after all of only 4 per cent., whereas standard commercial vinegar is rated at 5 per cent.

The method of determining sulphuric acid has already been given, under the head of ACIDIMETRY, and the same remark applies to hydrochloric acid and others.

Hydrochloric acid is rarely intentionally added to vinegar; but it may accidentally be present when the pyroligneous acid has been purified by Völckel's process. It is detected by the precipitate which it gives with solution of nitrate of silver in the presence of nitric acid.

Nitric acid is rarely found in vinegar. For its method of detection, see NITRIC ACID.

Wine vinegar generally contains tartaric acid and tartrates; but it is purified from them by distillation.

Sulphurous acid is occasionally met with in pyroligneous acid. This is recognised by its bleaching action on delicate vegetable colours, and by its conversion, under the influence of nitric acid, into sulphuric acid, which is detected by chloride of barium.

Sulphuretted hydrogen is detected by acetate of lead giving a black colouration or precipitate.

Metallic Salts.—If care be not taken in constructing the worm of the still of silver or earthenware, distilled acetic acid is frequently contaminated with small quantities of metal from the still, copper, lead, tin, &c. These metals are detected by the addition of sulphuretted hydrogen, as is fully discussed under the head of the individual metals. Copper is the most commonly found, and it may be detected in very minute quantities by the blue colour which the solution assumes on being supersaturated with ammonia.

It is not uncommon to add to pyroligneous acid, a little colouring-matter and acetic ether, to give it the colour and flavour of wine or malt vinegar; but this can hardly be called an adulteration.

The presence of the products of acetification of cider may be detected by neutralising the vinegar with ammonia, and then adding solution of acetate of lime. Tartrate of lime is, of course, precipitated from the wine vinegar, while the pearly malic acid of the cider affords no precipitate with the lime, but may be detected by acetate of lead, by the pearly scales of malate of lead, hardly soluble in the cold.

For a description of the manufacture of Wood-vinegar, see ACETIC ACID and PYROLIGNEOUS ACID.

The *Imports* of vinegar were:—

	1870		1873	
	Gals.	Computed real value	Gals.	Valued at
From France . . .	46,146	4,230*l.*	46,168	4,271*l.*
„ other parts . .	7,049	469*l.*	13,394	1,434*l.*

Of the quantity for 1873 54,956 gallons were entered for Home consumption, paying 687*l.* as duty.

The average price fixed for the value has been 1*s.* 10*d.* for the French vinegar, and 1*s.* 4*d.* for the other sorts. Since July 6, 1856, the duty on all vinegar imported has been 3*d.* per gallon.

That the importation of this article varies considerably is shown by the following statement:—

In 1843 we *Imported* 21,784 gallons; in 1845, 195,967 gallons; in 1856, 35,516 gallons; and in 1869, 49,316 gallons.

Of the vinegar made in the United Kingdom, the *Exports* for the three years ending 1870 were as follow:—

			£
1868 . .	Gallons,	6,903, computed real value,	647
1869 . .	„	735 „ „	64
1870 . .	„	1,560 „ „	137
1874 . .	„	3,450 „ „	251

VINEGAR, AROMATIC. Strong acetic acid combined with certain aromatics. See Acetic Acid.

VIOLET DYE is produced by a mixture of red and blue colouring-matters which are applied in succession. Silk is dyed a fugitive violet with either archil or brazil wood; but a fine fast violet, first by a crimson with cochineal, without tartar or tin mordant, and, after washing, it is dipped in the indigo-vat. A finish is sometimes given with archil. A violet is also given to silk, by passing it through a solution of verdigris, then through a bath of logwood, and, lastly, through alum-water. A more beautiful violet may be communicated by passing the alumed silk through a bath of brazil wood, and, after washing it in the river, through a bath of archil. Now, all the violets are produced from the aniline series. See Aniline, Murexide, Purple.

VIOLINE. See Aniline Violet.

VIRIDINE. See Carbolic Acid.

VITRIFIABLE COLOURS. See Enamels, Pastes, Pottery, and Stained Glass.

VITRIFIABLE PIGMENTS. The art of painting with vitrifiable pigments has not kept pace with the progress of science, and is far from having attained that degree of perfection of which it is capable. It still presents too many difficulties to prove a fertile field to the artist for his labours; and its products have, for this reason, never held that rank in art which is due to them from the indestructibility and brilliancy of the colours. The reason of this is attributable to the circumstance that the production of good vitrifiable pigments is mere chance work; and, notwithstanding the numerous papers published on the subject, is still the secret of the few. The directions given in larger works and periodicals are very incomplete and indefinite; and even in the otherwise highly valuable *Traité des Arts Céramiques* of Brongniart, the chapter on the preparation of colours is far from satisfactory, and is certainly no frank communication of the experience gathered in the Royal Manufactory of Sèvres.

The branch of painting with vitrifiable pigments which has acquired its greatest development is the art of painting on porcelain. The glaze of hard felspar porcelain, owing to its difficult fusion, produces less alteration upon the tone of a colour of the easily fusible pigments than is the case in painting upon glass, enamel, faïence, &c. The colours for painting upon porcelain are all of them, *after* the firing, coloured lead-glasses throughout; but before this operation, most of them are mere mixtures of colourless lead-glass, the *flux*, and a pigment. In the so-called gold colours, purple, violet and pink, the pigments are preparations of gold, the production of which has hitherto been considered as especially difficult and uncertain. The following are the processes recommended.

Light Purple.—5 grammes of tin turnings are dissolved in boiling nitromuriatic acid, and the solution concentrated in the water-bath until it solidifies on cooling. The perchloride of tin prepared in this manner, and which still contains a slight excess of muriatic acid, is dissolved in a little distilled water, and mixed with 2 grammes of solution of protochloride of tin of 1·700 sp. gr., obtained by boiling tin-turnings in excess with muriatic acid to the required degree of concentration. This mixed solution of tin is poured into a glass vessel, and gradually mixed with 10 itres of distilled water. It must still contain just so much acid that no turbidness results from the separation of oxide of tin; this may be ascertained previously by taking a drop of the concentrated solution of tin upon a glass rod, and mixing it in a watch-glass with distilled water. A clear solution of 0·5 gramme gold in nitromuriatic acid, which must be as neutral as possible, is poured into the solution of tin diluted with 10 litres of water, constantly agitating the whole time. The gold-solution should have been previously evaporated nearly to dryness in the water-bath, then diluted with water, and filtered in the dark.

On adding the gold-solution, the whole liquid acquires a deep red colour, without, however, any precipitate being formed; this instantly separates upon the addition of 50 grammes of solution of ammonia. But if no precipitate should result, which may happen if the amount of ammonia was too great in proportion to the acid contained in the liquid, and in which case the liquid forms a deep red solution, the precipitate immediately results upon the addition of a few drops of concentrated sulphuric acid. It subsides very quickly. The supernatant liquid should be poured off from it as soon as possible, and replaced 5 or 6 times successively by an equal quantity of fresh spring water. When the precipitate has been thus sufficiently washed, it is collected upon a filter: and as soon as the water has drained off completely, removed while still moist with a silver spatula, and mixed intimately upon a ground plate of a glass by means of a spatula and grinder with 20 grammes of lead-glass, previously ground very fine upon the same plate with water. The lead-glass is obtained by fusing together 2 parts of minium with 1 part of quartz-sand and 1 part of calcined borax.

The intimate mixture of gold-purple and lead-glass is slowly dried upon the same glass plate upon which it had been mixed in a moderately warm room, carefully protected from dust, and, when dry, rubbed to a fine powder, and mixed with three grammes of carbonate of silver.

In this manner we obtain 33 grammes of light purple pigments from 0·5 gramme of gold.

The above proportion of lead-glass and carbonate of silver to the gold precipitate holds good only for a certain temperature, at which the colour must be burnt-in upon the porcelain, and which is situated very near the fusing-point of silver.

To obtain the colour with a less degree of heat, the amount of lead-glass added to the gold must be greater, but that of the carbonate of silver less. The same holds good with respect to the preparation of the purple pigment for glass-painting.

The best purple may be spoiled in the baking in the muffle. When this is done at too low a temperature, the colour remains brown and dull; but if the right degree of temperature has been exceeded, it appears pale and bluish. Reducing, and especially acid vapours, vapours of oxide of bismuth, &c., have likewise an injurious effect upon it.

Dark Purple.—The clear and neutral solution of 0·5 gramme gold in nitromuriatic acid is diluted in a glass vessel with 10 litres of distilled water, and mixed under constant agitation with 7·5 grammes of the solution of protochloride of tin of 1·700 sp. gr. prepared in the manner described above. The liquid is coloured of a dark brownish-red; but the precipitate is only deposited on the addition of a few drops of concentrated sulphuric acid. The supernatant liquid is poured off, and replaced five or six times successively with an equal amount of spring water. The precipitate, which is sufficiently washed, is collected on a filter; and after the excess of water is drained off, removed while still moist with a spatula, and mixed, exactly as described for the light purple, upon a glass plate with 10 grammes of the above lead-glass, dried, then reduced to a fine powder, and mixed with 0·5 gramme carbonate of silver; it furnishes about 13 grammes of dark purple pigment. The stated proportion of lead-glass and carbonate of silver to the gold is for the same temperature of firing as given for the mixture of light purple; for a lower temperature, and also for painting upon glass, the quantity of lead-glass must be increased, and that of the silver salt diminished.

Red Violet.—The gold precipitate from 0·5 gramme gold is prepared in the same manner as for the dark purple, and whilst moist taken from the filter, and mixed intimately upon the plate of glass with 12 grammes of a lead-glass prepared by fusing 4 parts of minium with 2 parts of quartz-sand and 1 part calcined borax; it is then dried as above, and reduced to a fine powder upon a plate of glass, but without any addition of silver. The proportion of lead-glass to gold applies likewise for the same degree of temperature as in the case of the light and dark purple pigments; a lower temperature requires a larger proportion of lead-glass. A slight addition of silver to this pigment converts the red violet into a dark purple: and when employed alone for painting upon glass, it gives a very excellent purple.

Blue Violet.—This same gold precipitate of 0·5 gramme gold is mixed, while still moist, upon the glass plate with 10·5 grammes of a lead-glass obtained by fusing 4 parts of minium with 1 of quartz-sand, drying it slowly in the manner above mentioned, and then reducing it to a fine powder upon the glass plate. When the pigment is burnt-in at a lower temperature, a larger addition of lead-glass is required. This blue-violet pigment is more especially adapted for mixing with blue pigments. It is not applicable to glass-painting. The most important requisite in the preparation of good purple and violet vitrifiable pigment is the very minute state of division of the gold in the gold precipitate, and of the latter in the lead-glass, which is accomplished by mixing the moist precipitate with the glass.

By mixing the light purple with the dark purple or with the red-violet, or the red-violet with the dark purple, in different proportions, the artist is able to produce every possible tint of purple and violet. The light purple, without any additional silver, furnishes an amaranth-red colour, like that seen upon the porcelains of the preceding century, when the peculiar property of silver, of converting the amaranth-red into a rose-red colour, does not appear to have been known. Dr. Richter, who at the commencement of this century prepared the pigments for the Royal Berlin manufactory of porcelain, appears, however, to have employed it for his purple, as a very beautiful rose colour may be seen upon the painted porcelain of that time.

Pink.—One gramme of gold is dissolved in nitromuriatic acid; the solution mixed with one of 50 grammes of alum in 20 litres of spring water; then mixed, constantly agitating, with 1·5 gramme solution of protochloride of tin of 1·700 spec. grav., and so much ammonia added until all the alumina is precipitated. When the precipitate has subsided, the supernatant liquid is poured off, and replaced about 10 times successively by an equal amount of fresh spring water; the precipitate is then collected on a filter, and dried at a gentle heat. It weighs about 13·5 grammes; and to prepare the pigment is mixed with 2·5 grammes carbonate of silver, and 70 grammes of the same lead-glass, described under light purple (2 minium, 1 quartz-sand, 1 calcined borax), and reduced to a fine powder on the glass plate.

This colour is adapted only for the production of a light pink ground upon porcelain, and must only be applied in a thin layer; when laid on in a thick layer the gold separates in a metallic state, and no colour is produced.

All the gold colours above described do not furnish, when fused alone in a crucible, red or violet glasses, as might be expected, but dirty brown or yellowish glasses, which appear troubled from the separation of metallic gold and silver; this peculiar beautiful tint is only developed when they are fused upon the porcelain glaze in a layer, which must not be too thick; they then colour it through and through, as a piece of porcelain painted with it shows distinctly in the fracture. If the layer exceeds a certain thickness, the gold and silver separate in a metallic state; and they produce either a liver colour, as for instance the purple and violet pigments, or no colour at all, as is the case with the more fusible pink pigment.

Yellow Pigments for painting upon Porcelain.—The yellow vitrifiable pigments are lead-glasses, coloured either by antimonic acid or oxide of uranium. The antimoniate of potash is prepared by igniting 1 part of finely-powdered metallic antimony with 2 parts of nitre, in a red-hot Hessian crucible, and washing the residue with water. The oxide of uranium is obtained in the fittest state, by heating the nitrate, until the whole of the nitric acid is expelled.

Lemon Yellow.—8 parts of antimoniate of potash, 2½ parts of oxide of zinc, 36 parts of lead-glass (prepared by fusing together 5 parts minium, 2 parts of white sand, and 1 part of calcined borax), are intimately mixed, and heated to redness in a porcelain crucible, which is placed in a Hessian crucible, until the mixture forms a paste; it is then taken out with a spatula, pounded after cooling, and ground upon a plate glass. If the pigment is fused longer than requisite for the perfect union of the ingredients, the yellow colour is converted into a dirty grey by the destruction of the antimoniate of lead.

Light Yellow.—4 parts of antimoniate of potash, 1 part of oxide of zinc, and 36 parts of lead-glass (prepared by fusing together 8 parts of minium and 1 part of white sand), are well mixed, fused in a Hessian crucible, and after cooling, pounded and ground. In the preparation of this colour, long fusion is less injurious than with the preceding one, owing to the absence of the borate of soda in the lead-glass. The colour itself is more intensely yellow than the preceding one, and is extremely well adapted for mixing with red and brown pigments; but it does not furnish such pure tints as that when mixed with green; owing to its higher specific gravity, it flows more freely from the brush, and may be laid on in a thicker layer, without scaling off after the firing.

Dark Yellow, 1.—48 parts minium, 16 parts sand, 8 calcined borax, 16 antimoniate of potash, 4 oxide of zinc, and 5 parts peroxide of iron (*caput mortuum*), are intimately mixed and fused in a Hessian crucible, until the ingredients have perfectly combined, but no longer; otherwise, the golden-yellow colour is converted into a dirty grey, as in the case of the lemon-yellow pigment.

Dark Yellow, 2.—20 parts minium, 2½ white sand, 4¼ antimoniate of potash, 1 part peroxide of iron (*caput mortuum*), and 1 part oxide of zinc, are well mixed and fused in a Hessian crucible. Long fusion is less injurious in this case than in the preceding. Iron-red pigment may be laid on and near this dark yellow 2, without its being destroyed, or the harmony of the tints injuriously affected.

For landscape and figure painting, the above-mentioned yellow pigments should be made less readily fusible, in order to paint with them upon or beneath other colours, without any fear of what has been painted being dissolved by the subjacent or superposed pigment. This property is given to it by the addition of Naples yellow, which is best prepared for this purpose by long-continued ignition of a mixture of 1 part tartar-emetic, 2 parts of nitrate of lead, 4 parts of dry chloride of sodium, in a Hessian crucible, and washing the pounded residue with water. Very useful yellow colours are likewise obtained by mixing this Naples yellow with lead-glass; they are, however, more expensive than those above given. A very excellent yellow for landscape-painting may be prepared, for instance, by mixing 8 parts Naples yellow and 6 parts lead-glass (obtained by fusing 2 parts of minium with 1 of white sand and 1 of calcined borax).

The yellow pigments obtained with antimony, after being burnt-in upon the porcelain, appear under the microscope to be mixtures of a yellow transparent substance (antimoniate of lead?), and a colourless glass, and not homogeneous yellow glasses.

Uranium Yellow.—1 part oxide of uranium, 4 parts lead-glass (prepared by fusing 8 parts minium with 1 part white sand), are intimately mixed and ground upon a glass plate. This colour is not adapted for mixing with others, with which it produces discordant tints. It may be shaded with dark purple or violet.

Uranium Orange.—2 parts oxide of uranium, 1 part chloride of silver, and 3 parts bismuth glass, (prepared by fusing 4 parts of oxide of bismuth with 1 part of crystallised boracic acid), are intimately mixed and ground upon a plate glass. This orange is not adapted, any more than the yellow pigment, for being mixed with other colours. When examined under the microscope, after being burnt-in upon porcelain, the uranium pigments appear as pale yellow-coloured glasses, in which unaltered oxide of uranium is suspended. Only a small portion, therefore, of the oxide of uranium has dissolved in the fusing.

Green Pigments for painting upon Porcelain. Blue Green.—10 parts of the chromate of protoxide of mercury and 1 part of chemically pure oxide of cobalt are ground upon a glass plate, in order to produce as intimate a mixture as possible; the mixture is then heated in a porcelain tube, open at both ends, until the whole of the mercury is expelled. The beautiful blueish-green powder thus obtained is then transferred into a porcelain crucible, and the lid cemented to it with glaze. The full crucible is exposed to the highest temperature of the porcelain furnace during one firing, the crucible carefully broken after the cooling, and the pigment washed with water, to remove a small quantity of chromate of potash. In this manner a compound of oxide of chromium and oxide of cobalt is obtained in nearly equivalent proportions, which possesses the bluish-green colour of verdigris.

The blue-green pigment consists of a mixture of 1 part of the above compound of oxide of chromium and oxide of cobalt, ½ part of oxide of zinc, and 5 parts of lead-glass (prepared by fusing together 2 parts minium, 1 part white sand, and 1 part calcined borax), which are mixed and ground upon the glass plate. By mixing this blue-green with lemon-yellow, any desired intermediate tint may be produced. 1 part of blue-green to 6 parts of lemon-yellow furnishes a beautiful grass-green.

Dark Green.—The chromate of mercury is treated separately in the same way as the mixture of it with oxide of cobalt for the blue-green; and 1 part of the beautiful green oxide of chromium thus obtained is mixed with 3 parts of the same lead-glass as given under blue-green, and ground upon the glass plate.

Green for Shading.—8 parts chromate of mercury and 1 part oxide of cobalt are intimately mixed, and exposed in a shallow dish to the strongest heat of the porcelain furnace, during one of the bakings. In this manner a compound of oxide of chromium and oxide of cobalt is obtained, of a greenish-black colour, which, mixed with twice the weight of the lead-glass directed for the blue-green, furnishes a very infusible blackish-green colour, for shading other green colours.

When thin splinters of the green pigments of chromium, burnt-in upon porcelain, are examined under the microscope, it is distinctly seen that particles of the oxide of chromium, or of the oxide of chromium and cobalt, are suspended, undissolved, in the colourless lead-glass.

Blue Pigments for painting upon Porcelain. Dark Blue.—1 part chemically pure oxide of cobalt, 1 part oxide of zinc, 1 part lead-glass (prepared by fusing together 2 parts of minium and 1 of white sand), are well mixed and fused in a porcelain crucible, for at least 3 hours, at a red heat: then poured out, reduced to powder, and ground upon the glass. When this pigment cools slowly, it solidifies to a mass of acicular crystals. Long-continued fusion, at not too high a temperature, is requisite to obtain a beautiful tint; this is best attained by fusing it, during one of the bakings, in the second floor of the porcelain furnace; this is also the cheapest and best way of fusing the lead-glasses.

Light Blue.—1 part oxide of cobalt, 2 parts oxide of zinc, 6 parts lead-glass (prepared by fusing together 2 parts of minium and 1 of white sand, and $1\frac{1}{2}$ part lead-glass (prepared by fusing together 2 parts of minium, 1 part white sand, and 1 part calcined borax), are well mixed and fused, as directed for the dark blue.

Blue for Shading.—10 parts oxide of cobalt, 9 parts oxide of zinc, 25 parts of lead-glass (obtained by fusing 2 parts of minium and 1 of white sand), and 5 parts of lead-glass (prepared by fusing together 2 parts of minium, 1 part of white sand, and 1 part of calcined borax), are mixed and fused, as directed for the dark blue. The colour is only used for shading, or to be applied upon or beneath the two preceding blue pigments, for which purpose it is admirably suited, from its being very difficult of fusion.

Sky Blue.—2 parts of dark blue, 1 part oxide of zinc, and 4 parts of lead-glass (prepared by fusing 4 parts minium with 1 of white sand), are intimately mixed and ground upon the glass plate. This pigment is employed, either alone, or mixed with other colours, only for painting the sky in landscape.

The blue pigments described likewise appear under the microscope, after having been burnt-in upon the porcelain, not to be homogeneous blue glasses, but mixtures of a transparent blue substance (silicate of cobalt and zinc?) and a colourless glass.

Turquoise Blue.—3 parts of chemically pure oxide of cobalt, and 1 part of pure oxide of zinc, are dissolved together in sulphuric acid; then an aqueous solution of 40 parts ammonia-alum added, the mixed solutions evaporated to dryness, and the residue heated to expel the whole of the water; then reduced to a powder, and exposed in a crucible to an intense red heat for several hours. The colour is most beautiful, when it has been exposed, during one firing, to the heat of the porcelain furnace. It is a combination of nearly 4 equivs. alumina, 3 equivs. oxide of cobalt, and 1 equiv. oxide of zinc, and is of a beautiful turquoise-blue colour. When the oxides are mixed in other proportions than those above given, they do not furnish such beautiful coloured compounds. To impart to it a slightly greenish tint, a little moist recently-precipitated protochromate of mercury is mixed with the above-described solution of ammonia, alum, zinc, and cobalt; with the above quantities, $\frac{1}{10}$th part of the chromate, calculated in the dry state, suffices.

The turquoise-blue vitrifiable pigment is prepared by mixing one part of the compound of alumina-oxide of zinc and cobalt with 2 parts of bismuth glass (prepared by fusing 5 parts of oxide of bismuth with 1 part of crystallised boracic acid).

The receipt for the preparation of the turquoise-blue pigment, communicated in the *Traité des Arts Céramiques* by Brongniart, is incorrect; for a lead-glass of the composition there given (3 parts minium, 1 part sand, 1 part boracic acid) destroys the turquoise-blue pigment entirely on fusion, and only a dirty bluish-grey colour is produced. On examining under the microscope the turquoise-blue pigment burnt-in upon porcelain, it appears to be a mixture of a transparent blue substance and a colourless glass. The transparent blue substance in all probability is the above-described compound of oxide of cobalt and alumina, which is of itself transparent under the microscope, but the transparency of which is increased by the surrounding fused glass of bismuth, just like the fibres of paper by oil. This is probably the case also with the microscopic blue constituent of the other blue vitrifiable pigments, and which is probably silicate of zinc and cobalt; for this, when prepared separately, forms a pure blue transparent powder.

Black and Grey Colours for painting upon Porcelain. Iridium Black.—Iridium, as obtained in commerce from Russia in the state of a fine grey powder, is mixed with an equal weight of calcined chloride of sodium, and heated to a faint red in a porcelain tube, through which a current of chlorine is passed. In this manner a portion of the iridium is converted into the bichloride of iridium and sodium, which is dissolved out with water from the ignited mass. The aqueous solution of the double salt is evaporated to dryness with carbonate of soda, and then extracted with water, which furnishes black sesquioxide of iridium. This is dried and mixed with twice its weight of lead-glass (prepared by fusing together 12 parts of minium, 3 parts of white sand, and 1 part of calcined borax), and ground upon a plate of glass. The iridium, which remained undecomposed in the first treatment with sea-salt and chlorine, is again submitted to the same treatment.

Iridium Grey.—1 part of the sesquioxide of iridium, 4 parts of oxide of zinc, and 22 parts of lead-glass (prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax) are intimately mixed and ground fine upon a plate of glass. On microscopical examination of the iridium pigments after they have been burnt-in upon porcelain, the sesquioxide of iridium is seen to be suspended in the transparent fused lead-glass. It is owing to the unalterability of the sesquioxide of iridium that it admits of being mixed with all other vitrifiable colours without injuriously affecting the tints, as is the case with all the other vitrifiable grey and black pigments.

Black from Cobalt and Manganese.—2 parts of sulphate of cobalt deprived of its water of crystallisation, 2 parts of dry protosulphate of manganese, and 5 parts of nitre, are intimately mixed, and heated to redness in a Hessian crucible until the whole of the nitre is decomposed. The calcined mass, exhausted with boiling water, furnishes a deep black powder, which consists of a combination of oxide of cobalt and oxide of manganese. 1 part of this compound is mixed with 2½ parts of lead-glass (prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part calcined borax), and ground fine upon a plate of glass.

Grey from Cobalt and Manganese.—2 parts of the above compound of the oxide of cobalt and manganese, 1 part oxide of zinc, and 9 parts of lead-glass (prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax) are mixed and ground fine.

These black and grey pigments are far less expensive to prepare than those from iridium, and are not inferior to them in colour; but they do not mix so well with other colours, and when baked several times they vary their tint somewhat, which renders their application less certain. When these colours burnt-in upon porcelain are examined under the microscope, it is seen that the oxide of cobalt and manganese is not dissolved by the lead-glass, but merely suspended in it.

Besides these colours, a very infusible black is used in painting, which is not acted upon by the superposed colours in the fusion; it is the—

Ground Black, which consists of 5 parts of blue violet (gold-purple), 1⅔rds part of oxide of manganese and cobalt, and 1⅔rds part of oxide of zinc; these are intimately mixed and ground fine upon a plate of glass.

White for Covering.—1 part minium, 1 part white sand, and 1 part crystallised boracic acid, are well mixed, and fused in a porcelain crucible. This white enamel has the peculiarity of forming a colourless clear glass when quickly cooled, for instance, when poured into water; while, when slowly cooled, it remains perfectly white and opaque. On heating the clear glass to its melting point, it loses its transparency, and becomes opaque as before. This property it possesses in common with the enamels, the opacity of which is produced by arsenic or tungstic acid; probably the opacity in the present case is produced by the separation of silicate of lead, as in the white enamels by arseniate or tungstate of potash, or by oxide of zinc. It is, however, of excessive minuteness; for under the microscope, even with the highest power, the glass merely exhibits a yellowish turbidness, and no individual particles are visible.

This white serves for marking the lightest part of the pictures, where it is impossible to produce them by exposing the bare surface of the white porcelain; it is also frequently mixed in small quantity with the yellow and green pigments, to make them cover well.

Lead Flux.—A colourless lead-glass for touching-up those parts of the painting which have remained dull, and for mixing with those pigments which are not easy of fusion, is obtained by mixing together 5 parts of minium, 2 parts of white sand, and 1 part of calcined borax.

Red and Brown Vitrifiable Pigments derived from Peroxide of Iron for painting upon Porcelain. Yellow-Red.—Anhydrous sulphate of the peroxide of iron is heated to redness on a dish in an open muffle, and constantly stirred with an iron spatula until the greater portion of the sulphuric acid has been expelled, and a sample mixed with water upon a glass plate exhibits a beautiful yellowish-red colour; after cooling, the peroxide of iron is freed by washing with water from any undecomposed sulphate, and dried. To prepare the pigment, 7 parts of the yellowish-red peroxide of iron are well mixed with 24 parts of lead-glass (prepared by fusing together 12 parts of minium, 3 parts of sand, and 1 part of calcined borax), and ground fine upon a plate of glass.

Brown Red.—When the persulphate of iron is heated to redness until the whole of the sulphuric acid is expelled, and a sample exhibits a dark red colour, the peroxide of iron is well suited for a brownish-red pigment, which is prepared in the same manner as directed for the yellowish-red.

Bluish Red (Pompadour).—When the persulphate is heated still more strongly, it is deprived of its loose consistency, becomes heavier, and acquires a bluish-red colour.

To hit this point exactly when the oxide of iron has assumed the desired carmine tint is not so easy, as it changes very rapidly at these temperatures.

The pigment is prepared by mixing 2 parts of the purple-coloured peroxide of iron with 5 parts of lead-glass, obtained by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax.

Chestnut Brown.—This colour of various shades, even to black, is acquired by the peroxide of iron, at still higher degrees of heat than required for the preparation of red colours; the pigments are prepared by mixing 2 parts of the chestnut-brown peroxide of iron with 5 parts of lead-glass, prepared by fusing together 12 parts of minium, 3 parts of sand, and 1 part of calcined borax.

Chamois.—1 part of the hydrate of the peroxide of iron, prepared by precipitating the peroxide of iron with ammonia is mixed with 4 parts of the lead-glass, described in the preceding, and the mixture ground fine on a plate of glass. This colour is laid on very thin, and serves to produce a yellowish-brown ground.

Flesh Colour.—1 part of peroxide of iron, 4 parts of dark yellow 2, and 10 parts of lead-glass, prepared as described under chestnut-brown, are well mixed and ground fine upon a plate of glass. This colour can also only be employed in a thin layer. Various tints may be given to it by mixing it with a red peroxide of iron, sky-blue, or dark yellow 2. The red of the cheeks and lips are painted upon it with Pompadour-red.

When the above colours are burnt-in upon porcelain, it is distinctly seen under the microscope that the peroxide of iron is suspended unaltered in the clear lead-glass; at least the quantity dissolved by the fused lead-glass is so small that it is not perceptibly coloured.

Various Brown Pigments for painting upon Porcelain. Light Brown, 1.—6 parts of dry protosulphate of iron, 4 parts of dry sulphate of zinc, and 13 parts of nitre are well mixed, and heated to a redness in a Hessian crucible, until the whole of the nitre is decomposed. When cold, the crucible is broken, the residue removed, and separated by boiling with water from soluble matters. A yellowish-brown powder remains, which is a combination of oxide of zinc with peroxide of iron. The pigment is made by mixing 2 parts of this compound with 5 parts of lead-glass, prepared by fusing together 12 parts of minium, 3 parts of sand, and 1 part of calcined borax.

Light Brown, 2.—2 parts of dry sulphate of iron, 2 parts of dry sulphate of zinc, and 5 parts of nitre, are treated in the same manner as described for light brown 1. The resulting compound of oxide of zinc and iron is of a lighter tint; the pigment is prepared from it as above.

Light Brown, 3.—1 part of dry sulphate of iron, 2 parts of dry sulphate of zinc, and 4 parts of nitre are treated as directed for 1 and 2.

The light brown colours, after having been burnt-in upon porcelain, exhibited, under the microscope, the transparent particles of the yellowish oxide of iron and zinc suspended in the colourless lead-glass.

Bistre Brown, 1.—1 part dry sulphate of manganese, 8 parts of dry sulphate of zinc, 12 parts dry sulphate of iron, and 26 parts nitre, are treated as directed for light brown 1, and the resulting dark brown powder (a combination of the oxides of zinc, iron, and manganese), mixed with 2½ times its weight of lead-glass of the same composition as for light brown 1.

Bistre Brown, 2.—1 part dry sulphate of manganese, 4 parts dry sulphate of iron, 4 parts dry sulphate of zinc, 12 parts nitre, are treated as for bistre brown 1. The colour is somewhat darker.

Sepia Brown, 1.—1 part dry sulphate of iron, 1 part dry sulphate of manganese, 2 parts dry sulphate of zinc, and 5 parts nitre, are treated as directed for light brown 1, and the greyish-brown pigment thus obtained mixed with 2½ times its weight of lead-glass of the above composition.

Sepia Brown, 2.—1 part calcined sulphate of iron, 2 parts calcined sulphate of manganese, 6 parts calcined sulphate of zinc, and 10 parts nitre, are treated as for sepia 1.

Dark Brown.—1 part dry sulphate of cobalt, 4 parts dry sulphate of zinc, 4 parts dry sulphate of iron, and 10 parts of nitre, are mixed and treated as directed for light brown 1. The resulting beautiful dark reddish-brown combination of the oxides of cobalt, zinc, and iron is mixed with 2½ times its weight of the same lead-glass as for the preceding colours.

Chrome Brown.—1 part of hydrated peroxide of iron is intimately mixed with 2 parts of the chromate of the protoxide of mercury, and then heated to redness in a dish, in an open muffle, to expel the whole of the mercury. The dark reddish-brown compound of the oxides of chromium and iron is mixed with 3 times its weight of lead-glass, prepared by fusing together 5 parts of minium, 2 parts of sand, and 1 part of calcined borax.

When examined under the microscope, after being burnt-in upon porcelain, these different brown colours also show that the dark compounds are simply suspended in the lead-glass, and not, or merely to a small extent, dissolved. The direction above given for preparing the coloured combinations of the oxides in the dry way, for the bodies which constitute the different brown pigments, is cheaper and more certain than the precipitation of the mixed solutions by carbonate of soda and calcination of the washed precipitate, which also answers. If, however, the several oxides were to be mixed with the lead-glass separately, instead of combined, the colours would not be pure, that is to say they would exhibit after the firing different tints in a thick and thin layer; they would moreover possess a totally different colour before the burning from that which they acquire after that operation, and would thus contribute to deceive the artist.

Gold purple is obtained, according to the process of Ladersdorff, by mixing a solution of 1 part ducat gold, in 4 parts *aqua regia*, with 1 drachm of tin-salt dissolved in 4 oz. distilled water, and a solution of 1 drachm of gum in 3 oz. of water, in the following proportions:—

Distilled water	3 oz.
Solution of gum arabic	28 grs.
,, of tin-salt	14 ,,
,, of gold	23 ,,

and adding alcohol of 0·863 spec. grav., until the liquid begins to grows turbid. The purple is deposited and washed with spirit of 0·958. The dried precipitate has a brownish colour, and furnishes, when all the gum has been carefully removed by washing, a very beautiful purple after the firing.

According to Fuchs, 1 oz. *liq. ferri muriat. oxydati*, Ph. bor., is mixed with 3 oz. of distilled water, and a solution of 1 oz. protochloride of tin in 6 oz. distilled water, and 10 drops of muriatic acid added until the whole has acquired a greenish colour, when a further addition of 16 oz. of distilled water is made.

On the other hand, some ducat gold is heated to boiling with pure nitric acid, until all the gold is dissolved. An excess of acid should be avoided. 360 parts of distilled water are added to this solution of gold; and then the above solution of iron and tin gradually poured into it until the whole of the purple is precipitated. This precipitate has likewise a brownish tint after drying, but furnishes a beautiful purple after burning.

It has been found, however, that purple prepared according to the following process is preferable, especially as regards the external appearance. A mixture of 4 parts pure nitric acid of 1·24 spec. grav., and 1 part pure muriatic acid, which is mixed with half as much pure alcohol of 0·863, and chemically pure tin, gradually added in small portions until no more is dissolved; the solution must be effected slowly, on which account the vessel containing the mixture should be placed in snow or cold water. The carefully decanted solution is diluted with 80 times its weight of distilled water, and mixed with a solution of gold, prepared according to the above directions. The precipitate is purple-red, and remains so after drying. The tin-solution for this purpose cannot be preserved long, otherwise nitric ether is formed; and the higher oxidation of the tin-salt no longer furnishes such beautiful precipitates with gold as the recently-prepared solution.

For mixing with the purple in order to produce a rose colour, the author does not employ a carbonate of silver, but the metal in a very minute state of division, obtained by mixing the finest silver-leaf with honey and a few drops of ether, and well grinding it, when the honey is washed out with water. Mr. Waechter uses as a flux for the purple colours a lead-glass, consisting of 6 parts minium, 2 parts silica, and 2 parts calcined borax.

With respect to the chrome colours, he observes, that the expensive method for their preparation by means of the chromate of the protoxide of mercury is still the only one by means of which a fine colour can be obtained.

Cobalt Colours.—In purifying the cobalt for porcelain colours, the removal of the whole of the arsenic is of less consequence than that of the iron. Cobalt ores from various localities, Tunaberg, Saxony, and Thuringia, are treated in the following manner. The mineral is reduced to a fine powder in an iron mortar, kept for the purpose, and mixed with ⅛th its weight of charcoal-powder; then exposed in Hessian crucibles to a red heat under a chimney with a good draught or in the open air, and roasted as long as arsenical vapours escape, a very disagreeable operation, which lasts several hours. The ore thus prepared is now boiled over the fire with a mixture of 4 parts nitre and 1 part muriatic acid, 1 part of which is diluted with 3 parts of water. This operation is repeated about 3 times, with less acid. The liquids are allowed to settle, the clear portion decanted, the remainder diluted with water and filtered, and the solution evaporated to dryness. The dry mass is mixed with some water, heated, and separated by filtration from the residue of arseniate of iron. The green liquid, which now contains more or less cobalt, iron, nickel, and manganese, is mixed with a filtered solution of pearlash, until the dirty red precipitate begins to turn blue. Care and experience in this operation are requisite, otherwise a loss of cobalt might result. The precipitate of arseniate and carbonate of iron, which at the same time contains nickel and manganese, is separated by filtration, and the beautiful red liquid mixed with more of the solution of pearlash until the whole of the cobalt is precipitated; the precipitate is carefully washed and dried. This hydrated oxide of cobalt is sufficiently pure for technical purposes, and answers just as well as that prepared from oxalate of cobalt or by caustic ammonia.

For painting, the oxide of cobalt is heated in a Hessian crucible with 1 part silica, and 1½ part oxide of zinc for two hours in a blast-furnace, then reduced to a fine powder in a porcelain mortar, and mixed with an equal weight of lead-glass.

Yellow Colour.—A beautiful yellow is obtained from 2 oz. minium, ½ oz. *Stib. oxydat. alb. abl.* 2 drms. oxide of zinc, 2 drms. 2 scruples calcined borax, ½ oz. silica, ½ drm. dry carbonate of soda, and 1 scruple *ferr. oxydat. fuscum*, which are well mixed, fused in a crucible, and then ground fine.—*Waechter.*

VITRIOL, from *Vitrum*, 'glass,' is the old chemical, and still the vulgar appellation of sulphuric acid, and of many of its compounds. which in certain states have a glassy appearance: thus:—*Vitriolic acid*, or oil of vitriol, is sulphuric acid; *blue vitriol*, is sulphate of copper; *green vitriol*, is green sulphate of iron; *vitriol of Mars*, is red sulphate of iron; and *white vitriol*, is sulphate of zinc.

VIVIANITE. A blue iron ore, phosphate of iron. Some fine examples have been found in the mines of Cornwall and Devon. See Iron Ores.

VOLCANIC GLASS. See Obsidian.

VORTEX WATER-WHEEL. See Turbine.

VRIAC. A name given to kelp by the French makers; *vriac venant*, drift weed; *vriac scié*, cut weed. The same as Varec.

VULCANITE. Vulcanised india-rubber. See Caoutchouc.

VULPINITE. A siliceous variety of anhydrite; containing 8 per cent. of silica. The vulpinite from Vulpino, near Bergamo in Italy, takes a fine polish, and is used for ornamental purposes. It is known to artists as the *Marmo Bardiglio di Bergamo.*

W

WACKE is an obsolete name for a rock intermediate between clay-slate and basalt. It is generally an earthy decomposing igneous rock.

WAD, or **WADD**, is the provincial name of plumbago in Cumberland; and also of an ore of manganese in Derbyshire and elsewhere, which consists of the peroxide of that metal, associated with nearly its own weight of oxide of iron, &c.

WADDING (*Ouate*, Fr.; *Watte*, Ger.) is the spongy web which serves to line ladies' dresses, &c. *Ouate*, or *Wat*, was the name originally given to the glossy down tufts found in the pods of the plant commonly called *Apocyn*, and by botanists *Asclepias Syriaca*, which was imported from Egypt and Asia Minor for the purpose of stuffing cushions, &c. Wadding is now made with a lap or fleece of cotton prepared by the carding-engine (see *Carding*, Cotton Manufacture), which is applied to tissue-paper by a coat of size, made by boiling the cuttings of hare-skins, and adding a little alum to the gelatinous solution. When two laps are glued with their faces together, they form the most downy kind of wadding.

WAFERS. There are two manners of manufacturing wafers: 1, with wheat-flour and water, for the ordinary kind; and 2, with gelatine. 1. A certain quantity of fine flour is to be diffused through pure water, and so mixed as to leave no glotty particles. This thin pap is then coloured with one or other of the matters to be particularly described under the second head; and which are, vermilion, sulphate of indigo, and gamboge. The pap is not allowed to ferment, but must be employed immediately after it is mixed. Wafers are now but little used, adhesive envelopes having almost superseded them.

The colouring-matters ought not to be of an insalubrious kind.

For red wafers, carmine is well adapted, when they are not to be transparent; but this colour is dear, and can be used only for the finer kinds. Instead of it a decoction of brazil-wood, brightened with a little alum, may be employed.

For yellow, an infusion of saffron or turmeric has been prescribed; but a decoction of weld, fustic, or Persian berries, might be used.

Sulphate of indigo, partially saturated with potash, is used for the blue wafers; and it is mixed with yellow, for the greens. Some recommend the sulphate to be nearly neutralised with chalk, and to treat the liquor with alcohol, in order to obtain the best blue dye for wafers.

Common wafers, are, however, coloured with the substances mentioned at the beginning of this article; and for the cheap kinds, red lead is used instead of vermilion, and turmeric instead of gamboge.

Three new methods of manufacturing wafers were made the subject of a patent by Peter Armand De Comte de Fontainemoreau, in April 1850; the chief feature of which is a layer of metal-foil. In the first of the three forms described, the metal slip or band is to be coated with the ordinary farinaceous paste used for making wafers, for which purpose the slip is laid on one of the jaws of the ordinary iron mould, then a spoonful of paste is poured on it, the mould is shut, and the paste baked as usual. The metal band is lastly punched into wafers, either plain or ornamental.

The second method is to stick these slips to paper with paste, then to dry and punch them out.

By the third plan, strips of gummed paper are fixed to the slips, and a resinous cement is put on the other side. The first two methods require moistening, the third heating. This contrivance is susceptible of much variety of decoration.

WALNUT HUSKS, or **PEELS** (*Brout des noix*, Fr.), are much employed by the French dyers for rooting or giving dun colours.

WALNUT OIL. See Oils.

WANGEES, or *Japan Canes*. A cane imported from China.

WARP (*Chaîne*, Fr.; *Kette, Anschweif, Zettel, Werft*, Ger.) is the name of the longitudinal threads or yarns, whether of cotton, linen, silk, or wool, which being decussated at right angles by the woof or weft threads form a piece of cloth. The warp yarns are parallel, and continuous from end to end of the web. See Weaving, for a description of the *warping-mill*.

WASH is the fermented wort of the distiller.

WASHING COAL. M. Berard is the inventor of a very successful apparatus for purifying small coal. He exhibited his arrangement at the Great Exhibition of 1851, receiving the Council medal. The decoration of the Legion of Honour and a gold medal was also awarded to him at the Paris Exhibition in 1855. This apparatus, to be presently described, effects, without any manual labour, the following operations:—

1st. The sorting the coal by throwing out the larger pieces.

2nd. Breaking the coal, which is in pieces too large to be subjected to the operation of washing.

3rd. Continuous and perfect purification of the coal.

4th. Loading the purified coal into waggons.

5th. Loading the refuse (pyrites or schist) into waggons for removal.

The power required for the apparatus is that of from four to five horses, and the machine can operate upon from 80 to 100 tons of coal in about twelve hours, if fitted up near the colliery. The expense of the operation of purifying is stated to consist solely in the wages of the workmen charged to conduct the labour of the machine.

The following description of the *figs.* 2091 and 2092, will render the arrangements of M. Berard's machine readily intelligible.

The coal is carried from the mine on a staging, for example, and the tram-waggon, B (*fig.* 2091), is unloaded into a hopper, C, either by opening the bottom or by tilting it (as in the position represented by the dotted lines *b*), by means of a lever. It falls afterwards either on to a table or a moveable grating, D, formed of frames, or of a series of stages, of sloping perforated plates, which immediately sorts it into as many sizes as there are perforated plates.

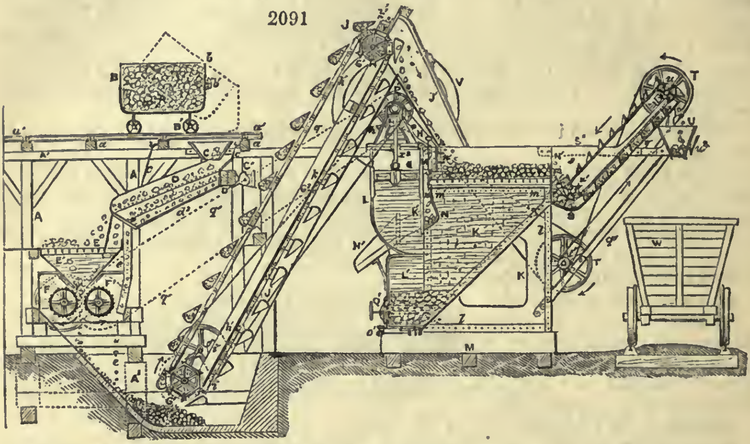
This grating is suspended out of perpendicular by four chains or iron rods, C C, fixed to the framework of the staging A. It is moved by means of a cam motion (an arrangement of a cam and tongue mentonnet), C′, and falls back by its own weight against the stops, which produce concussions or vibrations favourable to the clearing out of the holes and to the descent of the materials. The motion communicated to the grating admits of a much less inclination being given to it than would be the case if it were fixed: the sorting is effected quicker and more perfectly, besides which, the differences of level which it is necessary to preserve are maintained.

The larger pieces rejected by the first plate reach the picking-table E, where a labourer picks out the largest stones and extraneous substances, as fragments of castings, iron, &c.

The fragments which have passed through the upper plate, and are retained by that below, descend direct to the crushers F F′, situated below. Lastly, the fine portions of the coal which have passed through the second perforated plate, fall on to a solid bottom, A′, whence they are thrown, delivered direct into the pit by means of a fixed shoot, *e*.

The crushing-cylinders, F F, are made with a covering of cast iron, mounted on an iron shaft. This covering can be easily replaced when worn out. It has on its surface small grooves, which are usually placed longitudinally, parallel with the axis of the cylinder, in order to avoid the slipping of the substances operated on. But it is also necessary to crush fragments of slate which gain admission with the coal, and these consisting of thin, flattened laminæ, it would be necessary to bring the crusher

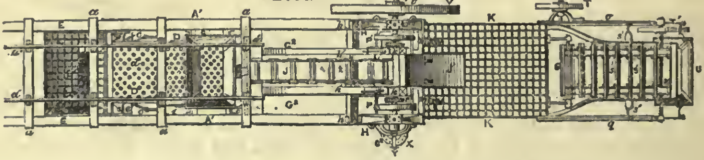
2091



closer than would be required to reduce the coal, which is of a more cubical form, to the proper size.

In order to obviate this difficulty, another series of grooves are formed on the surfaces of the crusher transversely to those already described, the intersection of the two producing projections in the form of quadrangular pyramids, with slightly rounded tops. In coming between the projections of the crushers, the fragments of slate, being unable to pass, are broken up without reducing the coal to a smaller size than is required.

2092



When the coal has undergone a preliminary sifting, which has removed all the pieces exceeding 6 or 7 centimeters in size, one pair of crushers is sufficient. In that case the grating may be dispensed with altogether by discharging the coal direct into the pit, and returning from the sifter to the washer the pieces of coal which have not been able to pass beyond the first perforated plate.

The small coal resulting from the washer, or from the sifter, by means of the jigger, is delivered into a common pit placed under the washers. The pit is shaped like an inverted quadrangular pyramid, the three faces of which are inclined to one another at an angle of 45°, to facilitate the descent of the substance, and the fourth is usually vertical. It is on the latter that an opening is made, which is regulated by a flood-gate.

An elevator, formed of an endless chain, with buckets, raises the coal from the bottom of the pit, and places itself sufficiently high to allow of the final discharge, which may take place into the waggon.

The rate of ascent of the buckets and their capacities are calculated so as to raise 160 to 200 tons of coal in the working hours; but this quantity may be diminished by means of the flood-gate in the pit.

The coal discharged by the elevator falls on the sorter, which ought immediately to divide it, according to size, and distribute it to the ferry-boats.

The classifier is formed of a kind of oblong rectangular chest, made of iron plates, in the inside of which are placed stages of perforated plates, the apertures in which decrease in a downward direction. Sufficient space is allowed between each plate for the motion of the materials. At the bottom of the perforated plates are disposed inclined planes for throwing on one side the product of the sifting, which escapes through a slope made on the side of the sifter. A bottom fixed to the classifier itself, and like it moveable, receives the dust in the finest numbers, if the sifting has been effected in the dry way, or else this bottom is immoveable and fixed to longerons which support the classifier, if the sifting take place in water, as we are about to point out.

The classifier is suspended by two or three pairs of articulated handles turning on axles fixed to longerons: by that means it enjoys an extreme freedom of motion in a longitudinal direction. A rapid reciprocating motion is communicated by a '*bielle*,' which receives the action of a bent axle firmly established on a foundation fixed on the principal wall of the chamber of the machine. The motion of rotation is communicated to the axle by the disposition of an iron pinion *d'angle* working into *a*.

The *bac* is formed of a rectangular chest in cast iron, L′, one part of the bottom of which is inclined at 45°, the other lower parts remaining horizontal.

Opposite one of the lesser sides of the rectangle is placed a cylinder O, opening into the oblong chest at about half its height. The chest L′ is prolonged under the cylinder, in order to increase the stability of the system and the capacity of the drain-well (*puisard*).

A cast-iron box, M M′, is firmly fixed in the interior of the bac, on flanges of cast iron with vertical faces. This box has a slight inclination from M towards M′. It is covered with a perforated plate, usually of copper, fastened to the frame by a number of iron pins or bolts easy of replacement. The size of the holes varies according to that of the matters brought into the bac.

A cast-iron door, N, traverses, opening outward, is fixed at a slight height above the frame, serving as a kind of partition dividing the materials in the bac, and against it a flood-gate N′, by means of which the opening beneath the cast-iron door may be closed at pleasure.

A counter flood-gate, N′, is placed at the lower extremity of the frame; in raising it a barrier is formed of variable height, by means of which the substances between the flood-gate and counter flood-gate may be arrested.

A piston, C, receives from the machine a sufficiently rapid reciprocating motion.

Everything being thus arranged, if the bac is supposed to be filled with water to the level of the front face at N′, and that the substances to be washed fill the space in the bac between this level and the perforated plate of the frame, the piston working upwards and downwards will press the water in the body of the cylinder, and will force it by its incompressibility to pass through the holes in the perforated plate; it will establish above this plate an ascending current, which, if of sufficient power, will raise the substances submerged.

The resistance to the rise of each body will be in proportion to its specific gravity, and the height it will be carried will follow an inverse law, supposing the fragments to be of nearly equal sizes.

The slates which fall over the counter flood-gate fall into a pocket or reservoir, N, whence they are discharged on opening a flood-gate, K′. Pressed by the upper column of water, they slide with a slight admixture of water on the inclined plane, K′ N′, which can be pierced with holes; the water escapes, and the slate only falls directly into the waggon of discharge.

The bent axle of transmission, S S, moves in a groove turning on a pivot at its extremity. The rotation of the axle communicates an oscillating motion to it.

The deposit formed in the drain-well is emptied through an opening of the flood-gate placed at the lower part. An opening serving as a man-hole is reserved for effecting internal repairs without the necessity of raising the frame.

All coal contains a portion of earthy matters or impurities which, in the form of bands or scales, are generally in some degree apparent to the eye, and constitute the ashes and clinker left by combustion. The small coal which is sent out of mines necessarily contains a still larger proportion, frequently exceeding 10 per cent., consisting chiefly of shale and iron pyrites derived from the roof or floor of the seam of coal, or from the bands of impurities interstratified with it. Generally these impurities are so incorporated with the mass of the coal that it must be crushed in order sufficiently to detach them. The pyrites, which contain nearly the whole of the sulphur found in coal-seams, is well known to be very injurious either in a heating or smelting furnace, in the manufacture or working of iron, in gas-making, in coking, and other processes.

Many seams of coal already sunk to, or portions of seams in work, are left underground as unsaleable in consequence of the impurities they contain. Small coal sells at a low price chiefly in consequence of its impurities and the defective coking property which they occasion. It has been estimated that an amount not far short of the quantity of coal sold is sacrificed in producing a commercial article of adequate quality and description. The enormous consumption of coal in this country, amounting to 127 millions of tons per annum, renders the utilisation of a larger portion of the more valuable seams now in course of being exhausted, and the bringing into the market of other seams, objects of national importance.

The differences between the specific gravities of coal and its impurities, allow of their being separated by the action of water when sufficiently crushed. The water process hitherto most commonly adopted is that known as 'jigging,' which consists in forcing the water alternately up and down through the mass of coal. The downward current of water in 'jigging' is prejudicial, and entails a large sacrifice of the finer particles of the best coal; whilst the upward current, from its rapidity and irregularity, is costly both in time and power, besides failing to effect the more perfect separation which is obtained by a slow, continuously ascending or pulsating current, regulated to the proportion of shale in the coal, and to the size of the particles to be acted upon.

Several coal-washing machines have been from time to time introduced, but the machine described sufficiently represents their general character.

Machines have been established in Scotland, Cumberland, Derbyshire, Gloucestershire, and Wales, to purify from 20 to 100 tons of coal per day, at a cost not exceeding 3*d.* per ton, and with a loss not exceeding 2 per cent. of coal.

WATER. (*Eau*, Fr.; *Wasser*, Ger.) There is no substance so extensively used in the operations of nature on our globe, as well as in the workshops of men, as water. To speak of its numerous relationships, even briefly, would demand too much space, and it will be needful to confine ourselves strictly to a consideration of its physical conditions.

A few analyses of river water will convey some idea of the composition of the solid matter held in solution, given in grains per gallon of this fluid:—

Rain is the probable source of all water. It is almost absolutely pure water if it falls through uncontaminated air. Water is almost colourless, brilliant, without taste or smell, and very transparent. When seen through great depths it has a slightly blue shade of colour. It weighs 252·45 grains per cubic inch at 60° Fahr. in the air. The specific gravity of all substances liquid and solid are taken by their relation to water, which is called 1·000 or 1. Its boiling point at 29·92 bar. pressure is 212° Fahr.; it freezes at 32°, and it evaporates at all temperatures. Its boiling point at 760 meters pressure is called 100° Cent.; freezing point 0°. It assumes, therefore, the gaseous, liquid, and solid states with great facility. The specific heat of water at 32°

Fahr. is taken as 1000. Water is taken to measure amounts of heat also. The heat required to raise 1 gramme of water 1° Cent. is a unit of heat. The amount of heat required to raise 1 lb. of water, one degree of Fahr., requires for its evolution the expenditure of a mechanical force equal to the fall of 772 lbs. through the space of 1 foot. Or 1 gramme of water is heated 1° (Cent.) by an amount of heat represented by the fall of 423·55 grammes through the space of 1 meter. The latent heat of water and the amount required to convert ice at the freezing point into water is 144°, or 144·6° Fahr. (80°–80·34° Cent.) The refractive power of water, or its index of refraction of light, is 1·336; that is, the sine of the angle of incidence is to the sine of the angle of refraction as 1·336 to 1. Refractive power increases below 39°, although density diminishes. Water expands when heated or cooled beyond 39° Fahr., or 3°·9 Centigrade: Playfair and Joule give 39·1; Fraukenhein, 38·85; Plücker and Gessler, 38·8. Hope, who discovered the property, gave 39·5. Water freezes in crystals; one form is not unlike Iceland spar, a rhomboïd. Hail crystallises in six-sided pyramids, base to base; snow frequently with various stellar radiations.

Specific gravity of the vapour of water is 0·622; it is nine times heavier than hydrogen. Water itself is 812 times heavier than the atmospheric air. Water expands by heat, between 32° and 212°, 1 in 21·3 volumes. It expands in cooling below 32°, even if it be not allowed to crystallise. The expansion may be prevented by using smooth vessels and preventing disturbance. It may be cooled in this way to about 7° Fahr. A slight agitation, or the presence of a rough substance, rapidly causes it to shoot out crystals in all directions. The spec. gr. of ice is 0·916, it therefore floats on water. It expands with irresistible force, bursting asunder iron vessels, however strong, in which it may be confined, water-pipes of whatever substance, porous stones which may have absorbed it, and vegetable-cells in which it may be enclosed.

Water heated to 212° Fahr. boils. Long before this period, and even in heating it only a few degrees, it gives off bubbles, which are those of air, from which it is never found free in nature. At 212° the bubbles of vapour are formed and rise to the surface. These bubbles form more readily on certain surfaces; on metals easily, especially if they are not polished. Gay-Lussac gave the difference of the boiling point in metal and glass as two degrees. M. Marcet found it raised to 221° when a glass flask had its inner surface coated with a thin film of shell-lac. When water has ceased to boil in a glass or porcelain vessel, it will begin again instantly if a metallic wire is introduced. Rough glass and porcelain vessels allow water to boil better than smooth. The boiling of water depends on the pressure of the air as well as temperature, as the following shows:—

Barometer, inches	Water boils at degs. Fahr.
27·74	208°
28·29	209°
28·84	210°
29·41	211°
29·92	212°
30·6	213°

This change of boiling point is used to ascertain the height of mountains, 550 feet making a difference of 1 degree. In a vacuum water will boil at 67°. In a Papin's digester it is raised to 300 or 400 without boiling.

WATER-GLASS. See Glass, Water.

WATERING OF STUFFS (*Moirage*, Fr.) is a process to which silk and other textile fabrics are subjected, for causing them to exhibit a variety of undulated reflections and plays of light. See Moire.

WATER-METER. An apparatus by which the quantity of water supplied to a manufactory or to a house can be satisfactorily measured. As a description of gas-meters has been given, it appears requisite that some notice should be taken of an equally important instrument for measuring water. These may be, and are, variously constructed. The principle upon which they are made is in all cases that which we see in action in a water-wheel, a given quantity of water in flowing performs a given quantity of work.

Siemens and Adamson's water-meter is shown in the following figures:—

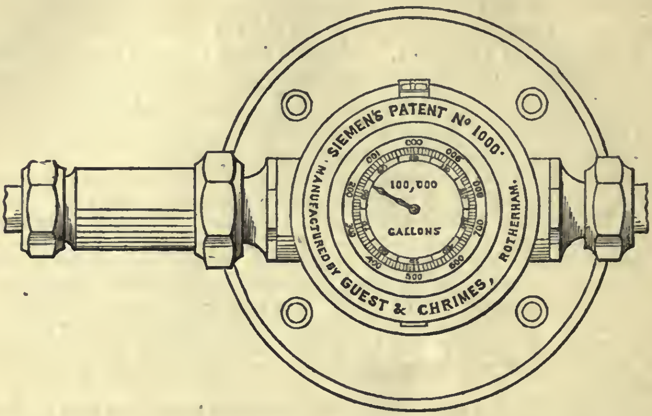
Fig. 2093 is a plan of a meter, looking on the dial and dial-cap.

Fig. 2094 is a section of meter, filter, and unions, complete.

Fig. 2095 is a perspective view of drum or measuring medium, showing the adjusting or regulating vanes *a a a*, and water-ways *b b b*; letters of reference refer to similar parts in all the drawings.

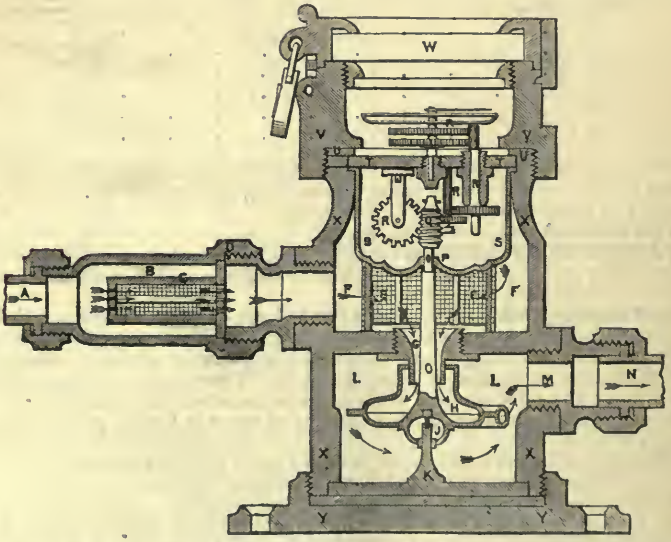
In *fig.* 2094, A is the inlet union of meter for connecting to the Water Company's supply pipe. B is the filter-case. C is a filter, which is for the purpose of preventing foreign and injurious substances passing into the drum of meter. D is a filter-case screw, which connects it with the meter, and is for the purpose of attaching to and detaching from the meter-case, to cleanse the filter C when required. E E is an inner filter, for the purpose of preventing any foreign and injurious matter which might pass the first filter, C (whether from being broken or from any other cause) from entering into the drum.

2093



F is an inlet chamber of the meter-case X, into which the water enters, and is conducted into the measuring drum H by means of the conducting tube G. G is the inlet or conducting tube into drum. H is the drum or measuring medium of meter, which is regulated so as to give uniformity of measurement by the adjusting vanes *a a*. J is an oil-cup attached to bottom of drum, which encloses and lubricates the bottom of spindle K. At the upper end of the oil-cup there is a steel boss, which the drum revolves upon. K is the bottom spindle, which has a steel pivot, on which the drum revolves, and is enclosed by the oil-cup or chamber J. L L is the outlet chamber of the meter-

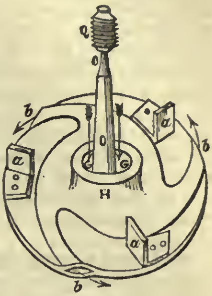
2094



case X, into which the water is measured or delivered from the drum, and is discharged through the outlet end M. N is the outlet union of case, for connecting to the consumer's or service pipe. O O is the spindle of drum, having a steel boss at the bottom, which revolves upon the steel pivot of the spindle K, and a collar at top, working into the

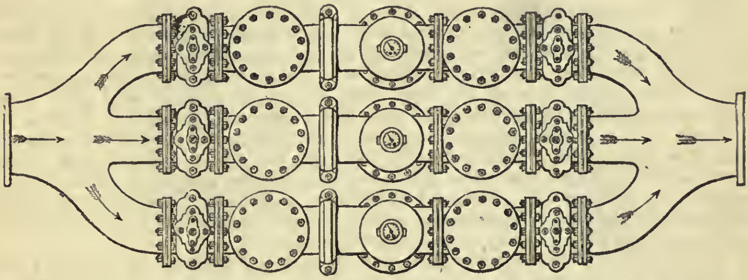
German silver bush P. Q is a screw attached to the top of the drum spindle, for the purpose of giving motion to the wheels of dial-work, and so indicating on a graduated dial the number of feet or gallons of water passed through the meter. R is the dial work. S S is an oil chamber, which is for the purpose of lubricating and protecting the wheels of the dial-work from the action of the water, and so preventing any foreign substance getting upon and injuring them. T is the dial-plate, used for the purpose of making, along with the india-rubber washer U, a sealed or water-tight joint between the oil chamber, where the bottom wheels work, and the upper portion or chamber, where the top or differential wheels and dial work. V is a dial-cap, screwed on to the top of meter-case. W is a glass plate, covering dial. X is an outside metal-case, in which the drum revolves. Y is a bottom plate, for putting in and taking out the drum.

2095

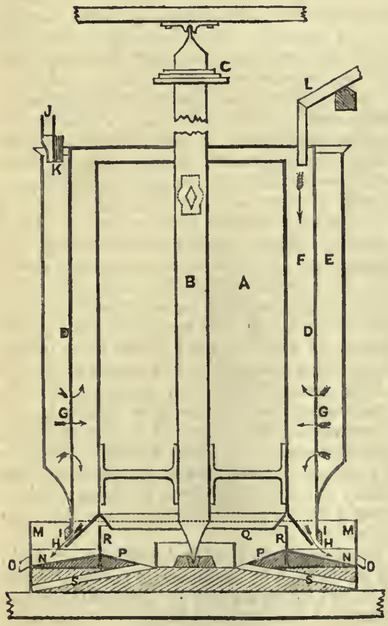


The annexed drawing, *fig.* 2096, shows the arrangement of the meters to measure large quantities of water in connection with town supply or district mains. The plan shown admits of the regular and periodical examination and repairs, when necessary, without interfering with the constant supply. A dirt box is attached to each end of the meters, so as to protect them from injury arising from anything (such as sticks, stones, shells, &c.) which might be in the pipes, and which if allowed to pass might, without this precaution, destroy the accuracy of the measurement, and damage the meter. The sluice valve at each end provides for the periodical examination of the meter and cleaning the dirt box, and when

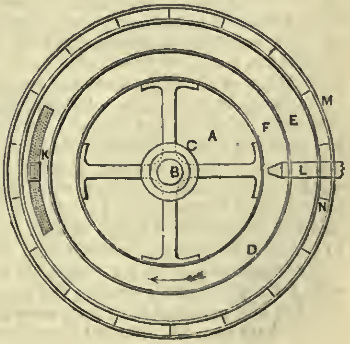
2096



2097



2098



necessary (for the purpose of repairs) the taking-out of the meter. As it is arranged that any two of the meters are of sufficient capacity to deliver the quantity required, it will be apparent that this can be done while the regular supply is going on.

Messrs. Walker and Son's duplex water-meter, *figs.* 2097 and 2098, is somewhat different from this. The water passes into an annular chamber A, in which is a rotator arbor, on which are fixed two measuring screws C, with their blades at contrary angles, and on the same arbor, between these screws, are two cones, which serve to guide the water smoothly on to the screw-blades, and likewise to lift the rotator off its lower pivot and keep it suspended in its bearings whilst in action, thereby preventing end-pressure. The water, by means of a partition, is divided as it enters, and it passes over the screws at opposite sides in two streams of equal force. In the central compartment the water is again divided into two streams, the one descending and passing between the blades of the lower screw, and the other ascending and passing between the blades of the upper screw; these two currents join, and the water passes off by the outlet.

The first example given in some respects resembles a Barker's Mill; while in the other the revolutions of the screws are made to measure the quantity of water passing through the meter.

WATERS, MINERAL. Those waters which contain such a proportion of foreign matter as render them totally unfit for ordinary purposes, and give them a sensible flavour, and a specific action upon the animal economy, are called *mineral* waters. They are various in their composition, temperature, and in their effect upon the system. In regard to temperature they are divided into *warm*, *thermal*, and *cold*. They are generally so far impregnated with acid or saline bodies as to derive from them their peculiarities, and are commonly divided into four classes. *Acidulous* or *carbonated* waters are characterised by an acid taste, and by the disengagement of gas. They contain five or six times their volume of carbonic acid gas; their salts are muriates and carbonates of lime and magnesia, carbonate or sulphate of iron, &c. *Saline* waters contain, in general, salts of soda and lime, or of magnesia and lime, with carbonic acid and oxide of iron. *Chalybeate* or *ferruginous* waters have a decided styptic taste; the iron is sometimes in the state of an oxide, held in solution by carbonic acid, sometimes exists as a sulphate, and sometimes both as a sulphate and carbonate. *Sulphureous* waters are easily recognised by their disagreeable smell, and their property of tarnishing silver and copper.

Dr. Gairdner, in his 'Natural History of Mineral and Thermal Springs,' has endeavoured to generalise the connection between the composition of mineral waters and the rock-formations from which they flow:—1. 'The salts held in solution in mineral waters have no connection with the acid, saline, or earthy matter which enter into the composition of the rocks which they traverse in their passage to the surface of the earth. 2. The mineral waters of the primitive formations are almost all thermal, and generally possess a very high temperature. Their predominant impregnation is sulphuretted hydrogen gas, free carbonic acid gas, carbonate of soda, and, in general, salts with a base of soda, silica, few calcareous salts, except carbonate of lime in some peculiar situations, and but a small quantity of iron. 3. The waters of the palæozoic and older secondary formations participate in those belonging to the primitive rocks. They are generally of a lower temperature, though some of them are still very hot; free carbonic acid is much less common, and sulphuretted hydrogen is almost entirely absent. Salts of soda still predominate, but carbonate is not so common; sulphate of lime is found in the greater number of these waters; silica exists in but two or three examples. 4. The waters of the newer secondary and tertiary formations are as distinctly characterised as those of the primitive rocks, placed at the other extremity of the series. They are all cold. Free carbonic acid is almost entirely absent. Their predominant ingredients are the carbonate and sulphate of lime, sulphate of magnesia, and oxide of iron. 5. The trachytic and basaltic formations, and modern volcanic rocks, present in their mineral waters many of the circumstances of temperature and composition which are found in the waters of granite and other primitive rocks. Sulphuretted hydrogen, carbonic acid, carbonate of soda, carbonate of lime, and silica reappear, and many contain the free sulphuric and hydrochloric acids. The sulphate of lime, magnesian salts, and oxide of iron, are again wanting. 6. It is often found that the mineral waters of a district have almost the same composition, in which case they generally issue from the crystalline and independent formations. In other cases they are subject to great varieties within a comparatively limited space, so that waters of a totally different composition rise close to each other when they emerge from sedimentary rocks.

Sir Charles Lyell, in his Address at the meeting of the British Association at Bath, stated that, 'Notwithstanding the general persistency in character of mineral waters and hot springs ever since they were first known to us, we find on enquiry that some few of them even in historical times have been subject to great changes. These have happened during earthquakes which have been violent enough to disturb the subterranean drainage and alter the shape of the fissures up which the waters ascend. Thus, during the great earthquake at Lisbon, in 1755, the temperature of the spring called La Source de la Reine at Bagnères-de-Suchon, in the Pyrenees, was suddenly raised as much as 75° Fahr., or changed from a cold spring to one of 122° Fahr., a heat which it has since retained. It is also recorded that the hot springs at Bagnères-de-Bigorre, in the same mountain-chain, became suddenly cold during a great earthquake which in 1660 threw down several houses in that town. It has been ascertained that the hot springs of the Pyrenees, the Alps, and many other regions, are situated in lines along with the rocks have been rent, and usually where they have been displaced or faulted.' . . . .

In the regions where volcanic eruptions still occasionally occur, hot-water springs are found in great abundance; sometimes the water of these springs attains a boiling temperature, and some emit steam considerably above boiling point. These springs are most conspicuous in districts where, as in Central France, and the Eifel in Germany, there are indications that the internal fires have comparatively recently become dormant.

At Carlsbad, in Bohemia, there are some very important mineral springs: one of these is a very copious stream, gushing forth with great vehemence. Its temperature is 165° Fahr. The analysis of Berzelius shows the water of this spring to contain:—

Sulphate of soda	2·58714
Carbonate of soda	1·25200
Chloride of sodium	1·04893
Carbonate of lime	0·31219
Fluoride of calcium	0·00331
Phosphate of lime	0·00019
Carbonate of strontia	0·00097
,, of magnesia	0·18221
Phosphate of alumina	0·00034
Carbonate of manganese	a trace
Silex	0·07504
Total	5·46232

Berzelius found that the substances dissolved by carbonic acid in this spring crystallise out, when the carbonic acid escapes, independently of the diminution of the liquid, but that the magnesia and silicic acid were not deposited until the evaporation had taken place.

There are many celebrated mineral springs in England; amongst the most important may be enumerated those of Buxton, Harrowgate, Cheltenham, Leamington, Tunbridge, Epsom, and Bath.

Sir Charles Lyell stated (in the same Address before alluded to) that:—'The thermal waters of Bath are far from being conspicuous among European hot springs for the quantity of mineral matter contained in them in proportion to the water which acts as a solvent.' 'Dr. Daubeny, after devoting a month to the analysis of the Bath waters in 1833, ascertained that the daily evolution of nitrogen gas amounted to no less than 250 cubic feet in volume. This gas, he remarks, is not only characteristic of hot springs, but is largely disengaged from volcanic craters during eruptions. Carbonic acid is another of the gaseous substances discharged by the Bath waters.'

The temperature of the Bath waters varies in different springs from 117° to 120° Fahr. Prof. Roscoe analysed the Bath waters, more particularly the water of the King's Bath spring: he found it contained strontium, lithium, sulphate of calcium, magnesium, and a small quantity of copper.

Dr. Muspratt, in a letter addressed to the Editor of the Chemical News, said:—

'The thermal springs of Buxton issue from fissures in the calcareous rocks, and are attended by often-repeated but suspended volumes of gas, which escape partly as large bubbles, and partly in countless minute vesicles of water, giving to the liquid freshly collected in glass vessels all the appearance of aërated water. As it gurgles up, the water is clear, sparkling, and almost tasteless. The temperature is a little above 32° Fahr., and the specific gravity 1·000339. The most remarkable feature of the Buxton water is the very large quantity of nitrogen which it eviscerates.'

	Cubic inches per gallon.
Nitrogen	204·00
Free Carbonic acid	8·50

The analysis made by Dr. Muspratt of the Buxton water is as follows:—

Carbonate of lime, $CaOCO^2$	8·541
Carbonate of magnesia, $MgOCO^2$	3·741
Carbonate of iron, $FeOCO^2$	0·082
Chloride of calcium, CaCl	1·227
Chloride of magnesium, MgCl	0·463
Chloride of sodium, NaCl	2·404
Chloride of potassium, KCl	0·260
Sulphate of lime, $CaOSO^3$	0·330
Silicic acid, SiO^2	1·044
Organic matter	0·341
Phosphate of lime and alumina, fluoride of calcium, nitric acid, &c.	1·076
	19·510

The celebrated Geysers of Iceland are the hottest known springs in the world. From experiments made by Prof. Bunsen, we learn that at the depth of only 74 feet, at the bottom of the tube a column of water may be in a state of rest, and yet possess a heat of 120° Cent. or 248 Fahr. What then will be the temperature of such water at the depth of a few thousand feet? The Geyser water contains in 10,000 parts:—

	Forchhammer.	Pfaff.
Silicic acid	4·09	8·00
Soda	1·32	—
Chloride of sodium	1·68	1·68
Sulphate of soda (and magnesia)	0·62	1·32
Sulphate of lime	0·34	—
	7·96	11·00

By cooling alone about one-tenth of the silicic acid separates; for the water which Forchhammer received in sealed flasks became cloudy, and left that quantity of silica.

WATER-PRESSURE MACHINERY FOR MINES. See HYDRAULIC MACHINERY.

WATER-PROOF CLOTH. See CAOUTCHOUC.

WATER, PURIFICATION OF. This subject has been already dealt with to some extent while on the subject of filters, and when speaking of the influence of animal-charcoal. Spencer, the discoverer of the electrotype process, appears to have made a discovery proving that magnetic oxide of iron and the protocarbide possess the property of purifying water.

After trying a number of experiments with various descriptions of rocks and minerals, Mr. Spencer found that those containing protoxide of iron (even where it was chemically combined with other substances) effected the filtration of water from even suspended impurity better than any others. Acting on the idea thus suggested, he found that the same oxide, when isolated in the state of 'magnetic oxide,' not only freed water from turbidity more effectually than an equal thickness of sand, but effected its decolouration with marvellous rapidity. On the other hand, the earthy substances entering into the composition of the same rocks, such as silica and alumina, when isolated, were, in the latter respect, perfectly *inert*. From this it was evident that the protoxide of iron, as magnetic oxide—a substance which enters into the composition of so many rocks—was one of nature's chief agents of purification. A most striking experiment was made with some bog-water, darker in colour than ordinary porter, which had been procured from the soakings of an Aberdeenshire peat-bed. *When brought into contact with the magnetic oxide, it was deprived of its colour almost instantaneously, and carbonic acid substituted in its place.*

Perhaps the most extraordinary circumstance is that *the magnetic filtering medium itself suffers no deterioration after any period of operation.* Of course, if its surface becomes fouled with slimy impurity, it requires washing. Its province is confined to forcing the oxygen, always present in the water, into combination with the impure organic matter, and thus *converting it into carbonic acid,* which gas conferred freshness and salubrity on all waters in which it was found. In these results the occult action of catalysis was, for the first time in the history of science, brought at will into artificial every-day operation.

The magnetic oxide was not to be understood as ordinary oxide (rust) of iron. It was, on the contrary, a black crystalline body, hard but brittle, and analogous, in perhaps all respects, to the body formerly termed 'loadstone.' Below redness it never oxidised. Though not plentiful as a natural body, Mr. Spencer had succeeded in forming it artificially, from several iron ores, at a very reasonable rate. Though the magnetic oxide he had obtained from the white carbonate of iron was very effective, yet it had a tendency to be reduced to fine powder by attrition. He became apprehensive, therefore, that this circumstance might ultimately interfere with the rapidity of his filtering operations. This led him to seek some mode of procuring an equally effective though less friable body. After various experiments, he succeeded beyond his anticipations. By very simple means, he had obtained a magnetic body combined with carbon from the hitherto refractory Cumberland hæmatite. This new compound body, which is thus added to metallurgical chemistry, consists of iron, oxygen, and carbon—an equivalent of each; its atomic number is therefore 42. It is very hard, and when polished, has a black metallic lustre. It is highly magnetic, and was said to be as incorrodible as gold or platinum. Its purifying powers were stated to be very great. It can be manufactured cheaply. Mr. Spencer named it protocarbide of iron. He stated that it was not always necessary in practice to have an equivalent of carbon combined with the oxide, as a smaller proportion conferred the requisite hardness, in which case it was prepared more quickly; but, in making, if kept at a low red heat along with uncombined carbon for a longer time, the combination took place in equivalent proportions.

WATER, SEA—*rendered fresh.* The analyses of sea water which have been made at various times, and the results of which will be found elsewhere, prove that that liquid contains from $3\frac{1}{2}$ to 4 per cent. of saline substances, two-thirds at least of which are common salt, and also a certain quantity of organic matters, all of which substances impart to it its well-known taste and odour, and render it unfit for drinking or other domestic purposes.

2099

To render sea water drinkable, and thus avoid the accidents resulting from an insufficient supply, or from an absolute want of fresh water, in sea-voyages, is a problem which may be said to have engaged the attention of men from the very moment they ventured to lose sight of the friendly shore and became navigators; gradually, as the enlargement of commercial operations extended the length of sea-voyages, the difficulty of preserving in a pure state the fresh water taken in store, the necessity of putting up at stations for procuring a fresh supply of it when it is exhausted, the great gain to be realised by being enabled to devote to the stowage of cargo the valuable space occupied by water-tanks and water-casks, have induced many people at various times, and for many years past, to contrive apparatus by means of which sea water would be rendered fit to drink, or by means of which good fresh water could be obtained therefrom.

Fresh water can be obtained from sea water in two ways: the one by distillation, the other by passing it through a layer or column of sand, or of earth, of sufficient thickness or length. In effect, if sea water be poured at A (*fig.* 2099), into a pipe 15 feet high, and full of clean dry sand, the water, which will at first flow at B, will be found pretty fresh and drinkable, but as the operation is continued, the water which flows at B soon becomes brackish; the brackishness gradually augmenting, until, in a very short time, the water which flows at B is actually more salted than that poured at A; because the latter dissolves the salt which had been first retained by the sand, which must then be renewed, or washed with fresh water, a process evidently useless for the purpose in question. This phenomenon, according to Berzelius, is due to the interstices between the grains of sand acting as capillary tubes; and as, at the beginning of the operation, the effect depends more on the attraction than on the pressure of the liquid poured in one of the branches of the tube, the salt is partly separated from the water which held it in solution, the latter lodging itself into the interstices of the sand, and filling them; if, when the mass of the sand is completely wetted, a greater quantity of sea water is poured upon it, the weight of the said sea water first displaces and expels the fresh water; but as soon as the interstices of the sand have thus been forcibly filled up with sea water, the water flowing at B becomes more and more salted; wherefore this filtration cannot yield more fresh water than can be contained in the interstices of a column of sand of a certain length, and proportionate to the saltness of the sea water.

Howbeit, the removal of the salt from sea water, so as to obtain fresh water therefrom, is, practically speaking, an impossibility, except by evaporation.

At first sight one would think that it is sufficient to submit sea water to distillation to convert it into fresh water, and that the solution of the problem is altogether dependent upon a still constructed so as to produce, by evaporation, a great quantity of distilled water, with a consumption of fuel sufficiently small to become practicable.

Distillation at a cheap rate is doubtless an important item, and fuel being a cumbrous and expensive article *on board ship*, it is superabundantly evident that, supposing all the apparatus which have hitherto been contrived for the purpose to answer equally well, that one would clearly merit the preference which would produce most at least cost; but there are, besides, other desiderata of a no less primary importance, and it is from having neglected, ignored, or been unable to realise them, that all the apparatus for obtaining fresh water from sea water, which have been from time to time brought before the public, have hitherto, without exception, proved total failures, or, after trial, have been quite discarded, or fulfil the object in view in a way so imperfect or precarious, that, practically speaking, the manufacture of fresh water at sea, or from sea water, may be said to have been, until quite lately, an unaccomplished feat. In order to understand the nature of the difficulties which stood in the way of success, a few words of explanation become necessary.

When ordinary water, whether fresh or salt, is submitted to distillation, the condensed steam, instead of being, as might be supposed, pure, tasteless, and odourless, yields on the contrary a liquid free from salt, it is true, but of an intolerably nauseous and empyreumatic taste and odour which it retains for many weeks; it is, moreover, insipid, flat, and vapid, owing to its want of oxygen and carbonic acid, which water in its natural state possesses, and of which it has been deprived by the process of distillation. In the absence of ordinary fresh water, this distilled water, however disagreeable and objectionable it may be, is of course of use so far as it is fresh, but the crews invariably refuse it as long as they can obtain a supply from natural sources.

With a view to remedy the defects just alluded to, various means have from time to time been proposed and employed: such as the addition of alum, sulphuric and other acids, chloride of lime, &c.; but it is evident that chemical reagents cannot effect the object; but if even they did, their use is always unsafe, for their continuous and daily absorption might, and doubtless would, cause accidents of a more or less serious nature, not to speak of the trouble and care required in making such additions. Liebig said, with both authority and reason, that, as a general rule, the use of chemicals should never be recommended for culinary (or food) purposes; for chemicals are seldom met with in commerce in a state of purity, and are frequently contaminated by poisonous substances. On the other hand, the percolation through perforated barrels or coarse sieves, porous substances, plaster, chalk, sand, &c., the pumps, ventilators, bellows, agitators, which have been proposed to aërate the distilled water obtained, and render it palatable, are slow in their action, of a difficult, inconvenient, or impossible application; and as to leaving the distilled water to become aërated by the agitation imparted to it in tanks or casks by the motion of the ship, this must be continued for a length of time, proportioned of course to the vigour of the oscillations imparted to the ship by the violence of the waves, and the time thus required is always considerable; yet in this way, and finally by pouring the water several times from one glass to another before drinking it, it may become fully aërated, but without entirely losing its vapid and nauseous taste and odour.

But before proceeding further, it may not be amiss to say a few words respecting another condition in the construction of marine condensing machines, which, from not being sufficiently taken into account, frequently puts them suddenly out of service, or necessitates constant repairs.

The question which had hitherto been left unanswered, and yet which must be integrally solved before success could be hoped for, is the following:—

To obtain, with a small proportion of fuel, large quantities of fresh, inodorous, salubrious, aërated water, without the help of chemical reagents, by means of a self-acting and compact apparatus capable of being worked at all hours, under all latitudes, in all weathers and conditions compatible with the existence of the ship itself, and incapable of becoming incrusted, or of otherwise going out of order.

How this complex and difficult problem was solved by Dr. Normandy we now proceed to explain:—

It is a known property of steam that it becomes condensed into water again, whenever it comes in contact with water at a temperature lower than itself, no matter how high the temperature of that condensing water may be.

It is known that the sea and other natural waters are saturated with air containing a larger proportion of oxygen and of carbonic acid than the air we breathe. In effect, 100 volumes of the air held in solution in water contain from 32 to 33 volumes of oxygen, whereas 100 volumes of ordinary atmospheric air contain only 24 volumes of oxygen. Again, ordinary atmospheric air contains only $\frac{1}{4000}$ of carbonic acid, whereas the air held in solution in water contains from 40 to 42 per cent. of carbonic acid.

Experiments undertaken with a view to determine the amount of these gases present in water, showed that this amount varied with the state of purity of the water; that whilst ordinary rain-water contains, on an average, 15 cubic inches of oxygenised air per gallon, it was constituted as follows:—

Carbonic acid	6·26
Oxygen	5·04
Nitrogen	3·70
	15·00

Sea water, owing to the various substances which it holds in solution, contains only on an average 5 cubic inches of gases, more than one-half of which is carbonic acid; or, in other words, 1 gallon of sea water contains about two-thirds less gases than ordinary rain-water, and one-half less gases than river water.

It has been ascertained that air begins to be expelled from such natural waters when the temperature reaches about 130° Fahr.; and we know that when the temperature reaches 212° Fahr., all the air which it contained has been expelled, and it is for this reason that distilled water contains no air.

The apparatus invented by Dr. Normandy is represented in *figs.* 2100, 2101. It consists of three principal parts—an evaporator, a condenser, and a refrigerator—joined so as to form one compact and solid mass, screwed and bolted, without soldering or brazing of any kind. The evaporator is a cylinder, partly filled with sea water, into which a sheaf of pipes is immersed, so that on admitting steam at a certain pressure into these pipes it is condensed into fresh, though non-aërated water by the sea water by which the pipes are surrounded, that sea water being thus heated and a portion of it evaporated at the same time; for it is one of the properties of steam to be condensed by water, no matter how high the temperature of that water may be, if it be only inferior to that of the steam. This non-aërated water becomes aërated, as will be explained below. On board steamers, the steam is obtained directly from the boilers of the ship; in sailing-vessels it is procured from a small boiler which may, or may not be connected with the hearth, galley, or caboose.

The steam at a pressure being, of course, hotter than ordinary boiling water, serves to convert a portion of the water contained in the evaporator into ordinary or non-pressure steam, which, as it reaches the pipes in the condenser, B, is resolved into fresh aërated water. By thus evaporating water under slight pressure, one fire performs double duty, and thus the first condition, that of economy, is completely fulfilled, for while, in the usual way, 1 lb. of coal evaporates at most 6 or 7 lbs. of water, the same quantity of coals, put under the same boiler, but in connection with this apparatus, is thus made to evaporate 12 or 14 lbs. of water; or, in other words, from the same amount of coals or of steam employed, the machine which is described will produce double the quantity of fresh water that can be obtained by simple or ordinary distillation; that is to say, double the quantity obtained by the ordinary condensers.

The comparative trials made in 1859 on board H.M. ships the Sphynx, Erebus, and Odin, at Portsmouth, before the Commissioners of the Admiralty, most conclusively proved the perfect accuracy of that statement.

The steam issuing from the evaporator, and which is condensed by the water in the condenser, imparts, of course, its heat to the sea water in it; and as this water is admitted cold at the bottom, whilst the steam of the evaporator is admitted at the top of the condenser, the water therein becomes hotter and hotter gradually as it ascends, and when it finally reaches the top its temperature is about 208° Fahr.

It has been already stated that water begins to part with its air at a temperature of about 130° Fahr., therefore the greater portion of the air contained in the water which flows constantly and uninterruptedly through the condenser is thus separated, and led through a pipe into the empty space left for steam-room within the evaporator, where it mixes with the steam.

Now, as about six gallons of sea water must be discharged for every gallon of fresh water which is condensed, and as each gallon of sea water contains, as was said before, 5 cubic inches of air, and whereas the utmost quantity of it that fresh water can naturally absorb is 15 cubic inches per gallon, it follows that the steam in the evaporator, before it is finally condensed, has been in contact with twice as much air as water can take up, the result being a production of fresh water to the maximum of aëration, that is, containing as much air as in pure rain-water.

This aëration of the water to the maximum and with the air naturally contained in the water in its original state, though a condition of the utmost importance, Dr. Normandy having failed in removing the odour and taste in question, it became necessary to try to discover whence came that flavour which no aëration could destroy, except after a considerable length of time, and even then never perfectly. That water has the power of absorbing and dissolving organic matter is, of course, well known, but it may be illustrated in a very simple manner, as follows:—If water, from whatever source, be distilled, the distillate will, of course, be fresh water, pure fresh water, but it will have a peculiar, nauseous, and empyreumatic taste and odour, stronger in proportion as the heat applied to evaporate it has been more elevated; it is that smell and taste which render it undrinkable for a while. If, when it has become sweet again by long standing, which period may be hastened by agitation in the atmosphere, that distilled water be then re-distilled, the distillate will be found to have acquired again the same empyreumatic taste and odour as when it was first distilled. How is this?—Because it will, by standing or agitation, have re-dissolved a portion of the air in the room in which it was kept, and along with that air it will have absorbed whatever substances were present, dissolved or suspended in it, and those substances by their contact with the heated surfaces of the still, yield an empyreumatic product, which taints the distillate. On board ships, the water which is stored in for the use of crews in the usual way, in the course of about a fortnight becomes putrid and almost undrinkable, because the organic matter which that water contains is undergoing putrefactive fermentation. But about a month or so afterwards the water gradually becomes sweeter and sweeter, until at last it becomes drinkable again; because, eventually, all the organic matter which it contained becomes decomposed, carbonic acid and water being the result, and although the air of a ship's hold is none of the sweetest, such water, as just said, generally remains afterwards perfectly good and palatable; because, the tanks in which it is kept, being covered up, it is sheltered from fresh pollutions, and because it is now saturated with pure air, and therefore cannot absorb that of the atmosphere.

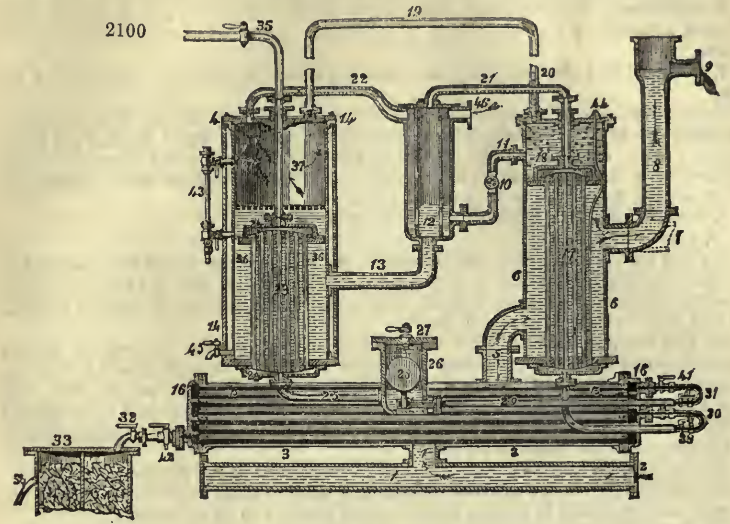
When the natural waters supplied to our habitations are obtained from impure sources, as is unfortunately too often the case, the evils resulting from their use may in some degree be remedied by putting in practice the recommendation which has been sometimes made, of boiling such water previous to employing it as a beverage; unfortunately, the water being thereby deprived of air is, like distilled water, though in a less degree, unpalatable and vapid and heavy; it is, in fact, of difficult digestion; but there is something worse than that; water which has been boiled, or which has been distilled, by reason of its containing *no air*, has a great tendency to absorb or to take that of the media where it is kept, so that if distilled water which contains no air be kept in a ship's hold, or in an impure and confined place, it will absorb precisely the quantity of air which it can absorb, namely, 15 cubic inches per gallon, and if that air be loaded with organic particles or impure emanations, it will soon become fœtid and putrid. The experiments of Dr. Angus Smith have proved that if a stream of air which has already been breathed be passed through water, the latter will retain a peculiar albuminoïd matter which undergoes putrefaction with extraordinary rapidity; and the water which condenses on the cold exterior surfaces of vessels in crowded rooms possesses the same character, and acquires in a short time an offensive odour; now this is to a great extent the case with the water of ordinary condensers when allowed to become spontaneously aërated on board ship. Thus water, though distilled, if kept in tainted rooms, will soon become foul. The only condition necessary for distilled water not to become putrid or offensive is to saturate it with *pure air*, because in that case there is no room left for other gases to impregnate it (at least, practically speaking, and in the ordinary conditions of domestic or of ship economy) and to keep it in covered vessels or tanks.

Fig. 2100 is a section, all on the same plane, showing the mode of action of the apparatus, without reference to the real position of its constituent parts. *Fig.* 2101 is a correct front elevation of the apparatus.

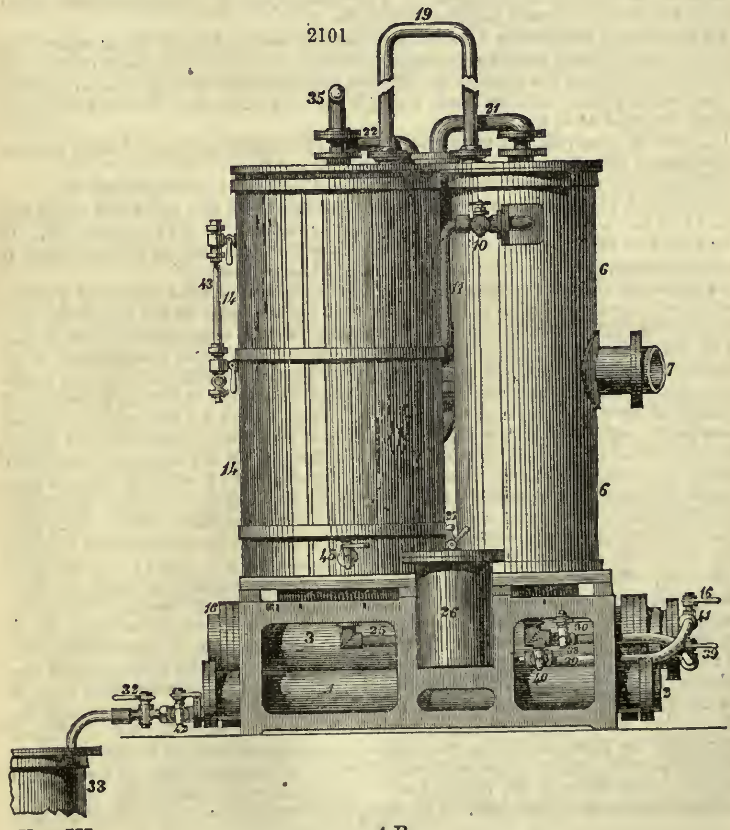
1 shows the large entrance tube for the sea water: this tube is connected to a large cock, communicating with the sea through the side or bottom of the ship; or else flanged to a much smaller pipe connected with a pump, by means of which the apparatus is supplied with water from the sea, which thus penetrates into the refrigerator 3, through the tube of communication 4, and thence passes round the sheaf of pipes 15, in the said refrigerator, through another communication tube 5, into the condenser 6, as shown by the arrows, and up the large vertical tube 8, whence the surplus sea water pumped up flows away through the pipe 9, in the direction indicated by the arrows. The condenser, 6, being thus completely filled up with sea water, on opening the cock 10, the sea water passing through pipe 11 falls into the feed and priming box 12, and thence through pipe 13 into the evaporator 14, filling it up to a certain level, regulated by opening or shutting the cock 10 so as to maintain the sea water at the proper level in the evaporator 14.

3, *Refrigerator.* It is a horizontal case pervaded with pipes 15, placed horizontally in it. The sea water being introduced into this refrigerator, circulates round a sheaf of pipes 15, held between the caps 16, at each end of the said refrigerator, so that the fresh water which has been condensed in the pipes 23, of the evaporator 14, and in the pipes 17 of the condenser 6, is thereby cooled down to the temperature of the sea water outside.

2100



2101



4, large pipe connecting the pipe 1 with the refrigerator 3.

5, large pipe connecting the refrigerator 3 with the condenser 6.

6, *Condenser.* It is a cylinder containing a sheaf of pipes 17, into which the non-aërated steam from the evaporator is condensed by the sea water which surrounds them.

7, large outlet tube, used only when the apparatus is put below the level of the sea.

8, large upright tube, which, when the apparatus is placed on deck is turned upwards, and is of such a length that the sea water which is forced through the apparatus by means of the pump, or otherwise, may be raised a few feet above the whole apparatus, so that there may be in the large tube 8, a column of sea water higher than the condenser 6, in order to keep it quite full.

9, overflow pipe for the escape of the excess of sea water.

10, cock of the feed pipe.

11, feed pipe, one end of which is inserted in the condenser 6, and the other end in the feed and priming box 12. It is through this feed pipe 11, that the sea water is led from the top of the condenser into the feed and priming box 12, by opening the cock 10 to a suitable degree, as said before 1.

12, feed and priming box. It is a box into which, on opening the cock 10, the sea water supplied from the condenser 6, by pipe 11, passes through pipe 13 into the evaporator 14, which is thus fed with the proper quantity of sea water. This feed box receives also any priming which might be mechanically projected by or carried along with the steam through pipe 22. In such a case the priming is then returned to the evaporator 14, through pipe 13.

13, feed-pipe leading to the sea water to be evaporated in the evaporator 14.

14, *Evaporator.* It is a cylinder containing a sheaf of pipes 23, with their caps, 24, at each end, immersed in the sea water, part of which is to be evaporated.

15, sheaf of pipes of the refrigerator 3, for the purpose of cooling the fresh water produced ; has been already described under No. 3.

16, caps of the refrigerator 3, so arranged that by means of the divisions reserved in the said caps, the steam from the boiler, and that evolved from the evaporator 14, are both made to travel to and fro through the different pipes 15 consecutively, so as eventually to flow out in a mixed and cold state through the cock 32 in the filter 33, and finally through the tube 34 in a perfect state.

17, sheaf of pipes placed between the two caps 18 of the condenser 6, for the purpose of condensing the aërated steam from the evaporator 14.

18, caps covering the end of the sheaf of pipes 17 placed in the condenser 6.

19, aërating pipe leading the air which separates from the sea water round the pipes 17 of the condenser 6 into the steam-room or chamber of the evaporator 14. It is by means of this aërating pipe that the fresh water condensed in the condenser 6 becomes aërated, and this aëration is accomplished as follows :—

As the steam from the evaporator 14 enters the pipes within the condenser 6 at the top thereof, through the pipe 21, it follows that the sea water at the top of the condenser 6 is brought, as was already said under No. 11, to a temperature which, at the top of the said condenser, is as high as 206° or 208° Fahr. ; this temperature, as we also said of No. 11, gradually diminishes from the top downwards, but at a zone corresponding to about the point marked by No. 7, the temperature of the sea water round the sheaf of pipes 17 is reduced to about 140° Fahr. As the air naturally contained in sea water begins to separate therefrom at about 130° Fahr., that in the sea water round the sheaf of pipes 17, between No. 7 and the top of the condenser, becoming entirely liberated, ascends, by virtue of its lighter weight, to the top of the said condenser 6 ; it then passes through the aërating pipe 19, and is then poured into the steam-room 37 of the evaporator 14, wherein it mixes with the secondary steam therein produced by the evaporating pipes 23. This mixture of air and steam passes then through pipes 22 into the feed and priming-box 12, and thence through pipe 21 into the sheaf of pipes 17. The air being there absorbed during the condensation of this secondary steam, with which it was mixed, the condensed fresh water resulting therefrom becomes thus super-aërated, and in passing subsequently through the cock 39 of pipe 30 into a portion of the pipes 15 of the refrigerator 3, it mixes there with the non-aërated fresh water, resulting from the steam of the boiler, which has condensed in the pipes 23 of the evaporator 14, which condensed water flows through pipe 25 into the steam-trap 26, thence along pipes 29 and 31, and through the cock 41, into the other portion of pipes 15 of the refrigerator 3. The condensed water from the pipes 23 of the evaporator 14 becomes aërated by the excess of air contained in the condensed water of the pipes 17 of the condenser, in its passage with the latter through the pipes 15 of the refrigerator 3, in traversing which the combined waters are cooled down to the temperature of the sea water round the said sheaf of pipes in the refrigerator. And the result is, that after passing through the filter it flows at 34 in the state of perfectly cold fresh water, thoroughly aërated, and of matchless quality.

20, level to which the sea water rises in the aërating pipe 19.

21, pipe conducting the mixture of steam and air from the feed and priming-box 12 into the sheaf of pipes 17 of the condenser 6.

22, pipe leading the mixture of steam and air from the evaporator 14 into the feed and priming-box 12, where any salt water, with which it may be mixed, is arrested and returned to the evaporator 14, through pipe 13, while the pure steam, passing through pipe 21, is next condensed in the sheaf of pipes 17 of the condenser 6.

23, sheaf of pipes immersed in the sea water 36 of the evaporator 14, and in which pipes the steam coming from the boiler through the steam-pipe 35 is condensed, after which it flows as distilled but *non-aërated* fresh water into the lower cap 24, and thence through pipe 25 into the steam-trap 26, thence through the pipes 29 and 31 and cock 41 into the sheaf of pipes 15 of the refrigerator 3.

24, upper and lower caps covering the two extremities of pipes 23 of the evaporator 14, into which pipes the steam from the boiler diffuses itself, and is condensed, after which it flows in the state of distilled but non-aërated fresh water, through pipe 25 into the steam-trap 26. and thence through pipes 29 and 31 into the pipes 15 of the refrigerator 3, in which it mixes with the *aërated* water coming through pipe 30, and passing through pipe 32 into the filter 33, finally issues at pipe 34 in the state of cold, matchless, aërated fresh water, *immediately fit for consumption.*

25, pipe for the exit of the condensed non-aërated fresh water from the sheaf of pipes 23, of the evaporator 14, which water, after entering the steam-trap 26, issues therefrom through pipe 29, and then enters the refrigerator as already said.

26, steam-trap. It is a box containing a float 28, provided with a plunger acting in such a way that when the box contains only steam, or a quantity of condensed water, not sufficient to buoy the float, it (the plunger) closes the exit pipe 29; but as soon as the condensed water has accumulated in quantity sufficient to buoy the float up, the plunger, of course, rising with the float, no longer obstructs the exit pipe 29, and accordingly the condensed water may then escape as fast as it is produced.

27, small pet cock on the top of the cover of the steam-trap 26.

28, float already described (26).

29, pipe leading the condensed non-aërated water from the steam trap 26, through pipe 31, into the pipes 15 of the refrigerator 3, in which it mixes with the aërated fresh water from the condenser.

30, pipes leading the condensed aërated water from the pipes 17 of the condenser 6, into the pipes 15 of the refrigerator 3, in which it mixes with the non-aërated water from the steam.26. This pipe is provided with two cocks, 38 and 39, for the purpose of cleaning the condenser 6.

31, pipe leading the condensed non-aërated water from pipe 29 into the pipes 15 of the refrigerator, in which it mixes with the aërated water from the condenser.

32, exit-pipe and cock, through which the mixed distilled waters (aërated and non-aërated), after passing through the pipes of the refrigerator, enter the filter 33.

33, filter for receiving the condensed water from both the evaporator and the condenser, as they issue in a mixed and cold state from the pipes 15 of the refrigerator 3, through cock and pipe 32.

34, pipe for the final exit of the perfect aërated fresh water.

35, steam-pipe and cock leading the steam more or less under pressure from any description of boiler to the pipes 23 of the evaporator 14. It is connected at one end with the steam-boiler, and at the other with the upper cap, 24, of the evaporating pipes 23.

36, sea water, to be evaporated by the steam-pipes 23, of the evaporator 14.

37, steam room, or space into which the air naturally contained in the sea water used for condensation in the condenser 6, is poured through the aërating pipe 19, so as to mix with the steam generated by the pipes 23 of the evaporator.

38 and 39, two cocks on pipe 30, placed between the condenser 6 and the refrigerator 3, for the purpose of clearing the pipes 17 of the condenser 6.

40 and 41, two cocks placed on pipe 31, for the purpose of clearing the pipes 23 of the evaporator 14, and steam-trap 26.

42, cock placed between the cap 16 of the refrigerator 3, and the cock 32, for the purpose of cleaning the pipes 15 of the refrigerator 3.

43, glass water-gauge.

44, breathing-pipe. It is a small pipe, one end of which is in communication with the lower cap 18 of the condensing-pipes 17, and the other end is open to the atmosphere. The object of this pipe is not only to remove pressure from the cylinders, but likewise to afford an exit for the excess of air generated.

45, brine cock.

46, opening reserved in the feed and priming-box.

The first thing to be done is, of course, to charge the apparatus with sea water. This is done by establishing a communication between the apparatus and the sea water round the ship. This is easily effected by turning on the large cocks, or Kingston valves, connected with the large orifices 2 and 7 (see the figures), whereupon the salt water immediately fills up both the refrigerator 3 through the passage 4 and the condenser 6 through the passage 5, up to a certain point 20 of the aërating pipe.

Opening now the cock 10 of the feed pipe 11 the sea water will pass from the condenser 6 into the feed and priming-box 12 and thence through pipe 13 into the evaporator 14, where it should be allowed to rise up to about one third of the glass gauge, 43, when the cock 10 should be shut up. The apparatus being thus charged with its proper quantity of sea water; the steam-boiler being ready to furnish the necessary steam; and admitting, of course, that the steam-pipe 35 is in communication with the said boiler, the next thing to be done is to open the steam-cock, 35, shutting at the same time the cocks, 39, 41, and 32, and opening cocks, 38, 40, and 42, and likewise the small pet cock 27 of the steam-trap 26. On opening the small pet cock 27 nothing but air will at first rush out; but, presently, steam will issue from it; it should then be closed more and more gradually as the steam is seen issuing from it with rapidity; and it should eventually be left *almost*, but not altogether, shut up, so as to leave only room for the smallest possible wreath of steam slowly to issue from it. As soon as the steam-cock 35 is open, and the steam from the boiler will rush through that cock into the sheaf of pipes 23 of the evaporator 14, in which pipes it will be condensed by the sea water which surrounds them, and it will then flow in the state of condensed non-aërated distilled water through the pipe 25 into the steam-trap 26; lift up the float 22, and passing through pipe 29, will flow through cock 40, its further progress being intercepted by cock 41, which is shut, as said before. As soon as the condensed water flows out in a clear state from cock 40, shut it, and open cock 41, so that it may pass into the pipes 15 of the refrigerator 3, and out at cock 42. In a few moments the condensed water will flow out in a clear state from that cock, 42, which should then be closed, opening at the same time cock 32, so that it may pass into the filter 33.

But the steam within the sheaf of pipes 23 of the evaporator 14 soon brings the sea water round them to the boiling point, and converts part of it into steam. This pure secondary steam from the evaporator, issuing then from the priming-box 12, passes through pipe 21 into the pipes 17 immersed in the salt water of the condenser 6, and being condensed in the said pipes, is allowed to flow out at the cock 38 (which has been opened at starting), as long as it is not clear. In a short time, however, it will flow out from that cock 38, in a perfectly clear state; when this takes place shut this cock 38, and open cock 39, whereupon it will flow into the pipes 15 of the refrigerator 3, in which pipes it will mix with that coming from the pipes 23 of the evaporator 14, and flow with it through the said pipes 15, and thence into the filter 33 through the cock 32, the whole issuing finally from the filter 33 through pipe 34, in the state of perfectly aërated fresh water.

From this brief description of Dr. Normandy's marine fresh-water apparatus it may be seen that a quantity of fresh water is produced *always double* that which can be evaporated from any boiler whatever, and indeed by increasing the number of evaporators 1 lb. of coals may thus be made to yield 30 or 40 lbs. of fresh water of matchless quality. The small volume of the apparatus, the large quantity of fresh aërated water which it produces, at an extremely small cost, its perfect safety, permanent order, and the ease with which it can be disconnected, and all its parts reached, not only render it pre-eminently suited to naval purposes, but likewise to such stations or places as are deficient in one of the first necessaries of life, salubrious fresh water, or where it cannot be obtained at all, or only in an insufficient, precarious, or expensive manner.

WATTLE BARK. See Bark.

WAX (*Cire*, Fr.; *Wachs*, Ger.) is the substance which forms the cells of bees. It was long supposed to be derived from the pollen of plants, swallowed by these insects, and merely voided under this new form; but it has been proved by the experiments, first of Mr. Hunter, and more especially of M. Huber, to be the peculiar secretion of a certain organ, which forms a part of the small sacs situated on the sides of the median line of the abdomen of the bee. On raising the lower segments of the abdomen these sacs may be observed, as also scales or spangles of wax, arranged in pairs upon each segment. There are none, however, under the rings of the males and the queen. Each individual has only eight wax sacs, or pouches; for the first and the last wing are not provided with them. M. Huber satisfied himself by precise experiments that bees, though fed with honey or sugar alone, produced nevertheless a very considerable quantity of wax; thus proving that they were not mere collectors of this substance from the vegetable kingdom. The pollen of plants serves for the nourishment of the larvæ.

But wax exists also as a vegetable product, and may, in this point of view, be regarded as a concrete fixed oil. It forms a part of the green fecula of many plants, particularly of the cabbage; it may be extracted from the pollen of most flowers, as also from the skins of plums and many stone-fruits. It constitutes a varnish upon the upper surface of the leaves of many trees, and it has been observed in the juice of the *cow-tree*. The berries of the *Myrica angustifolia*, *M. latifolia*, as well as the *M. cerifera*, afford abundance of wax.

Bees' wax, as obtained by washing and melting the comb, is yellow. It has a peculiar smell, resembling honey, and derived from it, for the cells in which no honey has been deposited yield a scentless white wax. Wax is freed from its impurities, and bleached, by melting it with hot water or steam, in a tinned-copper or wooden vessel, letting it settle, running off the clear supernatant oily-looking liquid into an oblong trough with a line of holes in its bottom, so as to distribute it upon horizontal wooden cylinders made to revolve half immersed in cold water, and then exposing the thin ribbons or films thus obtained to the blanching action of air, light, and moisture. For this purpose the ribbons are laid upon long webs of canvas stretched horizontally between standards, 2 feet above the surface of a sheltered field, having a free exposure to the sunbeams. Here they are frequently turned over, then covered by nets to prevent their being blown away by winds, and watered from time to time, like linen upon the grass field in the old method of bleaching. Whenever the colour of the wax seems stationary, it is collected, re-melted, and thrown again into ribbons upon the wet cylinder, in order to expose new surfaces to the bleaching operation. By several repetitions of these processes, if the weather proves favourable, the wax eventually loses its yellow tint entirely, and becomes fit for forming white candles. If it be finished under rain, it will become grey on keeping, and also lose in weight.

In France, where the purification of wax is a considerable object of manufacture, about 4 ounces of cream of tartar or alum are added to the water in the first melting-copper, and the solution is incorporated with the wax by diligent manipulation. The whole is left at rest for some time, and then the supernatant wax is run off into a settling cistern, whence it is discharged by a stopcock or tap over the wooden cylinder revolving at the surface of a large water-cistern, kept cool by passing a stream continually through it.

The bleached wax is finally melted, strained through silk sieves, and then run into circular cavities in a moistened table, to be cast or moulded into thin disk pieces, weighing from 2 to 3 ounces each, and 3 or 4 inches in diameter.

Neither chlorine nor even the chlorides of lime and alkalis can be employed with any advantage to bleach wax, because they render it brittle, and impair its burning quality.

Wax purified as above is white and translucent in thin segments; it has neither taste nor smell; it has a specific gravity of from 0·960 to 0·996; it does not liquefy till heated to 154½° Fahr.; but it softens at 86°, becoming so plastic that it may be moulded by the hand into any form. At 32° it is hard and brittle.

It is not a simple substance, but consists of two species of wax, which may be easily separated by boiling alcohol. The resulting solution deposits, on cooling, the waxy body called *cerine*. The undissolved wax being once and again treated with boiling alcohol, finally affords from 70 to 90 per cent. of its weight of cerine. The insoluble residuum is the *myricine* of Dr. John, so called because it exists in a much larger proportion in the wax of the *Myrica cerifera*. It is greatly denser than wax, being of the same specific gravity as water; and may be distilled without decomposition, which cerine undergoes. Professor B. C. Brodie made an extensive series of researches into the constitution of wax. He applies the name *cerotic acid* to cerine, and represents its formula as $C^{54}H^{54}O^{4}$ ($\mathbf{C^{27}H^{54}O^{2}}$). Pure myricine he considers to be represented by $C^{92}H^{92}O^{4}$ ($\mathbf{C^{46}H^{92}O^{2}}$). Myricine is a palmitate of myricyl.

Wax is adulterated sometimes with starch; a fraud easily detected by oil of turpentine, which dissolves the former and leaves the latter substance: and more frequently with mutton-suet. This fraud may be discovered by dry distillation; for wax does not thereby afford, like tallow, sebasic acid (benzoic), which is known by its occasioning a precipitate in a solution of acetate of lead. It is said that 2 per cent. of a tallow sophistication may be discovered in this way.

Wax is sometimes adulterated with stearine, which can be detected, according to Lebel, even when only in 1–20th part. It may be recognised by dissolving the specimens in two parts of oil, agitating with water, and adding acetate of lead. The precipitate thus obtained is said to exhibit a very high degree of solidity.

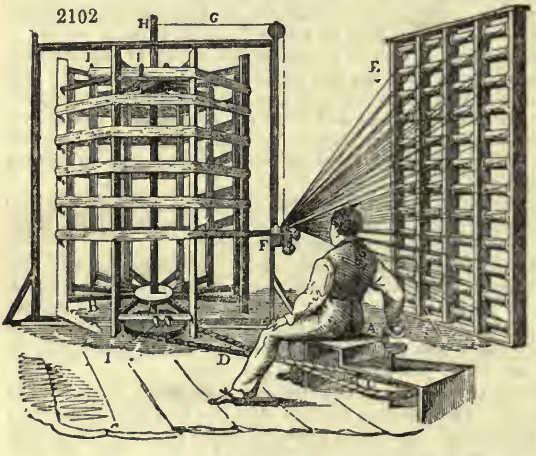
Wax *Imported* in 1873:—42,689 tons; value, 221,951*l*.
Wax *Exported* in 1873:—20,260 cwts.; value, 104,600*l*.

WAX CANDLES. Wax contains 81·75 parts of carbon in 100, which generate by combustion 300 parts of carbonic acid gas. Now, since 125 grains of wax constitute the average consumption of a candle per hour, these will generate 375 grains of carbonic acid; equivalent in volume to 800 cubic inches of gas. According to the most exact experiments on respiration, a man of ordinary size discharges from his lungs 1,632 cubic inches of carbonic acid gas per hour, which is very nearly the double of the quantity produced from the wax candle. Hence the combustion of two such candles vitiates the air much the same as the breathing of one man. A tallow candle, three or four in the pound, generates nearly the same quantity of carbonic acid as the wax candle; for though tallow contains only 79 per cent. of carbon, instead of 81·75, yet it consumes so much faster, as thereby to compensate fully for this difference.

When a tallow candle of 6 to the lb. is not snuffed, it loses in intensity, in 30 minutes, 80-hundredths, and in 39 minutes, 86-hundredths; in which dim state it remains stationary, yet still consuming nearly the same proportion of tallow. A wax candle attains to its greatest intensity of light when its wick has reached the greatest length, and begins to bend out of the flame. The reason of this difference is, that only the lower part of the wick in the tallow candle is charged with the fat, so as to emit luminiferous vapour, while the upper part remains dry; whereas, in the wax candle the combustible substance being less fusible and volatile, allows a greater length of the wick to be charged by capillary attraction, and of course to emit a longer train of light.

WEAVING (*Tissage*, Fr.; *Weberei*, Ger.) is performed by the implement called *loom* in English, *métier à tisser* in French, and *Weberstuhl* in German. The process of warping must always precede weaving. Its object is to arrange all the longitudinal threads, which are to form the chain of the web, alongside of each other in one parallel plane. Such a number of bobbins, filled with yarn, must therefore be taken as will furnish the quantity required for the length of the intended piece of cloth. One-sixth of that number of bobbins is usually mounted at once in the warp mill, being set loosely in a horizontal direction upon wire-skewers, or spindles, in a square frame, so that they may revolve, and give off the yarn freely. The warper sits at A, *fig.* 2102, and causes the reel B to revolve, by turning round with his hand the wheel B, with the endless rope or band D. The bobbins filled with yarn are placed in the frame E. There is a sliding piece at F, called the *heck* box, which rises and falls by the coiling and uncoiling of the cord G, round the central shaft of the reef H. By this simple contrivance the band of warp-yarns is wound spirally from top to bottom upon the reel. I, I, I, are wooden pins which separate the different bands. Most warping-mules are of a prismatic form, having twelve, eighteen, or more sides. The reel is commonly about 6 feet in diameter and 7 feet in height, so as to serve for measuring exactly upon its periphery the total length of the warp. All the threads from the frame E pass through the heck F, which consists of a series of finely-polished, hard-tempered steel pins, with a small hole at the upper part of each to receive and guide one thread. The heck is divided into two parts, either of which may be lifted by a small handle below, while their eyes are placed alternately. Hence, when one of them is raised a little, a vacuity is formed between the two bands of the warp; but when the other is raised, the vacuity is reversed. In this way the lease is produced at each end of the warp, and it is preserved by appropriate wooden pegs. The lease being carefully tied up affords a guide to the weaver for inserting his lease-rods. The warping-mill is turned alternately from right to left, and from left to right, till a

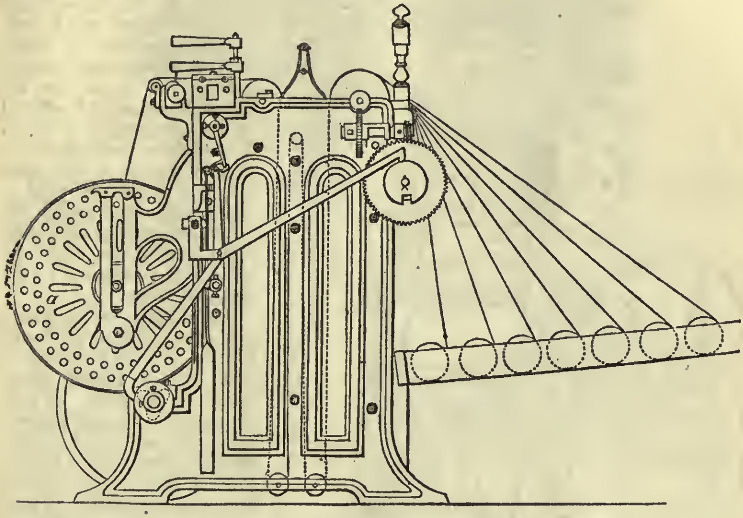
2102



sufficient number of yarns are coiled round it to form the breadth that is wanted; the warper's principal care being to tie immediately every thread as it breaks, otherwise, deficiencies would be occasioned in the chain, injurious to the appearance of the web, or productive of much annoyance to the weaver.

Fig. 2103 shows another form of warping-mill, known as the beam-warping machine, and generally in use for yarns above 20*s.* in counts, as by its use more perfect work can be produced, and at a less cost than on the vertical warping-mill. It is supplied with a letting-back motion, whereby, when a thread is broken, the motion of the winding-on beam, or drum, is reversed, and by the aid of a simple arrangement of falling iron rods, the thread may be easily found and reunited. It has also a self-acting measuring and stopping motion, by means of which the machine is promptly stopped the

2103



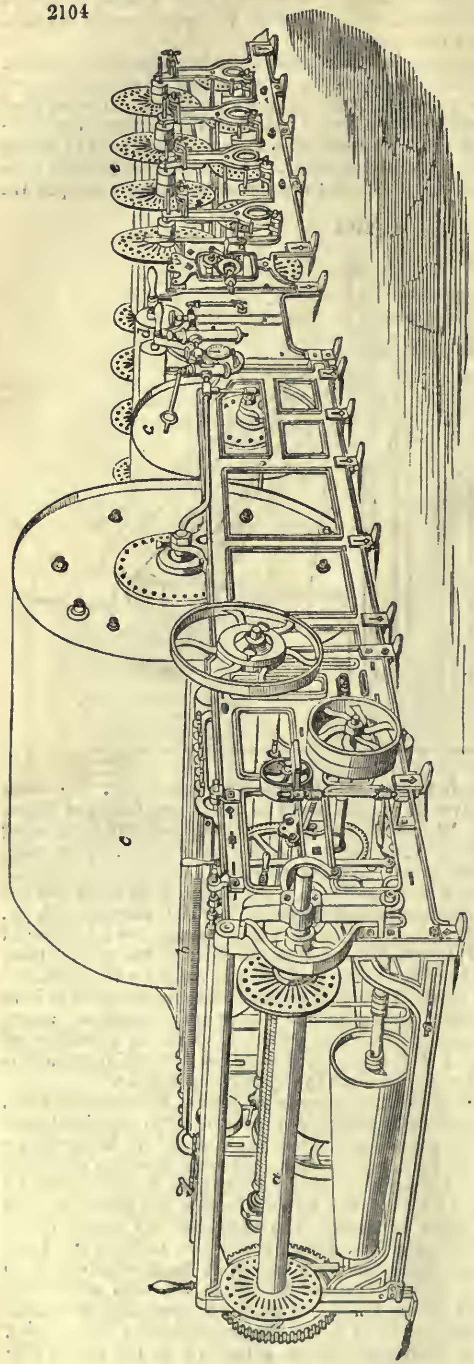
moment the proper length of yarn is wound on to the weavers' warp-beam. The drum on which the weavers' beam revolves, is so constructed as to suit any length of beam, by being expanded or contracted. A comb or raithe, on the expanding or contracting principle, guides the threads with precision on to any length of beam. As a rule, young women are preferred to men for working this machine.

When a warp has been made, it requires to be sized before it is ready for the loom; for that purpose, it is taken as a ball from the vertical warping-mill, *fig.* 2102, and sized in a sizing-trough, and then dried by being passed over a number of hot cylinders, when it is wound by the beamer into the weavers' beam, and then, having been drawn in or twisted in to the healds and reeds, is ready for the loom.

In the case of a warp made in the horizontal or beam-warping machine, it is at once wound on a beam, and thence taken to the slasher sizing-machine, where, forming one of six or eight beams, its yarn is passed through the operations of sizing and drying, in one passage, and at once wound on to the weavers' beam, and is then ready to have attached the healds and reeds in the ordinary manner.

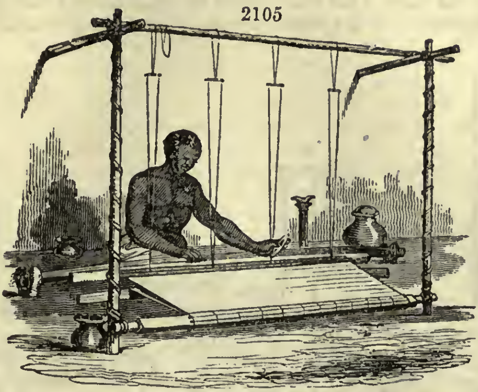
Fig. 2104 shows the slasher sizing-machine, as made by Messrs. Harrison and Sons, machinists, Blackburn. This machine is sufficient to size for 300 shirting-looms, and is managed by one man. The yarn is taken from the weavers' (8) beams shown in *fig.* 2103, and passed through boiling size, and then over the two cylinders, which are heated by steam, and having been dried by them, is at once wound on to the weavers' beam. The stand on which the warpers' beams are placed, is made so as to be adjustible to any length of beam. The flanges of the beams are of lined iron, and are convex on the inner side, to allow the yarn to leave the beam freely. The boiling box through which the yarn passes, is lined with copper to prevent oxidisation. The rollers in the box are hooped at the ends with brass, and run upon brass pullies, thus saving the roller ends, and producing a smooth motion. The size roller, or squeezer, is of heavy copper, without a seam, being cast solid, afterwards bored, and then expanded on a mandril to the proper diameter. By being made seamless, the acid in the size does not effect any brazed part, and by being thick and heavy, the rollers last longer and squeeze better. The machine is supplied with an apparatus which prevents any undue tension on the yarn while in a wet state; the elasticity of the yarn is thus retained, and broken threads in weaving largely prevented, thus securing quantity and quality in the loom. By the introduction of syphon-boxes and a self-acting apparatus to admit only a definite and certain quantity of steam into the cylinders, economy is effected in the consumption of steam. The machine *itself* gives notice, by ringing a bell, when a given length of yarn is sized, and also marks the length of a cut: an expanding comb guides the even and sheet-like threads on to the weavers' beam.

2104



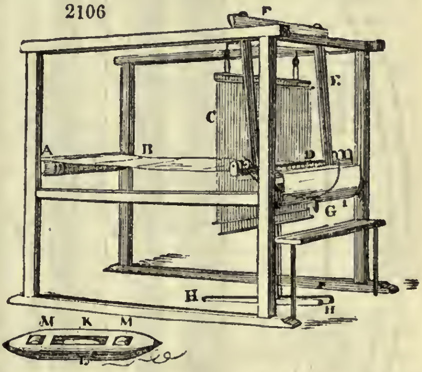
The simplest and probably the most ancient of looms now to be seen in action is that of the Hindû *tanty*, shown in *fig.* 2105. It consists of two bamboo rollers: one for the warp, and another for the woven cloth; with a pair of heddles, for parting the warp, to permit the weft to be drawn across between its upper and under threads. The shuttle is a slender rod, like a large netting-needle, rather longer than the web is broad, and is made use of as a batten or lag, to strike home or condense each successive thread or weft, against the closed fabric. The Hindu carries this simple implement, with his water pitcher, rice pot, and hooka, to the foot of any tree which can afford him a comfortable shade; he there digs a large hole, to receive his legs, along with the traddles or lower part of the harness; he next extends his warp, by fastening his two bamboo rollers at a proper distance from each other, with pins, into the sward; he attaches the heddles to a convenient branch of the tree overhead: inserts his great toes into two loops under the gear, to serve him for treddles; lastly, he sheds the warp, draws through the weft, and beats it close up to the web with his rod shuttle or batten.

2105



The European loom is represented in its plainest state, as it has existed for several centuries, in *fig.* 2106. A is a warp-beam, round which the chain has been wound; B represents the flat rods, usually three in number, which pass across between its threads, to preserve the lease, or the plane of decussation for the weft; C shows the heddles or healds, consisting of twines looped in the middle, through which loops the warp-yarns are drawn, one-half through the front heddle, and the other through the back one; by moving which, the decussation is readily effected. The yarns then pass through the dents of the reed under D, which is set in a moveable swing-frame E, called the lathe, lay, and also batten, because it *beats* home the weft to the web. The lay is freely suspended to a cross-bar F, attached by rulers, called the *swords*, to the top of the lateral standards of the loom, so as to oscillate upon it. The weaver, sitting on the bench G, presses down one of the treddles at H, with one of his feet, whereby he raises the corresponding heddle, but sinks the alternate one; thus sheds the warp, by lifting and depressing each alternate thread through a little space, and opens a pathway or race-course for the shuttle to traverse the middle of the warp, upon its two friction rollers M M. For this purpose, he lays hold of the picking-peg in his right hand, and with a smart jerk of his wrist drives the fly-shuttle swiftly from one side of the loom to the other, between the shed warp-yarns. The shoot of weft being thereby left behind from the shuttle pirn or cop, the weaver brings home, by pulling the lay with its reed towards him by his left hand, with such force as the closeness of the texture requires. The web, as thus woven, is wound up by turning round the cloth beam I, furnished with a ratchet-wheel, which takes into a holding-tooth. The plan of throwing the shuttle by the picking-peg and cord, is a great improvement upon the old way of throwing it by hand. It was contrived upwards of a century ago, by John Kay, of Bury, in Lancashire, but then resident in Colchester, and was called the 'fly-shuttle,' from its speed, as it enabled the weaver to make double the quantity of narrow cloth, and much more broad cloth, in the same time.

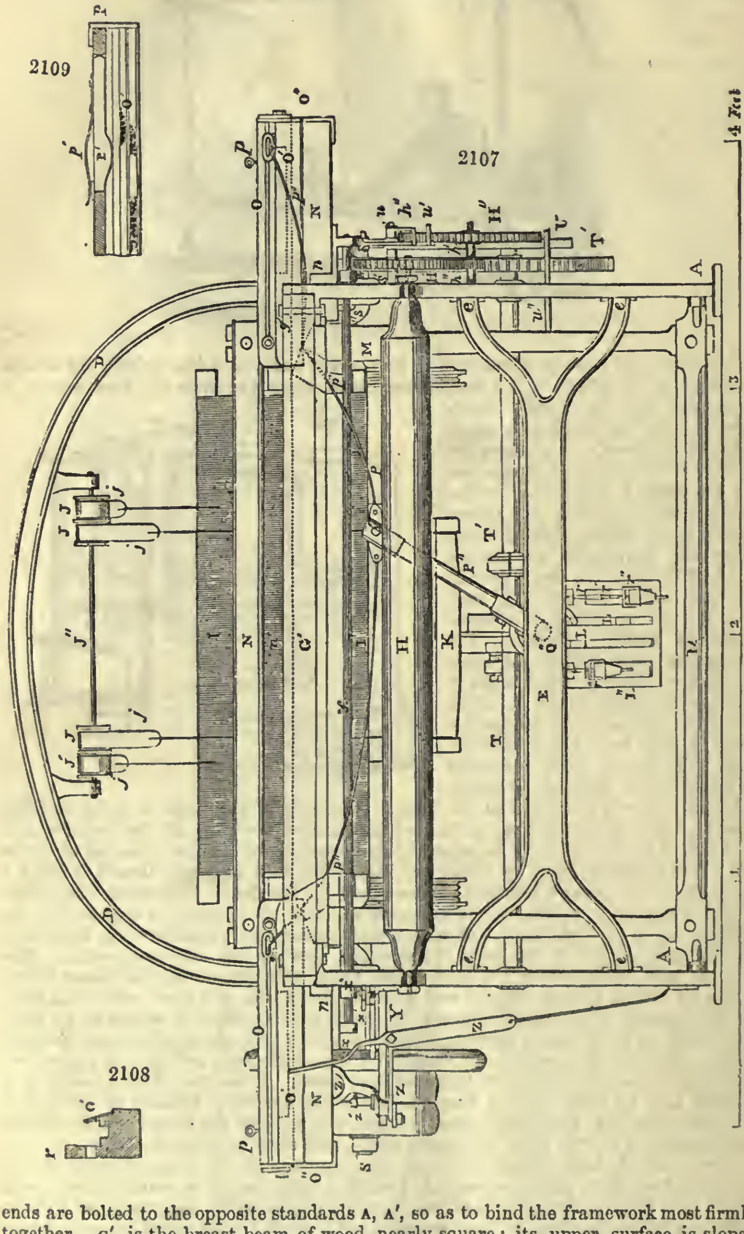
2106



The cloth is kept distended during the operation of weaving, by means of two pieces of hard wood, called 'a templet,' furnished with sharp iron points in their ends, which take hold of the opposite salvages or lists of the web. The warp and web are kept longitudinally stretched by a weighted cord, which passes round the warp-beam, and which tends continually to draw back the cloth from its beam, where it is held fast by the ratchet-tooth. See FUSTIAN, JACQUARD LOOM, REED, and TEXTILE FABRICS.

The greater part of plain weaving, and much even of the figured, is now performed by the power-loom, called *métier mécanique à tisser* in French. *Fig.* 2107, represents the cast-iron power-loom of Sharp and Roberts. A, A', are the two side uprights, or standards, on the front of the loom, D, is the great arch of cast iron which binds the two sides together. E, is the front cross-beam, terminating in the forks e, e; whose

2109 2107 2108



ends are bolted to the opposite standards A, A', so as to bind the framework most firmly together. G', is the breast beam of wood, nearly square; its upper surface is sloped a little towards the front, and its edge rounded off for the web to slide smoothly over it in its progress to the cloth beam. The beam is supported at its end upon brackets, and is secured by the bolts g', g'. H, is the cloth beam, a wooden cylinder mounted with iron gudgeons at its ends, that on the right hand being prolonged to carry the tooth winding wheel H′. h', is a pinion in gear with H′. H″, is a ratchet-wheel, mounted upon the same shaft h''', as the pinion h'. h'', is the click of the ratchet-wheel H″. h''', is a long bolt fixed to the frame, serving as a shaft to the ratchet-wheel H″, and the pinion h'. I, is the front heddle-leaf, and I′, the back one. J, J, J′, J′, jacks or pulleys and straps for raising and depressing the leaves of the heddles. J″, is the iron shaft which carries the jack or system of pulleys, J, J, J′, J′. K, a strong wooden ruler, connecting the front heddle with its treddle. L, L′, the front and rear marches or treddle pieces for depressing the heddle-leaves alternately, by the intervention of the rods k (and k', hid behind k). M, M, are the two swords (swing bars) of the lay or batten. N, is the upper cross-bar of the lay, made of wood, and supported upon the squares of the levers n, n', to which it is firmly bolted. N′, is the lay-cap, which is placed higher or lower, according to the breadth of the reed; it is the part of the lay which the hand-loom weaver seizes with his hand, in order to swing it towards him. n', is the reed contained between the bar N, and the lay-cap N′. O, O, are two rods of iron, perfectly round and straight, mounted near the ends of the batten-bar N, which serve as guides to the drivers or peckers o, o, which impel the shuttle. These are made of buffalo-hide, and should slide freely on their guide-rods. O′, O′, are the fronts of the shuttle-boxes; they have a slight inclination backwards; P is the back of them. (See *figs.* 2108 and 2109.) O″, O″, are iron plates, forming the bottom of the shuttle-boxes. p, small pegs or pins, planted in the posterior faces P (*fig.* 2107) of the boxes, round which the levers P′ turn. These levers are sunk in the substance of the faces P, turned round pegs p, being pressed from without inwards, by the springs p'. P″, *fig.* 2107 (to the right of K), is the whip or lever-end; Q″, its centre of motion (corresponding to the right arm and elbow of the weaver), which serves to throw the shuttle by means of the pecking-cord p'', attached at its other end to the drivers O, O.

On the axis of Q″, a kind of excentric or heart wheel is mounted, to whose concave part, the middle of the double band or strap r, being attached, receives impulsion; its two ends are attached to the heads of the bolts r', which carry the stirrups r'', that may be adjusted at any suitable height, by set screws.

S (see the left-hand side of *fig.* 2107) is the moving shaft of wrought iron, resting on the two ends of the frame. S′ (see the right-hand side), is a toothed wheel, mounted exteriorly to the frame, upon the end of the shaft S. S″ (near S′), are two equal elbows in the same direction, and in the same plane, as the shaft S, opposite to the swords M, M, of the lay.

Z, is the loose, and Z′, the fast pulley, or riggers, which receive motion from the steam-shaft of the factory. Z′, a small fly-wheel, to regulate the movements of the main shaft of the loom.

T, is the shaft of the excentric tappets, cams, or wipers, which press the treddle-levers alternately up and down; on its right end is mounted T′, a toothed wheel in gear with the wheel S′, of one half its diameter. T′, is a cleft clamping collar, which serves to support the shaft T.

U, is a lever which turns round the bolt u. as well as the clink h''. U′, the click of traction, for turning round the cloth beam, jointed to the upper extremity of the lever U; its tooth u', catches in the teeth of the ratchet-wheel H″. u'' is a long slender rod, fixed to one of the swords of the lay M, serving to push the lower end of the lever U, when the lay retires towards the heddle-leaves.

X, is a wrought-iron shaft, extending from the one shuttle-box to the other, supported at its ends by the bearings, x, x.

Y, is a bearing, affixed exteriorly to the frame, against which the spring bar Z rests near its top, but is affixed to the frame at its bottom. The spring falls into a notch in the bar Y, and is thereby held at a distance from the upright A, as long as the band is upon the loose pulley z'; but when the spring bar is disengaged, it falls towards A, and carries the band upon the fast pulley z, so as to put the loom in gear with the steam-shaft of the factory.

Weaving, by this powerful machine, consists of four operations: 1, to shed the warp by means of the heddle-leaves, actuated by the tappet-wheels upon the axis Q′, the rods k, k', the cross-bar E, and the eyes of the heddle-leaves I, I′; 2, to throw the shuttle (see *fig.* 2107), by means of the weft lever P″, the driver cord p, and the pecker o; 3, to drive home the weft by the batten N, N′; 4, to unwind the chain from the warp beam, and to draw it progressively forwards, and wind the finished web upon the cloth beam H, by the click and toothed wheel mechanism at the right-hand side of the frame.

See COTTON, FLAX, TEXTILE FABRICS, &c.

WEAVING BY ELECTRICITY. So long ago as 1852, M. Bonelli constructed an electric loom, which was exhibited at that time in Turin; but the first trial to which the machine was submitted gave but small hope to those who saw it that the inventor would succeed in his object. The public trial at Turin, in 1853, in the presence of manufacturers, was not so successful as to remove all doubts as to the merits of the novel apparatus. In the following year it was submitted to the judgment of the Academy of Sciences at Paris, who appointed a committee to examine it, but it is believed that no report was ever made. In 1855, a model of the loom had a place at the Universal Exhibition of Paris, but the lateness of its arrival there prevented any official report being made in reference to its merits. M. Bonelli afterwards devoted much time and attention in endeavouring to remedy its defects and to perfect its working, so as to render it capable of holding its place in the factory. This M. Bonelli believed he had at last accomplished, and he brought over to this country not merely a model, but a loom in complete working order, which he submitted to the judgment of manufacturers, as a machine, which, from its economy and efficiency, might be put in favourable comparison with the Jacquard loom.

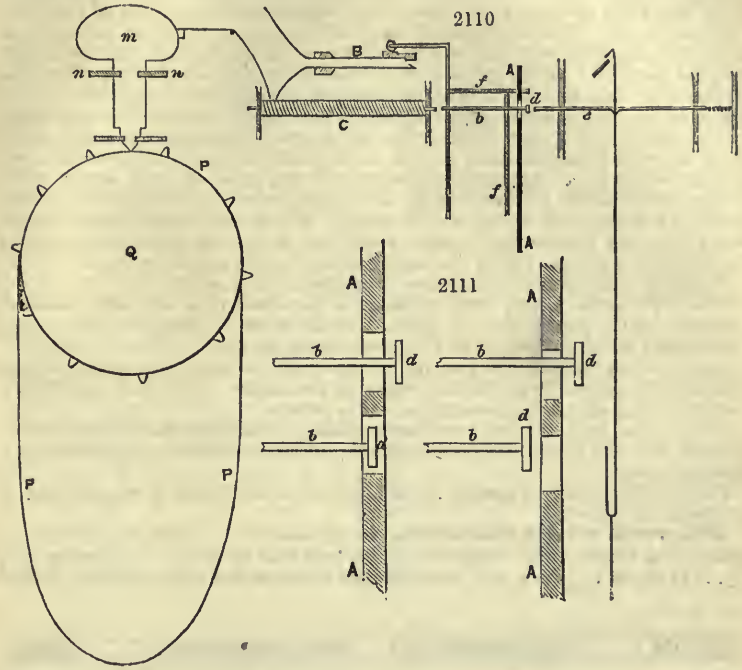
In the first place, it must be understood that the special object of M. Bonelli's machine was to do away with the necessity for the Jacquard cards used to produce the pattern at the present time, the source of delay and very considerable cost, more especially in patterns of any extent and variety of treatment. M. Bonelli used an endless band of paper, of suitable width, the surface of which is covered with tin-foil. On this metallised surface, the required pattern is drawn, or rather painted with a brush in black varnish, rendering the parts thus covered non-conducting to a current of electricity. This band of paper, bearing the pattern, being caused to pass under a series of thin metal teeth, each of which is in connection with a small electro-magnet, it will be readily conceived that as the band passes under these teeth, a current of electricity from a galvanic battery may be made to pass through such of the teeth as rest on the metallised or conducting portion of the band, and from such teeth, through the respective coils, surrounding small bars of soft iron, thus rendering them temporary magnets, while no current passes through those connected with the teeth resting on the varnished portions. Thus, at every shift of the band, each electro-magnet in connection with the teeth becomes active or remains inactive according to the varying portion of the pattern which happens to be in contact with the teeth. In a moveable frame opposite the ends of the electro-magnets, which, it should be stated, lie in a horizontal direction, are a series of small rods or pistons, as M. Bonelli termed them, the ends of which are respectively opposite to the ends of the electro-magnets. These pistons are capable of sliding horizontally in the frame, and pass through a plate attached to the front of it. When this frame is moved so that the ends of the pistons are brought into contact with the ends of the electro-magnets they are seized by such of them as are in an active state, and on moving the frame forward, those are retained while the others are carried back with it, and, by means of a simple mechanical arrangement, becomes fixed in their places; thus there is in front of the frame a plate, with holes, which are only open where the pistons have been withdrawn, and this plate, as will be readily understood, acts the part of the Jacquard card, and is suitable for receiving the steel needles which govern the hooks of the Jacquard in connection with the warp threads as ordinarily used.

The ordinary Jacquard cards are shown in the following woodcut, *fig.* 2110.

Instead of this arrangement, which will be understood by reference to the article Jacquard, M. Bonelli, as we have said, instead of the cards prepares his design on metal foil, in a resinous ink, which serves to interrupt the current, and thus effect the object of the machine.

Figs. 2110 and 2111 explain generally the arrangements by which the process is effected.

A, *fig.* 2110, represents the plate pierced with holes, which plays the part of the card. Each of the small pistons or rods, *b*, forming the armatures of the electro-magnets *c*, have a small head, *d*, affixed to the end, exactly opposite the needles, *e*, of the Jacquard, and are capable of passing freely through the holes of the plate, A. At a given moment the plate is slightly lowered, which prevents the heads of the pistons passing, and the surface of the plate then represents a plain card. The pistons are supported on a frame, *f f*, which allows them to move horizontally in the direction of their length. At each stroke of the shuttle, the frame, carrying with it the plate A, has, by means of the treddle, a reciprocating motion backwards and forwards, and in its backward movement presents the end of the pistons to one of the poles of the electro-magnets, and, by means of certain special contrivances, contact with the magnets is secured. When the frame, *f f*, returns with the plate A towards the needles of the Jacquard, the electro-magnets, which become temporarily magnetised by the electric current, hold back the pistons, the heads of which pass through the plate A, and rest behind it. On the other hand, the electro-magnets which are not magnetised, owing to the course of the current being interrupted, permit the other pistons to be carried back, their heads remaining outside the plate and in front of it. At this moment, the plate, by means of an inclined plane beneath it, is lowered slightly, thus preventing the heads of the pistons passing through the holes, by the edges of which they are stopped, so as to push against the needles of the Jacquard;



2110

2111

on the other hand, the heads of the pistons which have passed within and to the back of the plate, leave the corresponding holes of the plate free, and the needles of the Jacquard which are opposite to them are allowed to enter.

The electro-magnets are put into circuit in the following manner: One of the ends of the wire forming the coil of each of the magnets is joined to one common wire in connection with one of the poles of a galvanic battery. The other end of the coil-wire of each magnet is attached to a thin metallic plate, *m*, having a point at its lower extremity. All these thin metallic plates are placed side by side, with an insulating material between them, formed like the teeth of a comb, *n n*. At a given time, these thin plates rest with their lower extremities on the sheet bearing the design P, which, in the form of an endless band, is wrapped round and hangs upon the cylinder, Q, and according as the thin metal-plate rests on a metallised or on a non-conducting portion of the design, the corresponding electro-magnet is or is not magnetised, and its corresponding piston does not or does press against the needle of the Jacquard. The wire from the other pole of the battery of course communicates with the band bearing the design, by being attached to a piece of metal, which lies in constant contact with the metallic edge of the band. At B is a contact-breaker, which is put in motion by the movement of the frame. Besides this, by means of a mechanical arrangement connected with the treddle, which raises or depresses the griff frame, the band bearing the design is carried forward at each stroke, and the rapidity with which it is made to travel can readily be regulated, by means of gearing, at the will of the workman. By regulating the speed of the band, and by the use of thicker or thinner weft, an alteration in the character of the woven material may be made, whilst the same design is produced, though in a finer or coarser material.

Such are the arrangements by which the loom will produce a damask pattern, or one arising from the use of two colours, one in the warp, and the other in the weft. The method adopted by M. Bonelli for producing a pattern where several colours are required will now be explained.

The design is prepared on the metallised paper, so that the coloured parts are represented by the metallised portion of the band, but each separate colour is, by removing a very thin strip of the foil at the margin, insulated from its neighbouring colour. Then all the pieces of foil thus insulated, which represent one colour or shade, are connected with each other by means of small strips of tin-foil, which pierce through the paper and are fastened at the back, and are conducted to a strip of tin-foil which runs along the edge of the band, there being as many such strips of tin-foil as there are colours. Thus each special colour of the pattern, in all its parts, is connected by a conductor with its own separate strip of tin-foil, and by bringing the wire from the pole of the battery successively into contact with the several strips, a current of electricity may be made to pass in succession through the several parts of the design on the band representing the separate colours of the design. Thus, assuming four colours, 1, 2, 3, 4, there would be four strips of tin-foil running the length of the band, insulated from each other, each of which would be in connection with its own separate colour only. At any given moment, the thin plates of metal resting on the pattern would touch in a line which, as it passes over the width of the pattern, would run through all, or any one or more of the colours, but the electric current would pass only through those plates which rest on the one colour represented by the strip with which the pole of the battery at that instant was in contact.

The inventor claims the following as the results of his invention :—

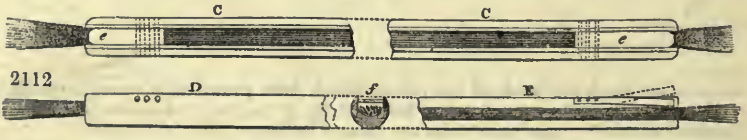
First.—The great facility with which, in a very short time, and with precision, reductions of the pattern may be obtained on the fabric by means of the varying velocity with which the pattern may be passed under the teeth.

Second.—That without changing the mounting of the loom or the pattern, fabrics thinner or thicker can be produced by changing the number of the weft, and making a corresponding change in the movement of the pattern.

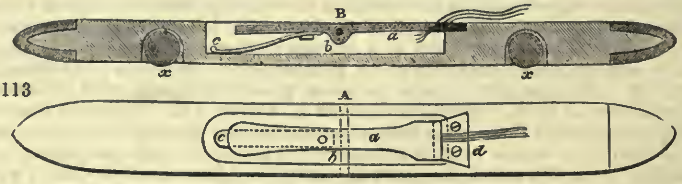
Third.—The loom and its mounting remaining unchanged, the design may be changed in a few minutes by the substitution of another metallised paper having a different pattern.

Fourth.—The power of getting rid of any part of the design if required, and of modifying the pattern.

WEAVING OF HAIR-CLOTH. In addition to the description of this art under Hair, a short notice is required of the best kind of shuttle for weaving hair. *Fig.* 2113 shows in plan A, and in longitudinal section B, a shuttle which differs from



2112



2113

that of the common cloth-weaver only in not having a pirn enclosed in the body of the box-wood, but merely an iron trap *a*, which turns in the middle upon the pin *b*. This trap-piece is pressed up at the one end, by the action of the spring *c*, so as to bear with its other end upon the cleft of the iron plate *d*, which is intended to hold fast the ends of the hair-weft: *d* and *c* together are called 'the jaws' or 'mouth,' whence the popular name of this shuttle. The workman opens this jaw by the pressure of his thumb upon the spring end of the trap *a*, introduces with the other hand one or more hairs (according to the description of hair-cloth,) into the mouth, and removing his thumb, lets the hairs be seized by the force of the spring. The hairs having one end thus made fast are passed across the warp by the passage of the shuttle, which is received at the other end by the weaver's left hand. The friction rollers, *x*, *x*, are like those of fly-shuttles, but are used merely for convenience, as the shuttle cannot be thrown swiftly from side to side. The hand which receives the shuttle opens at the same time the trap, in order to insert another hair, after the preceding has been drawn through the warp on both sides and secured to the list. A child attends to count and stretch the hairs. This assistant may, however, be dispensed with by means of the following implement, represented in *fig* 2112. C, C is the view of it from above, or the plan; D is a side view; E a longitudinal section, and *f* an oblique section across. The chief part consists in a wooden groove, or chamfered slip of wood, open above, and rounded on the sides. It is about 21 inches in length, about as long nearly as the web is broad, therefore a little shorter than the horse-hairs inserted in it, which project about an inch beyond it at each end. They are herein pressed down by elastic slips, *e*, of india-rubber, so that the others remain, when one or more are drawn out by the ends. The ends of the grooves are flat where the india-rubber spring exerts its pressure, as shown by the dotted line *f*. The spring is formed by cutting out a double piece from the curvature of the neck of a caoutchouc bottle or flask, fastening the one end of the piece by a wire staple in the groove of the shuttle, whereby the other end, which alone can yield, presses upon the inlaid hair. Wire staples like *f* (in the section E) are passed obliquely through two places of the groove or gutter, to prevent the hairs from springing up in the middle of the shuttle, which is suitably charged with them. The workman shoves the tool across the opened warp with the one hand, seizes with the other the requisite number of hairs by the projecting ends, and holds them fast while he draws the shuttle once more through the warp. The remaining hairs are retained in the groove by the springs, and only those for the single decussation remain in the web, to be secured to the list on either side. A weaver with this tool can turn out a length of cloth double of what he could do with the mouth-shuttle.

WEBSTERITE. A hydrous subsulphate of alumina, found at Newhaven and Brighton, in Sussex; at Halle; and in several French localities.

WEFT (*Trame*, Fr.; *Eintrag*, Ger.) is the name of the yarns or threads which run from selvage to selvage in a web.

WEIGHING MACHINE. See BALANCE.

WEIGHTS and **MEASURES.** *Metrical and Imperial.* The metrical system originated with the government of Louis XV., who named a commission to pursue the investigations necessary to decide the principles upon which such a system could be carried out. An extensive series of observations were conducted during the reign of Louis XVI. Under his consent the Academy of Sciences decided that all the different weights, measures, and coinages should be established accessory to certain definite relations to the dimensions of the globe itself.

Delambre and Méchain ascertained the length of the earth's meridian in the portion between Dunkirk and Barcelona, and Arago and Biot that between Barcelona and Formentera. The length of the meridian from the Pole to the Equator, passing through Paris, was then divided into 10,000,000 parts, and one of these parts, called the *mètre*, became the basis of the new system.

Maupertuis had, in the year 1736, measured a portion of the arc of the meridian passing through the North Cape. His observations were therefore combined with the others by the commission. The distance from the Equator to the Pole, which is really 10,000,738, was fixed at 10,000,000. This standard is, therefore, the ten-millionth part of the quadrant of the terrestrial meridian; and from the measurements and calculations which were made at that period on the arc of the meridian which extended from Barcelona to Dunkirk, it was reckoned to be 39·371 inches of the English standard yard, which contained 36 inches. Thus the French mètre, which is longer than the English yard by $3\frac{1}{4}$ inches, or more accurately by $3\frac{10}{27}$ inches, is the standard of all the measures and weights of France. Its decimal multiples are successively denoted by the prefixes *deca, heca, kilo*, &c., which signify 10, 100, 1000, &c., times respectively; and its decimal submultiples or fractions successively by the prefixes *deci, centi, milli*, &c., which signify $\frac{1}{10}$, $\frac{1}{100}$, $\frac{1}{1000}$, &c., parts respectively. The mètre itself was made the unit of lineal measure and itinerary distances.

A bar of platinum was constructed representing the length of the mètre as accurately as possible; and this bar, or others directly or indirectly copied from it, is the standard unit of length throughout France, and in many other countries which have herein followed her example. It is equal to 39·371 English inches, and is about $\frac{1}{4}$ of an inch longer than a pendulum vibrating seconds at the level of the sea in London.

2114

The mètre is divided decimally downwards, into décimètres, centimètres, and millimètres (*fig.* 2114); and multiplied decimally upwards into décamètres, hectomètres, kilomètres, and myriamètres; the latter being, as is implied by its name, equal to 10,000 mètres of the scale.

A *décimètre*, as its name implies, is the tenth part of a mètre. In like manner a *centimètre* is the hundredth part, and a *millimètre* is the thousandth part, of a mètre.

A square formed upon a line of ten mètres is the unit of superficial or land measure; and a cube which has a *décimètre* (or one-tenth of a mètre) for its measuring line, is called a *litre*—the unit of capacity. Each of these is increased or diminished by multiples or submultiples of ten; but for the convenience of those who prefer halves and quarters to tenths, each may be, and often is, divided in this manner, though all arithmetical calculations are performed decimally. The fundamental unit of weight is the *kilogramme*. which is the weight of a litre of distilled water, at its greatest density, which is a little above the freezing-point. The thousandth part of a kilogramme is called a *gramme*.

To recapitulate:—

The multiples of the *mètre* are the *déca*mètre = 10 mètres.
" " *hecto*mètre = 100 mètres.
" " *kilo*mètre = 1000 mètres.
" " *myria*mètre = 10,000 mètres.

The submultiples of the mètre are the *déci*mètre = the 10th part of a mètre.
" " *centi*mètre = the 100th part of a mètre.
" " *milli*mètre = the 1000th part of a mètre.

The unit of surface is the *are*, which is the square of 10 mètres on a side, or 100 superficial mètres. The usual multiples and submultiples are the *hect*-are, a square of 100 mètres on a side, and the *centi*-are, the mètre superficial. These terms are employed in the sale of land, and in agricultural discussions.

The unit of weight is the *gramme*, which is the equivalent of a cube of distilled water, at the zero of the Centigrade scale (32° of Fahrenheit), measuring a centimètre every way. The multiples are:—

The *Décagramme* . . . . . . = 10 grammes.
" *Hectogramme* . . . . . . = 100 grammes.
" *Kilogramme* . . . . = 1000 grammes.

The submultiples are:—

The *Décigramme* . . . . . = the 10th part of a gramme.
" *Centigramme* . . . . . = the 100th part of a gramme.
&c. &c.

A thousand kilogrammes will form a cube measuring a mètre on every side, and it is made the legal *ton* for heavy weights.

The unit of capacity is the *litre*, which is the equivalent of a cube measuring one-tenth part of a mètre every way. The multiples are the *décalitre*, the *hectolitre*, the *kilolitre*, and the submultiples, the *décilitre*, the *centilitre*, &c. The *litre* is usually employed in expressing the quantities of liquids. A thousand litres of water are equal to a mètre cube every way, and one ton in weight. The *hectolitre* is used in expressing the measures of grain.

The following Tables, constructed by Mr. Warren De La Rue, and published in his 'Diary and Almanack,' are reproduced here by his obliging permission:—

French Measures of Length.

	In English inches	In English feet = 12 inches	In English yards = 3 feet	In English fathoms = 6 feet	In English miles = 1760 yards

1 lb. avoirdupois=0·453593 kilogramme. 1 cwt.=50·802377 kilogrammes.

Troy Weight, so called from Troyes, a town in the province of Champagne in France, now in the department of Aube, where a celebrated fair was held, appears to have come into general use in England about the time of Henry IV. The first mention of the term *Avoir du pois* occurs in a charter of 31 Edward I. 'Pound' is derived from the Latin *pondus*; 'ounce,' from *uncia*, or twelfth part, being the $\frac{1}{12}$th part of a lb. Troy.

Al measures of capacity were first taken from Troy weight; and several laws were passed in the reign of Henry III., enacting that 8 lbs. troy of wheat, taken from the middle of the ear, and well dried, should make 1 gallon of wine measure; and 8 such gallons made a bushel.

Avoirdupois Weight was first made legal in the reign of Henry VII., and its particular use was to weigh provisions and coarse, heavy articles. Henry fixed the stone at 14 lbs., which has been confirmed by a recent Act of Parliament.

Agreeably to the Act of uniformity, which took effect 1st January, 1826, the term 'measure' may be distinguished into eight kinds: viz., length, surface, volume, specific gravity, capacity, space, time, and motion.

Troy Weight.

Marks		Ounces	Dwts.	Grains
dwt.	Pennyweight . .	...	...	24
oz.	Ounce	...	20	480
lb.	Pound	12	240	5760

Troy weight is used for money, precious metals, and jewels. Also in philosophical experiments, though the more convenient decimal divisions of the French gramme are almost universally preferred by scientific chemists of the present time.

Apothecaries' Weight.

Marks		Ounces	Drams	Scruples	Grains
℈	Scruple . . .	...	...	...	20
ʒ	Dram . . .	...	...	3	60
℥	Ounce . . .	...	8	24	480
lb	Pound . . .	12	96	288	5760

The ounce and pound are the same as in Troy weight, but differently subdivided. A grain is alike in all weights.

Avoirdupois Weight.

	Cwts.	Quarters	Pounds	Ounces	Drams
Ounce (437½ grains).	...	...	...	...	16
Pound (7000 grains)	...	...	...	16	256
Stone	...	...	14	224	3584
Quarter . . .	...	...	28	448	7168
Hundred-weight .	...	4	112	1792	28672
Ton	20	80	2240	35840	573440

This weight is used for all substances, except gold, silver, and precious stones. Drugs are sold by this weight, but medicines are compounded by Apothecaries' weight.

Measures of Length.—The imperial standard yard is divided into 3 feet, and each foot into 12 inches, and its length is fixed (see Act of Parl. 5 Geo. IV. c. 74) by reference to the length of the pendulum vibrating seconds in the latitude of London, in a vacuum at the level of the sea; the former being to the latter in the proportion of 36 imperial inches to 39·1393 imperial inches. The length of the seconds pendulum at Greenwich is 39·13929 inches; at Leith Fort (nearly the parallel of Glasgow), under the same circumstances, it is 39·1555 imperial inches; and at New York, 39·1017 imperial inches. The imperial standard yard may, however, be more distinctly defined as the distance between the points of oscillation and suspension of a pendulum vibrating in a mean solar day (in a vacuum at the level of the sea,) at London 90,088 times. The Scotch standard ell (the use of which is now abolished,) measured 37 imperial inches.

An inch, formerly divided into 3 barleycorns, is now the smallest lineal measure to which a name is given, but subdivisions are used for many purposes.

Cloth Measure.

	Quarters	Nails	Inches
Nail	...	...	2¼
Quarter	...	4	9
Yard	4	16	36
Ell	5	20	45
French ell . . .	6	24	54

Long Measure.

Inches	Links	Feet	Yards	Pole or Perch	Chains	Furlongs	Mile
7·92	1	...	...	...	...	...	...
12	1·515	1	...	...	...	...	...
36	4·545	3	1	...	...	...	...
198	25	16·5	5·5	1	...	...	...
792	100	66	22	4	1	...	...
7920	1000	660	220	40	10	1	...
63360	8000	5280	1760	320	80	8	1

In Ireland the perch contains 7 yards, and the mile 2240.

Scotch and Irish linens, all sorts of woollen cloths, muslins, ribbons, cords, tapes, &c., are measured by the yard. Dutch linens, called Hollands, are bought by the Flemish ell, and sold by the English ell.

The yard in Cloth Measure is the same as in Long Measure, but differs in its divisions and subdivisions, as under:—

2¼ inches	make	1 nail	nl.	3 quarters	make	1 Flemish ell	Fl. ell.
4 nails	„	1 quarter	qr.	5 quarters	„	1 English ell	Eng. ell.
4 quarters	„	1 yard	yd.	6 quarters	„	1 French ell	Fr. ell.

Linear Measure.

	Furlongs	Chains	Poles	Yards	Feet	Inches
Foot	...	...	...	...	...	12
Yard	...	...	...	...	3	36
Pole or Rod	...	...	...	5½	16½	198
Chain of 100 links	...	...	4	22	66	792
Furlong	...	10	40	220	660	7920
Mile	8	80	320	1760	5280	63360

A League is 3 miles. A Hand (used in measuring horses), 4 inches. A Fathom, 2 yards, or 6 feet, or 72 inches.

A pendulum, which vibrates seconds of mean time in the latitnde of London, at the level of the sea and in a vacuum, measures 39·1393 inches. It is by an accurate subdivision of the length of such a pendulum that an inch, the fonndation of all other measures and weights, is obtained.

Land or Square Measure.

	Roods	Chains	Poles	Yards	Feet	Inches
Square foot	...	...	...	...	...	144
Square yard	...	...	...	...	9	1296
Square pole or rod	...	...	...	30¼	272¼	39204

Peck	...	...	...	2
Bushel	...	...	4	8
Quarter	...	8	32	64
Load or wey	5	40	160	320

The imperial gallon is the legal standard measure both for dry goods and liquids. It contains 277·274 cubic inches of distilled water when the barometer stands at 30 inches and thermometer at 62° Fahr. Under the same conditions an imperial gallon of water weighs 10 avoirdupois pounds or 70,000 grains. A cubic inch of water weighs 252·458 grains. A cubic inch of air weighs 0·310 grain.

Time Table.

	Days	Hours	Minutes	Seconds
Minute	...	...	...	60
Hour	...	...	60	3600
Day	...	24	1440	86400
Week	7	168	10080	604800

A common year is 52 weeks 1 day, or 365 days. Every year which will divide by 4 without leaving any remainder is a leap year, and contains 366 days, except 1900, 2100, &c. A century contains 36,524 days.

Memoranda connected with various Irregular Weights and Measures.

A barrel of beer, 36 gallons.
„ ale, 32 „
A butt of sherry, 108 gallons, or 52 dozen bottles.
Hogshead of French wine, 43 to 46 gals.
Aum of hock, 30 gallons.
Pipe of madeira, 92 gallons.
„ port, 115 „ or 57$\frac{1}{4}$ dozen bottles.
(Hogsheads one half, and quarter-casks one fourth part of that quantity.)
Pipe of Teneriffe, 100 gallons.
„ Lisbon, 117 „
„ Malaga, 105 „
Tun of wine, 252 gallons.
Hogshead of claret, 46 gallons.
Puncheon of brandy, 100 to 115 gallons.
Puncheon of rum, 90 to 100 gallons.
„ whisky, 120 „
A dicker of hides, 10 skins.
A last of hides, 20 dickers.
A dicker of gloves, 10 dozen pairs.
A box of raisins, 56 lbs.
Cask of rice, 7 to 8 cwts.
Chest of congou tea, 80 to 100 lbs.
Chest of hyson tea, 60 to 80 lbs.
Drum of figs, 6 to 14 lbs.
Pocket of hops, 1$\frac{1}{2}$ to 2 cwts.
A bag of hops, nearly 3$\frac{1}{2}$ cwts.
Firkin of butter, 56 lbs.
Load of hay or straw, 86 trusses.
Truss of hay, old, 56 lbs.
„ new, 60 lbs.
„ straw, 36 lbs.

Load of bricks, 500.
„ plain tiles, 1000.
Sack of flour, 280 lbs.
Tierce of sugar, 9 to 12 cwts.
„ coffee, 4 to 9 cwts.
Barrel of tar, 26¼ gallons.
Fodder of lead, 19½ cwts.
Gross, 144, or 12 dozen.
Quire of paper, 24 sheets.
Ream „ 480 sheets, or 20 quires.
Roll of parchment, 60 skins.
A weigh of cheese, 236 lbs.
5 quarters, a weigh or load.
A last of corn or rape-seed, 10 quarters or 80 bushels.
A last of potashes, cod-fish, white herrings, meal, pitch, and tar, 12 barrels.
A last of flax and feathers, 17 cwts.
A last of gunpowder, 24 barrels, or 2,400 lbs.
A last of wool, 4,568 lbs.
A tod of wool is 28 lbs.
A pack of ditto, 364 lbs.
48 solid feet of timber, a ton.
A stone of fish, 14 lbs., and of wool, 14 lbs. The same for horseman's weight, hay, iron, shot, &c.
A stone of glass, 5 lbs., and a seam of ditto, 24 stone.
A cade of red herrings, 500, and sprats, 1000.
A load of timber unhewed, 40 feet.
Flour, peck or stone, 14 lbs.
„ boll of 10 pecks or stones, 140 lbs.
„ sack of 2 bolls, 280 lbs.
„ barrel, 196 lbs.

Measures of Length.

A line is one-twelfth part of an inch.
A nail is 2¼ inches (used in measuring cloth).
A palm is 3 inches.
A hand is 4 inches (used in measuring the height of horses).
A span is 9 inches.
A cubit is 1½ foot.
A military pace is 2½ feet.
An itinerary pace is 5 feet.
A cable length is 120 fathoms, or 240 yards.
A league is 3 miles.
The knot, or nautical mile, 2,000 yards.
The old Scotch and Irish miles are 1⅛ and $1\frac{3}{11}$ English.

Coal Weights and Measures.

'From and after January 1, 1836, all coals, slack, culm, and cannel of every description shall be sold by weight and not measure, under a penalty of forty shillings.'
5 & 6 William IV.

The Chaldron. By this measure coal was formerly sold; it was 36 bushels or 12 sacks of coal.

The London imperial chaldron is about 25 cwts.
The Newcastle chaldron . . „ 53 cwts., or as about 11 to 21.

The relation of the chaldron to the ton in London is shown by the following results:—

			cwts.	qrs.	lbs.
1 chaldron of	Russell's Hatton's Wallsend	weighed	25	0	8
„	Lambton's Wallsend	„	25	3	9
„	Russell's „	„	25	0	0
„	Northumberland	„	25	1	25
„	Tanfield Moor	„	26	0	17
„	Stewart's Wallsend	„	26	0	18
„	Killingworth	„	25	0	13

Mean, 25 cwts. 2 qrs. 4 lbs.

3 wains of 17½ cwts. }
6 carts of 8½ „ } make a Newcastle chaldron, which is only 52½.

The Keel is 8 chaldrons or 21 tons 7 cwts. (sometimes 4 cwts.), or 8 tubs = 21 tons 4 cwts.

The Bolls or *Boults.* In 1600, at a 'Courte of the Hostmen,' wains were ordered to be marked and measured. 'For time out of mind it hath been ordered that all coal wains did usually carry and bring 8 boults of coals to all staithes upon the river Tyne.'

Pecks	Boll	Chaldron	tons	cwts.	lbs.
8	1	... . . .	0	4	23½
...	24	1 . . .	2	13	0
...	440	18¾ or 1 ten .	48	11	74

The Ten. A local customary and arbitrary weight, being usually 440 coal bushels of 36 gallons Winchester, or 48 tons 11 cwts. 2 qrs. 17 lbs. 9 ozs. The Dean and Chapter of Durham, to avoid fractions, make the Ten 432 bushels, or 47 tons 14 cwts. 420 bolls, or sometimes 440 bolls make 1 Ten.

A Load of Coals.

At Newcastle is	1 ton of 20 cwts.
„ Morpeth	⅔ ton.
„ „ (cart load) . .	15 to 16 cwts.
„ Lancashire	25 cwts.

A Waggon.

The Newcastle chaldron, 53 cwts. At Whitehaven, in 1826, 24 Carlisle bushels, weighing a little more than 2 tons.

About 25 years since the weight was 48 cwts. and it was increased to 50 cwts.

The Tub. In the Wear the best coal is put into tubs, these are waggons without wheels, containing each 53 cwts.

The Basket.

West Lancashire 6 cwts.
East „ 3 „ sometimes 4 cwts., according to the thickness of the 'mine.'

The Room. Coal-barges are divided into rooms, containing 180 bushels and 1 vat more, or 5 chaldrons and a vat.

The Vat, a quarter of a chaldron.
The Creel, sold in Ayrshire = 3 cwts.
An Acre of Stratum 1 foot thick is 31 tens.
An Acre of Coal = 1,510 tons.
A Fother of Coal = 17 cwts.

The Bushel.

Carlisle, 3 streaked Winchester weighing from 1 cwt. 2 qrs. 21 lbs. to 1 cwt. 3 qrs

Cornish . .	94 lbs. (Lean's Engine Report).	
London . .	82½ „	
Standard . .	86 „ avoirdupois	Distilled water
Imperial . .	79 to 82 lbs. contains	2218·192 C. I.
Winchester .	... ...	2150·42 C. I.

In Gutch's 'Literary and Scientific Register and Almanack' for 1872 the following statement of measures was given, which is so curious that it deserves preservation :—

'The Winchester bushel contains 2150·42 cubic inches, or 4 pecks; the *Waterside* measure contains 5 pecks. The old standard Scotch pint or sterling jug contains about 104 cubic inches, or 3 imperial pints; and the Scotch gallon contains 3 imperial gallons. The Scotch wheat firlot contains 24¼ Scotch pints; and the Scotch barley firlot, 31 Scotch pints. In Chester wheat is sold at 75 lbs. the bushel, or 9·23–28 gallons. In Cornwall (Launceston and Callington) the customary bushel is 16 gallons; at Helston, Falmouth, St. Austell, and Truro, the bushel consists of 24 gallons; at Redruth it is sold per 196 lbs. Cornish bushel; at St. Columb, 186 lbs., and at Bodmin, 62 lbs., per imperial bushel. In Devon a sack contains 40 gallons, a bag 16 gallons (in some parts 32 gallons); at Hereford wheat is sold sometimes by the bushel of 8 gallons, sometimes by the old bushel of 10 gallons, sometimes by weight, varying from 62 lbs. imperial, or 64 lbs. Winchester, to 80 lbs. old 10 gallons; in Norfolk, by the coomb of 4 bushels; in Northumberland (Alnwick, Morpeth, and Hexham markets), per new boll of 16 gallons; in Bedford and Wooller markets by the old boll of 48 gallons; in Salop the bushel is 75 lbs. net; York (North Riding), 63 lbs. per bushel; West Riding, at Wakefield corn exchange, per bushel of 60 lbs.; at the farmers' market, per the load of 3 bushels or 24 gallons measure, or load weighing 12 stone 12 lbs. (or 180 lbs.) to 14 stone (or 196 lbs.); at Leeds, Barnsley, Pontefract, Doncaster, Selby, Otley, Knaresborough, Ripon, Skipton, and Snaith, the same as at one or the other of Wakefield markets; Wales (Anglesea), at 63 lbs. per bushel; at Brecon, by the bushel of 8 gallons and the bushel of 10 gallons; Cardigan, 63 lbs.; Carmarthen, 64 lbs.; Flint, by the hobbet of 21 gallons, or 168 lbs.; Glamorgan (borough of Swansea), by the bushel or stack of 24 gallons, or by a measure called 'a peck,' containing 6 gallons. In the eastern part of the county there is also a bushel measure in use, called 'the Welsh bushel.' In Montgomery and Radnor the bushel is 10 gallons, or 80 lbs. weight. All local weights and measures are abolished, and a standard adopted that all grain, meal, flour, butter, and potatoes shall be sold by the Avoirdupois, by the score of 20 lbs., by the cwt. of 100 lbs., and by the ton of 2,000 lbs.; and that all hay, straw, turnips, and mangold-wurtzel shall be sold by the Avoirdupois, by the score of 20 lbs., by the cwt. of 100 lbs., and by the ton of 2,000 lbs.'

The *Ton* varies in a similarly unfortunate manner:—

The Statute ton	called short ton .	. 20 cwts. of	112 lbs.	= 2240 lbs

WELD, or *Dyer's Weed* (*Gande*, Fr.; *Wan*, Ger.) A biennial plant, native of Britain, Italy, and various parts of Europe; the *Reseda luteola* of botanists. Weld is preferred to all other substances in giving the lively green-lemon yellow to silk. Although the quercitron bark has almost superseded it in calico-printing, weld is still largely used in dyeing silk a golden yellow, and in paper-staining.

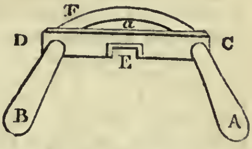
WELDING (*Souder*, Fr.; *Schweissen*, Ger.) is the property which pieces of wrought iron possess when heated to whiteness of uniting intimately under the hammer without any appearance of junction. See Iron.

WELLS, ARTESIAN. See Artesian Wells.

WHALEBONE (*Baleine*, Fr.; *Fischbeine*, Ger.) is the name of the horny laminæ, consisting of fibres laid lengthways, found in the mouth of the whale, which, by the fringes upon their edges, enable the animal to allow the water to flow out, as through rows of teeth (which are absent), from between its capacious jaws, but to catch and detain the minute creatures upon which it feeds. The fibres of whalebone have little lateral cohesion, as they are not transversely decussated, and may, therefore, be readily detached in the form of long filaments or bristles. The *blades*, or scythe-shaped plates, are externally compact, smooth, and susceptible of a good polish. They are connected, in a parallel series, by what is called the *gum* of the animal, and are arranged along each side of its mouth, to the number of about 300. The length of the longest *blade*, which is usually found near the middle of the series, is the gauge adopted by the fishermen to designate the size of the fish. The greatest length hitherto known has been 15 feet, but it rarely exceeds 12 or 13. The breadth, at the root end, is from 10 to 12 inches; and the average thickness, from four to five tenths of an inch. The series, viewed altogether in the mouth of the whale, resemble, in general form, the roof of a house. They are cleansed and softened before cutting, by boiling for 2 hours in a long copper.

Whalebone, as brought from Greenland, is commonly divided into portable junks or pieces, comprising ten or twelve blades in each; but it is occasionally subdivided into separate blades, the gum and the hairy fringes having been removed by the sailors during the voyage. The price of whalebone fluctuates from 50*l.* to 150*l.* per ton. The blade is cut into parallel prismatic slips, as follows:—It is clamped horizontally, with its edge up and down, in the large wooden vice of a carpenter's bench, and is then planed by the following tool, *fig.* 2115. A, B, are its two handles; C, D, is an iron plate, with a guide-notch E; F, is a semicircular knife, screwed firmly at each end to the ends of the iron plate C D, having its cutting edge adjusted in a plane, so much lower than the bottom of the notch E, as the thickness of the whalebone slip is intended to be for different thicknesses: the knife may be set by the screws at different levels, but always in a plane parallel to the lower guide surface of the plate C D. The workman, taking hold of the handles A, B, applies the notch of the tool at the end of the whalebone blade furthest from him, and with his two hands pulls it steadily along, so as to shave off a slice in the direction of the fibres; being careful to cut none of them across. These prismatic slips are then dried, and planed level upon their other two surfaces. The fibrous matter detached in this operation, is used, instead of hair, for stuffing mattresses.

2115



From its flexibility, strength, elasticity, and lightness, whalebone is employed for many purposes; for ribs to umbrellas or parasols; for stiffening stays; for the framework of hats, &c. When heated by steam- or a sand-bath, it softens, and may be bent or moulded, like horn, into various shapes, which it retains if cooled under compression. In this way, snuff-boxes, and knobs of walking-sticks, may be made from the thicker parts of the blade. The surface is polished at first with ground pumice-stone, felt, and water; and finished with dry quicklime spontaneously slaked, and sifted. Whalefins *Imported* in 1873—177 tons; valued at 64,618*l.* *Exported* in 1873—960 cwts.; valued at 18,710*l.*

WHALE OIL. See Oils.

WHARPE. See Trent Sand.

WHEAT. *Triticum vulgare*, Linn.; (*Froment*, Fr.; *Waizen*, Ger.) See Bread, Gluten, and Starch.

WHEAT-FLOUR; *To detect Adulteration of.* Potato-starch is insoluble in cold water, unless it be triturated in thin portions in a mortar. If pure wheat-flour be thus triturated, it affords no trace of starch to iodine, as the former does, because the particles of wheat-starch are very minute, and are sheathed in gluten.

Bean-flour digested with water at a heat of 68° Fahr., and triturated, affords on filtration a liquid which becomes milky on the addition of a little acetic acid, by its reaction on the legumine present in the beans.

British Wheat returned as sold in various (150) *Market Towns of England and Wales in each month.*

WHEEL CARRIAGES. This article is omitted from this edition to make room for articles more directly connected with the subjects legitimately belonging to it.

WHEEL ORE. See BOURNONITE.

WHETSLATE is a massive mineral of a greenish-grey colour; feebly glimmering; fracture slaty or splintery; fragments tabular; translucent on the edges; feels rather greasy; and has a spec. grav. of 2·722. It occurs in beds, in primitive and transition slates. Very fine varieties of whetslate are brought from Turkey, called *honestones*, which are in much esteem for sharpening steel instruments. See HONES.

WHEY (*Petit lait*, Fr.; *Molken*, Ger.) is the greyish-green liquor which exudes from the curd of milk. Scheele states, that when a pound of milk is mixed with a spoonful of proof spirit, and allowed to become sour, the whey filtered off, at the end of a month or a little more, is a good vinegar, devoid of lactic acid.

WHISKY. A spirit obtained by distillation from corn, sugar, or molasses, though generally from the former. It is extensively manufactured and used in Scotland and in Ireland. See USQUEBAUGH.

WHITE LEAD, *Carbonate of lead*, or *Ceruse.* (*Blanc de plomb*, Fr.; *Bleiweiss*, Ger.) This is the principal preparation of lead in general use for painting wood and the plaster walls of apartments white. It mixes well with oil, without having its bright colour impaired, spreads easily under the brush, and gives a uniform coat to wood, stone, metal, &c. It is employed either alone, or with other pigments, to serve as their basis, and to give them body. This article has been long manufactured with much success at Klagenfurth in Carinthia, and its mode of preparation has been described with precision by Marcel des Serres. The great white-lead establishments at Krems, whence, though incorrectly, the term *white of Kremnitz* became current, on the Continent, have been abandoned.

In Germany the manufacture of white lead is conducted as follows:—

The lead mostly comes from Bleiberg; it is very pure, and particularly free from contamination with iron, a point essential to the beauty of its factitious carbonate. It is melted in ordinary pots of cast iron, and cast into sheets of various thickness, according to the pleasure of the manufacturer. These sheets are made by pouring the melted lead upon an iron plate placed over the boiler; and whenever the surface of the metal begins to consolidate, the plate is slightly sloped to one side, so as to run off the still liquid metal, and leave a lead sheet of a desired thickness. It is then lifted off like a sheet of paper; and as the iron plate is cooled in water, several hundredweight of lead can be readily cast in a day. In certain white-lead works these sheets are one twenty-fourth of an inch thick; in others half that thickness; in some, one of these sheets takes up the whole width of the conversion-box; in others, four sheets are employed. It is of consequence not to smooth down the faces of the leaden sheets; because a rough surface presents more points of contact, and is more readily attacked by acid vapours than a polished one.

These plates are now placed so as to expose an extensive surface to the acid fumes, by folding each other over a square slip of wood. Being suspended by their middle, like a sheet of paper, they are arranged in wooden boxes, from 4½ to 5 feet long, 12 to 14 inches broad, and from 9 to 11 inches deep. The boxes are very substantially constructed; their joints being mortised, and whatever nails are used, being carefully covered. Their bottom is made tight with a coat of pitch about an inch thick. The mouths of the boxes are luted over with paper in the works where fermenting horse-dung is employed as the means of procuring heat, to prevent the sulphuretted and phosphuretted hydrogen from injuring the purity of the white lead. In Carinthia it was formerly the practice, as also in Holland, to form the lead sheets into spiral rolls, and to place them so coiled up in the chests; but this plan is not to be recommended, because these rolls present obviously less surface to the action of the vapours, are apt to fall down into the liquid at the bottom, and thus to impair the whiteness of the lead. The lower edges of the sheets are suspended about two inches and a half from the bottom of the box; and they must not touch either one another or its sides, for fear of obstructing the vapours in the first case, or of injuring the colour in the second. Before introducing the lead, a peculiar acid liquor is put into the box, which differs in different works. In some, the proportions are four quarts of vinegar, with four quarts of wine-lees; and in others a mixture is made of 20 pounds of wine-lees, with 8½ pounds of vinegar, and a pound of carbonate of potash. It is evident that in the manufactories where no carbonate of potash is employed in the mixture, and no dung for heating the boxes, it is not necessary to lute them.

The mixture being poured into the boxes, and the sheets of lead suspended within them, they are carried into a stove-room, to receive the requisite heat for raising round the lead the corrosive vapours, and thus converting it into carbonate. This apartment is heated generally by stoves, is about 9 feet high, 30 feet long, and 24 feet wide, or of such a size as to receive about 90 boxes. It has only one door.

The heat should never be raised above 86° Fahr.; and it is usually kept up for 15 days, in which time the operation is, for the most part, completed. If the heat be too high, and the vapours too copious, the carbonic acid in a great measure escapes, and the metallic lead, less acted upon, affords a much smaller product.

When the process is well managed, as much carbonate of lead is obtained as there was employed of metal; or, for 300 pounds of lead, 300 of ceruse are procured, besides a certain quantity of metal after the crusts are removed, which is returned to the melting-pot. The mixture introduced into the boxes serves only once; and if carbonate of potash has been used, the residuary matter is sold to the hatters.

When the preceding operation is supposed to be complete, the sheets, being removed from the boxes, are found to have grown a quarter of an inch thick, though previously not above a twelfth of that thickness. A few crystals of acetate of lead are sometimes observed on their edges. The plates are now shaken smartly, to cause the crust of carbonate of lead formed on their surfaces to fall off. This carbonate is put into large cisterns, and washed very clean. The cistern is of wood, most commonly of a square shape, and divided into from seven to nine compartments. These are of equal capacity, but unequal height, so that the liquid may be made to overflow from one to the other. Thereby, if the first chest is too full, it decants its excess into the second, and so on in succession.

The water poured into the first chest passes successively into the others, a slight agitation being meanwhile kept up, and there deposits the white lead diffused in it proportionally, so that the deposit of the last compartment is the lightest and finest. After this washing, the white lead receives another in large vats, where it is always kept under water. It is lastly lifted out, in the state of a liquid paste, with wooden spoons, and laid on drying-tables to prepare it for the market.

The white lead of the last compartment is of the first quality, and is called on the Continent 'silver white.' It is employed in fine painting.

When white lead is mixed in equal quantities with ground sulphate of baryta, it is known in France and Germany by the name of 'Venice white.' Another quality, adulterated with double its weight of sulphate of baryta, is styled 'Hamburgh white;' and a fourth, having three parts of sulphate to one of white lead, gets the name of 'Dutch white.' When the sulphate of baryta is very white, like that of the Tyrol, these mixtures are reckoned preferable for certain kinds of painting, as the barytes communicates opacity to the colour, and protects the lead from being speedily darkened by sulphurous smoke or vapours.

The high reputation of the white lead of Krems was by no means due to the barytes, for the first and whitest quality was mere carbonate of lead. The freedom from silver of the lead of Villach, a very rare circumstance, is one cause of the superiority of its carbonate; as well as the skilful and laborious manner in which it is washed, and separated from any adhering particle of metal or sulphide.

In England, lead is converted into carbonate in the following way:—The metal is cast into the form of a network grating, in moulds about 20 inches long, and 8 or 9 broad. Several rows of these are placed over cylindrical glazed earthen pots, about 6 or 7 inches in diameter, containing some wood-vinegar, which are then covered with planks and spent tan; above these pots another range is piled, and so in succession, to a convenient height. The whole are imbedded in spent bark from the tan-pit, brought into a fermenting state by being mixed with some bark used in a previous process. The pots are left undisturbed under the influence of a fermenting temperature for 8 or 9 weeks. In the course of this time the lead gratings become, generally speaking, converted throughout into a solid carbonate, which when removed, is levigated in a proper mill, and elutriated with abundance of pure water. The plan of inserting coils of sheet lead into earthenware pipkins containing vinegar, and imbedding the pile of pipkins in fermenting horsedung and litter, has now ceased to be used; because the coil is not uniformly acted on by the acid vapours, and the sulphuretted hydrogen evolved from the dung is apt to darken the white lead.

In the above processes, the conversion of lead into carbonate seems to be effected by keeping the metal immersed in a warm humid atmosphere, loaded with carbonic and acetic acids.

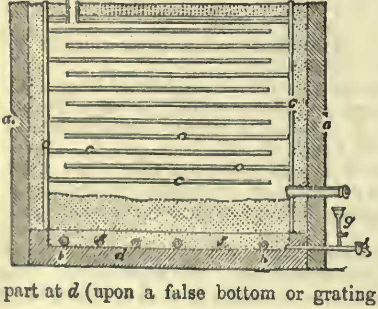
Another process has been practised to a considerable extent in France, though it does not afford a white lead equal in body and opacity to the products of the preceding operations. M. Thénard first established the principle, and MM. Brechoz and Lesseur contrived the arrangements of this method, which was subsequently executed on a great scale by MM. Roard and Brechoz.

A subacetate of lead is formed by digesting a cold solution of uncrystallised acetate, over litharge, with frequent agitation. It is said that 65 pounds of purified pyroligneous acid, of specific gravity 1·056, require, for making a neutral acetate, 58 pounds of litharge; and hence, to form the subacetate, three times that quantity of base, or 174 pounds, must be used. The compound is diluted with water as soon as it is formed, and being decanted off quite limpid, is exposed to a current of carbonic acid gas, which, uniting with the two extra proportions of oxide of lead in the subacetate, precipitates them in the form of a white carbonate, while the liquid becomes a faintly acidulous acetate. The carbonic acid may be extricated from chalk, or other compounds, or generated by combustion of charcoal, as at Clichy; but in the latter case it must be transmitted through a solution of acetate of lead before being admitted into the subacetate, to deprive it of any particles of sulphuretted hydrogen. When the precipitation of the carbonate of lead is completed and well settled down, the supernatant acetate is decanted off, and made to act on another dose of litharge. The deposit being first rinsed with a little water, this washing is added to the acetate: after which the white lead is thoroughly elutriated. This repetition of the process may be indefinitely made; but there is always a small loss of acetate, which must be repaired, either directly or by adding some vinegar.

It is customary on the Continent to mould the white lead into conical loaves before sending it into the market. This is done by stuffing well-drained white lead into unglazed earthen pots, of the requisite size and shape, and drying it to a solid mass by exposing these pots in stove-rooms. The moulds being now inverted on tables, discharge their contents, which then receive a final desiccation; and are afterwards put up in pale-blue paper, to set off the white colour by contrast.

It has been supposed that the differences observed between the ceruse of Clichy and the common kinds, depend on the greater compactness of the particles of the latter, produced by their slower aggregation; as also, according to M. Robiquet, on the former containing considerably less carbonic acid.

2116



Mr. Ham proposed, in a patent dated June 1826, to produce white lead with the aid of the following apparatus. *a*, *a*, *fig.* 2116, are the side-walls of a stove-room constructed of bricks; *b* is the floor of bricks laid in Roman cement; *c*, *c*, are the side-plates, between which and the walls a quantity of refuse tanners' bark, or other suitable vegetable-matter, is to be introduced. The same material is to be put also into the lower part at *d* (upon a false bottom or grating?). The tan should rise to a considerable height, and have a series of strips of sheet lead, *e*, *e*, *e*, placed upon it, which are kept apart by blocks or some other convenient means, with a space open at one end of the plates, for the passage of the vapours; but above the upper plates, boards are placed, and covered with tan, to confine them there. In the lower part of the chamber, coils of steam-pipes, *f*, *f*, are laid in different directions to distribute heat; *g* is a funnel-pipe, to conduct vinegar into the lower part of the vessel; and *h* is a cock to draw it off, when the operation is suspended. The acid vapours raised by the heat pass up through the spent bark, and on coming into contact with the sheets of lead, corrode them. The quantity of acid liquor should not be in excess; a point to be ascertained by means of the small tube *i*, at top, which is intended for testing it by the tongue. *k* is a tube for inserting a thermometer, to watch the temperature, which should not exceed 170° Fahr. We are not aware what success attended this patented arrangement.

A factory was many years since erected at West Bromwich, near Birmingham, to work a patent obtained by Messrs. Gossage and Benson, for making white lead by mixing a small quantity of acetate of lead in solution with slightly-damped litharge, contained in a long stone trough, and passing over the surface of the trough currents of hot carbonic acid, while its contents were powerfully stirred up by a travelling-wheel mechanism. The product was afterwards ground and elutriated, as usual. The carbonic acid gas was produced from the combustion of coke. This factory has long been abandoned.

Messrs. Button and Dyer obtained a patent for making white lead by transmitting a current of purified carbonic acid gas, from the combustion of coke, through a mixture of litharge and nitrate of lead, diffused and dissolved in water, which was kept in constant agitation and ebullition by steam introduced through a perforated coil of pipes at the bottom of the tub. The carbonate of lead was formed here upon the principle of Thénard's process upon the subacetate; for the nitrate of lead formed with the litharge a subnitrate, which was forthwith transformed into carbonate and neutral nitrate, by the agency of the carbonic acid gas. It is known that all sorts of white lead produced by precipitation from a liquid, are in a semi-crystalline condition; appear, therefore, semi-transparent when viewed in the microscope; and do not cover so well as white lead made by the process of vinegar and tan, in which the lead has remained always solid during its transition from the blue to the white state; and hence consists of opaque particles.

A patent was obtained in December 1833, by John Baptiste Constantine Torassa, and others, for making white lead by agitating the granulated metal or shot, in trays or barrels, along with water, and exposing the mixture of lead-dust and water to the air, to be oxidised and carbonated. The whole of these projects for preparing white lead are inferior in economy and quality of produce to the old Dutch process, which may be so arranged as to convert sheets of blue lead thoroughly into the best white lead, within the space of ten weeks, at less expense of labour than by any other plan.

The composition of the different varieties of white lead has been carefully examined by J. Arthur Phillips.[1] The result of this investigation shows that those specimens, which are obtained by precipitation from solutions of the nitrate by means of an alkaline carbonate, contain very variable quantities of oxide of lead, whilst in white lead prepared by the ordinary Dutch process, the relations existing between the amounts of carbonate and oxide, although definite, are usually very simple. The most usual composition of the white lead of commerce is represented by the formula $2(PbO.CO^2) + PbO.HO$ (**$2PbCO^3.PbH^2O^2$**), although specimens represented by the formulæ $3(PbO.CO^2) + PbO.HO$ (**$3PbCO^3.PbH^2O^2$**), and $5(PbO.CO^2) + PbO.HO$ (**$5PbCO^3.PbH^2O^2$**) are also occasionally met with.

On examining the ordinary corroded leads in a finely-divided state, by the aid of a powerful microscope, no traces of a crystalline structure will be perceived, but when precipitated specimens are subjected to a power of 300 diameters, distinct hexagonal plates become visible. These vary from $\frac{1}{5000}$th to $\frac{1}{10000}$th of an inch in diameter, and appear slightly yellow by transmitted light.

Mr. Thomas Richardson, of Newcastle, obtained a patent in December 1839, for a preparation of sulphate of lead, applicable to some of the purposes to which the carbonate is applied. His plan is to put 56 lbs. of flake litharge into a tub, to mix it with 1 lb. of acetic acid (and water) of spec. grav. 1·046, and to agitate the mixture till the oxide of lead becomes an acetate. But whenever this change is partially effected, he pours into the tub, through a pipe, sulphuric acid of spec. grav. 1·5975, at the rate of about 1 lb. per minute, until a sufficient quantity of sulphuric acid has been added to convert all the lead into a sulphate; being about 20 parts of acid to

[1] Journal of the Chemical Society, p. 145.

112 of the litharge. The sulphate is afterwards washed and dried in stoves for the market, but is very inferior to ordinary white lead.

Mr. Leigh, surgeon in Manchester, prepared his patent white lead by precipitating a carbonate from a solution of the chloride of the metal by means of carbonate of ammonia. On this process, in a commercial point of view, no remarks need be made.

A patent was granted to Mr. Hugh Lee Pattinson, in September 1841, for improvements in the manufacture of white lead, &c. This invention consists in dissolving carbonate of magnesia in water impregnated with carbonic acid gas, by acting upon magnesian limestone, or other earthy substances containing magnesia in a soluble form, or upon rough hydrate of magnesia in the mode hereafter described, and in applying this solution to the manufacture of magnesia and its salts, and the precipitation of carbonate of lead from any of the soluble salts of lead, but particularly the chloride of lead; in which latter case the carbonate of lead so precipitated is triturated with a solution of caustic potash or soda, by which a small quantity of chloride of lead contained in it is converted into hydrated oxide of lead, and the whole rendered similar in composition to the best white lead of commerce. The manner in which these improvements are carried into effect is thus described by the patentee:—

'I take magnesian limestone, which is well known to be a mixture of carbonate of lime and carbonate of magnesia in proportions varying at different localities; and on this account I am careful to procure it from places where the stone is rich in magnesia. This I reduce to powder, and sift it through a sieve of forty or fifty apertures to the linear inch. I then heat it red-hot, in an iron retort or reverberatory furnace, for two or three hours, when the carbonic acid being expelled from the carbonate of magnesia, but not from the carbonate of lime, I withdraw the whole from the retort or furnace, and suffer it to cool. The magnesia contained in the limestone is now soluble in water impregnated with carbonic acid gas, and to dissolve it I proceed as follows:—I am provided with an iron cylinder lined with lead, which may be of any convenient size, say 4 feet long by 2½ feet in diameter; it is furnished with a safety-valve and an agitator, which latter may be an axis in the centre of the cylinder, with arms reaching nearly to the circumference, all made of iron and covered with lead. The cylinder is placed horizontally, and one extremity of this axis is supported within it by a proper carriage, the other extremity being prolonged and passing through a stuffing-box at the other end of the cylinder, so that the agitator may be turned round by applying manual or other power to its projecting end. A pipe, leading from a force-pump, is connected with the under side of the cylinder, through which carbonic acid gas may be forced from a gasometer in communication with the pump, and a mercurial gauge is attached, to show at all times the amount of pressure within the cylinder, independently of the safety-valve. Into a cylinder of the size given I introduce from 100 to 120 lbs. of the calcined limestone with a quantity of pure water, nearly filling the cylinder; I then pump in carbonic acid gas, constantly turning the agitator, and forcing in more and more gas, till absorption ceases under a pressure of five atmospheres. I suffer it to stand in this condition three or four hours, and then run off the contents of the cylinder into a cistern, and allow it to settle. The clear liquor is now a solution of carbonate of magnesia in water impregnated with carbonic acid gas, or, as I shall hereafter call it, a solution of bicarbonate of magnesia, having a spec. grav. of about 1·028, and containing about 1,600 grains of carbonate of magnesia to the imperial gallon.

'I consider it the best mode of obtaining a solution of bicarbonate of magnesia from magnesian limestone, to operate upon the limestone after being calcined at a red heat in the way described; but the process may be varied by using in the cylinder the mixed hydrates of lime and magnesia, obtained by completely burning magnesian limestone in a kiln, as commonly practised, and slaking it with water in the usual manner: or, to lessen the expenditure of carbonic gas, the mixed hydrates may be exposed to the air a few weeks till the lime has become less caustic by the absorption of carbonic acid from the atmosphere. Or the mixed hydrates may be treated with water, as practised by some manufacturers of Epsom salts, till the lime is wholly or principally removed; after which the residual rough hydrate of magnesia may be acted upon in the cylinder, as described; or hydrate of magnesia may be prepared for solution in the cylinder, by dissolving magnesian limestone in hydrochloric acid, and treating the solution, or a solution of chloride of magnesium, obtained from sea-water by salt-makers in the form of bittern, with its equivalent quantity of hydrate of lime, or of the mixed hydrates of lime and magnesia, obtained by completely burning magnesian limestone, slaking it as above. When I use this solution of bicarbonate of magnesia for the purpose of preparing magnesia and its salts, I evaporate it to dryness, by which a pure carbonate of magnesia is at once obtained, without the necessity of using a carbonated alkali, as in the whole process; and from this I prepare pure magnesia by calcination in the usual manner; or, instead of boiling to dryness, I merely heat the solution for some time to the boiling point, by which the excess of carbonic acid is partly driven off, and pure carbonate of magnesia is precipitated, which may then be collected, and dried in the same way as if precipitated by a carbonated alkali. If I require sulphate of magnesia, I neutralise the solution of bicarbonate of magnesia with sulphuric acid, boil down, and crystallise; or I mix the solution with its equivalent quantity of sulphate of iron, dissolved in water, heated to the boiling point, and then suffer the precipitated carbonate of iron to subside; after which I decant the clear solution of sulphate of magnesia, boil down, and crystallise as before. When using this solution of bicarbonate of magnesia for the purpose of preparing carbonate of lead, I make a saturated solution of chloride of lead in water, which at a temperature of 50° or 60° Fahr., has a specific gravity of about 1·008, and consists of 1 part of chloride of lead dissolved in 126 parts of water. I then mix the two solutions together, when carbonate of lead is immediately precipitated; but in this operation I find it necessary to use certain precautions, otherwise a considerable quantity of chloride of lead is carried down along with the carbonate. These precautions are, first, to use an excess of the solution of magnesia; and secondly, to mix the two solutions together as rapidly as possible. As to the first, when using a magnesian solution containing 1,600 grs. of carbonate of magnesia, per imperial gallon, with a solution of chloride of lead saturated at 55° or 60° Fahr., 1 measure of the former to 8½ of the latter is a proper proportion; in which case there is an excess of carbonate of magnesia employed, amounting to about an eighth of the total quantity contained in the solution. When either one or both the solutions vary in strength, the proportions in which they are to be mixed must be determined by preliminary trials. It is not, however, necessary to be very exact, provided there is always an excess of carbonate of magnesia amounting to from one-eighth to one-twelfth of the total quantity employed. If the excess is greater than one-eighth, no injury will result, except the unnecessary expenditure of the magnesian solution. As to the second precaution, of mixing the two solutions rapidly together, it may be accomplished variously; but I have found it a good method to run them in two streams, properly regulated in quantity, into a small cistern, in which they are to be rapidly blended together by brisk stirring, before passing out, through a hole in the bottom, to a large cistern or tank, where the precipitate finally settles. The precipitate thus obtained is to be collected, washed and dried in the usual manner. It is a carbonate of lead, very nearly pure, and suitable for most purposes; but it always contains a small portion of chloride of lead, seldom less than from 1 to 2 per cent., the presence of which, even in so small a quantity, is somewhat injurious to the colour and body of the white lead. I decompose this chloride, and convert it into a hydrated oxide of lead by grinding the dry precipitate with a solution of caustic alkali, in a mill similar to the ordinary mill used in grinding white lead with oil, adding just so much of the lye as may be required to convert the precipitate into a soft paste. I allow this paste to lie a few days, after which, the chloride of lead being entirely, or almost entirely, decomposed, I wash out the alkaline chloride formed by the reaction, and obtain a white lead, similar in composition to the best white lead of commerce. I prepare the caustic alkaline lye by boiling together, in a leaden vessel, for an hour or two, 1 part by weight of dry and recently-slaked lime, 2 parts of crystallised carbonate of soda (which being cheaper than carbonate of potash, I prefer), and 8 parts of water. The clear and colourless caustic lye, obtained after subsidence, will have a specific gravity of about 1·090, and when drawn off from the sediment, must be kept in a close vessel for use.'

More recently Mr. Peter Spence, of Manchester, has patented a process for obtaining white lead directly from the ores.

As we have before stated, the manufacture of white lead by the Dutch process is one the nature of which seems yet enveloped in considerable obscurity. So far as appearances go, the action would seem to consist: first, in the oxidation of metallic lead by the atmosphere, under the influence of the vapour of acetic acid; secondly, in the production of acetate of lead, by the combination of the oxide of lead with the acetic acid; and thirdly, in the displacement of the acetic acid from its union with the oxide of lead, by the action of carbonic acid, and the consequent formation of white lead. But this in no way accounts for the fact, that, when acetate of lead is decomposed by carbonic acid, it is carbonate of lead, and not white lead, which is formed. Nor can we conceive how an acid like the acetic is capable of being wholly expelled from a metallic oxide by a quantity of another acid incapable of completely saturating the oxide. In other words, as white lead contains free or uncombined oxide of lead, how happens it that the free acetic acid does not remain united to this? We confess our inability to reconcile the facts of the case with the preceding hypothesis, and therefore pass on to another, in which we will assume that acetate of lead, but not the neutral acetate, is formed as we have already supposed. Now there are two subacetates: one composed of six molecules of oxide of lead to one of acetic acid; and the other consisting of three molecules of oxide of lead to one of acetic acid. We select, in preference the former, as it is the one which forms naturally when acetic acid acts, at common temperatures, on an excess of oxide of lead. The composition of this salt is such, that, if we can conceive slow combustion to take place, or that its acetic acid combining with the oxygen of the air is resolved into water and carbonic acid, then the carbonic acid produced would be exactly sufficient to saturate four atoms of the oxide of lead, and leave a compound of the precise composition of white lead. On this view, the first action in a white lead stack would be the production of sexbasic acetate of lead; and the next would be the destruction of this by eremacausis, and the formation of white lead.

The apparatus employed in the manufacture of white lead is extremely simple, and consists merely of certain large enclosures or spaces, called 'beds,' in which the stacks are built up, together with the earthenware-pots needed for holding the vinegar, and the machinery used in casting the lead and grinding the white lead, so as to fit it for the market. The metallic lead was formerly used in the shape of sheets or coils, which were placed perpendicularly over the vinegar pots; but this practice has been almost everywhere abandoned, and at present the lead is generally cast into what are called 'crates' or 'grates,' and having the appearance of lattice-work; the object being to expose as large a surface as possible of metallic lead to the action of the vapour of the vinegar. The beds are of considerable size; and, in this respect, some diversity of opinion prevails amongst practical men; but it seems pretty certain that no advantage is gained when the area of a bed comes to exceed 300 square feet; and there are many reasons for believing that, with beds of twice this area, the gain, in point of diminished labour, is much more than compensated for by the reduced produce in white lead. Nevertheless, each manufacturer seems to entertain an opinion of his own in respect to this matter; and there are even some pretensions to secresy concerning it. In fact, everything depends upon the construction of the bed, for it is this which regulates the production of white lead; and, as a proof of the great importance connected with this circumstance, we may here mention, that, whilst one manufacturer has produced as much as 65 per cent. of corrosion during a long course of years, another in his immediate neighbourhood has never been able to exceed 52 per cent. The beds of the former are 16 feet square, whilst those of the latter are 19½ feet square; and, in dwelling upon the details of this operation, we shall find that theoretically, a bed may be too large, as the above practical fact indicates.

In forming a stack, it is necessary to begin by laying, in the first instance, a bed of spent tanners' bark, 3 feet in thickness, over the surface of the bed; and upon this are placed the earthenware-pots containing the vinegar. These are arranged side by side, and filled to about one-third of their contents with vinegar, of a strength equal to 6 per cent. of anhydrous acetic acid. Upon these pots are placed the crates of lead, and over all a series of boards are arranged, which form a floor for the next layer of spent tan. Such an arrangement as we have described is denominated 'a bed,' but there is this difference between the beds, viz. that the lowest or bottom bed has a bed of tan 3 feet in thickness, whereas but one foot only is needed in the others. Having finished the lowest bed, 12 inches of spent tan are now placed upon the boards, and a similar arrangement of pots, crates, and boards takes place, which constitutes the second bed; this is followed by a third, a fourth, and so on, until at last the uppermost bed is finished; when a layer of spent tan, 30 inches in thickness, is placed over the whole, and the operation may be said to commence. In six or eight days the tan begins to ferment and evolve heat; and this goes on increasing for some weeks, when it gradually diminishes, and at the end of about three months the whole has become cool, and the stack is fit to be taken down. When examined, the pots, which formerly contained vinegar, will now be found to be quite empty, or to hold a little water merely, but no acetic acid; the leaden crates will be discovered to have increased sensibly in bulk, to have become coated with a thick and dense incrustation of white lead, and in some places even to have become altogether converted into this substance; whilst the tan, having lost its fermentative quality, is now useless, except as fuel.

The successive beds constituting the entire stack are next carefully removed, so as to obtain the white lead with the least possible admixture of the tan; and as a portion of this substance always adheres to the crates, these are washed in a kind of wear or trough, by which the whole of the tan is thoroughly separated. When this is seen to be complete, the corroded part of the plate or 'white lead' is detached from the uncorroded or 'blue lead,' either by means of rollers or with a mallet. The blue lead is weighed, and, for the most part, remelted and again cast into crates; whilst the white lead is first crushed, and afterwards ground in water into a fine powder, when it is collected by elutriation and deposition, and dried in stoves, a little below the boiling point of water. Formerly this grinding was performed in the dry way, and much injury to the health of the workmen thus resulted; but for many years past the wet mode of grinding has been general, and is greatly to be preferred.

WHITING. Chalk levigated and carefully washed, after which it is formed into balls.

WICK (*Mèche*, Fr.; *Docht*, Ger.) is a spongy cord, usually made of soft spun cotton threads, which by capillary action draws up the oil in lamps, or the melted tallow or wax in candles, in small successive portions, to be burned. In common wax and tallow candles the wick is formed of parallel threads; in the stearine candles the wick is plaited upon the braiding machine, moistened with a very dilute sulphuric acid, and dried, whereby as it burns it falls to one side and consumes without requiring to be snuffed; in the patent candles of Mr. Palmer one-tenth of the wick is first imbued with subnitrate of bismuth ground up with oil; the whole is then bound round in the manner called *gimping*; and of this wick, twice the length of the intended candle is twisted double round a rod. This rod with its coil being inserted in the axis of the candle-mould is to be enclosed by pouring in the melted tallow; and when the tallow is set the rod is to be drawn out at top, leaving the wick in the candle. As this candle is burned, the ends of the double wick stand out sideways beyond the flame; and the bismuth attached to the cotton being acted on by the oxygen of the atmosphere causes the wick to be completely consumed, and therefore the trouble of snuffing it is saved. See CANDLES.

WINCING MACHINE is the English name of the dyers' reel, which he suspends horizontally, by the ends of its iron axis in bearings, over the edge of the vat, so that the line of the axis, being placed over the middle partition in the copper, will permit the piece of cloth which is wound upon the reel to descend alternately into either compartment of the bath, according as it is turned by hand to the right or the left. See DYEING.

WINE is the fermented juice of the grape. This beverage has been in use from the earliest periods of man's history. We have, however, only space to deal with wine in its modern relations.

In the reign of Elizabeth the wines chiefly in use in England were those of Gascony, Burgundy, and Guienne, which, with Canary, Cyprus, Grecian Malmsey, Italian Vernage, Rhenish Tent, Malaga, and others, were 'accompted of, because of their strength and valure.'

In the time of Charles II. 'the consumption of French wines was two-fifths that of the whole of England. The favourite wines were then Bordeaux, Burgundy, and Hermitage. Champagne, although known in England in the reign of Henry VIII., did not come into use till that of Charles II.

The strong wines of Burgundy, the white wines of Spain (*Sherris-sack* or *Sec*), and the red wines of Portugal, first came into use about 1690 A.D. Port wine was at first a much lighter wine than it afterwards became. According to Baron Forrester, the first Port wine introduced into this country was not from the Douro, or even shipped at Oporto. It was a wine resembling the Claret of Burgundy.

The wine-growing countries are especially the more southern states of Europe, where the grapes, being very saccharine, afford a more abundant production of alcohol, and stronger wines, as exemplified in the best Port, Sherry, and Madeira. In the more temperate climates, such as the district of Burgundy, the finer-flavoured wines are produced; and there the vines are usually grown upon hilly slopes fronting the south, with more or less of an easterly or westerly direction, as on the Côte-d'Or, at a distance from marshes, forests, and rivers, whose vapours might deteriorate the air. The plains of this district, even when possessing a similar or analogous soil, do not produce wines of so agreeable a flavour. The influence of temperature becomes very manifest in countries further north, where, in consequence of a few degrees of thermometric depression, the production of generous, agreeable wine becomes impossible.

The land most favourable to the vine is light, easily permeable to water, but somewhat retentive by its composition; with a sandy subsoil, to allow the excess of moisture to drain readily off. Calcareous soils produce the highly-esteemed wines of the Côte-d'Or; a granitic *débris* forms the foundation of the lands where the Hermitage wines are grown; siliceous soil interspersed with flints furnishes the celebrated wines of Château-Neuf, Ferté, and La Gaude; schistose districts afford also good wine, as that called *la Malque*. Thus we see that lands differing in chemical composition, but possessed of the proper physical qualities, may produce most agreeable wines. As a striking example of these effects, we may adduce the slopes of the hills which grow the wines of Montrachet. The insulated part towards the top furnishes the wine, called *Chevalier Montrachet*, which is less esteemed, and sells at a much lower price, than the delicious wine grown on the middle height, called *true Montrachet.* Beneath this district and in the surrounding plains the vines afford a far inferior article, called *bastard Montrachet.* The opposite side of the hills produces very indifferent wine. Similar differences, in a greater or less degree, are observable relatively to the districts which grow the Pomard, Volnay, Beaune, Nuits, Clos-de-Vougeôt, Chambertin, Romanée, &c. Everywhere it is found that the reverse side of the hill, the summit and the plain, although generally consisting of like soils, afford inferior wine to the middle southern slopes.

In the district of Médoc the soil is mainly a quartzose gravel, with a subsoil of argillaceous sand, sometimes compacted by brown iron ore, known as *alios*, which in the neighbouring or southern district of Graves becomes more sandy, and marly, overlying the limestones which form considerable cliffs in the neighbouring department of Dordogne. These latter are known as the Côtes, the thin soils above them producing the generous wine of St.-Emilion. Other examples of limestone soils are furnished by the Côte-d'Or, the great wine-producing district of Burgundy, a chain of limestone hills which extends for about 36 miles, from Dijon to Châlons-sur-Saône, and include the famous vineyards of Clos-de-Vougeôt, Chambertin, Nuit-sur-Ravier, &c., which are situated on their eastern slope. In Champagne the soils are mainly a clayey and sandy alluvium above chalky limestones, very usually barren when too exclusively sandy or calcareous, so that it is necessary to dress the soils with clay, in order to produce the fertility required for vine-growing. On the Rhine and the tributary vine-growing valleys of the Maine, Moselle, Lahn, and Ahr, the soils are generally decomposed clay-slate, more or less quartzose, of Devonian age. The vineyards are situated on the steep hill-sides, the soil being retained by terrace-walls, the wash of the winter rains being received by earth carried up in baskets every spring. In the Sherry-producing districts, of the neighbourhood of Cadiz, the finest wines are produced from an argillaceous calcareous soil known as *albariza*, while a lighter and less valuable wine is given in the lower sandy soils or *arenas*. On the southern slopes of the Sierra Nevada, in Spain, the vines grow in a deep natural soil produced from the decomposition of clay-slate, without terracing up to a height of about 3,000 feet above the sea-level. The produce is a sweet wine used in the production of Sherry and Malaga at various places in the south of Spain.

For the vine, a manure supplying azotised or animal nutriment may be used with great advantage, provided care be taken that it may not, by absorption in too crude a state, impart any disagreeable odour to the grape, as sometimes happens to the vines grown in the vicinity of great towns, like Paris, and near Argenteuil. There is a compost used in France called *animalised black*, of which from $\frac{1}{5}$ to $\frac{1}{4}$ of a litre (old English quart) serves sufficiently to fertilise the root of one vine when applied every year or two years. An excess of manure, in rainy seasons especially, has the effect of rendering the grapes large and insipid.

The famous vineyards of Steinberg and Johannisberg, on the Rhine, and Château-Margaux, in Médoc, are heavily manured, each consuming the whole of the manure produced on a large grazing farm of about 600 acres, or from 6 to 8 times its own area.

The ground is tilled at the same time as the manure is applied, towards the month of March; the plants are then dressed, and the props are inserted. The weakness of the plants renders this practice useful; but in some southern districts the stem of the vine, when supported at a proper height acquires, after a while, sufficient size and strength to stand alone. The ends of the props or poles are either dipped in tar, or charred, to prevent their rotting. The bottom of the stem must be covered over with soil after the spring rains have washed it down. The principal husbandry of the vineyard consists in digging or ploughing, to destroy the weeds, and to expose the soil to the influence of the air during the months of May, June, and occasionally in August.

The fruit of the same plant when transferred to a different soil loses its peculiar characteristics; thus one and the same vine produces Hock upon the Rhine, Bucellas in Portugal, and Sercial at Madeira. It has been found that vines from Germany, France, Portugal, and Spain transplanted to the Cape of Good Hope and Australia, have in no one instance produced wine assimilating to the peculiarities of the original plant; and no European vine has hitherto succeeded when transplanted to the United States, although wine is made at Cincinnati from American grapes.

The finest known wines are the produce of soils the combination and proportions of whose ingredients are extremely rare and exceptional; and co-operating with these they require the agency of peculiar degrees of light, moisture, and heat. The district of Xeres, which has so long supplied us with Sherry, is mapped out so accurately by the line of its peculiar soil that its dimensions are known by the acre. The vine which produces Port on the hills above the Douro yields a totally different wine in the vicinity of the Tagus. The wine district of the Rhinegau, between Mayence and Rudesheim, is but 9 miles in length by half as much broad. The south side of a single hill produces Johannisberg; and Steinberg is the vineyard of a suppressed monastery. The numerous wines of Burgundy and the Garonne take their names respectively from circumscribed spots; and so narrow and apparently so capricious are the respective limits, that a ditch divides portions which from time immemorial have been sought with avidity, from others which in the market will uniformly bring but one-fifth the price. The produce of the celebrated vineyard of Lafitte, near Bordeaux, for the year 1848, was sold at 4,000 francs per tun, while the wines of the immediate neighbourhood realised only 200 francs. The proprietor of a vineyard which is only separated from that of Lafitte by a narrow gully, a few years since expended a large sum of money in endeavouring, by improved cultivation, to assimilate his wines to that of Lafitte. To some extent he improved the quality, but the wines never approached the peculiar character of the Lafitte, while the expense incurred was so enormous that the enterprising proprietor was ruined. The costly Clos-de-Vougeôt grows in a farm of 80 acres. Romanée-Conti is but 6½; and the famous Montrachet of the Côte-d'Or is distinguished into three classes, of which one sells at one-third less than the other two, 'yet these qualities are produced from vineyards only separated from one another by a footpath; they have the same aspect, and apparently the same soil, in which the same vines are cultivated and managed in precisely the same manner.'—(*Henderson on Wines.*) One small valley in Madeira alone produces the finest Malmsey. (See Sir Emerson Tennent *On Wine, its Uses and Taxation.*) Art and horticultural science have, he remarks, been applied to extend the limits thus circumscribed by nature, but with such unsatisfactory results, that, as a rule, it may be stated that the higher class wine of any known district has not been successfully reproduced beyond it. The red wines of Portugal grown in the Alto Douro can no more be made in the adjoining provinces of the Minho or Beira than the white wines of Spain could be successfully imitated on the Rhine.

Vine Diseases.—The *Oïdium Tuckeri* is the name given to one of the diseases, Mr. Tucker having first carefully observed the growth of this destructive microscopic fungus. In connection with the cultivation of the vine, and the manufacture of wine, it is necessary that the peculiar characteristics of this disease should be described.

It is stated that the epidemic first showed itself in a hothouse in England in 1845. White efflorescences were remarked, which covered the vine; the grapes were soon after attacked, and, hindered from swelling, the skin burst, and at last they became rotten and fell off. In 1847 it appeared in France; attacking first the hothouses, it spread rapidly to the trellised vines, and to those cultivated near the ground. It then invaded Spain, which it devastated; and finally, in 1851, made its appearance in Italy. This fungus attacks the hinder parts of the vine, and rarely the stems. The leaves and tendrils also become more or less affected, the green colour of those parts becoming paler, and marked with a dark yellow, as if burnt, and emitting an offensive smell. It was fancied at first that the fungus was produced by the puncture of an insect, and its presence was actually ascertained in the seed of the grape, and on the hinder side of the leaf. This insect established itself on the leaves, and formed a cobweb-like film, rising like a blister on the upper part of the leaf. The birth of it is, however, now generally admitted to be posterior to the invasion of the *oïdio.*

The 'Reports of Her Majesty's Secretaries of Embassy and Legation on the Effects of the Vine Disease on the Commerce of the Countries in which they reside' all point to sulphur as the only reliable remedy for this disease. The most practical method of applying sulphur to the vines was that introduced by Dr. Ashby Price. By boiling sulphur and lime together in water we obtain a brilliant yellow solution, which is a sulphide of lime; with a diluted solution of this the vines are washed over every part. By the action of the carbonic acid of the plant it is speedily decomposed, and over every part a thin white film of sulphur is produced, which effectually destroys the parasite without injuring the vine.

Within the last few years the vines of the south of France have been ravaged by a new disease due to the invasion of a parasitic insect named by M. Planchon *Phylloxera vastata.* The first appearance of the disease was in 1865, when it was observed in the neighbourhood of Avignon, Dep. of the Gard. In the following year it spread from this centre, and also appeared in several localities in the Deps. of Vaucluse and the Bouches-du-Rhône. Spreading at first gradually, but afterwards with alarming rapidity, the disease has extended to such an extent that in 1873 it had established itself in no fewer than twelve departments. The dreadful destruction which it causes may be seen by comparing the statistics of the grape-crops of recent years with those of the same localities prior to the appearance of the Phylloxera. For example, in the Commune of Graveson the mean crop just before the year 1865 was 10,000 hectolitres; this amount then became reduced year by year, until in 1873 it reached only 50 hectolitres. In some Communes the crops have been almost entirely destroyed. The Phylloxera, which is undoubtedly the cause of all this mischief, is a very minute insect, measuring not more than 1-33rd of an inch in length. From April to October it continues active, but during the rest of the year it hybernates. When the Phylloxera attacks a vine, the rootlets exhibit peculiar swellings, and the insects multiply so rapidly as soon to overrun all the roots, and by absorbing nourishment from the plant, reduce it to a totally exhausted state. Soon after the disease appeared, the French Academy of Sciences appointed a commission to investigate the subject. Although a large number of remedies have been suggested and tried, it can hardly be said that any of them have as yet (1874) been successful in coping with the difficulty. Perhaps the best means of eradicating the parasite is to place the vineyard under water as soon as the disease appears; but such means evidently admit of only local application.

Vintage.—The vintage, in the temperate provinces, generally takes place about the end of September, and it is deteriorated whenever the fruit is not ripe enough before the 15th or 20th of October; for, in this case, not only is the must more acid and less saccharine, but the atmospheric temperature is apt to fall so low during the nights, as to obstruct more or less its fermentation into wine. The grapes should be plucked in dry weather, at the interval of a few days after they are ripe; being usually gathered in baskets, and transported to the vats in dorsels, sufficiently tight to prevent the juice from running out. Whenever a layer about 14 or 15 inches thick has been spread on the bottom of the vat, the treading operation begins, which is usually repeated after macerating the grapes for some time, when an incipient fermentation has softened the texture of the skin and the interior cells. When the whole bruised grapes are collected in the vat, the juice, by means of a slight fermentation, reacts, upon the colouring-matter of the husks, and also upon the tannin contained in the stones and the fruit-stalks. The process of fermentation is suffered to proceed without any other precaution, except forcing down from time to time the pellicles and pedicles floated up by the carbonic acid to the top.

With whatever kind of apparatus the fermentation may have been regulated, as soon as it ceases to be tumultuous, and the wine is not sensibly saccharine or muddy, it must be racked off from the lees, by means of a spigot, and run into the ripening tuns. The marc being then gently squeezed in a press, affords a tolerably clear wine, which is distributed among the tuns in equal proportions; but the liquor obtained by stronger pressure is reserved for the casks of inferior wine.

In the south of France the fermentation sometimes proceeds too slowly, on account of the must being too saccharine: an accident which is best counteracted by maintaining a temperature of about 65° or 68° Fahr. in the tun-room. When the must, on the other hand, is too thin, and deficient in sugar, it must be partially concentrated by rapid boiling before the whole can be made to ferment into a good wine. By boiling up a part of the must for this purpose, the excess of ferment is at the same time destroyed. Should this concentration be inconvenient, a certain proportion of sugar must be introduced, and immediately after racking it off.

The specific gravity of must varies with the richness and ripeness of the grapes which afford it; being in some cases so low as 1·0627, and in others so high as 1·283. This happens particularly in the south of France. In the district of the Necker in Germany, the spec. grav. varies from 1·050 to 1·090; in Heidelberg, from 1·039 to 1·091, but it varies much in different years.

After the fermentation is complete, the vinous part consists of water, alcohol, a colouring-matter, a peculiar aromatic principle, a little undecomposed sugar, bitartrate and malate of potash, tartrate of lime, chloride of sodium, and tannin; the latter substances being in small proportion.

It is known that a few green grapes are capable of spoiling a whole cask of wine, and therefore they are always allowed to become completely ripe, and even sometimes to undergo a species of slight fermentation before being plucked, which completes the development of the saccharine principle. At other times the grapes are gathered when they are ripe, but are left for a few days on wicker-floors, to sweeten, before being pressed.

In general the whole vintage of the day is pressed in the evening, and the resulting must is received in separate vats. At the end usually of six or eight hours, if the temperature be above 50° Fahr., and if the grapes have not been too cold when plucked, a froth or scum is formed at the surface, which rapidly increases in thickness. After it acquires such a consistency as to crack in several places, it is taken off with a skimmer, and drained; and the thin liquor is returned to the vat. A few hours afterwards another coat of froth is formed, which is removed in like manner, and sometimes a third may be produced. The regular vinous fermentation now begins; characterised by air-bubbles rising up the sides of the staves, with a peculiar whizzing as they break at the surface. At this period all the remaining froth should be quickly skimmed off, and the clear subjacent must be transferred into barrels, where it is left to ripen by a regular fermentation.

The white wines, which might be disposed to become stringy, from a deficient supply of tannin, may be preserved from this malady by a due addition of the foot-stalks of ripe grapes. The tannin, while it tends to preserve the wines, renders them also more easy to clarify, by the addition of white-of-egg or isinglass.

The white wines should be racked off as soon as the first frosts have made them clear, and at the latest by the end of the February moon. By thus separating the wine from the lees, the fermentation which takes place on the return of spring, and which, if too brisk, would destroy all its sweetness by decomposing the remaining portion of sugar, is avoided or rendered of little consequence.

The characteristic odour possessed by all wines, in a greater or less degree, is produced by a peculiar substance, which possesses the characters of an essential oil. As it is not volatile, it cannot be confounded with the aroma of wine. When large quantities of wine are distilled, an oily substance is obtained towards the end of the operation. This may also be procured from the wine lees which are deposited in the casks after the fermentation has commenced. It forms 1-40,000th part of the wine, and consists of a peculiar acid, and ether, each of which has been called the *œnanthic*. The acid is analogous to the fatty acids, and the ether is liquid, but insoluble in water. The acid is perfectly white when pure, of the consistency of butter at 60°, melts with a moderate heat, reddens litmus, and dissolves in caustic and carbonated alkalis, as well as in alcohol and ether. Œnanthic ether is colourless, has an extremely strong smell of wine, which is almost intoxicating when inhaled, and a powerful disagreeable taste.—*Liebig and Pelouze.*

Portugal.—Port wine is the produce of a single well-defined district in the north of Portugal, extending 8 leagues west and east from the Serra do Marão, an elevation of 4,400 feet above the level of the sea, to the Quinta da Baleira, near San João da Pesqueira, and 4 leagues north and south between Villa Real and Lamego. The returns of the vintages in this area, known as the Alto Douro, from 1843 to 1851, show the average production of qualities fit for use in ordinary years to be 63,568 pipes, in addition to which there are 20,633 pipes of refuse, fit only for distillation; in all 84,211 pipes.

The alcoholic contents of Port wine, as given by Brande, are:—The maximum quality, 23·92; the minimum, 19·82.

Dr. Christison gives the alcoholic contents of Port wine in volume as:—Weak, 18; average of seven kinds, 20; strong, 21.

Red wine of a good character is grown in the vicinity of Figueira, and sometimes shipments have taken place from that port and from Aviero for the English market.

Portugal, in addition to Port wine and its congeners, yields a variety of other wines of a sound and good character; and at one time England consumed, though never very largely, the white wines of Lisbon and Bucellas, and the red wines of the Minho and Beira; but the taste for them changed; it was transferred to the drier and stronger-bodied wines of Spain, and their importation came to an end.

Spain.—The Sherries of Spain have long been favourite wines in England and the United States. In 1840, Sir E. Tennent informs us the consumption attained an average of 2,500,000 gallons, and in 1854 it had risen to 2,751,230 gallons. The more recent imports into this country will be seen in the Table at the end of this article.

In the *Basque Provinces* a light wine, called *Chacoli*, is produced, but not in large quantities. Mr. Lumley gives the value of the wines of this district as 17,072*l.*

Alicante produced about 21,118 pipes of wine in 1857.

Valencia produced about 150,000 pipes of 100 gallons each.

Cadiz produces annually from 60,000 to 70,000 butts of new wine (*Mosto*) at about 7*l.* per butt. The Sherries exported from this district are never under three to four years old.

Barcelona is stated to produce 85,000,000 gallons.

Tarragona exports by sea about 35,000 butts, and a large portion is consumed in the province.

Malaga.—Many kinds of grapes are cultivated in this province. The Pedro Ximenes, Doradillo, and Don Bueno are cultivated entirely for the manufacture of wine. The Uvas de Parra or trellis vine, the Passa larga or bloom raisin grape, and the Loja, which is shipped green for England for table use, are cultivated for exportation as fruit. Of Malaga wine the annual produce is on the average about 20,000 butts. Three butts of Malaga wine yield one of brandy, while ten butts of French wine are required to produce the same quantity of spirit. This brandy is used to cure the wines.

Aragon produces a large quantity of wine, those which are most preferred being the wines of Campo de Cariñena. Many of the wine districts of Old Castile produce also large quantities of wine.

'At present many of the Spanish wines are not only so badly made that they will not keep for two years, but their quality is much injured from their being kept and transported in pig-skins.'—*Correspondent of the Secretary of Legation at Madrid.*

Spain produces an enormous quantity of wine which is not suitable for the English market. Mr. Porter estimated that, good, passable, and bad, it amounted to 120,000,000 gallons; but (says Sir E. Tennent) the testimony is concurrent that, except in Andalusia and a few other minor localities, its manufacture is so imperfect, its qualities so peculiar, and its flavour so extraordinary, from carelessness, dirt, and other causes, that it is not presentable in the English market. Dr. Gorman, in his evidence before the House of Commons Committee, says:—'No natural Sherry comes to this country; no wine house will send it; the article you get is a mixed article; if they gave you the natural produce of Xeres it would not suit you; in all probability you would say it was an inferior wine; our taste is artificial, because we are not a wine-drinking people.'

Brande gives the alcohol in Sherry 18·37 the maximum, and 17·00 the minimum, while Dr. Christison gives the following result from his examination:—Weak, 17 in volume; average of 13 old wines, 18; strong, 20; Madre de Xeres, 21.

The *Montillado* of Spain is a wine which appears to depend for its character on the soil, which is a white soil called *albariza*, containing 70 per cent. of carbonate of lime, with alumina, silica, and a little magnesia. The *Manzanilla* is the produce of the *barros*, or red earths, somewhat sandy.

Sicily, as producing the celebrated *Sicilian Marsala*, is perhaps next in importance. Marsala resembles ordinary sherry in many respects; it is, when good, a wholesome, and, as it is technically described in the trade, a *clean* wine. Of Marsala, Sicily produces not less than 2,143,370 gallons. Sicily also produces red wine, but of a very coarse quality.

Madeira and the Canaries produce a wine, the former under the name of the place of its production, being well known. Its consumption has never, however, been very large. The produce of the island has rarely exceeded 25,000 pipes. In 1854 we imported 42,874 gallons.

Cape of Good Hope.—*Cape wine* has never found much favour in this country. In 1854 we imported 275,382 gallons, whereas in 1825 we obtained 670,000 gallons. This wine is used to some extent in the manufacture of 'British wines.'

South African Port and Sherry were at one time sent to the English market; and, as the price was remarkably low as compared with the Portuguese and Spanish wines, a large demand was created; but on the abolition of the differential duties in their favour on the conclusion of the Treaty of Commerce with France, they were unable to compete with the better qualities of wine produced in Europe.

The only Cape wine of any reputation is *Constantia*, a red liqueur wine produced on the farm of J. P. Kloete.

Australia.—Vine-growing and the manufacture of wine is practised in each of the three southern colonies of Australia, New South Wales, Victoria, and South Australia. The total produce being about 1,500,000 gallons annually. The wines are of different qualities, mainly red, and resemble Burgundy or the fuller wines of the South of France. The white wines resemble Sauternes or Muscatel, but all are more or less disguised by the addition of alcohol. Lately, however, this practice has been to a great extent discontinued.

Before we proceed to the more important wines of France and Germany, we must say a few words on—

United States.—*Catawba Wine.*—About the year 1826, 'the Catawba,' a native American grape, was first brought into notice by Major Adlum, who had found it growing in a garden at Georgetown, near Washington. This vine, which is derived from the wild fox grape, has gradually supplanted all others, and is now adopted, almost universally, throughout the United States for making wine. It imparts a very peculiar musty flavour to the wine, displeasing when first tasted to many palates; but this dislike is easily removed by habit, and the wine is much relished in Ohio and Missouri, where it sells readily at good prices.

About 3,000 acres are cultivated as vineyards in the state of Ohio; 500 in Kentucky; 1,000 in Indiana; 500 in Missouri; 500 in Illinois; 100 in Georgia; 300 in North Carolina; and 200 in South Carolina. It is calculated that at least 2,000,000 gallons of wine are now raised in the United States, the value of which may be taken at a dollar and half the gallon. This is in addition to a large amount produced in California.

In the United States the wine-press is constructed much on the same principle as the ordinary screw cider-press. It has an iron screw 3 or 4 inches in diameter, in a strong, upright frame. A box platform, 6 or 7 feet square, of 3-inch plank, is wedged into heavy timbers, and in this a box to contain the mashed grapes is placed, the box being perforated with holes. Bands to fit loosely inside the box, and pieces of scantling to receive the pressure, complete the implement. The power is applied by a strong lever, and the juice runs out through a hole in the floor, and is led into the cellar beneath by means of india-rubber pipes. Before being subjected to pressure, the grapes are bruised in a small wooden mill. When it is intended to make red wine, the grapes mashed by this process are allowed to stand for two or three days, and are then pressed, in order that the colouring-matter in the skins may be absorbed by the grape juice or 'must.' A sample of good Catawba wine examined by Dr. Chapman was found to contain 11·5 per cent. of alcohol.

Large quantities of sparkling wine are made at Cincinnati, and at St. Louis, and sold as sparkling Catawba.

GERMANY.—The principal wine-producing districts of Germany are situated in the Rhine valley and its tributaries; the chief vineyards being in the narrow portion of the river known as the Rheingau, between Mainz and Assmannshausen. The generic name of *Hock*, given to the produce of this district in England, is derived from Hockheim, which is, however, not on the Rhine, but on the north bank of the Main, about 3 miles east of Mainz. The fine wines of the Rheingau are among the most perfect products of the wine-grower's skill; being remarkable for their delicate flavour and bouquet. The first place is held by the low vineyards of Steinberg, belonging to the Prussian Government and Schloss Johannisberg, the property of Prince Metternich. The practice of allowing the grapes to become dead ripe before gathering prevails here, in the same manner as described in the picking of the fine wines of Sauternes. The other principal centres of production in the Rheingau are at Rudesheim, Marcobrunn, and Geisenheim. At Assmannshausen and Ingelheim, red wines are produced from a Burgundy grape. Other red wines are made at Runkel, on the Lahn, and more particularly in the valley of the Ahr, which, under the names of Walportzheimer and Ahrbleichart, is in considerable demand for local consumption at Bonn, Cologne, and other towns on the lower Rhine.

The principal vineyards of the Moselle are situated between Trier (Treves) and Coblentz, the villages giving their names to the best known growths, being Zeltingen, Piesport, and Brauneberg. The wines resemble those of the Rhine valley, but are lighter, and have less flavour. They mature quickly, but will not keep for any length of time.

A considerable amount of effervescing wine is produced at various manufactories (*Schaumweinfabrik*), at Coblentz, and other places on the Rhine; both Rhenish and Moselle wines being so treated. The natural deficiency of saccharine matter in the wine is supplied by the addition of sugar. The so-called muscatel flavour of the sparkling Moselle and Hock is mainly derived from the alcoholic infusion of elder-flowers.

AUSTRIA.—The total average vintage in Austria is estimated at 158,986,000 florins =3,974,650*l.*, while the value of the wine production amounts only to 40,000,000 florins, or about 1,000,000*l.* sterling.

The Austrian wines are on the average but of middling quality; yet there are some which can bear comparison with all but the very best Rhine, French, and Spanish wines. The principal wines of Austria and Hungary are—

'*Red wines*,' grown at Erlan, Carlowitz, Szeksard, Buda, Adelsberg, Villau, and St. André;

'*Schiller wines*,' a pale, reddish-coloured wine, grown at Erlan and Carlowitz;

'*White wines*,' grown at Pesth, Steinbruch-Berg, Totfaln, Moor, Teting, Vöslan, and Rust;

'*Wines of the first press*,' grown at Rust and Oedenburg.

FRANCE.—The chief wine-growing districts of France are Provence, Languedoc, Roussillon, Auvergne, Bourgogne, Saintonge, and Champagne, the rich valleys of the Gard, Hérault, Garonne, Dordogne, the Loire and the Rhône, and the neighbouring departments as far as the Pyrénées, the Hautes-Pyrénées, and the Pyrénées-Orientales.

The average production of wine per annum is between 40,000,000 and 42,000,000 hectolitres (of 22·0096 gallons English).

The following account of the principal French wines is condensed from Viscount Chelsea's Report on the *Effects of the Vine Disease.* He divides France into six principal districts:—

1st. The southern, including Corsica, Roussillon, Languedoc, and Provence.

(*a.*) *Corsican.* Corsica produces both dry and sweet wines, but in quantities too small for exportation.

(*b.*) *Roussillon.* These wines are produced exclusively in the Department of the Pyrénées-Orientales, which contains about 125,000 acres of vineyards. Sweet, dry, and ordinary wines are equally abundant. Strong, rich in colour, and being generous, they keep long, travel well, and are good for mixing with others. There are three recognised varieties, 1st, those of Banyuls, of Collioure, and of Port Vendres, red wines which generally improve with age: 2nd, those of Rivesaltes; the greater portion being ordinary wines of commerce, deep and brilliant in colour; 200 acres alone produce fine wines, as *Muscat, Manabes, Grenache, Malvoisie,* and *Raneio*: 3rd, Perpignay; the wines of this district will keep an indefinite time, and are sent to North and South America.

(*c.*) *Languedoc.* Under this name are included all the wines of the Hérault, Aude, and a part of Gard. The most important of these districts is that of Hérault, producing two kinds of wine; those for conversion into spirit and ordinary wines, which may be subdivided into red and white ordinary wines, fine red wine, white wines, dry and sweet, and Muscats.

Aude. This district produces a red wine at Limoux, and a white wine known by the name of Blanquette, which is nearly double the value of the preceding. Hérault is the most important wine country in the south of France; it is the largest producer of raw spirits in Europe. The red wines of Hérault are produced in the vineyards of St.-Georges-d'Orques; these are generally heady.

The white wines of Picardan include both dry and sweet.

Muscat, *Frontignan*, and *Lunel.* The cultivation of these wines has considerably diminished of late years; they have less flavour and do not keep so well as those of Rivesaltes.

The vineyards of St.-Gilles (Gard) produce a less delicate wine than those of Roussillon, but which serves to bring up the colour of other wines.

(*d.*) *Provence.* The wines of Provence have not the importance of those of Roussillon or of Languedoc. The chief growths of the region are:

1st. In the Var, that of Gande producing a fine wine, at first highly coloured and heady, but becoming dry with age.

2nd. That of Malgue, producing a wine which does not mature, but that bears the sea well.

3rd. That of Bandol, an excellent wine for export, improving much with age: it is sent to India, Brazil, and California.

In the Basses-Alpes, the vineyards of Mées yield a generous wine. In the Bouches-du-Rhône, Cassis produces the finest wines in the region, both red and white, much sought after by foreigners. The sour and flat wines of Roquevaire are little appreciated. The methods of cultivation are nearly the same in all the districts of the south of France. The soil is generally dug up before the vines are planted; in Roussillon only is this omitted, when the ground has been previously cultivated. In the latter, the operation of planting is carried on in January and February; in Languedoc it is put off until April.

With those varieties of the vine which produce the Muscat, it is the custom to rub off part of the buds. The vines are dressed four times during the first year, but afterwards only twice. They commence bearing in from three to four years. The grapes are pressed by the feet or between channelled rollers without being picked off the bunches. The wine is slightly sprinkled with lime or plaster-of-Paris when it is intended for commerce. It is allowed to ferment for ten, twenty, or even thirty days.

2nd. The south-eastern, including Gard, Vaucluse, Ardèche, Drôme, and Rhône. This region embraces all the lower part of the basin of the Rhône; the wines produced are generally known as wines of the Côte-du-Rhône.

(*a.*) That part of *Gard* which is included in this region produces, 1st, the red wine of *Tavel*—very dry, and improving much by age—and the red wine of *Lirac.* 2nd. The sweet wines of *Chusclan*, wines of the finest quality, and those of *Orsan* and *St.-Geniez*, of the second. The Gard also produces the ordinary wines of *St.-Laurent-des-Arbres* and *Roquemaure.*

(*b.*) *Vaucluse.* The chief growths are the *Château-Neuf-du-Pape*, a very celebrated wine, and the growth of *La Nerthe*, which is decreasing both in quality and quantity; it is sent to Bordeaux and Burgundy, for the purpose of colouring other wines. In Vaucluse also are the vineyards of the *Château-Vieux*, of *Nettes*, and of *Etret.*

(*c.*) *Ardèche* includes the famous vineyards of *St.-Peray.* This white wine, when in a state of effervescence, almost equals Champagne, which, however, has more lightness, delicacy, and softness. It is sent to England, Germany, Belgium, and Holland. The best sparkling sort sells at 2 francs 50 centimes the bottle. There are also the vineyards of St.-Jean, Comas, and St.-Joseph. The sparkling wine of St.-Peray is produced in the same way as Champagne.

(*d.*) *Drôme.* The *Hermitage*, the most famous vineyard in the Côte-du-Rhône, consists only of 140 hectares. It produces red wine, white wine, and 'vins de paille' (straw-coloured); the other vineyards are *Larnage*, *Rochegude*, *Crozes*, and *Mercurol*, all of which wines are esteemed.

(*e.*) *Rhône.* The southern part of the Rhône produces wine very similar to the preceding. The best known are of those of *Condrieux* and *St.-Michel.*

The vineyards of the Hermitage are managed with great care; the soil is dry to the depth of a meter (39 inches); the leaves are picked off the vine, and it is dressed and tended five times a year during the first two years; the grapes are stripped off the stalks, and the fermentation lasts ftom fifteen to twenty days.

3rd. The eastern region is formed principally of the Valley of the Saône.

(*a.*) *Beaujolais*, the *Mâconnais*, and the *Côte-Chalonnaise.* These wines are delicate, light, well-flavoured, but not highly-coloured; they are principally consumed in the interior of France. The principal growths are of *Chênas* and that of *Fleury.* The *Mâconnais* produces the highly-esteemed white wine of *Pouilly*, a dry wine which keeps badly, and the red wine of *Romanèche.* The wines of *Côte-Chalonnaise* are common wines, amongst which the *Mercurey* alone is remarkable.

(*b.*) *Haute-Burgogne*, consisting of the Côte-d'Or, produces the most famous wines in Burgundy. The white wines of the Côte-d'Or, most known are those of *Montrachet*, very superior wines; of *Meursault*, very delicate, light, and with a delicious 'bouquet;' and those of Blaquy. It is the red wines, however, which give pre-eminence to this district. Here grow the renowned *Volnay, Pomard, Beaune, Nuits,* more spirituous than the others, and which require to be kept five or six years in the wood; *Vosne, Romanée-Conti, Clos-de-Vougeôt,* and *Chambertin.*

(*c*). *Basse-Burgogne.* The wines of Lower Burgundy are brisk, delicate, and light, but too spirituous. The *Tonnerre* is fit for drinking after the third year, and the wines of *Auxerrois*, which are sooner matured. In Auxerrois also are the vineyards of *Chablis*; these white wines, so much esteemed for their lightness, are made in the early part of October, under the name of *Chablis.* A large quantity of other white wine from the neighbouring vineyards finds its way into the market. The wines of *Avallonais*, and those of Joigny are sent to Flanders and Belgium.

(*d.*) *Jura.* The wines of this district are in general dry, heady, brisk, but with some acidity, which arises from their bad cultivation and the unskilful mixture of the vines, and reduces their reputation. In addition to the inferior wines, the Jura produces also rose-coloured wines ('*Vins Rosés*'); these are sparkling wines, and the luscious wine known under the name of '*Vin de Garde du Château Chalons.*' This vineyard only comprises 96 hectares. The wines produced there require to be kept from twelve to fifteen years in the cask. All these wines are consumed where they are grown, or sent to Switzerland.

At Seyssel, and other places, in the neighbourhood of Lyons, and in Savoy, a pleasant white sparkling wine is produced and known locally as *Vin-des-Asphaltes*, the vineyards being situated on the asphaltic limestones now so extensively used as a paving material in Paris and London.

(*e.*) *Alsace* produces only common wine, with the exception of the *Turchemi* and *Ribeauviller.*

(*f.*) *Lorraine.* The principal growths are those of *Thiancourt, Pagny,* and *Scy.*

(*g.*) *Champagne.* The wines of the Department of the Marne, known under the name of *Champagne*, have a universal reputation.

Champagne Wines are divided into four categories:—*Sparkling Granot, Ordinary Sparkling, Half Sparkling, Tisane de Champagne.*

The following are the principal growths:—

On the Marne	By the Avise	On the Mountains of Rheims
Mareuil.	*Avise.*	*Bouzy.*
Ay.	*Cramant.*	*Ambonnay.*
Hautvillers.	*Oger.*	*Mailly.*
Epernay.	*Mesnil.*	*Sillery.*
		Romont.

The most esteemed kinds are the *Sillery, Ay, Cramant,* and *Bouzy.* In good seasons this district does not produce less than 15,000,000 bottles of white wine. The average produce is 7,000,000, of which 6,000,000 are sent to England, Russia, and Germany.

The methods employed in Lower Burgundy and Champagne are nearly the same. It is not as respects the cultivation of the plant, but in the methods adopted in making the wine, that the latter is remarkable.

In the manufacture of Champagne black grapes of the first quality are usually employed, especially those gathered upon the vine called by the French *noirien*, cultivated on the best exposures. As it is important, however, to prevent the colouring-matter of the skin from entering into the wine, the juice is squeezed as gently and rapidly as possible. The liquor obtained by a second and a third pressing is reserved for inferior wines, on account of the reddish tint which it acquires. The marc is then mixed with the grapes of the red-wine vats.

The above nearly colourless must is immediately poured into tuns or casks, till about three-fourths of their capacity are filled, when fermentation soon begins. This is allowed to continue for about 15 days, and then three-fourths of the casks are filled up with wine from the rest. The casks are now closed by a bung secured with a piece of hoop-iron nailed to two contiguous staves. The casks should be made of new wood, but not of oak; though old white wine-casks are occasionally used.

In the month of January the clear wine is racked off, and is fined by a small quantity of isinglass dissolved in old wine of the same kind. Forty days afterwards a second fining is required. Sometimes a third may be useful, if the lees be considerable. In the month of May the clear wine is drawn off into bottles. Viscount Chelsea says, 'The wine is bottled between April and August. Warm weather is necesssary to produce the sparkling wine. The effervescence is the result of carbonic acid gas produced by fermentation, which being interrupted in the cask, reproduces and developes itself in the bottles. For this a temperature of from 70° to 75° Fahr. are required. The bottles, as soon as they are filled, which process is effected by women, are handed over to men called "boucheurs," who add a certain quantity of a mixture of brandy and sugar-candy (in the proportion of 15 to 16 per cent. for those wines intended for the English market), taking care to leave about 2½ to 3 inches space between the cork and the wine; they then introduce by a machine a moistened cork, and pass the bottle on to other men called "maillochers," whose business it is to drive the cork home with a mallet, who again transfer them to those who fasten them with a string or wire; sometimes this is done by a machine. It takes an hour to bottle a tun of 88 gallons. The bottles are ranged against the cellar-walls in horizontal layers, each being reversed as it regards the previous layer. Eight or ten days afterwards a deposit, called '*griffe*,' is found at the bottom of the bottle. This indicates the time for removing the bottles to the second or permanent cellar; this is the period also when breakage commences. This loss can neither be foreseen nor prevented, and is often dangerous; it happens mostly at the season when the vine blossoms. The bottles are first placed in the coldest cellars and afterwards removed to warmer temperatures. In the second winter means are taken to remove the deposit formed in the summer; the bottles are placed with their mouths downwards, and are shaken for twenty days, to cause the sediment to fall into the neck. At the end of this time the bottle is uncorked, the sediment thrown out, and a fifth part of the contents replaced by the sweetened liquor, when the bottles are again corked, tied, and stacked as before.' The bottles being filled, and their corks secured by packthread and wire, they are laid on their sides, in this month, with their mouths sloping downwards at an angle of about 20 degrees, in order that any sediment may fall into the neck. At the end of 8 or 10 days the inclination of the bottle is increased, when they are slightly tapped, and placed in a vertical position; so that after the lees are all collected in the neck, the cork is partially removed for an instant, to allow the sediment to be expelled by the pressure of the gas. If the wine be still muddy in the bottles, along with a new dose of *liquor*, a small quantity of fining should be added to each, and the bottles should be placed again in the inverted position. At the end of two or three months the sediment collected over the cork is dexterously discharged; and if the wine be still deficient in transparency, the same process of fining must be repeated.

Sparkling wine (*Vin mousseux*), prepared as above described, is fit for drinking usually at the end of from 18 to 30 months, according to the state of the seasons. It is in Champagne that the lightest, most transparent, and most highly flavoured wines have been hitherto made. The breakage of the bottles in these sparkling wines amounts frequently to 30 per cent., a circumstance which adds greatly to their cost of production. The tension of the carbonic acid gas in the best quality of champagne is from 4½ to 5 atmospheres. If higher, the greater part of the gas is liberated on drawing the cork, and the wine is in great part lost. About 7 or 8 atmospheres is the highest pressure that the bottles will bear without bursting; this is about the working pressure of a high-pressure steam-boiler, from 105 lbs. to 124 lbs. per square inch.

(4.) *Central Region.* In the five departments comprised in this district the common wines alone are produced; the white wine of *Pouilly* being the only celebrated one.

(5.) *Western Region.* The two departments lying on the banks of the Loire, Indre-and-Loire and Maine-and-Loire, possess 40,000 hectares of vineyards; the principal growths are those of *Joué, Bourgueil, Vouvray*, and the white wine of *Saumur*. More than 2,000,000 hectolitres of wine are annually devoted in Aunis, Saintonge, and Angoumois, to the distillation of brandy, so well known as *Cognac*. Of the 200,000 hectares of vineyards in the Charente and Charente-Inferior, only one-third is cultivated for home consumption or exportation, the remaining two-thirds being employed in making brandy. This is divided into two classes, that which is produced in the plain of Champagne in the arrondissement of Cognac, which is again divided, according to the quality, into *Champagne* fine and common *Champagne de Bois*, and *Eau de Vie de Bois*, and that of Aunis, produced from the vines on the banks of the river.

(6.) *South-Western District.* The Gironde and Jurançon are the only localities of any special interest. Although the wines of the Gironde have a common origin, they are divided in commerce into five great classes: *Médoc, De Grave, Des Côtes Palus*, and '*D'Entre Deux-mers.*'

The district known as Médoc, or the promontory between the left bank of the Gironde and sea to the west and north of the city of Bordeaux, is remarkable for the great value and extent of its wine production, the produce of the vineyards of this district being estimated at a value of 11,000,000*l.* in ordinary years. The centre of the trade is at Bordeaux, where the following classification of the different growths is adopted:

1st class. *Premiers Crus.* This includes only three growths: those of Château-Lafitte, Château-Margaux, and Château-Latour.

2nd class. Twelve growths: includes Mouton, Leoville, Larose, and Braue Cautenac.

3rd class. Fourteen growths: including Kirwan, Cautenac, Lagrange, and Giscours.

4th class. Twenty-eight growths: including St.-Pierre, Beycherille, and others in Pauillae and St.-Estèphe districts.

Besides the above, there is a fifth class of named wines, below which the qualities are distinguished as Bourgeois, superior and inferior, and Paysans, the latter being the lowest class.

The proportional scale of prices in an average year may be taken as follows:—

	£		£	
1st class	80	to	200	per tonneau.
2nd "	48	"	56	"
3rd "	32	"	36	"
4th "	28	"	36	"
5th "	24	"	28	"
Bourgeois, superior	16	"	20	"
" ordinary	14	"	16	"
Paysans	12	"	13	"

Much of the red wine exported from Bordeaux is fortified with red Hermitage, Spanish red, or other similar Southern wine, for the purpose of increasing its alcoholic strength. The demand for Bordeaux wines is so large and constantly increasing that it would be difficult to meet it without having recourse to sources of supply not lying within the district.

White Wines of the Gironde.—The principal white-wine producing districts in the Gironde are those of Graves and Sauterne, which are on the left bank of the Garonne above Bordeaux.

The most celebrated vineyards are those of Château-Yquem and Château-Latour Blanche. The treatment of the grapes differs from that in other districts, for they are allowed to remain on the vines until they are rotten ripe, and are then gathered berry by berry, care being taken to reject such as may be too far gone, or not sufficiently ripe. By this means a greater amount of saccharine-matter and higher flavour is obtained in the must than is the case in any other wine. Each picking is crushed separately, and the process is so arranged that the vintage of each day is kept apart. The first seven days' collection gives the so-called head wines, *vins de tête*, which are the sweetiest and heaviest; the second or *vins de milieu*, contain less sugar, while the third or *queues*, which are made by pressing all the grapes remaining from the former selections, are the driest. From their great sweetness and strength the highest class of Sauternes require to be kept for several years before their peculiar fineness and richness of flavour is developed. The wines of Château-Yquem when five years old, are valued on the spot at from 400*l.* to 600*l.* per tonneau, according to the vintage.

Such is a somewhat concise statement of the varieties of wines known in commerce. It is not possible to enter into all the details of the manufacture, varying as it does in every locality, the numerous peculiarities being due in some cases to the conditions of the grape itself, and in others to the methods pursued with regard to the fermentation and the subsequent treatment of the wine.

There are many persons who confound the 'flavour' of wine with the 'bouquet.' The differences are well determined by the writer on wine in the 'Penny Cyclopædia.' 'The flavour of wine, called by the French *sève*, indicates the vinous power and the aromatic savour which are felt in the act of swallowing the wine, embalming the mouth, and continuing to be felt after the passage of the liquor. It seems to consist of the impression made by the alcohol and the aromatic particles which are liberated and volatilised as soon as the wine receives the warmth of the mouth and stomach. The *sève* differs from the *bouquet*, inasmuch as the latter declares itself the moment the wine is exposed to the air; it is no criterion of the vinous force or quantity of alcohol present (being, in fact, greatest in weak wines), and influences the organ of smell rather than of taste.'

The *bouquet* of wine is a new product, and in no way dependent on the perfume of the grape from which the wine is made. Red wines scarcely ever retain a trace of the odour of the grapes; the white muscadine wines do in some degree, especially *Frontignan*.

Liebig, in his 'Organic Chemistry,' has the following remarks on the *bouquet*:—'It is well known that wine and fermented liquors generally contain, in addition to alcohol, other substances which could not be detected before their fermentation, and which must therefore have been formed during that process. The smell and taste which distinguish wine from all other fermented liquids are known to depend upon an ether of a volatile and highly combustible acid, which is of an oily nature, and to which the name of *œnanthic ether* has been given.'

On the Rhine an artificial *bouquet* is often given to wine, by hanging orris-root in the casks, or by the use of aromatic herbs.

The volatile substance existing in wine which imparts to it, conjointly with œnanthic ether, its vinous aroma, is partly alcohol. There are other odoriferous substances developed in the course of time; these are compounds of oxide of ethyl, amyl, or propylene, with acetic, propionic, pelargonic, butyric, caproic, caprylic, or capric acids. *Acetic ether* is present in all aromatic wines, and fraudulent dealers will add acetic ether in small quantities to their artificial compounds.

Butyric ether is much used by confectioners, who call it 'pine-apple oil.' *Caprylic ether* has a similar flavour; these are slowly developed in some wines by time. In Watts's 'Dictionary of Chemistry' the other chemical compounds will be found fully described.

Wine produced from grape-juice alone is perfectly colourless or white; but as the whole mass of the grapes is pressed together, it is impossible but that some admixture of the components of the grape-skins should occur. White wine may be prepared from purple grapes, but if the skins are allowed to ferment, red or yellow wine will be obtained. The Italian wine, *Vino Cebedino*, is about the most colourless of wines.

The colour in wines appears to be due to the presence of extractive matter, which, when oxidised, assumes a red or brown colour. This colouring-matter has been called *apothema* by Berzelius, but it is, in fact, humic acid, retaining traces of the substance from which it has been derived.

Whilst the juice of grapes ferments, the skins being present, the wine which is in process of formation extracts tannic acid from the skins, and this gives the yellow colour—when by oxidation it is converted into apothema—to Muscadel, Champagne, Teneriffe, and Madeira.

What we call Red wines are prepared from either black, purple, or red grapes, the juice of which is colourless, and the skins of which are allowed to ferment. During fermentation the weak spirit which is formed extracts not only tannic acid but blue colouring-matter from the skins. This blue colouring-matter is tinged more or less red by the tartaric acid of the wine, and may afterwards be rendered more decidedly red by the formation of acetic acid. In the change of colour undergone by red wine, five periods, according to Mulder, must be distinguished. As soon as alcoholic liquid is formed during fermentation, blue colouring-matter begins to be extracted from the skins. As the small amount of blue colouring-matter is brought into contact with grape-juice, which has an acid reaction, it becomes red. The fermentation and formation of alcohol proceed, as does also the solution of blue colouring-matter, and the young wine is rather blue than red, and may be called 'dark violet.' This new wine now undergoes fermentation, during which a great deal of colouring-matter and red tartar, as well as apothema of tannin and albumen, is precipitated. The loss of the colouring-matter causes the wine to become lighter. In the meantime the formation of acetic acid begins, and at a later period increases; the amount of colouring-matter is not thereby diminished, but the larger proportion of acid in the liquid reddens its colour. Another period now begins, during which the tannic acid is slowly converted into apothema, whereby red colouring-matter is again precipitated out of the liquid, for example, in Port wine; it thus gradually diminishes, and finally, after a length of time, disappears entirely from the wine, which then remains what is called 'yellow.' This will explain the alterations produced by keeping wines.

According to the character of the wine, as already stated, is its power of enduring unchanged, or of improving by age. Weak wines of bad growths ought to be consumed within twelve or fifteen months after being manufactured; and should be kept meanwhile in cool cellars. White wines of middling strength ought to be kept in casks constantly full, and carefully excluded from contact of air, and the racking off should be done as quickly as possible. As the most of them are injured by too much fermentation, this process should be so regulated as always to leave a little sugar undecomposed. It is useful to counteract the absorption of oxygen, and the consequent tendency to acidity, by burning a sulphur-match in the casks into which they are about to be run. This is done by hooking the match to a bent wire, kindling and suspending it within the cask through the bung-hole. Immediately on withdrawing the match, the cask should be corked, if the wine be not ready for transfer. If the burning sulphur be extinguished on plunging it into the cask, it is a proof of the cask being unsound, and unfit for receiving the wine; in which case it should be well cleansed, first with lime-water, then with very dilute sulphuric acid, and lastly with boiling water.

Wine-cellars ought to be dry at bottom, floored with flags, have windows opening to the north, be so much sunk below the level of the adjoining ground as to possess a nearly uniform temperature in summer and winter; and be at such a distance from a frequented highway or street as not to suffer vibration from the motion of carriages.

Wines should be racked off in cool weather; the end of February being the fittest time for light wines. Strong wines are not racked off till they have stood a year or eighteen months upon the lees, to promote their slow or insensible fermentation. A syphon well managed serves better than a faucet to draw off wine clear from the sediment. White wines, before being bottled, should be fined with isinglass; red wines are usually fined with white-of-egg beat up into a froth, and mixed with two or three times their bulk of water. But some strong wines, which are a little harsh from excess of tannin, are fined with a little sheep or bullock's blood. Occasionally a small quantity of sweet glue is used for this purpose.

For further information, see 'Chemistry of Wine,' by G. J. Mulder, edited by H. Bence Jones, M.D. F.R.S.; and Watts's 'Dictionary of Chemistry.' Also A 'Treatise on Wine,' by Thudicum and Dupré, London, 1872. This is the most comprehensive work on the subject in the English language.

The following Maladies of Wines are certain accidental deteriorations, to which remedies should be speedily applied:—

La-Pousse ('pushing out of the cask'), is a name given to a violent fermentative movement, which occasionally supervenes after the wine has been run off into the casks. If these have been tightly closed, the interior pressure may increase to such a degree as to burst the hoops, or cause the seams of the staves or ends to open. One remedy is, to transfer the wine into a cask previously fumigated with burning sulphur; another is, to add to it about 1000th part of sulphite of lime; and a third, and perhaps the safest, is to introduce ½ lb. of mustard-seed into each barrel. At any rate the wines should be fined whenever the movements are allayed, to remove the floating ferment which has been the cause of the mischief.

Turning Sour.—The production of too much acid in a wine is a proof of its containing originally too little alcohol, of its being exposed too largely to the air, or to vibration, or to too high a temperature in the cellar. The best thing to be done in this case is, to mix it with its bulk of a stronger wine in a less advanced state, to fine the mixture, to bottle it, and to consume it as soon as possible, for it will never prove a good keeping wine.

Ropiness or Viscidity of Wines.—The cause of this phenomenon, which renders wine unfit for drinking, was altogether unknown, till M. François, an apothecary of Nantes, demonstrated that it was owing to an azotised matter, analogous to gluten; and, in fact, it is the white wines, especially those which contain the least tannin, which are subject to this malady. He also pointed out the proper remedy, in the addition of tannin under a rather agreeable form, namely, the bruised berries of the mountain-ash (*sorbier*) in a somewhat unripe state; of which 1 lb. well stirred in, is sufficient for a barrel. After agitation, the wine is to be left in repose for a day or two, and then racked off. The tannin by this time will have separated the azotised matter from the liquor, and removed the ropiness. This wine is to be fined and bottled off.

The taste of the cask, which sometimes happens to wine put into casks which have remained long empty, is best remedied by agitating the wine for some time with a spoonful of olive oil. An essential oil, the chief cause of the bad taste, combines with the fixed oil, and rises with it to the surface.

The quantity of alcohol contained in different wines has been made the subject of elaborate experiments by Brande and Fontenelle, and several others; but as it must evidently vary with different seasons, the results can be received merely as approximate. The proportion given by Brande (Table I. page 1147), has been reduced to the standard of absolute alcohol by Fesser; and that by Fontenelle (Table II.), to the same standard by Schubarth, as in the following Tables. Table III. gives the alcoholic strength of the Rhine wines.

From the known prices of these wines, it is obvious that the proportion of alcohol, although one factor in determining the value of a wine, is not the only absolute one nor does it stand in any fixed relation to the commercial value of the wine. It is remarkable that the finest sorts of wines contain a much greater proportion of solid substances in solution than the inferior sorts; and that the weight of the residue, which the Rhenish wines yield on evaporation, offers a safer criterion for determining their commercial value than the proportion of alcohol. These solids disguise the acid, take off the acrid taste, and at the same time impart body, mellowness, and oiliness. Among the extractive matters of new wines are sugar, which gradually disappears by keeping; and also some imperfectly known gummy substances, which become brownish when the wine is submitted to evaporation. The presence of these in wine appears chiefly to be determined by the soil, and the condition and locality of the vineyard; and it is obvious that the qualities dependent upon these extractive matters cannot by replaced by sugar.

Port is one of the wines which is richest in alcohol. Ginjal has stated that genuine Port wines never contain more than 12·75 per cent. of pure alcohol.

With regard to alcoholic contents, Madeira ranks next to Port wine, in which respect they differ but little from each other. Liquor wines are as a rule stronger than red wines. Jurançon, Lachrymæ Christi, Benicario, and Sauterne, all contain from 12 to 15 per cent. alcohol and more. Red French wines contain less—from 9 to 14 per cent. Good Bordeaux contains 10, 11, 12 per cent. Burgundy 9, 10, 11 per cent. Champagne 10, 11 per cent. Rhine wine from 6 to 12 per cent., generally from 9 to 10 per cent.—*Mulder*.

Under the title of the 'Deacidification of Wines,' Professor Liebig published in his *Annalen* a process for effecting that valuable object on old stored (*alte abgelagerte*) Rhine wines. 'Most of these wines,' he says, 'even of the most propitious growths, and in the best condition, contain a certain quantity of free tartaric acid, on whose presence many of their essential properties depend. The juice of all sorts of grapes contains bitartrate of potash, and that of those of the young shoots, in good years, is saturated with it. When the must of these sorts of grapes becomes fermented, the tartar diminishes in solubility proportionally as the alcohol increases, and a part of it falls along with the yeast. This deposit of tartar increases during the first years of the vatting; the sides of the casks become encrusted more and more with its crystals, in consequence of the continual addition of the new wine to replace what of the liquid is lost by evaporation, so as to keep the casks full, and prevent the destruction of the whole. But this deposition has a limit. By the filling up, the wine receives a certain quantity of free tartaric acid, and thereby acquires, at a certain point of concentration, the faculty of re-dissolving the deposited tartar. In the storing of many of the finer wines, the tartar again disappears at a certain period. By progressive filling up, the proportion of acid proportionally augments, the taste and flavour of the wine are exalted, but the acid contents make the wine less agreeable in use. Amateurs and manufacturers should therefore welcome a means of taking away the free tartaric acid without altering in any respect the quality of the wine. This is pure neutral tartrate of potash. When this salt, in concentrated solution, is added to such a fluid as the above, there results the sparingly soluble tartar (one part of which requires from 180 to 200 parts of water of ordinary temperature for its solution), the free acid combines with the neutral salt, and separates as bitartrate from the liquid. If we add to 100 parts of a wine which contains one part of free tartaric acid, one and a half part of neutral tartrate of potash, there will separate by rest at 18°—19° Cent., 2 parts of crystalline tartar, and the wine contains now one half part of tartar dissolved, in which there are only 0·2 part of the original free acid. In this case 0·8 of the free acid has been withdrawn from the wine.'

Wines, British, are made either from infusions of dried grapes (raisins) or from the juices of native fruits, properly fermented. These wines are called *sweets* in the language of the Excise, under whose superintendence they were placed till 1834, when the duties upon them were repealed, as onerous to the trade and unproductive to the revenue. The raisins called Lexias are said to produce a dry flavoured wine; the Denias a sweet wine; the black Smyrnas a strong-bodied wine, and the red Smyrnas and Valencias a rich and full wine. The early spring months are the fittest time for this wine-manufacture. The masses of raisins, on being taken out of the packages, are either beaten with mallets or crushed between rollers in order to loosen them, and are then steeped in water in large vats, between a perforated board at bottom and another at top. The water being after some time drawn off the swollen and softened fruit, pressure is applied to the upper board to extract all the soluble sweet matter, which passes down through the false bottom, and flows off by an appropriate pipe into fermenting tuns. The residuary fruit is infused with additional water, and then squeezed: a process which is repeated till all the sweets are drained off, after which the 'rape' is subjected to severe pressure in a screw or hydraulic press. The wine, in the process of the vinous fermentation, is occasionally passed through a great body of the rape to improve its flavour, and also to modify the fermentative action; it is afterwards set to ripen in casks, clarified by being repeatedly racked off, and fined with isinglass.

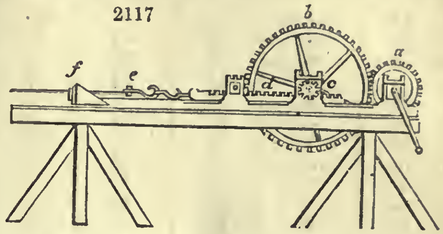
WINE-STONE is the deposit of crude tartar, called 'argal,' which settles on the sides and bottoms of wine-casks. See WINE.

WIRE-DRAWING. (*Tréfilerie*, Fr.; *Drahtziehen*, *Drahtzug*, Ger.) When an oblong lump of metal is forced through a series of progressively diminishing apertures in a steel plate, so as to assume in its cross-section the form and dimensions of the last hole, and to be augmented in length at the expense of its thickness, it is said to be wire-drawn. The piece of steel called the *draw-plate* is pierced with a regular gradation of holes, from the largest to the smallest; and the machine for overcoming the lateral adhesion of the metallic particles to one another is called the *draw-bench.* The pincers which lay hold of the extremity of the wire, to pull it through the successive holes, are adapted to bite it firmly, by having the inside of the jaws cut like a file. For drawing thick rods of gilt silver down into stout wire, the hydraulic press has been had recourse to with advantage.

Fig. 2117 represents a convenient form of the draw-bench, where the power is applied by a toothed wheel, pinion, and rack-work, moved by the hands of one or two men working at a winch; the motion being so regulated by a fly-wheel, that it does not proceed in fits and starts, and cause inequalities in the wire. The metal requires to be annealed, now and then, between successive drawings, as otherwise it would become too hard and brittle for further extension. The reel upon which it is wound is sometimes mounted in a cistern of sour small beer, for the purpose of clearing off, or loosening at least, any crust of oxide formed in the annealing, before the wire enters the draw-plate.

2117



When, for very accurate purposes of science or the arts, a considerable length of uniform wire is to be drawn, a plate, with one or more jewelled holes, that is, filled with one or more perforated rubies, sapphires, or chrysolites, can alone be trusted to, because the holes even in the best steel become rapidly wider by abrasion. Through a hole in a ruby 0·0033 of an inch in diameter, a silver wire 170 miles long has been drawn, which possessed at the end the very same section as at the beginning: a result determined by weighing portions of equal length, as also by measuring it with a micrometer. The hole in an ordinary draw-plate of soft steel becomes so wide, by drawing 14,000 fathoms of brass wire, that it requires to be narrowed before the original sized wire can be again obtained.

Wire, by being diminished one-half, one-third, one-fourth, &c., in diameter, is augmented in length respectively four, nine, sixteen times, &c. The speed with which it may be prudently drawn out depends upon the ductility and tenacity of the metal; but may be always increased the more the wire becomes attenuated, because its particles progressively assume more and more of the filamentous form, and accommodate themselves more readily to the extending force. Iron and brass wires, of 0·3 inch in diameter, bear drawing at the rate of from 12 to 15 inches per second; but when of 0·025 ($\frac{1}{40}$) of an inch, at the rate of from 40 to 45 inches in the same time. Finer silver and copper wire may be extended from 60 to 70 inches per second.

By enclosing a wire of platinum within one of silver ten times thicker, and drawing down the compound wire till it be $\frac{1}{300}$ of an inch, a wire of platinum of $\frac{1}{3000}$ of an inch will exist in its centre, which may be obtained apart, by dissolving the silver away in nitric acid. This pretty experiment was first made by Dr. Wollaston.

The French draw-plates are so much esteemed, that one of the best of them used to be sold in this country for its weight in silver. The holes are formed with a steel punch; being made large on that side where the wire enters, and diminishing with a regular taper to the other side.

WIRE-ROPE. The manufacture of ropes made of wire has, of late years, become a most important one. Not only are ropes of this description now employed in the most extensive coal mines of this country, and for winding generally, but they are used for much of the standing rigging of ships, and for numerous ordinary purposes. Perhaps the most important application of wire-rope has been, however, in the construction of the electric cables. See ELECTRO-TELEGRAPHY.

The Tables on the following page show the relative values of ropes of hemp, iron, and steel.

The applications of wire are extraordinarily numerous and interesting. Many thousands of lives are every day trusted to wire in the form of wire-rope for collieries and mines, and the lives of the men ascending and descending a coal pit literally depend from these iron threads. The standing rigging of ships is now generally made of wire-rope. The introduction of telegraphy has given great development to the manufacture of wire. The conducting portion of submarine electric telegraph cables is simply a wire-rope made of copper wires, while the outside protective sheathing generally consists of iron wire. One of the most important applications of wire of late years is that of steel wire in the form of the wire-rope used for

steam ploughing, and it may safely be said that steam ploughing would have remained an impossible project without the steel wire-rope. The very great distances, often reaching to 300 yards or more, to which the power is carried by means of the wire-rope in steam ploughing, would seem to point to its application to other purposes in which power is required to be transmitted to great distances. Many and varied are what may be termed the domestic applications of wire. Wire fences, bell-pulls, and, in the form of gauze, to ventilators, are only a few of these. Another most interesting employment of wire, even in a strictly scientific sense, is for the strings of pianofortes. Steel wire is now solely used for this purpose. Professor W. Pole, at the request of the Messrs. Broadwood, the pianoforte-makers, some time ago made a number of experiments on this kind of wire; of which he gave a short account at the Birmingham Institution of Mechanical Engineers. Some of the steel wire he tested, which was made in Germany, bore as much as 110 and 120 tons to the square inch, or about double the breaking strength of good steel. Suspension bridges, a few years ago, used to be made very extensively of wire. The two most celebrated erections of this kind are those of Niagara and Freiberg; the wire of the first was made in Manchester, and broke at 40 tons to the square inch, while that of Freiberg was made in Switzerland, and stood 50 tons to the square inch. The carding of wool and cotton is also effected by means of wire. Brushes of all kinds are now made of steel and iron in this form, even hair-brushes. It is more than probable that wire would be much more used for constructive purposes if some good and generally applicable means for preventing the corrosion of iron and steel could be brought forward. In fact, that is, for all applications of iron, almost the problem of the day. It has been noticed by careful observers that, though Swedish charcoal iron-wire has about the same ultimate breaking tensile strength as other wire, it is nevertheless much more economical than common wire for rope and other purposes in which elasticity and suppleness are required—another proof that breaking strength alone is a very unreliable quality.

The ultimate strength of wire generally, and especially that of iron and steel wire, almost always decreases as the diameter increases—as is also the case with forged and rolled bars, in which the metals are united in greater bulk. Some very small kinds of charcoal wire only break with loads of about 100 tons to the square inch; while the average strength of wire may be taken as double that of rolled bar. Rolled bars, of various qualities, possess breaking strengths ranging from 20 to 40 tons to the square inch, and iron wire will, on an average, be also found to vary from 40 to even 80 tons to the square inch. The most extensive series of experiments on wires has been due to M. Leblanc, who built a rather considerable bridge of wire at Roche-Bernard, in France. Amongst other important inquiries, he also investigated the question whether wires of a great length did not give less resistance than shorter lengths on account of the probable greater number of flaws. He thus took from twelve sets of different wire twelve pieces two meters long and twelve pieces twenty-six meters long, and submitted them to tensile loads. The wire was rather more than one-eighth of an inch in diameter. The resistance of the short pieces was found to be almost the same as that of the long lengths. By means of some experiments extending over a lengthened period, M. Leblanc also found that a wire can support during three months a tension at least equal to nine-tenths of that which would break it without diminishing its ultimate breaking strength, though undergoing elongations of 0·00596 of its original length. General Morin also carried out, some years ago, a number of experiments on long lengths of wire, in order to determine the important question whether wires take a permanent set with the smallest loads: a fact maintained by Mr. Hodgkinson, and which would appear to militate against the doctrine of the elastic limit. The trials were conducted with very great nicety, and their results seem to show that the permanent sets observed by Mr. Hodgkinson were due to the bends taken by the wire when coiled, and which afterwards get stretched out under the loads, as also partly to variations of temperature. In general it may be observed that wire, as compared with bar iron, seems to be better for undergoing impulsive forces, as it is perfectly elastic under loads which, cross-section for cross-section, would break rolled or forged iron. Both rolled iron and wire seem to be able to support for a length of time static loads of an amount very near that which would produce rupture. The elongations are also in proportion to the loads, but this proportionality seems to cease sooner with wire than with wrought iron. The irregularity of the elongations begins with wrought iron with loads of about half the breaking loads, and with wire at about one-third or one-fourth of the load that would cause rupture. Annealing, or cooling down slowly from a red heat, has the same effect on wire as on wrought iron; that is to say, the ductility, and the softness, of both is increased, but their elasticity, and also breaking strength, are considerably diminished. But few experiments have yet been published on the strength and other mechanical qualities of steel wire. It may, however, be taken to have, on an average, twice the ultimate strength of iron wire, and a proportionately greater elasticity, comparing diameter with diameter. These qualities allow steel wire-rope to be made little more than half the weight of iron wire-rope, with the same ultimate breaking strength. The additional elasticity of steel wire and of steel wire-rope renders it much more supple, and less liable to injury through being bent over a drum. A steel rope easily straightens of itself after being bent even to a small angle, which is not the case with iron wire-rope. The duration of all ropes is very greatly influenced by the many bendings to and fro to which they are subjected, and these influences are intensified by corrosion. Both the mechanical and the chemical sources of deterioration act in a less degree on steel wire, as it is stronger, and is, at the same time, less subject to corrosion, as the carbon it contains, however slight, greatly impedes the action of rust. It has been proved that wire-rope which is made of soft annealed wire cannot stand one-quarter or one-sixth of the bending to and fro that it can stand if made of the same wire after it has been hardened. It is to be noticed that, although it can matter but little as regards absolute length whether a wire-rope elongates or takes a permanent set, in practice this is not the case as to its cross-section or the arrangement of its strands, which is injured if the material too easily takes a permanent set. It is easy to imagine cases in which this very softness and ductility is of great value. In the same way we should imagine that the best pianoforte-wire ought to have a certain elastic limit or a limit up to which it will elongate temporarily without taking a permanent set, and a certain amount of ductility or power of elongation without rupture, while it should have a certain ultimate breaking strength. The same is the case with the other many applications of wire; most of which, however, will be best suited by a high limit of elasticity, or the power of elongating temporarily without taking a permanent set. The principal seat of the iron wire manufacture in England is Birmingham. The most important improvement to be looked for in the wire manufacture is some easy and cheap means of drawing very long lengths of wire.

WOAD (*Guède*, *Pastel*, Fr.; *Waid*, Ger.; *Guado*, It.), the *Isatis tinctoria*, Linn., is almost the only plant growing in the temperate zone which is known to produce indigo. It is an herbaceous, biennial plant, belonging to the natural order *Cruciferæ*, and bears yellow flowers and large flattened seed-vessels, which are often streaked with purple. The leaves, which are the only part of the plant employed in dyeing, are large, smooth, and glaucous, like cabbage-leaves, but exhibit no external indication of the presence of any blue colouring-matter, which indeed, according to modern researches, is not contained in them ready formed. The plant called by the Romans *glastum*, with which, according to Pliny, the Britons, dyed their skins blue, is supposed to be identical with woad. Before the introduction of indigo into the dye-houses of Europe, woad was generally used for dyeing blue, and was extensively cultivated in various districts of Europe, such as Thuringia, in Germany; Languedoc, in France; and Piedmont, in Italy. To these districts its cultivation was a source of great wealth. Beruni, a rich woad manufacturer of Toulouse, became surety for the payment of the ransom of his king, Francis I., then a prisoner of Charles V., in Spain. The term *Pays de cocaigne*, denoting a land of great wealth and fertility, is indeed supposed to be derived from the circumstance that the woad balls, called in French *cocaignes*, were manufactured chiefly in Languedoc.

The woad-leaves were not employed by the dyer in their crude state, but were previously subjected to a process of fermentation, for the purpose of eliminating the colouring-matter. The seed having been sown in winter, or early spring, the plants were allowed to grow until the leaves were about a span long, and had assumed the rich glaucous appearance indicative of maturity, when they were stripped or cut off. The cropping was repeated several times, at intervals of five or six weeks, until the approach of winter put a stop to the growth of the plant. The leaves set up in the succeeding spring yielded only an inferior article (called in German *Kompsowaid*), and it was therefore customary to keep only as many plants until the following year as were required for obtaining seed, which, the plant being biennial, is only produced in the second year. The leaves, after being gathered, were slightly dried, and then ground in a mill to a paste. In Germany it was usual to lay this paste into a heap for about twenty-four hours, and then form it by hand into large balls, which were first dried partially in the sun, on lattice-work or rushes, and then piled up in heaps a yard high, in an airy place, but under cover, when they diminished in size and became hard. These balls, when of good quality, exhibited, on being broken, a light blue or sea-green colour. They are usually sold in this state to manufacturers, by whom they were subjected to a second process in order to render them fit for the use of the dyer. This process was conducted in the following manner:—The woad balls were first broken by means of wooden hammers, and the triturated mass was heaped up on a wooden floor, sprinkled with water, sometimes with a little wine, and allowed to ferment or putrefy. The mass became very hot, and emitted a strong ammoniacal odour, and much vapour. In order to regulate the process, it was frequently turned over with shovels, and again sprinkled with water. When the heat had subsided, the mass, which had become dry, was pounded, passed through sieves, and then packed in barrels ready for use. It had the appearance of pigeons' dung.

In France the paste obtained by pounding the woad-leaves was taken to a room with a sloping pavement, open at one end, laid in a heap at the higher end of the room, and allowed to ferment for a period of twenty or thirty days. The mass swelled up and often showed cracks or fissures, which were always carefully closed as soon as they appeared, whilst a black juice exuded and ran away in gutters constructed for the purpose. When the fermented heap had become moderately dry, it was ground again and formed into cakes, called in French *coques*, which were then fully dried, and in this state brought to market. In France and Italy a second fermentation was not generally thought essential, but when performed it was conducted exactly in the manner just described.

At the present day woad is nowhere employed alone for the purpose of dyeing blue, since it is found more economical to use indigo, and the cultivation of the plant has therefore declined considerably, and has even become nearly extinct in districts where it was formerly carried on extensively. By woollen dyers, however, it is still used, but only as a means of exciting fermentation, and thus reducing the indigo blue in their vats; indeed, the woad employed by them contains little or no blue colouring-matter. See INDIGO.

Numerous attempts have been made to extract the blue colouring-matter from woad, in the same way that indigo is extracted from the leaves of the *Indigofera* in the East Indies and other countries. At the commencement of the present century, when the price of indigo on the Continent of Europe was very high, a prize of 100,000 francs was even offered by the French Government for the discovery of a method of obtaining from the *Isatis tinctoria*, or some other native plant, a dyeing material, which, both in regard to price and the beauty and solidity of its colour, should form a perfect substitute for indigo. The experiments which were made in consequence served to prove that it was quite possible to obtain genuine indigo from woad-leaves, but that the process could never be carried on profitably on account of the very small proportion of colouring-matter contained in the plant. Nine parts of fresh leaves yield only one part of the prepared material or pastel, and the latter does not afford more than 2 per cent. of its weight of indigo. According to Chevreul, the leaves of the *Indigofera anil*, even when grown in the neighbourhood of Paris, contain 30 times as much indigo-blue as those of the *Isatis tinctoria*, and, when cultivated in tropical countries, the amount is probably still higher. The comparatively high price of land and labour would probably itself prove a sufficient obstacle to the successful manufacture of indigo in most European countries, even if the yield were equal to what it is in the tropics.

In 1808 Chevreul published the results of his analysis of woad and pastel. It has more recently been made the subject of chemical investigation, for the purpose of ascertaining the state in which indigo-blue exists in plants and other organisms. See INDIGO.—E. S.

WOOD-PRESERVING. The preservation of wood from decay depends upon the combination of the vegetable albumen with some metallic salt or some powerful antiseptic agent. Bethell's invention, which was much employed, consists in impregnating wood throughout with oil of tar and other bituminous matters containing creosote, and also with pyrolignite of iron, which holds more creosote in solution than any other watery menstruum.

The wood was put in a close iron tank, like a high-pressure steam-boiler, which was closed and filled with the tar oil or pyrolignite. The air being exhausted by air-pumps, afterwards more oil or pyrolignite was forced in by hydrostatic pumps, until a pressure equal to from 100 to 150 lbs. to the inch was obtained. This pressure was kept up by the frequent working of the pumps during six or seven hours, whereby the wood became thoroughly saturated with the tar oil, or the pyrolignite of iron, and weighed from 8 to 12 pounds per cube foot heavier than before.

In a large tank 20 loads of timber per day could be prepared. The atmospheric action on wood thus prepared renders it tougher, and infinitely stronger. A post made of beech, or even of Scotch fir, is rendered more durable, and as strong as one made of the best oak; the bituminous mixture with which all its pores are filled acting as a cement to bind the fibres together in a close tough mass; and the more porous the wood is, the more durable and tough it becomes, as it imbibes a greater quantity of the bituminous oil, which is proved by its increased weight. The materials which are injected preserve iron and metals from corrosion; and an iron bolt driven into wood so saturated remains perfectly sound and free from rust. It also resists the attack of insects.

The effect produced is that of perfectly coagulating the albumen in the sap, thus preventing its putrefaction. For wood that will be much exposed to the weather, and alternately wet and dry, the mere coagulation of the sap is not sufficient; for although the albumen contained in the sap of the wood is the most liable and the first to putrefy, yet the ligneous fibre itself, after it has been deprived of all sap, will, when exposed in a warm damp situation, rot and crumble into dust. To preserve wood, therefore, that will be much exposed to the weather, it is not only necessary that the sap should be coagulated, but that the fibres should be protected from moisture.

Wood prepared with petroleum for sleepers, piles, poles, fencing, &c., is not affected by alternate exposure to wet and dry; it requires no painting, and after it has been exposed to the air for some days it loses every unpleasant smell.

For railway sleepers it is highly useful, as the commonest Scotch-fir sleeper, when thus prepared, will last. Posts for gates or fencing, if prepared in this manner, may be made of Scotch fir. The processes which have been introduced for impregnating wood with the protosulphate of iron, corrosive sublimate, chloride of lime, and similar substances, are also much employed, and many of them have been found to be very useful as preservative agents. The tungstate of soda has been found to be a useful preservative of wood.

WOOF is the same as WEFT.

WOOL. In reference to textile fabrics, sheep's wool is of two different sorts, the short- and the long-stapled; each of which requires different modes of manufacture in the preparation and spinning processes, as also in the treatment of the cloth after it is woven, to fit it for the market. Each of these is, moreover, distinguished in commerce by the names of 'fleece wools' and 'dead wools,' according as they have been shorn at the usual annual period from the living animal, or are cut from its skin after death. The latter are comparatively harsh, weak, and incapable of imbibing the dyeing principles, more especially if the sheep has died of some malignant distemper. The annular pores, leading into the tubular cavities of the filaments, seem, in this case to have shrunk and become obstructed. The time of year for sheep-shearing most favourable to the quality of the wool, and the comfort of the animal, is during the month of June—the period when Lord Leicester holds his celebrated rural fête for that interesting purpose.

The wool of the sheep has been surprisingly improved by its domestic culture. The *mouflon* (*Ovis aries*), the parent stock from which our sheep is undoubtedly derived, and which is still found in a wild state upon the mountains of Sardinia, Corsica, Barbary, Greece, and Asia Minor, has a very short and coarse fleece, more like hair than wool. When this animal is brought under the fostering care of man, the rank fibres gradually disappear; while the soft wool round their roots, little conspicuous in the wild animal, becomes singularly developed. The male most speedily undergoes this change, and continues ever afterwards to possess far more power in modifying the fleece of the offspring than the female parent. The produce of a breed from a coarse-woolled ewe and a fine-woolled ram, is not of a mean quality between the two, but half-way nearer that of the sire. By coupling the female thus generated with such a male as the former, another improvement of one-half will be obtained, affording a staple three-fourths finer than that of the grandam. By proceeding inversely, the wool would be as rapidly deteriorated. It is, therefore, a matter of the first consequence in wool husbandry, to exclude from the flock all coarse-fleeced rams.

Long wool is the produce of a peculiar variety of sheep, and varies in the length of its fibres from 3 to 8 inches. Such wool is not carded like cotton, but combed like flax, either by hand or appropriate machinery. Short wool is seldom longer than 3 or 4 inches; it is susceptible of carding and felting, by which processes the filaments become densely matted together. The shorter sorts of combing wool are used principally for hosiery, though of late years the finer kinds have been extensively worked up into merino and mousseline-de-laine fabrics. The longer wools of the Leicestershire breed are manufactured into hard yarns, for worsted-pieces, such as bombazines, poplins, crapes, orleans, &c.

The wool of which good broad-cloth is made should be not only shorter, but, generally speaking, finer and softer than the worsted wools, in order to fit them for the fulling process. Some wool-sorters and wool-staplers acquire by practice great nicety of discernment in judging of wools by the touch and traction of the fingers. The filaments of the finer qualities vary in thickness from $\frac{1}{1100}$ to $\frac{1}{1500}$ of an inch; their structure is very curious, exhibiting, in a good achromatic microscope, at intervals of about $\frac{1}{300}$ of an inch, a series of serrated rings, imbricated towards each other, like the joints of *Equisetum*, or rather like the scaly zones of a serpent's skin.

The fleece of an average English sheep contains five distinct long sorts and three short sorts. The short sorts grow on the belly of the sheep, the finest being under the neck and the fore-legs. Of the long sorts, the finest is on the shoulders. The next occupies a position almost semicircular round the finest sort, commencing at the head, and extending to the belly. The third sort adjoins the second, and is of a somewhat triangular shape, the base being on the top of the back. The fourth adjoins the third on one side, the other side of it being the fifth, which covers the rump, and runs down almost straight, 3 or 4 inches wide, to where the wool terminates on the hind-legs.

The harshness of wools is dependent not solely upon the breed of the animal, or the climate, but is owing to certain peculiarities in the pasture, derived from the soil. It is known, that in sheep fed upon chalky districts, wool is apt to get harsh; but in those upon a rich loamy soil, it becomes soft and silky. The ardent sun of Spain renders the fleece of the Merino breed harsher than it is in the milder climate of Saxony. The Angora, or Angola, or Angona wool, from Agnolia, 39° 53′ N. lat., 32° 52′ E. long., owes its beautiful character to the place of its growth. This wool is the same as *Mohair*. Smearing sheep with a mixture of tar and butter is deemed, in cold countries, favourable to the softness of their wool.

All wool, in its natural state, contains a quantity of a peculiar potash-soap, secreted by the animal, called in this country the *yolk*; which may be washed out by water alone, with which it forms a sort of lather. It constitutes from 25 to 50 per cent. of the wool, being most abundant in the Merino breed of sheep; and, however favourable to the growth of the wool on the living animal, should be taken out before or soon after it is shorn, lest it injure the fibres by fermentation, and cause them to become hard and brittle. After being washed in water, somewhat more than lukewarm, the wool should be well pressed, and carefully dried. See Suint.

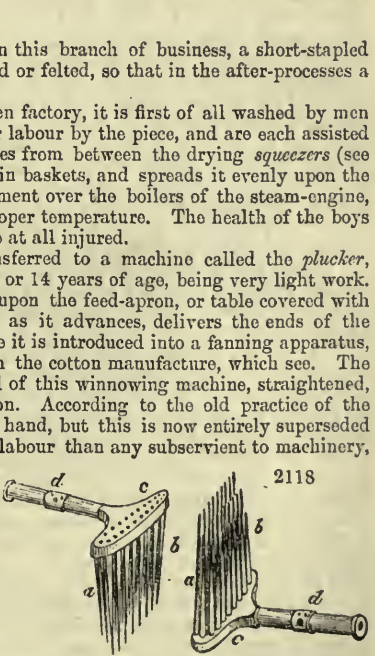
Mr. Hicks, of Huddersfield, obtained a patent some years ago for a machine for cleaning wool from burs. It consists of 4 rotatory beaters, which act in succession. The wool having been opened and spread upon a feeding-cloth, is carried by it to the drawing-rollers, and is then delivered to the action of the beater, by which it is carried along a curved grating to the feed-cloth of another beater, so as to be made eventually quite clean.

WOOL DYEING. See Dyeing.

WOOLLEN MANUFACTURE. In this branch of business, a short-stapled soft wool is required capable of being milled or felted, so that in the after-processes a finer finish may be brought upon the cloth.

When the wool is brought into the woollen factory, it is first of all washed by men with soap-and-water, who are paid for their labour by the piece, and are each assisted by a boy, who receives the wool as it issues from between the drying *squeezers* (see Bleaching). The boy carries off the wool in baskets, and spreads it evenly upon the floor of the drying-room, usually an apartment over the boilers of the steam-engine, which is thus economically heated to the proper temperature. The health of the boys employed in this business is not found to be at all injured.

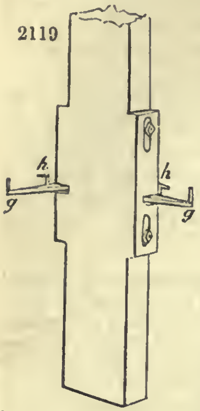
The wool, when properly dried, is transferred to a machine called the *plucker*, which is always superintended by a boy 12 or 14 years of age, being very light work. He lays the tresses of wool pretty evenly upon the feed-apron, or table covered with an endless moving web of canvas, which, as it advances, delivers the ends of the long tufts to a pair of fluted rollers, whence it is introduced into a fanning apparatus, somewhat similar to the *willow* employed in the cotton manufacture, which see. The filaments are turned out at the opposite end of this winnowing machine, straightened, cleaned, and ready for the combing operation. According to the old practice of the trade, the wool was carded and combed by hand, but this is now entirely superseded by machinery. This was far more severe labour than any subservient to machinery, and was carried on in rooms rendered close and hot by the number of stoves requisite to heat the combs, and so enable them to render the fibres soft, flexible, and elastic. This was a task at which only robust men were engaged. They use three implements: 1, a pair of combs for each person; 2, a post, to which one of the combs can be fixed; 3, a comb-pot or small stove for heating the teeth of the combs. Each comb is composed either of two or three rows of pointed tapering steel teeth, *b*, *fig.* 2118, disposed in two or three parallel planes, each row being a little longer than the preceding. They are made fast at the roots to a wooden stock or head *c*, which is covered with horn and has a handle *d*, fixed into it at right angles to the lines of the teeth. The spaces between these two or three planes of teeth is about one-third of an inch at their bottoms, but somewhat more at their tips. The first combing, when the fibres are most entangled, is performed with



2118

the two-row toothed combs; the second or finishing combing, with the three-row toothed.

2119



In the workshops a post, *fig.* 2119, is planted upright, for resting the combs occasionally upon, during the operation. An iron stem *g*, projects from it horizontally, having its end turned up, so as to pass through a hole in the handle of the comb. Near its point of insertion into the post, there is another staple point, *h*, which enters into the hollow end of the handle; which, between these two catches, is firmly secured to the post. The stove is a very simple affair, consisting merely of a flat iron plate, heated by fire or steam, and surmounted with a similar plate, at an interval sufficient to allow the teeth to be inserted between them at one side, which is left open, while the space between their edges, on the other side, is closed to confine the heat.

In combing the wool, the workman takes it up in tresses of about four ounces each, sprinkles it with oil, and rolls it about in his hands, to render all the filaments equally unctuous. Some harsh dry wools require one-sixteenth of their weight of oil, others no more than a fortieth. He next attaches a heated comb to the post, with its teeth pointed upwards, seizes one-half the tress of wool in his hands, throws it over the teeth, then draws it through them, and thus repeatedly: leaving a few straight filaments each time upon the comb. When the comb has in this way collected all the wool, it is placed with its points inserted into the cell of the stove, with the wool hanging down outside, exposed to the influence of the heat. The other comb, just removed in a heated state from the stove, is planted upon the post, and furnished in its turn with the remaining two-ounce tress of wool; after which it supplants the preceding at the stove. Having both combs now hot, he holds one of them with his left hand over his knee, being seated upon a low stool, and seizing the other with his right hand, he combs the wool upon the first, by introducing the teeth of one comb into the wool stuck in the other, and drawing them through it. This manipulation is skilfully repeated, till the fibres are laid truly parallel like a flat tress of hair. It is proper to begin by combing the tips of the tress, and to advance progressively, from the one end towards the other, till at length the combs are worked with their teeth as closely together as is possible, without bringing them into collision. If the workman proceeded otherwise, he would be apt to rupture the filaments, or tear their ends entirely out of one of the combs. The flocks left at the end of the process, because they are too short for the comber to grasp them in his hand, are called *noyls*. They are unfit for the worsted spinner, and are reserved for the coarse cloth manufacturer.

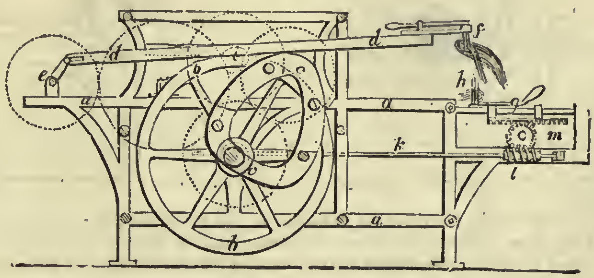
The wool finally drawn off from the comb, though it may form a uniform tress of straight filaments, must yet be combed again at a somewhat lower temperature, to prepare it perfectly for the spinning operation. From ten to twelve slivers are then arranged in one parcel.

To relieve the workman from this laborious and not very salubrious task has been the object of many mechanical inventions. One of these, considerably employed in this country and in France, is the invention of the late Mr. John Collier, of Paris, for which a patent was obtained in England, under the name of John Platt, of Salford, in November 1827. It consists of two comb-wheels about ten feet in diameter, having hollow iron spokes filled with steam, in order to keep the whole apparatus at a proper combing heat. The comb forms a circle, made fast to the periphery of the wheel, the teeth being at right angles to the plane of the wheel. The shafts of the two wheels are mounted in a strong frame of cast iron; not, however, in horizontal positions, but inclined at acute angles to the horizon, and in planes crossing each other, so that the teeth of one circular comb sweep with a steady obliquity over the teeth of the other, in a most ingenious manner, with the effect of combing the tresses of wool hung upon them. The proper quantity of long wool, in its ordinary state, is stuck in handfuls upon the wheel, revolving slowly, by a boy, seated upon the ground at one side of the machine. Whenever the wheel is dressed, the machine is made to revolve more rapidly, by shifting its driving-band on another pulley; and it is beautiful to observe the delicacy and precision with which it smooths the tangled tress. When the wools are set in rapid rotation, the loose ends of the fleece, by the centrifugal force, are thrown out, in the direction of radii, upon the teeth of the other revolving comb-wheel, so as to be drawn out and made truly straight. The operation commences upon the tips of the tresses, where the wheels, by the oblique posture of their shafts, are at the greatest distance apart; but as the planes slowly approach to parallelism, the teeth enter more deeply into the wool, till they progressively comb the whole length of its fibres. The machine being then thrown out of gear, the teeth are stripped of the tresses by the hand of the attendant; the *noyls*, or short refuse wool, being also removed, and kept by itself.

This operation being one of simple superintendence, not of handicraft effort and skill, like the old combing of long wool, is now performed by boys or girls of 13 and 14 years of age; and places in a striking point of view the influence of automatic mechanism, in so embodying dexterity and intelligence in a machine, as to render the cheap and tractable labour of children a substitute for the high-priced and often refractory exertions of workmen too prone to capricious combinations. The chief precaution to be taken with this machine, is to keep the steam-joints tight, so as not to wet the apartments, and provide due ventilation for the operatives.

The machine patented by James Noble, of Halifax, worsted-spinner, deserves particular notice, as its mode of operation adapts it well also for heckling flax. In *fig.* 2120, its internal structure is exhibited. The framework, *a*, *a*, supports the axle of a wheel, *b*, *b*, in suitable bearings on each side. To the face of this wheel is affixed the excentric or heart-wheel cam, *c*, *c*. On the upper part of the peri-

2120



phery of this cam or heart-wheel, a lever, *d*, *d*, bears merely by its gravity; one end of which lever is connected by a joint to the crank, *e*. By the rotation of the crank, *e*, it will be perceived that the lever *d*, will be slidden to and fro on the upper part of the periphery of the excentric or heart-wheel cam, *c*, the outer end of the lever, *d*, carrying the upper or working comb or needle-points, *f*, as it moves, performing an elliptical curve, which curve will be dependent upon the position of the heart-wheel cam, *c*, that guides it. A moveable frame, *g*, carries a series of points, *h*, which are to constitute the lower comb or frame of needles. Into these lower needles the rough uncombed wool is to be fed by hand, and to be drawn out and combed straight by the movements of the upper or working comb.

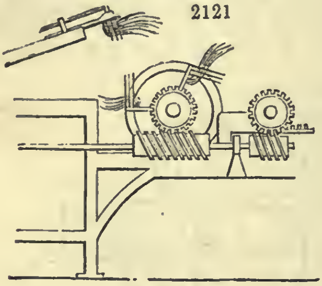
As it is important, in order to prevent waste, that the ends of the wool should be first combed out, and that the needle-points should be made to penetrate the wool progressively, the moveable frame, *g*, is in the first instance placed as far back as possible; and the action of the lever, *d*, during the whole operation, is so directed by the varying positions of the cam-wheel, as to allow the upper comb to enter at first a very little way only into the wool; but as the operation of combing goes on, the frame with the lower combs is made to advance gradually, and the relative positions of the revolving heart cam-wheel *c*, being also gradually changed, the upper or working needles are at length allowed to be drawn completely through the wool, for the purpose of combing out straight the whole length of its fibre.

In order to give the machine the necessary movements, a train of toothed wheels and pinions is mounted, mostly on studs attached to the side of the frame; which train of wheels and pinions is shown by dots in the figure, to avoid confusion. The driving power, a horse or steam-engine, is communicated by a band to a rigger on the short axle *i*; which axle carries a pinion, taking into one of the wheels of the train. From this wheel the crank *c*, that works the lever *d*, is driven; and also, by gear from the same pinion, the axle of the wheel *b*, carrying the excentric or heart-wheel cam, is also actuated, but slower than the crank-axle.

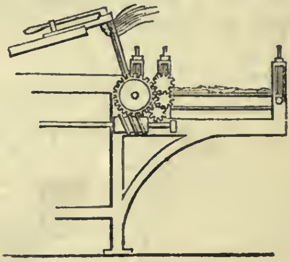
At the end of the axle of the wheel *b*, and cam *c*, a bevel-pinion is affixed, which gears into a corresponding bevel-pinion on the end of the lateral shaft *k*. The reverse end of this shaft has a worm or endless screw *l*, taking into a toothed-wheel *m*; and this last-mentioned toothed-wheel gears into the rack at the under part of the frame *g*.

It will hence be perceived, that by the movements of the train of wheels, a slow motion is given to the frame *g*, by which the lower needles carrying the wool are progressively advanced as the operation goes on; and also, that by the other wheels of the train, the heart-wheel cam is made to rotate, for the purpose of giving such varying directions to the stroke of the lever which slides upon its periphery, and to the working comb, as shall cause the comb to operate gradually upon the wool as it is brought forward. The construction of the frames which hold the needles, and the manner of fixing them in the machine, present no features of importance; it is therefore unnecessary to describe them further, than to say, that the heckles are to be heated when used for combing wool. Instead of introducing the wool to be combed into the lower needles by hand, it is sometimes fed in, by means of an endless feeding-cloth, as shown in *fig.* 2121. This endless cloth is distended over two rollers, which are made to revolve, for the purpose of carrying the cloth with the wool forward, by means of the endless screw and pinions.

2121



2122



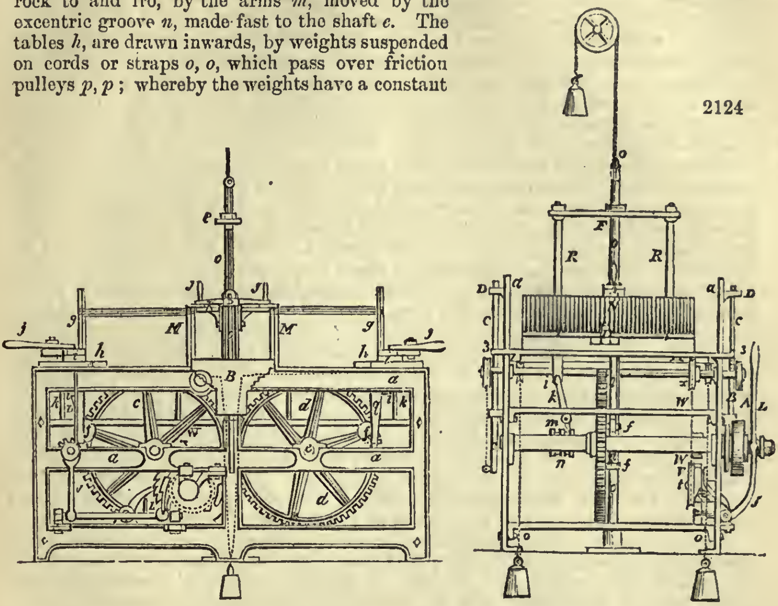
A slight variation in the machine is shown at *fig.* 2122, for the purpose of combing wool of long fibre, which differs from the former only in placing the combs or needle-points upon a revolving cylinder or shaft. At the end of the axle of this shaft, there is a toothed wheel, which is actuated by an endless screw upon a lateral shaft. The axle of the cylinder on which the needles are fixed, is mounted in a moveable frame or carriage, in order that the points of the needles may, in the first instance, be brought to act upon the ends of the wool only, and ultimately be so advanced as to enable the whole length of the fibres to be drawn through. The progressive advancement of this carriage, with the needle-cylinder, is effected by the agency of the endless screw on the lateral shaft before mentioned.

Some combing-machines reduce the wool into a continuous sliver, which is ready for the drawing-frame; but the short slivers produced by the hand-combing, must be first joined together, by what is called *planking*. These slivers are rolled up by the combers ten or twelve together, in balls called 'tops,' each of which weighs a half pound. At the spinning-mill these are unrolled, and the slivers are laid on a long plank or trough, with the ends lapping over, in order to splice the long end of one sliver into the short end of another. The long end is that which was drawn off first from the comb, and contains the longer fibres; the short is that which comes last from the comb, and contains the shorter. The wool-comber lays all the slivers of each ball the same way, and marks the long end of each by twisting up the end of the sliver. It is a curious circumstance, that when a top or ball of slivers is unrolled and stretched out straight, they will not separate from each other without tearing and breaking, if the separation is begun at the short ends; but if they are first parted at the long ends they will readily separate.

The machine for combing long wool, for which Messrs. Donisthorpe and Rawson obtained a patent in April 1835, has been found to work well, and therefore merits a detailed description.

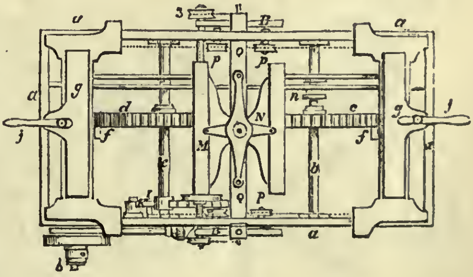
Fig. 2123 is an elevation, *fig.* 2124 an end view, and *fig.* 2125 a plan, in which *a*, *a*, is the framing; *b*, the main shaft, bearing a pinion, which drives the wheel and shaft *c*, in gear with the wheel *d*, on the shaft *e*. Upon each of the wheels *c* and *d*, there are two projections or studs *f*, which cause the action of the combs *g*, *g*, of which *h*, *h*, are the tables or carriages. These are capable of sliding along the upper guide-rails of the framing *a*. Through these carriages or tables *h*, *h*, there are openings or slits, shown by dotted lines, which act as guides to the holders *i*, *i*, of the combs *g*, *g*, rendering the holders susceptible of motion at right angles to the course pursued by the tables *h*. The combs are retained in the holders *i*, *i*, by means of the lever-handles *j*, *j*, which move upon inclined surfaces, and are made to press on the surface of the heads of the combs *g*, *g*, so as to be retained in their places; and they are also held by studs affixed to the holders, which pass into the comb-heads. From the under side of the tables, forked projections *i*, *i*, stand out, which pass through the openings or slits formed in the tables *h*, *h*; these projections are worked from side to side by the frame *k*, *k*, which turning on the axis or shaft *l*, *l*, is caused to vibrate, or rock to and fro, by the arms *m*, moved by the excentric groove *n*, made fast to the shaft *e*. The tables *h*, are drawn inwards, by weights suspended on cords or straps *o*, *o*, which pass over friction pulleys *p*, *p*; whereby the weights have a constant

2124



tendency to draw the combs into the centre of the machine, as soon as it is released by the studs *f*, passing beyond the projecting arms *g*, on the tables. On the shaft *c*, a driving-tooth or catch *r*, is fixed, which takes into the ratchet-wheel *s*, and propels one of its teeth at every revolution of the shaft *c*. This ratchet-wheel turns on axis at *t*; to the ratchet the pulley *v* is made fast, to which the cord or band *w* is secured, as also to the pulley *x*, on the shaft *y*. On the shaft *y*, there are two other pulleys, *z*, *z*, having the cords or bands A, A, made fast to them, and also to the end of the gauge-plates B, furnished with graduated steps, against which the tables *h*, *h*, are drawing at each operation of the machine. In proportion as these gauge-plates are raised, the nearer the carriages or tables *h* will be able to advance to the centre of the machine, and thus permit the combs *g*, *g*, to lay hold of, and comb, additional lengths of the woolly fibres. The gauge-plates B, are guided up by the bars C, which pass through openings, slots, or guides, made in the framing *a*, as shown by D.

2125

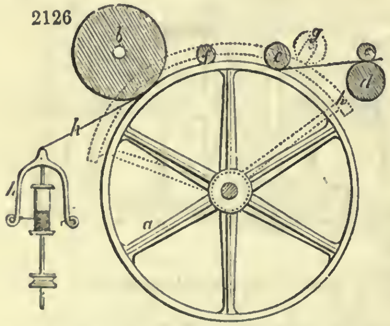


To the ratchet-wheel *s*, an inclined projection F, is made fast, which in the course of the rotation of the ratchet-wheel, comes under the lever F, fixed to the shaft G, that turns in bearings H. To this shaft the levers I and J, are also affixed; I serving to throw out the click or catch K, from the ratchet-wheel, by which the parts of the machine will be released, and restored to positions ready for starting again. The lever J, serves to slide the drum upon the driving shaft *b*, out of gear, by means of the forked handle L, when the machine is to be stopped, whenever it has finished combing a certain quantity of wool. The combs which hold the wool have a motion upwards, in order to take the wool out of the way of the combs *g*, *g*, as these are drawn into the centre of the machine; while the holding combs descend to lay the wool among the points of the combs *g*, *g*. For obtaining this upward-and-downward motion, the combs M, M, are placed between the frame N, and retained there just as the combs *g*, *g*, are upon the holders *i*, *i*. The framing N, is made fast to the bar or spindle O, which moves vertically through openings in the cross-head P, and the cross-framing of the machine Q; from the top of which there is a strap passing over pulleys with a suspended weight to it; the cross-head being supported by the two guide-rods R, fixed to the cross-framing Q. It is by the guide-rods R, and the spindle O, that the frame N is made to move up and down; while the spindle is made to rise by the studs *f*, as the wheels *c* and *d* come successively under the studs *s*, on the spindle O.

A quantity of wool is to be placed on each of the combs *g*, *g*, and M, M, the machine being in the position shown in *fig.* 2125. When the main-shaft *b*, is set in motion, it will drive by its pinion the toothed wheel *c*, and therefrom the remaining parts of the machine. The first effect of the movement will be to raise the combs M, M, sufficiently high to remove the wool out of the way of the combs *g*, *g*, which will be drawn towards the centre of the machine, as soon as they are released by the studs *f*, passing the projecting arms *q*, on the tables *h*; but the distance between the combs *g*, *g*, and the combs M, M, will depend on the height to which the gauge-plates B have been raised. These plates are raised one step at each revolution of the shaft *c*; the combs *g*, *g*, will therefore be continually approaching more nearly to the combs M, M, till the plates B, are so much raised as to permit the tables *h* to approach the plates B, below the lowest step or graduation, when the machine will continue to work. Notwithstanding the plates B continuing to rise, there being only parallel surfaces against which the tables come, the combs *g*, *g*, will successively come to the same position, till the inclined projection E, on the ratchet-wheel *s*, comes under the lever F, which will stop the machine. The wool which has been combed, is then to be removed, and a fresh quantity introduced. It should be remarked that the combs *g*, *g*, are continually moving from side to side of the machine, at the same time that they are combing out the wool. The chief object of the invention is obviously to give the above peculiar motion to the combs *g*, *g*, and M, M, which may be applied also to combing goat-hair.

For the purposes of the worsted manufacture, wool should be rendered inelastic to a considerable degree, so that its fibres may form long lines, capable of being twisted into straight level yarn. Mr. Bayliffe, of Kendal, has sought to accomplish this object, first, by introducing into the *drawing* machine a rapidly revolving wheel, in contact with the front drawing roller, by whose friction the filaments are heated, and at the same time deprived of their curling elasticity; secondly, by employing a moveable regulating roller, by which the extent of surface on the periphery of the wheel that the lengths of wool is to act upon, may be increased or diminished at pleasure, and, consequently, the effect regulated or tempered as the quality of the wool may require; thirdly, the employment of steam in a rotatory drum or hollow wheel, in place of the wheel first described, for the purpose of heating the wool, in the process of drawing, in order to facilitate the operation of straightening the fibres.

2126



These objects may be effected in several ways; that is, the machinery may be variously constructed, and still embrace the principles proposed. *Fig.* 2126, shows one mode:—*a*, is the friction wheel; *b*, the front drawing roller, placed in the drawing-frame in the same way as usual; the larger wheel *a*, constituting the lower roller of the pair of front drawing rollers; *c* and *d* are the pair of back drawing rollers, which are actuated by gear connected to the front rollers, as, in the ordinary construction of drawing machines, the front rollers moving very considerably faster than the back rollers, and, consequently, drawing or extending the fibres of the sliver of wool, as it passes through between them; *e* is a guide-roller, bearing upon the periphery of the large wheel; *f* is a tension roller, which presses the fibres of the wool down upon the wheel *a*.

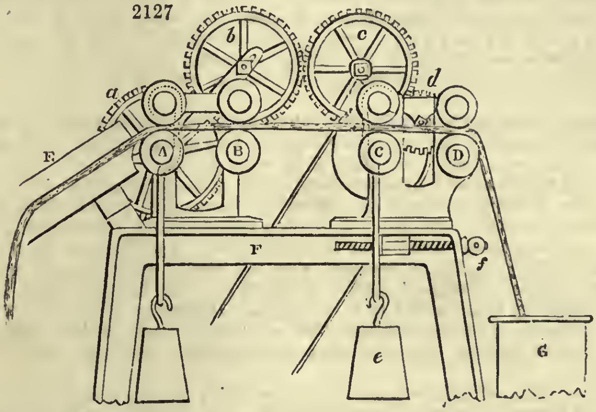
Now, supposing the back rollers *c* and *d*, to be turned with a given velocity, and the front roller *b* to be driven much faster, the effect would be, that the fibres of wool constituting the sliver, passing through the machine, would be considerably extended between *b* and *d*, which is precisely the effect accomplished in the ordinary drawing frame; but the wheel *a*, introduced into the machine in place of the lower front drawing roller, being made to revolve much faster than *b*, the sliver of wool extended over the upper part of its periphery from *b*, to the tension roller *f*, will be subjected to very considerable friction from the contact; and, consequently, the natural curl of the wool will be taken out, and its elasticity destroyed, which will enable the wool to proceed in a connected roving down to the spindle or flyer *h*, where it becomes twisted or spun into a worsted thread.

In order to increase or diminish the extent to which the fibres of wool are spread over the periphery of the wheel *a*, a regulating roller is adapted to the machine, as shown at *g*, in place of the tension roller *f*. This regulating roller *g*, is mounted by its pivots in bearings on the circular arms *h*, shown by dots. These circular arms turn loosely upon the axle of the wheel *a*, and are raised or depressed by a rack and a winch, not shown in the figure; the rack taking into teeth on the periphery of the circular arms. It will hence be perceived, that by raising the circular arms, the roller *g*, will be carried backward, and the fibres of wool pressed upon the periphery of the wheel to a greater extent. On the contrary, the depression of the circular arms will draw the roller *g*, forward, and cause the wool to be acted upon by a smaller portion of the periphery of the wheel *a*, and consequently subject it to less friction.

When it is desired to employ steam for the purpose of heating wool, the wheel *a*, is formed as a hollow drum, and steam from a boiler, in any convenient situation, is conveyed through the hollow axle to the interior of the drum, which, becoming heated by that means, communicates heat also to the wool, and thereby destroys its curl and elasticity.

Breaking-frame.—Here the slivers are *planked*, or spliced together, the long end of one to the short end of another; after which they are drawn out and extended by the rollers of the breaking-frame. A sketch of this machine is given in *fig.* 2127. It con-

2127



sists of four pairs of rollers A, B, C, D. The first pair A, receives the wool from the inclined trough E, which is the planking-table. The slivers are unrolled, parted, and hung loosely over a pin, in reach of the attendant, who takes a sliver, and lays it flat in the trough, and the end is presented to the rollers A, which being in motion, will draw the wool in; the sliver is then conducted through the other rollers, as shown in the figure: when the sliver has passed half through, the end of another sliver is placed upon the middle of the first, and they pass through together; when this second is passed half through, the end of a third is applied upon the middle of it, and in this way the short slivers produced by the combing are joined into one regular and even sliver.

The lower roller C, receives its motion from the mill, by means of a pulley upon the end of its axis, and an endless strap. The roller which is immediately over it, is borne down by a heavy weight, suspended from hooks, which are over the pivots of the upper roller. The fourth pair of rollers D, moves with the same velocity as C, being turned by means of a small wheel upon the end of the axis of the roller C, which turns a wheel of the same size upon the axis of the roller D, by means of an intermediate wheel *d*, which makes both rollers turn the same way round. The first and second pair of rollers, A and B, move only one-third as quick as C and D, in order to draw out the sliver between B and C, to three times the length it was when put on the planking-table. The slow motion of the rollers A, is given by a large wheel *a*, fixed upon the axis of the roller A, and turned by the intermediate cog-wheels *b*, *c*, and *d*; the latter communicates between the rollers C and D. The pinions on the rollers C and D, being only one-third the size of the wheel *a*, C and D turn three times as fast as A, for *b*, *c*, and *d* are only intermediate wheels. The rollers B turn at the same rate as A. The upper roller C is loaded with a heavy weight, similar to the rollers A; but the other rollers, B and D, are no further loaded than the weight of the rollers.

The two pairs of rollers A, B, and C, D, are mounted in separate frames; and that frame which contains the third and fourth pairs C, D, slides upon the cast-iron frame F, which supports the machine, in order to increase or diminish the distance between the rollers B and C. There is a screw *f*, by which the frame of the rollers is moved, so as to adjust the machine according to the length of the fibre of the wool. The space between B and C should be rather more than the length of the fibres of the wool. The intermediate wheels *b* and *c* are supported upon pieces of iron, which are moveable on centres; the centre for the piece which supports the wheel *b* is concentric with the axis of the roller A; and the supporting piece for the wheel *c* is fitted on the centre of the wheel *d*. By moving these pieces the intermediate wheels *b* and *c* can be always kept in contact, although the distance between the rollers is varied at times. By means of this breaking-frame, the perpetual sliver, which is made up by planking the sliver together, is equalised, and drawn out three times in length, and delivered into the can G.

Drawing-frame.—Three of these cans are removed to the drawing-frame, which is similar to the breaking-frame, except that there is no planking-table E. There are five sets of rollers, all fixed upon one common frame F, the breaking-frame, which we have described, being the first. As fast as the sliver comes through one set of rollers it is received into a can, and then three of these cans are put together and passed again through another set of rollers. In the whole the wool must pass through the breaker and four drawing-frames before the roving is begun. The draught being usually four times at each operation of drawing, and three times in the breaking, the whole will be $3 \times 4 \times 4 \times 4 \times 4 = 768$; but to suit different sorts of wool the three last drawing-frames are capable of making a greater draught, even to five times, by changing the pinions; accordingly the draught will be $3 \times 4 \times 5 \times 5 \times 5 = 1500$ times.

The size of the sliver is diminished by these repeated drawings, because only three slivers are put together, and they are drawn out four times; so that in the whole the sliver is reduced to a fourth or a ninth of its original bulk.

The breaking-frame and drawing-frame which are used when the slivers are prepared by the combing-machines, are differently constructed; they have no planking-table, but receive three of the perpetual slivers of the combing-machine from as many tin cans, and draw them out from ten to twelve times. In this case all the four rollers contribute to the operation of drawing: thus the second rollers B move $2\frac{1}{2}$ times as fast as the rollers A; the third rollers C move 8 times as fast as A; and the fourth rollers E move $10\frac{1}{2}$ times as fast as A. In this case the motion is given to the different rollers by means of bevelled wheels, and a horizontal axis, which extends across the ends of all the four rollers, to communicate motion from one pair of rollers to another.

There are three of these systems of rollers, which are all mounted on the same frame; and the first one through which the wool passes is called the 'breaking-frame'; but it does not differ from the others, which are called 'drawing-frames.' The slivers which have passed through one system of rollers are collected four or five together, and put through the drawing-rollers. In all the slivers pass through three drawings, and the whole extension is seldom less than 1,000 times, and for some kinds of wool much greater.

After the drawing of the slivers is finished, a pound weight is taken, and is measured by means of a cylinder, in order to ascertain if the drawing has been properly conducted; if the sliver does not prove of the length proposed, according to the size of worsted which is intended to be spun, the pinions of some of the drawing-frames are changed, to make the draught more or less, until it is found by experiment that one pound of the sliver measures the required length.

Roving-frame.—This is provided with rollers, the same as the drawing-frames: it takes in one or two slivers together, and draws them out four times. By this extension the sliver becomes so small that it would break with the slightest force, and it is therefore necessary to give some twist; this is done by a spindle and flyer. See *Roving*, under COTTON SPINNING.

Spinning-frame.—This is so much like the roving-frame that a short description will be sufficient. The spindles are more delicate, and there are three pairs of rollers, instead of two; the bobbins, which are taken off from the spindles of the roving-frame when they are quite full, are stuck upon skewers, and the roving which proceeds from them is conducted between the rollers. The back pair turns round slowly; the middle pair turns about twice for once of the back rollers; and the front pair makes from twelve to seventeen turns for one turn of the back roller, according to the degree of extension which is required.

The spindles must revolve very quickly in the spinning-frame, in order to give the requisite degree of twist to the worsted. The hardest twisted worsted is called 'tammy warp'; and when the size of this worsted is such as to be 20 or 24 hanks to the pound weight, the twist is about 10 turns in each inch of length. The least twist is given to the worsted for fine hosiery, which is from 18 to 24 hanks to the pound. The twist is from 5 to 6 turns per inch. The degree of twist is regulated by the size of the whirls or pulleys upon the spindle, and by the wheel-work which communicates the motion to the front rollers from the band-wheel, which turns the spindles.

It is needless to enter more minutely into the description of the spinning machinery, because the fluted roller construction, invented by Sir Richard Arkwright, fully described under COTTON SPINNING, is equally applicable to worsted. The difference between the two is chiefly in the distance between the rollers, which in the worsted-frame is capable of being increased or diminished at pleasure, according to the length of the fibres of the wool; and the draught or extension of the roving is far greater than in the cotton.

Reeling.—The bobbins of the spinning-frame are placed in a row upon wires before a long horizontal reel, and the threads from 20 bobbins are wound off together. The reel is exactly a yard in circumference, and when it has wound off 80 turns it rings a bell; the motion of the reel is then stopped, and a thread is passed round the 80 turns of folds which each thread has made. The reeling is then continued till another 80 yards is wound off, which is also separated by interweaving the same thread; each of these separate parcels is called 'a ley,' and when 7 such leys are reeled it is called 'a hank,' which contains 560 yards. When this quantity is reeled off, the ends of the binding thread are tied together, to bind each hank fast, and one of the rails of the reel is struck to loosen the hanks, and they are drawn off at the end of the reel. These hanks are next hung upon a hook, and twisted up hard by a stick; then doubled, and the two parts twisted together to make a firm bundle. In this state the hanks are weighed by a small index-machine, which denotes what number of the hanks will weigh a pound. And they are sorted accordingly into different parcels. It is by this means that the number of the worsted is ascertained as the denomination for its fineness: thus No. 24 means that 24 hanks each containing 560 yards will weigh a pound, and so on.

This denomination is different from that used for cotton, because the hank of cotton contains 840 yards instead of 560; but in some places the worsted hank is made of the same length as the cotton.

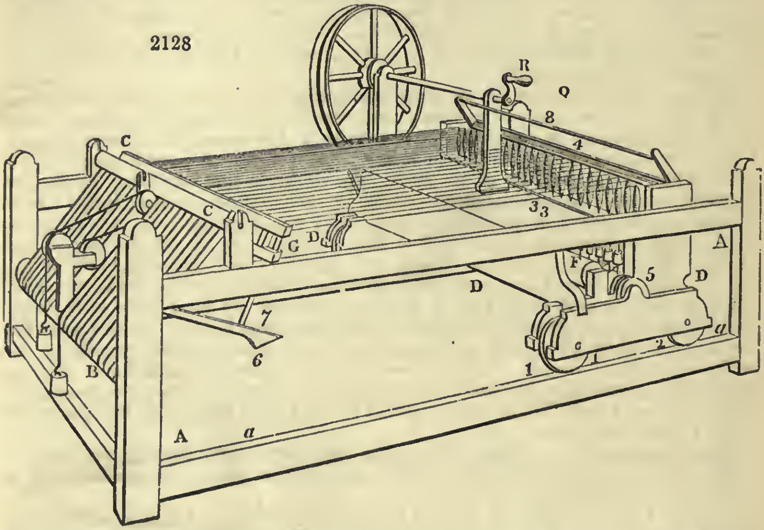
To pack up the worsted for market, the proper number of hanks is collected to make a pound, according to the number which has been ascertained; these are weighed as a proof of the correctness of the sorting, then tied up in bundles of one pound each, and four of these bundles are again tied together. Then 60 such bundles are packed up in a sheet, making a bale of 240 lbs. ready for market.

Of the treatment of short wool for the cloth manufacture.—Short wool resembles cotton not a little in the structure of its filaments, and is cleaned by the *willy*, as cotton is by the *willow*, which opens up the matted fleece of the wool-stapler, and cleans it from accidental impurities. Sheep's wool for working into coarse goods must be passed repeatedly through this machine, both before and after it is dyed; the second last time for the purpose of blending the different sorts together, and the last for imbuing the fibres intimately with oil. The oiled wool is next subjected to a first carding operation called *scribbling*, whereby it is converted into a broad thin fleece or lap, as cotton is by the breaker-cards of a cotton-mill. The woollen lap is then worked by the cards proper, which deliver it in a narrow band or sliver. By this process the wool expands greatly in all its dimensions; while the broken or short filaments get entangled by crossing in every possible direction, which prepares them for the fulling operation. See *Carding*, under COTTON SPINNING.

The *slubbing machine*, or *billy*, reduces the separate rolls of *cardings* into a continuous slightly-twisted spongy cord, which is sometimes called a roving. *Fig.* 2128 is a perspective representation of the slubbing machine in most common use. A, A, is the wooden frame; within which is the moveable carriage D, D, which runs upon the lower side rails at *a*, *a*, on friction wheels at 1, 2, to make it move easily backwards and forwards from one end of the frame to the other. The carriage contains a series of steel spindles, marked 3, 3, which receive rapid rotation from a long tin drum F, by means of a series of cords passing round the pulley or whorl of each spindle. This drum, 6 inches in diameter, is covered with paper, and extends across the whole breadth of the carriage. The spindles are set nearly upright in a frame, and about 4 inches apart; their under ends being pointed conically, turn in brass sockets, called 'steps,' and are retained in their position by a small brass collet, which embraces each spindle at about the middle of its length. The upper half of each spindle projects above the top of the frame. The drum revolves horizontally before the spindles, having its axis a little below the line of the whorls; and receives motion, by a pulley at one of its ends, from an endless band which passes round a wheel E, like the large domestic wheel formerly used in spinning wool by hand, and of similar dimensions. This wheel is placed upon the outside of the main frame of the machine, and has its shafts supported by upright standards upon the carriage D. It is turned by the spinner placed at Q, with his right hand applied to a winch R, which gives motion to the drum, and thereby causes the spindles to revolve with great velocity.

Each spindle receives a soft cylinder or carding of wool, which comes through beneath a wooden roller C, C, at the one end of the frame. This is the *billy roller*, so

2128



much talked of in the controversies between the operatives and masters in the cotton-factories, as an instrument of cruel punishment to children, though no such machine has been used in cotton-mills for half a century at least. These wooden rolls proceed to the series of spindles, standing in the carriage, in nearly a horizontal plane. By the alternate advance and retreat of the carriage upon its railway, the spindles are made to approach to, and recede from, the roller C, with the effect of drawing out a given length of the soft cord, with any desired degree of twist, in the following manner:—

The carding-rolls are laid down straight, side by side, upon the endless cloth, strained in an inclined direction between two rollers, one of which is seen at B, and the other lies behind C. One carding is allotted to a spindle; the total number of each in one machine being from 50 to 100. The roller C, of light wood, presses gently with its weight upon the cardings, while they move onwards over the endless cloth, with the running-out of the spindle carriage. Immediately in front of the said roller, there is a horizontal wooden rail or bar G, with another beneath it, placed across the frame. The carding is conducted through between these two bars, the moveable upper one being raised to let any aliquot portion of the roll pass freely. When this bar is again let down, it pinches the spongy carding fast; whence this mechanism is called the 'clasp.' It is in fact the *clove*, originally used by Hargreaves in his cotton-jenny. The moveable upper rail G, is guided between sliders, and a wire 7, descends from it to a lever C. When the spindle carriage D, D, is wheeled close home to the billy roller, a wheel 5, lifts the end 6 of the lever, which, by the wire 7, raises the upper bar or rail G, so as to open the clasp, and release all the card-rolls. Should the carriage be now drawn a little way from the clasp bars, it would tend to pull a corresponding length of the cardings forward from the inclined plane B, C. There is a small catch, which lays hold of the upper bar of the clasp G, and hinders it from falling till the carriage has receded to a certain distance, and has thereby allowed from 7 to 8 inches of the cardings to be taken out. A stop upon the carriage then comes against the catch, and withdraws it; thus allowing the upper rail to fall and pinch the carding, while the carriage, continuing to recede, draws out or stretches that portion of the roll which is between the clasp and the spindle-points. But during this time the wheel has been turned to keep the spindles revolving, communicating the proper degree of twist to the cardings in proportion to their extension, so as to prevent them from breaking.

It might be imagined that the slubbing cords would be apt to coil round the spindles; but as they proceed in a somewhat inclined direction to the clasp, they receive merely a twisting motion, continually slipping over the points of the spindles, without getting wound upon them. Whenever the operative or slubber has given a due degree of twist to the rovings, he sets about winding them upon the spindles into a conical shape, for which purpose he presses down the faller-wire 8, with his left hand, so as to bear it down from the points of the spindles, and place it opposite to their middle part. He next makes the spindles revolve, while he pushes in the carriage slowly, so as to coil the slubbing upon the spindle into a conical cop. The wire 8, regulates the winding-on of the whole series of slubbings at once, and receives its proper angle of depression for this purpose from the horizontal rail 4, which turns upon pivots in its ends, in brasses fixed on the standards, which rise from the carriage D. By turning this rail on its pivots, the wire 8 may be raised or lowered in any degree. The slubber seizes the rail 4 in his left hand, to draw the carriage out; but in returning it, he depresses the faller-wire, at the same time that he pushes the carriage before him.

The cardings are so exceedingly tender, that they would readily draw out, or even break, if they were dragged with friction upon the endless cloth of the inclined plane. To save this injurious traction, a contrivance is introduced for moving the apron. A cord is applied round the groove in the middle part of the upper roller, and after passing over pulleys, as shown in the figure, it has a heavy weight hung at the one end, and a light weight at the other, to keep it constantly extended, while the heavy weight tends to turn the rollers with their endless cloth round in such a direction as to bring forward the rovings, without putting any strain upon them. Every time that the carriage is pushed home, the larger weight gets wound up; and when the carriage is drawn out, the greater weight turns the roller, and advances the endless apron, so as to deliver the carding at the same rate as the carriage runs out; but when the proper quantity is delivered, a knot in the rope arrives at a fixed stop, which does not permit it to move any further; while at the same instant the roller 5 quits the lever 6, and allows the upper rail G, of the clasp to fall, and pinch the carding fast; the wheel E, being then set in motion, makes the spindles revolve; and the carriage being simultaneously drawn out, extends the slubbings while under the influence of twisting. In winding up the slubbings the operative must take care to push in the carriage, and to turn the wheel round at such rates that the spindles will not take up faster than the carriage moves on its railway, or he would injure the slubbings. The machine requires the attendance of a child, to bring the cardings from the card-engine, to place them upon the sloping feed-cloth, and to join the ends of the fresh ones carefully to the ends of the others newly-drawn under the roller. Slubbings intended for warp-yarn must be more twisted than those for weft; but each must receive a degree of torsion relative to the quality of the wool and of the cloth intended to be made. In general, however, no more twist should be given to the slubbings than is indispensable for enabling them to be drawn out to the requisite slenderness without breaking. This twist forms no part of the twist of the finished yarn, for the slubbing will be twisted in the contrary direction, when spun afterwards in the jenny or mule.

It may here be remarked, that various machines have been constructed of late years for making continuous card-ends, and slubbings, in imitation of the carding and roving of the COTTON SPINNING; to which article therefore the reader may be referred. The wool slubbings are now spun into yarn, in many factories, by means of the mule. Indeed, in France the finest yarn, for the *mousseline-de-laine* fabrics, is beautifully spun upon the self-actor mule of Sharp and Roberts.[1]

Tentering.—When the cloth is returned from the fulling-mill it is stretched upon the tenter frame, and left in the open air till dry.

In the woollen manufacture, as the cloth suffers, by the operation of the fulling-mill, a shrinkage of its breadth to well-nigh one-half, it must at first be woven of nearly double its intended width when finished. Superfine six-quarter broad cloths must therefore be turned out of the loom twelve-quarters wide.

[1] See this admirable machine fully described and delineated in Dr. Ure's *Cotton Manufacture of Great Britain*, vol. ii.

Burling is the name of a process, in which the dried cloth is examined minutely in every part, freed from knots or uneven threads, and repaired by sewing any little rents, or inserting sound yarns in the place of defective ones.

Teasling.—The object of this operation is to raise up the loose filaments of the woollen yarn into a nap upon one of the surfaces of the cloth, by scratching it either with thistle-heads, called 'teasels,' or with teasling-cards or brushes, made of wire. The natural teasels are the balls which contain the seeds of the plant called *Dipsacus fullonum*; the scales which form the balls, project on all sides and end in sharp elastic points, that turn downwards like hooks. In teasling by hand, a number of these balls are put into a small wooden frame, having crossed handles, eight or ten inches long, and when thus filled, form an implement not unlike a curry-comb, which is used by two men, who seize the teasel-frame by the handles, and scrub the face of the cloth, hung in a vertical position from two horizontal rails, made fast to the ceiling of the workshop. First, they wet the cloth and work three times over, by strokes in the direction of the warp, and next of that of the weft, so as to raise all the loose fibres from the felt, and to prepare it for shearing. In large manufactories, this dressing operation is performed by a machine called a 'gig-mill,' which originally consisted, and in most places still consists of a cylinder bristled all over with the thistle-heads, and made to revolve rapidly while the cloth is drawn over it in a variety of directions. If the thistle be drawn in the line of the warp, the points act more efficaciously upon the weft, being perpendicular to its softer spun yarns. Inventors who have tried to give the points a circular or oblique action between the warp and the weft, proceed apparently upon a false principle, as if the cloth were like a plate of metal, whose substance could be pushed in any direction. Teasling really consists in drawing out one end of the filaments, and leaving the body of them entangled in the cloth; and it should cease and pull them perpendicularly to their length, because in this way it acts upon the ends, which being least implicated, may be most readily disengaged.

When the hooks of the thistles become clogged with flocks of wool, they must be taken out of the frame or cylinder, and cleaned by children with a small comb. Moisture, moreover, softens their points, and impairs their teasling powers; an effect which needs to be counterbalanced, by taking them out, and drying them from time to time. Many contrivances have, therefore, been proposed, in which metallic teasels of an unchangeable nature, mounted in rotatory machines, driven by power, have been substituted for the vegetable, which being required in prodigious quantities, become sometimes excessively scarce and dear in the clothing districts. In 1818, several schemes of that kind were patented in France, of which those of M. Arnold-Merick, and of MM. Taurin frères, of Elbœuf, are described in the 16th volume of 'Brevets d'Invention Expirés.' Mr. Daniell, cloth-manufacturer in Wilts, renewed this invention under another form, by making his rotatory cards with two kinds of metallic wires, of unequal lengths; the one set long, thin, and delicate, representing the points of the thistle; the other, shorter, stiffer, and blunter, being intended to stay the cloth, and to hinder the former from entering too far into it. But none of these processes have succeeded in discarding the natural teasel from the most eminent manufactories.

The French Government purchased in 1807, the patent of Douglas, an English mechanist, who had, in 1802, imported into France, the best system of gig-mills then used in the west of England. A working set of his machines having been placed in the *Conservatoire des Arts*, for public inspection, they were soon introduced into most of the French establishments, so as generally to supersede teasling (*lainage*) by hand. A description of them was published in the third volume of the 'Brevets d'Invention.' The following is an outline of some subsequent improvements:—

1. As it was imagined that the seesaw action of the hand-operative was in some respects more effectual than the uniform rotation of a gig-mill, this was attempted to be imitated by an alternating movement.

2. Others conceived that the seesaw motion was not essential, but that it was advantageous to make the teasels or cards act in a rectilinear direction, as in working by hand; this action was attempted by placing the two ends of the teasel-frame in grooves formed like the letter D, so that the teasel should act on the cloth only when it came into the rectilinear part. Mr. Wells, machine-maker, of Manchester, obtained a patent, in 1832, for this construction,

3. It was supposed that the teasels should not act perpendicularly to the weft, but obliquely or circularly upon the face of the cloth. Mr. Ferrabee, of Gloucester, patented in 1830, a scheme of this kind, in which the teasels are mounted upon two endless chains, which traverse from the middle of the web to the selvage or list, one to the right, and another to the left hand, while the cloth itself passes under them with such a velocity, that the effect, or *resultant*, is a diagonal action, dividing into two equal parts the rectangle formed by the weft and warp yarns. Three patent machines

of Mr. George Oldland—the first in 1830, the second and third in 1832—all proceed upon this principle. In the first, the teasels are mounted upon disks made to turn flat upon the surface of the cloth; in the second, the rotating disks are pressed by cork-screw spiral springs against the cloth, which is supported by an elastic cushion, also pressed against the disks by springs; and in the third machine, the revolving disks have a larger diameter, and they turn, not in a horizontal, but in a vertical plane.

4. Others fancied that it would be beneficial to support the reverse side of the cloth by flat hard surfaces, while acting upon its face with cards or teasels. Mr. Joseph Cliseld Daniell, having stretched the cloth upon smooth level stones, teasels them by hand.

5. Messrs. Charlesworth and Mellor obtained a patent, in 1829, for supporting the back of the cloth with elastic surfaces, while the part was exposed to the teasling action.

6. Elasticity has also been imparted to the teasels, in the three patent inventions of Mr. Sevill, Mr. J. C. Daniell, and Mr. R. Atkinson.

7. It has been thought useful to separate the teasel-frames upon the drum of the gig-mill, by simple rollers, or by rollers heated with steam, in order to obtain the combined effect of calendering and teasling. Mr. J. C. Daniell, Mr. G. Haden, and Mr. J. Rayner, have obtained patents for contrivances of this kind.

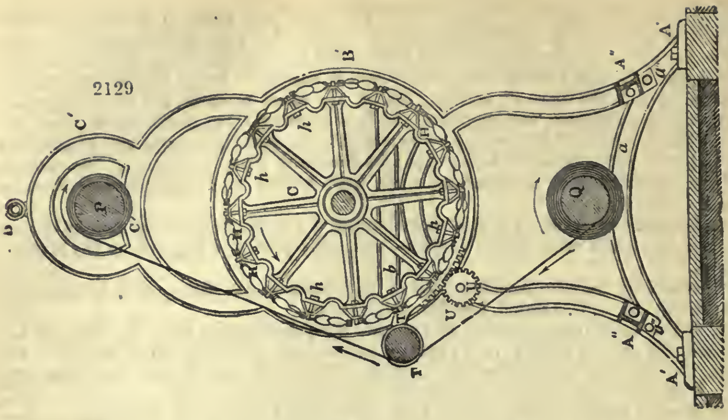
8. Several French schemes have been mounted for making the gig-drum act upon the two sides of the cloth, or even to mount two drums on the same machine.

Mr. Jones, of Leeds, contrived a very excellent method of stretching the cloth, so as to prevent the formation of folds or wrinkles. (See Newton's 'Journal,' vol. viii. 2nd series, page 126). Mr. Collier, of Paris, obtained a patent, in 1830, for a greatly improved gig-mill, upon Douglas's plan, which is now much esteemed by the French clothiers. The following figures (*figs.* 2129, 2130) and description exhibit one of the latest and best teasling machines. It is the invention of M. Dubois & Co., of Louviers, and is now doing excellent work in that celebrated seat of the cloth manufacture.

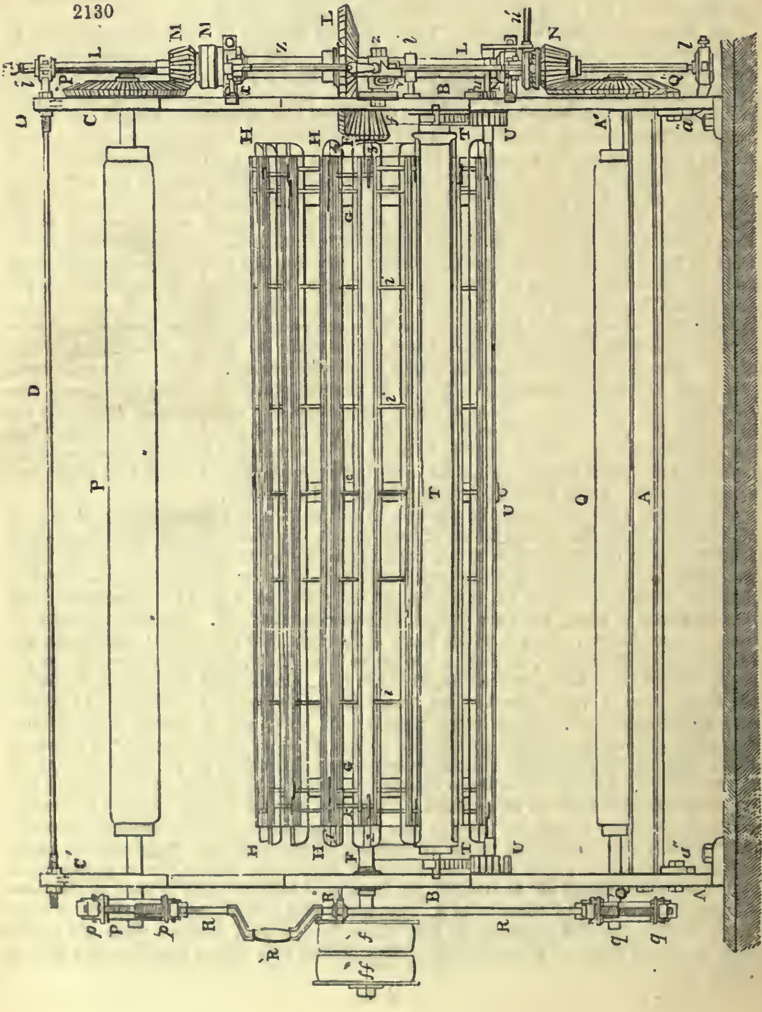
In the fulling mill, the woollen web acquires body and thickness, at the expense of its other dimensions; for being thereby reduced about one-third in length, and one-half in breadth, its surface is diminished to one-third of its size as it comes out of the loom; and it has, of course, increased threefold in thickness. As the filaments drawn forth by teasling, are of very unequal lengths, they must be shorn to make them level, and with different degrees of closeness, according to the quality of the stuff, and the appearance it is desired to have. But, in general, a single operation of each kind is insufficient; whence, after having passed the cloth once through the gig-mill, and once through the shearing-machine (*tondeuse*), it is ready to receive a second teasling, deeper than the first, and then to suffer a second shearing. Thus, by the alternate repetition of these processes, as often as is deemed proper, the cloth finally acquires its wished-for appearance. Both of these operations are very delicate, especially the first; and if they be ill conducted, the cloth is weakened, so as to tear or wear most readily. On the other hand, if they be skilfully executed, the fabric becomes not only more sightly, but it acquires strength and durability, because its face is changed into a species of fur, which protects it from friction and humidity.

Figs. 2129, 2130, represent the gig-mill in section, and in front elevation. A, B, C, D, A′, B′, C′, D′, being the strong frame of iron, cast in one piece, having its feet enlarged a little more to the inside than to the outside and bolted to large blocks in the stone pavement. The two uprights are bound together below by two cross-beams A″, being fastened with screw-bolts at the ears *a″*, *a″*; and at top, by two wrought-iron stretcher-rods D, whose ends are secured by screw-nuts at D, D′. The drum is mounted upon a wrought-iron shaft F, which bears at its right end (*fig.* 2130), exterior to the frame, the usual riggers, or fast-and-loose pulley, *ff″*, *f′*, which give motion to the machine by a band from the main shaft of the mill. On its right end, within the frame, the shaft F, has a bevel-wheel F′, for transmitting movement to the cloth, as will be afterwards explained. Three crown wheels G, of which one is shown in the section, *fig.* 2129, are, as usual, keyed by a wedge to the shaft F. Their contour is a sinuous band, with six semi-cylindrical hollows, separated alternately by as many portions of the periphery. One of these three wheels is placed in the middle of the shaft F, and the other two, towards its extremities. Their size may be judged of, from inspection of *fig.* 2129. After having set them so that all their spokes or radii correspond exactly, the 16 sides H are made fast to the 16 portions of the periphery, which correspond in the three wheels. These sides are made of sheet-iron, curved in a gutter form, *fig.* 2129, but rounded off at the end, *fig.* 2130, and each of them is fixed to the three felloes of the wheels by three bolts *h*. The elastic part of the plate iron allows of their being sufficiently well adjusted, so that their flat portions furthest from the centre may lie pretty truly on a cylindrical surface, whose axis would coincide with that of the shaft F.

2129

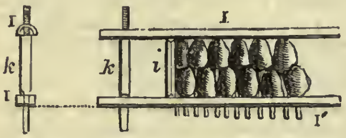


2130



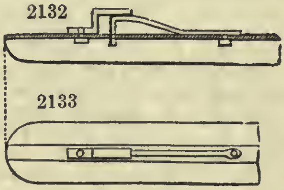
Between the 16 sides there are 16 intervals, which correspond to the 16 hollowings of each of the wheels. Into these intervals are adjusted, with proper precautions, 16 frames bearing the teasels which are to act upon the cloth. These are fitted in as follows:—Each has the shape of a rectangle, of a length equal to that of the drum, but their breadth only large enough to contain two thistle-heads set end to end, thus making two rows of parallel teasels throughout the entire length (see the contour in *fig.* 2129). A portion of the frame is represented in *fig.* 2131. The large side I, against which the tops of the teasels rest, is hollowed out in a semi-cylinder, and its opposite side is cleft throughout its whole length, to receive the tails of the teasels, which are seated and compressed in it. There are, moreover, cross-bars *i*, which serve to maintain the sides of the frame I, at an invariable distance, and to form short compartments for keeping the thistles compact. The ends are fortified by stronger bars *k*, *k*, with projecting bolts to fasten the frames between the ribs. The distance of the sides of the frame I, I′, ought to be such, that if a frame be laid upon the drum, in the interval of two ribs, the side I will rest upon the inclined plane of one of the ribs, and the side I′ upon the inclined plane of the other (see *fig.* 2129); while at the same time the bars *k*, of the two ends of the frame rest upon the flat parts of the ribs themselves. This point being secured, it is obvious, that if the ends of the bars *k* be stopped, the frame will be made fast. But they need not be fixed in a permanent manner, because they must be frequently removed and replaced. They are fastened by the clamp, *figs.* 2132, 2133, which is shut at the one end, and furnished at the other with a spring, which can be opened or shut at pleasure. 2 and 4, in *fig.* 2130 (near the right end of the shaft F), shows the place of the clamp, *figs.* 2132, 2133. The bar of the right hand is first set in the clamp, by holding up its other end; the frame is then let down into the left-hand clamp.

2131



2132

2133



The cloth is wound upon the lower beam Q, *fig.* 2129; thence it passes in contact with a wooden cylinder T, turning upon an axis, and proceeds to the upper beam P, on to which it is wound; by a contrary movement, the cloth returns from the beam P to Q, over the cylinder T; and may thus go from the one to the other as many times as shall be requisite. In these successive circuits it is presented to the action of the teasels, under certain conditions. In order to be properly teasled, it must have an equal tension throughout its whole breadth during its traverse; it must be brought into more or less close contact with the drum, according to the nature of the cloth, and the stage of the operation; sometimes being a tangent to the surface, and sometimes embracing a greater or smaller portion of its contour, it must travel with a determinate speed, dependent upon the velocity of the drum, and calculated so as to produce the best result: the machine itself must make the stuff pass alternately from one winding beam to the other.

In *fig.* 2130, before the front end of the machine, there is a vertical shaft L, as high as the framework, which revolves with great facility, in the bottom step *l*, the middle collet *l*′, and top collet *l*″, in the prolongation of the stretcher D. Upon this upright shaft are mounted—1, a bevel-wheel L′; 2, an upper bevel-pinion M, with its boss M′; 3, a lower bevel-pinion N, with its boss N′. The bevel-wheel L′ is keyed upon the shaft L, and communicates to it the movement of rotation which it receives from the pinion *f*, with which it is in gear; but the pinion *f*, which is mounted upon the shaft F of the drum, participates in the rotation which this shaft receives from the prime mover, by means of the fast rigger-pulley *f*′. The upper pinion M is independent upon the shaft L; that is to say, it may be slidden along it, up and down, without being driven by it; but it may be turned in an indirect manner by means of six curved teeth, projecting from its bottom, and which may be rendered active or not at pleasure; these curved teeth, and their intervals, correspond to similar teeth and intervals upon the top of the boss M′, which is dependent, by feathered indentations, upon the rotation of L, though it can slide freely up and down upon it. When it is raised, therefore, it comes into gear with M. The pinion N, and its boss, have a similar mode of being thrown into and out of gear with each other. The bosses M′ and N′, ought always to be moved simultaneously, in order to throw one of them into gear, and the other out of gear. The shaft L serves to put the cloth in motion, by means of the bevel-wheels P″ and Q″, upon the ends of the beams P and Q, which take into the pinions M and N.

The mechanism destined to stretch the cloth is placed at the other end of the machine, where the shafts of the beams, P, Q, are prolonged beyond the frame, and bear at their extremities P′ and Q′, armed each with a brake. The beam P (*fig.* 2129), turns in an opposite direction to the drum; consequently the cloth is wound upon P, and unwound from Q. If, at the same time as this is going on, the handle R, of the brake-shaft, be turned so as to clasp the brake of the pulley Q′ and release that of the pulley P′, it is obvious that a greater or smaller resistance will be occasioned in the beam Q, and the cloth which pulls it in unwinding, will be able to make it turn only when it has acquired the requisite tension; hence it will be necessary, in order to increase or diminish the tension, to turn the handle R′ a little more or a little less in the direction which clasps the brake of the pulley Q′; and as the brake acts in a very equable manner, a very equable tension will take place all the time that the cloth takes to pass. Besides, should the diminution of the diameter of the beam Q render the tension less efficacious in any considerable degree, the brake would need to be unclamped a very little, to restore the primitive tension.

When the cloth is to be returned from the beam P to the beam Q, Z must be lowered, to put the shaft L out of gear above, and in gear below; then the cloth-beam Q, being driven by that vertical shaft, it will turn in the same direction as the drum, and will wind the cloth round its surface. In order that it may do so, with a suitable tension, the pulley Q′ must be left free, by clasping the brake of the pulley P′ so as to oppose an adequate resistance.

The cloth is brought into more or less close contact with the drum as follows:—There is for this purpose a wooden roller T, against which it presses in passing from the one winding beam to the other, and which may have its position changed relatively to the drum. It is obvious, for example, that in departing from the position represented in *fig.* 2129, where the cloth is nearly a tangent to the drum, if the roller T′ be raised, the cloth will cease to touch it; and if it be lowered, the cloth will, on the contrary, embrace the drum over a greater or less portion of its periphery. For it to produce these effects, the roller is borne at each end, by iron gudgeons, upon the heads of an arched rack T″ (*fig.* 2129), where it is held merely by pins. These racks have the same curvature as the circle of the frame, against which they are adjusted by two bolts; and by means of slits, which these bolts traverse, they may be slidden upwards or downwards, and consequently raise or depress the roller T. But to graduate the movements, and to render them equal in the two racks, there is a shaft U, supported by the uprights of the frame, and which carries, at each end, pinions U′, U″, which work into the two racks T′, T″: this shaft is extended in front of the frame, upon the side of the head of the machine (*fig.* 2130), and there it carries a ratchet-wheel *u*, with a handle *u*′. The workman, therefore, requires merely to lay hold of the handle, and turn it in the direction of the ratchet-wheel, to raise the racks, and the roller T, which they carry; or to lift the click or catch, and turn the handle in the opposite direction, when he wishes to lower the roller, so as to apply the cloth to a larger portion of the drum.

Cloth Cropping.

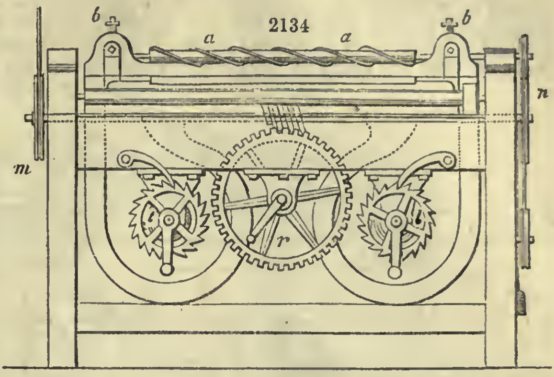
Of machines for cropping or shearing woollen cloths, those of Lewis and Davis have been very generally used.

Fig. 2134 is an end view, and *fig.* 2135 is a side view, of Lewis's machine for shearing cloth from list to list. *Fig.* 2136 is an end view of the carriage, with the rotatory cutter detached from the frame of the machine, and upon a larger scale: *a* is a cylinder of metal, on which is fixed a triangular steel wire; this wire is previously bent round the cylinder in the form of a screw, as represented at *a*, *a*, in *fig.* 2134, and, being hardened, is intended to constitute one edge of the shear or cutter.

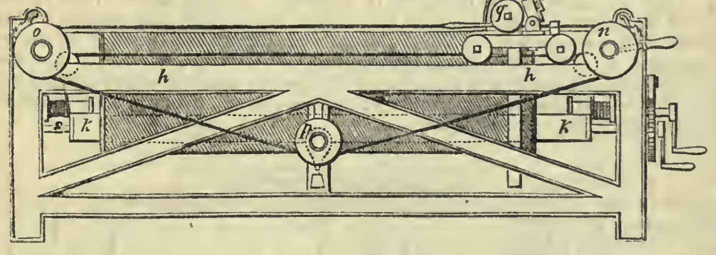
The axis of the cylindrical cutter *a* turns in the frame *b*, which, having proper adjustments, is mounted on pivots *c*, in the standard of the travelling carriage *d*, *d*; and *e* is the fixed or ledger blade, attached to a bar *f*, which constitutes the other edge of the cutter; that is, the stationary blade, against which the edges of the rotatory cutter act; *f* and *g* are flat springs, intended to keep the cloth (shown by dots) up against the cutting edges. The form of these flat springs *f g* is shown at *figs.* 2137 and 2138, as consisting of plates of thin metal cut into narrow slips (*fig.* 2138), or perforated with long holes (*fig.* 2137). Their object is to support the cloth which is intended to pass between them, and operate as a spring bed, bearing the surface of the cloth against the cutters, so that its pile or nap may be cropped off or shorn as the carriage *d* is drawn along the top rails of the standard or frame of the machine *h h*, by means of cords.

The piece of cloth to be shorn is wound upon the beam *k*, and its end is then conducted through the machine, between the flat springs *f* and *g* (as shown in *fig*. 2136), to the other beam *l*, and is then made fast; the sides or lists of the cloth being held and stretched by small hooks, called 'habiting hooks.' The cloth being thus placed in the machine, and drawn tight, is held distended by means of ratchets on the ends of the beams *k* and *l*, and palls. In commencing the operation of shearing, the carriage *a* must be brought back, as in *fig*. 2136, so that the cutters shall be close to the list; the frame of the cutters is raised up on its pivots as it recedes, in order to keep the cloth from injury, but is lowered again previously

2134

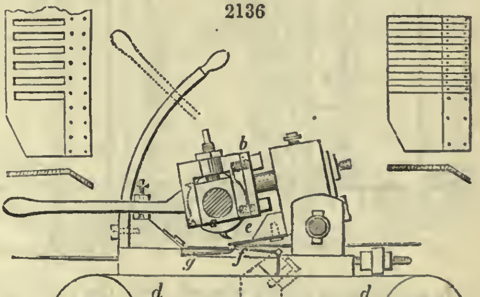


2135



to being put in action. A band or winch is applied to the rigger or pulley *m*, which, by means of an endless cord passed round the pulley *n*, at the reverse end of the axle of *m*, and round the other pulleys *o* and *p*, and the small pulley *q*, on the axle of the cylindrical cutter, gives the cylindrical cutter a very rapid rotatory motion; at the same time a worm, or endless screw, on the axle of *m* and *n*, taking into the teeth of the large wheel *r*, causes that wheel to revolve, and a small drum *s*, upon its axle, to coil up the cord, by which the carriage *d*, with the cutters *a* and *e*, and the spring bed *f* and *g*, are slowly, but progressively, made to advance, and to carry the cutters over the face of the cloth, from list to list; the rapid rotation of the cutting cylinder *a*, producing the operation of cropping or shearing the pile.

2137 2136 2138

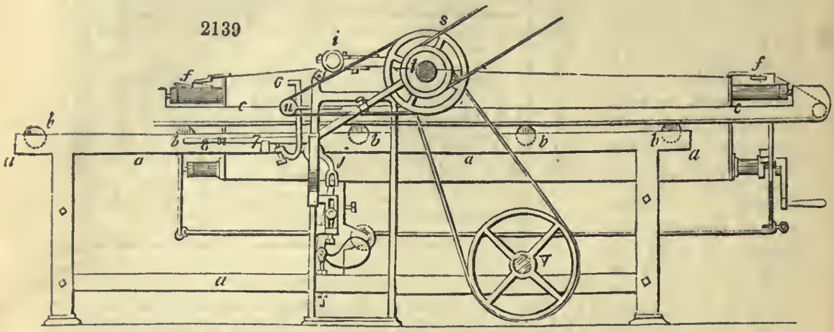


Upon the cutting cylinder, between the spiral blades, it is proposed to place strips of plush, to answer the purpose of brushes, to raise the nap or pile as the cylinder goes around, and thereby assist in bringing the points of the wool up to the cutters.

The same contrivance is adapted to a machine for shearing the cloth lengthwise.

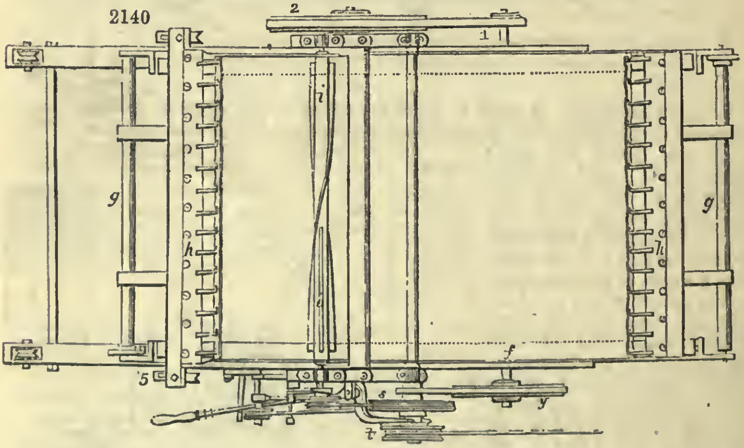
Fig. 2139, is a geometrical elevation of one side of Mr. Davis's machine. *Fig*. 2140, a plan or horizontal representation of the same, as seen at top; and *fig*. 2141, a section taken vertically across the machine near the middle, for the purpose of displaying the working parts more perfectly than in the two preceding figures. These three figures represent a complete machine in working condition, the cutters being worked by a rotatory motion, and the cloth so placed in the carriage as to be cut from list to list. *a, a, a,* is a frame or standard, of wood or iron, firmly bolted together by cross braces at the ends and in the middle. In the upper side-rails of the standard, there is a series of axles carrying anti-friction wheels, *b, b, b,* upon which

2139



the side-rails *c, c,* of the carriage or frame that bears the cloth runs, when it is passing under the cutters in the operation of shearing. The side-rails *c, c,* are straight bars of iron, formed with edges *v,* on their under sides, which run smoothly in the grooves of the rollers *b, b, b.* These side-rails are firmly held together by the end stretchers *d, d.* The sliding frame has attached to it the two lower rollers *e, e,* upon which the cloth intended to be shorn is wound; the two upper lateral rollers *f, f,* over which the cloth is conducted and held up; and the two end rollers *g, g,* by which the habiting rails *h, h,* are drawn tight.

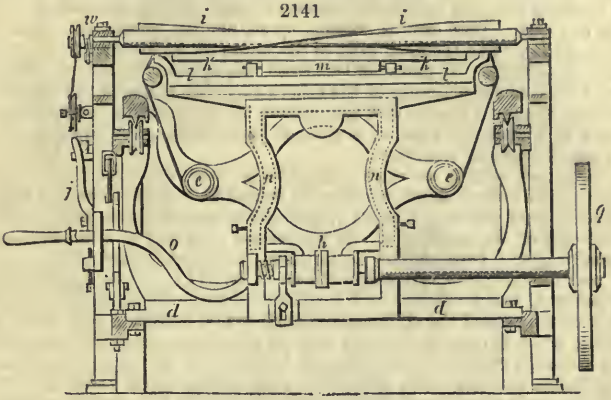
2140



In preparing to shear a piece of cloth, the whole length of the piece is, in the first place, tightly rolled upon one of the lower rollers *e,* which must be something longer than the breadth of the cloth from list to list. The end of the piece is then raised and passed over the top of the lateral rollers *f, f,* whence it is carried down to the other roller *e,* and its end or farral is made fast to that roller. The hooks of the habiting rails *h, h,* are then put into the lists, and the two lower rollers *e, e,* with the two end rollers *g, g,* are then turned, for the purpose of drawing up the cloth, and straining it tight, which tension is preserved by ratchet-wheels attached to the ends of the respective rollers, with palls dropping into their teeth. The frame carrying the cloth is now slidden along upon the stop standard rails by hand, so that the list shall be brought nearly up to the cutter *i, i,* ready to commence the shearing operation; the bed is then raised, which brings the cloth up against the edges of the shears.

The construction of the bed will be seen by reference to the cross-section *fig.* 2141. It consists of an iron or other metal roller, *k*, *k*, turned to a truly cylindrical figure, and covered with cloth or leather, to afford a small degree of elasticity. This roller is mounted upon pivots in a frame, *l*, *l*, and is supported by a smaller roller *m*, similarly mounted, which roller *m*, is intended merely to prevent any bending or depression of the central part of the upper roller or bed *k*, *k*, so that the cloth may be kept in close contact with the whole length of the cutting blades.

2141

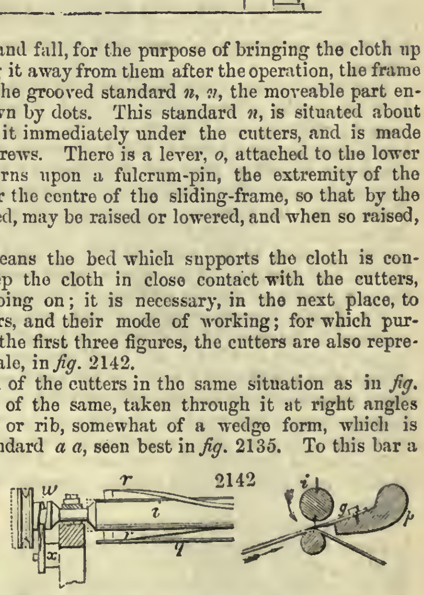


In order to allow the bed *k* to rise and fall, for the purpose of bringing the cloth up to the cutters to be shorn, or lowering it away from them after the operation, the frame *l*, *l*, is made to slide up and down in the grooved standard *n*, *n*, the moveable part enclosed within the standard being shown by dots. This standard *n*, is situated about the middle of the machine, crossing it immediately under the cutters, and is made fast to the frame *a*, by bolts and screws. There is a lever, *o*, attached to the lower cross-rail of the standard, which turns upon a fulcrum-pin, the extremity of the shorter arm of which lever acts under the centre of the sliding-frame, so that by the lever *o*, the sliding-frame, with the bed, may be raised or lowered, and when so raised, be held up by a spring-catch *j*.

It being now explained by what means the bed which supports the cloth is constructed, and brought up, so as to keep the cloth in close contact with the cutters, while the operation of shearing is going on; it is necessary, in the next place, to describe the construction of the cutters, and their mode of working; for which purpose, in addition to what is shown in the first three figures, the cutters are also represented detached, and upon a larger scale, in *fig.* 2142.

In this figure is exhibited a portion of the cutters in the same situation as in *fig.* 2136; and alongside of it is a section of the same, taken through it at right angles to the former; *p*, is a metallic bar or rib, somewhat of a wedge form, which is fastened to the top part of the standard *a a*, seen best in *fig.* 2135. To this bar a straight blade of steel *g*, is attached by screws, the edge of which stands forward even with the centre or axis of the cylindrical cutter *i*, and forms the ledger blade, or lower fixed edge of the shears. This blade remains stationary, and is in close contact with the pile or nap of the cloth, when the bed *k*, is raised, in the manner above described.

2142



The cutter or upper blade of the shears, is formed by inserting two or more strips of plate steel, *r*, *r*, in twisted directions, into grooves in the metallic cylinder *i*, *i*, the edges of which blades *r*, as the cylinder *i* revolves, traverse along the edge of the fixed or ledger-blade *g*, and by their obliquity produce a cutting action like shears; the edges of the two blades taking hold of the piled or raised nap, as the cloth passes under it, shaves off the superfluous ends of the wool, and leaves the face smooth.

Rotatory motion is given to the cutting cylinder *i*, by means of a band leading from the wheel *s*, which passes round the pulley fixed on the end of the cylinder *i*, the wheel *s* being driven by a band leading from the rotatory part of the steam-engine, or any other first mover, and passed round the rigger *t*, fixed on the axle *s*. Tension is given to this band by a tightening pulley, *u*, mounted on an adjustable sliding-piece *v*, which is secured to the standard by a screw; and this trigger is thrown in and out of gear by a clutch-box and lever, which sets the machine going, or stops it.

In order to give a drawing stroke to the cutter, which will cause the piece of cloth to be shorn off with better effect, the upper cutter has a slight lateral action, produced by the axle of the cutting cylinder being made sufficiently long to allow of its sliding laterally about an inch in its bearings; which sliding is effected by a cam *w*, fixed at one end. This cam is formed by an oblique groove, cut round the axle (see *w*, *fig.* 2142), and a tooth, *x*, fixed to the frame or standard which works in it, as the cylinder revolves. By means of this tooth, the cylinder is made to slide laterally, a distance equal to the obliquity of the groove *w*, which produces the drawing stroke of the upper shear. In order that the rotation of the shearing cylinder may not be obstructed by friction, the tooth *x*, is made of two pieces, set a little apart, so as to afford a small degree of elasticity.

The manner of passing the cloth progressively under the cutters is as follows:—On the axle of the wheel *s*, and immediately behind that wheel, there is a small rigger, from which a band passes to a wheel *y*, mounted in an axle turning in bearings on the lower side-rail of the standard *a*. At the reverse extremity of this axle, there is another small rigger 1, from which a band passes to a wheel 2, fixed on the axle 3, which crosses near the middle of the machine, seen in *fig.* 2141. Upon this axle there is a sliding pulley 4, round which a cord is passed several times, whose extremities are made fast to the ends of the sliding carriage *d*; when, therefore, this pulley is locked to the axle, which is done by a clutch box, the previously-described movements of the machine cause the pulley 4 to revolve, and by means of the rope passed round it, to draw the frame, with the cloth, slowly and progressively along under the cutters.

It remains only to point out the contrivance whereby the machinery throws itself out of gear, and stops its operations, when the edge of the cloth or list arrives at the cutters.

At the end of one of the habiting rails, *h*, there is a stop affixed by a nut and screw 5, which, by the advance of the carriage, is brought up and made to press against a lever 6; when an arm from this lever 6, acting under the catch 7, raises the catch up, and allows the hand-lever 8, which is pressed upon by a strong spring, to throw the clutch-box 10, out of gear with the wheel 8; whereby the revolution of the machine instantly ceases. The lower part of the lever 6, being connected by a joint to the top of the lever *j*, the receding of the lever 6, draws back the lower catch *j*, and allows the sliding frame *l*, *l*, within the bed *k*, to descend. By now turning the lower rollers *e*, *e*, another portion of the cloth is brought up to be shorn; and when it is properly habited and strained, by the means above described, the carriage is slidden back, and the parts being all thrown into gear, the operation goes on as before.

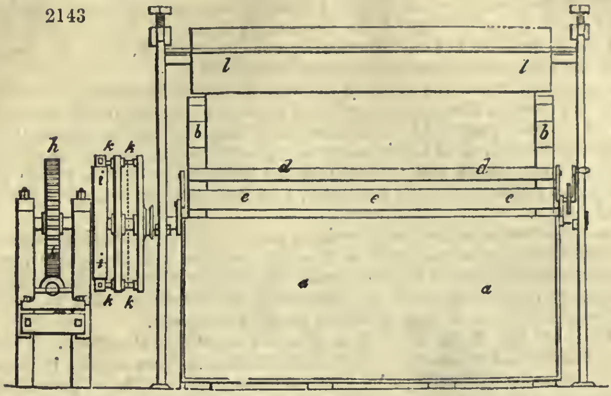
Mr. Hirst's improvements in manufacturing woollen cloths, for which a patent was obtained in February 1830, apply to that part of the process where a permanent lustre is given usually by what is called roll-boiling; that is, stewing the cloth, when tightly wound upon a roller, in a vessel of hot water or steam. As there are many disadvantages attendant upon the operation of roll-boiling, such as injuring the cloths, by overheating them, which weakens the fibre of the wool, and also changes some colours, he substituted, in place of it, a particular mode of acting upon the cloths, by occasional or intermitted immersion in hot water, and also in cold water; which operations may be performed either with or without pressure upon the cloth, as circumstances may require.

The apparatus which he proposed to employ for carrying on his improved process is shown in the accompanying drawings. *Fig.* 2143, is a front view of the apparatus, complete, and in working order; *fig.* 2144, is a section, taken transversely through the middle of the machine, in the direction of *fig.* 2145; and *fig.* 2145 is an end view of the same. *a*, *a*, *a*, is a vessel or tank, made of iron or wood, or any other suitable material; sloping at the back and front, and perpendicular at the ends. This tank must be sufficiently large to admit of half the diameter of the cylinder or drum, *b*, *b*, *b*, being immersed into it, which drum is about four feet in diameter, and about six feet long, or something more than the width of the piece of cloth intended to be operated upon. This cylinder or drum, *b*, *b*, is constructed by combining segments of wood cut radially on their edges, secured by screw-bolts to the rims of the iron wheels, having arms, with an axle passing through the middle.

The cylinder or drum being thus formed, rendered smooth on its periphery, and mounted upon its axle in the tank, the piece of cloth is wound upon it as tightly as possible, which is done by placing it in a heap upon a stool, as at *c*, *fig.* 2144, passing its end over and between the tension rollers *d*, *e*, and then securing it to the drum;

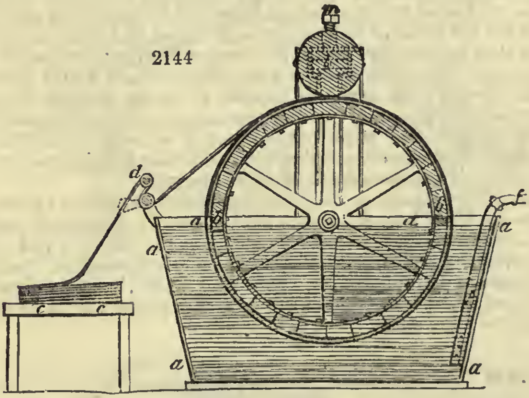
the cloth is progressively drawn from the heap, between the tension-rollers, which are confined by a pall and ratchet, on to the periphery of the drum, by causing the

2143



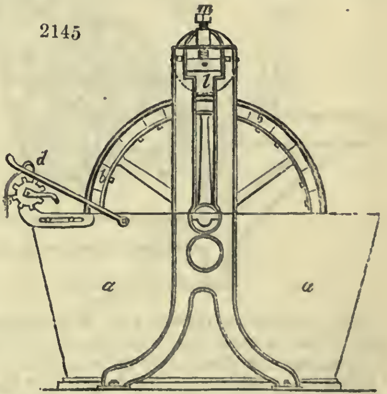
drum to revolve upon its axis, until the whole piece of cloth is tightly wound upon the drum; it is then bound round with canvas or other wrappers, to keep it secure.

2144



If the tank has not been previously charged with clean and pure water, it is now filled to the brim, as shown at *fig.* 2144, and opening the stopcock of the pipe *f*, which leads from a boiler, the steam is allowed to blow through the pipe, and discharge itself at the lower end, by which means the temperature of the water is raised in the tank to about 170° Fahr. Before the temperature of the water has got up, the drum is set in slow rotatory motion, in order that the cloth may be uniformly heated throughout; the drum making about one rotation per minute. The cloth, by immersion in the hot water, and passing through the cold air, in succession, for the space of about 8 hours, gets a smooth soft face, the texture not being rendered harsh, or otherwise injured, as is frequently the case by roll-boiling.

2145



Uniform rotatory motion to the drum is shown in *fig.* 2143, in which an endless screw or worm is placed horizontally, and driven by a steam-engine or any other first mover employed in the factory. This endless screw takes into the teeth of, and drives, the vertical wheel *h*, upon the axle of which the coupling-box *i*, *i*, is fixed, and, consequently, continually revolves with it. At the end of the shaft of the drum, a pair of sliding clutches *k*, *k*, are mounted, which, when projected forward, as shown by dots in *fig.* 2143, produce the coupling or locking of the drum-shaft to the driving-wheel, by which the drum is put in motion; but on withdrawing the clutches *k*, *k*, from the coupling-box *i*, *i*, as in the figure, the drum immediately stands still.

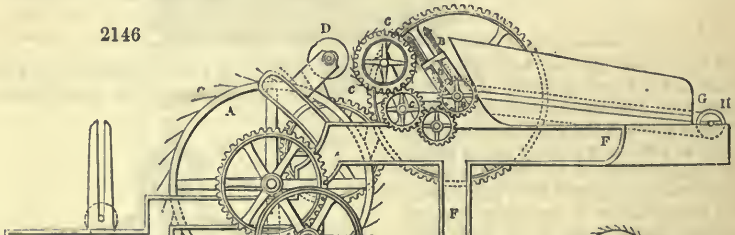
After operating upon the cloth in the way described, by passing it through hot water for the space of time required, the hot water is to be withdrawn by a cock at the bottom, or otherwise, and cold water introduced into the tank in its stead; in which cold water the cloth is to be continued turning, in the manner above described, for the space of 24 hours, which will perfectly fix the lustre that the face of the cloth has acquired by its immersion in the hot water, and leave the pile or nap, to the touch, in a soft silky state.

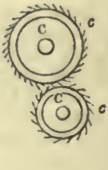
In the cold-water operation he sometimes employs a heavy pressing-roller *l*, which, being mounted in slots in the frame or standard, revolves with the large drum, rolling over the back of the cloth as it goes round. This roller may be made to act upon the cloth with any required pressure, by depressing the screws *m*, *m*, or by the employment of weighted levers, if that should be thought necessary.

Pressing is the last finish of cloth to give it a smooth level surface. The piece is folded backwards and forwards in yard-lengths, so as to form a thick package on the board of a screw or hydraulic press. Between every fold sheets of glazed paper are placed to prevent the contiguous surfaces of the cloth from coming into contact; and at the end of every 20 yards, three hot iron plates are inserted between the folds, the plates being laid side by side, so as to occupy the whole surface of the folds. Thin sheets of iron not heated are also inserted above and below the hot plates to moderate the heat. When the packs of cloth are properly folded, and piled in sufficient number in the press, they are subjected to a severe compression, and left under its influence till the plates get cold. The cloth is now taken out and folded again, so that the creases of the former folds may come opposite to the flat faces of the paper, and be removed by a second pressure. In finishing superfine cloths, however, a very slight pressure is given with iron plates but moderately warmed. The satiny lustre and smoothness given by strong compression with much heat is objectionable, as it renders the surface apt to become spotted and disfigured by rain.

Ross's Patent Improvements in Wool-combing Machinery, March 13, 1851.—The first improvements described have relation to the machine for forming the wool into sheets of a nearly uniform thickness, technically known as the 'sheeter,' and consists chiefly in combing with the ordinary sheeting-drum or cylinder-rollers, designated, from their resemblance to porcupine quills, 'porcupine rollers;' these rollers having their teeth or quills set in rows, and the rows of one roller gearing or taking into the spaces between the rows of the other.

2146

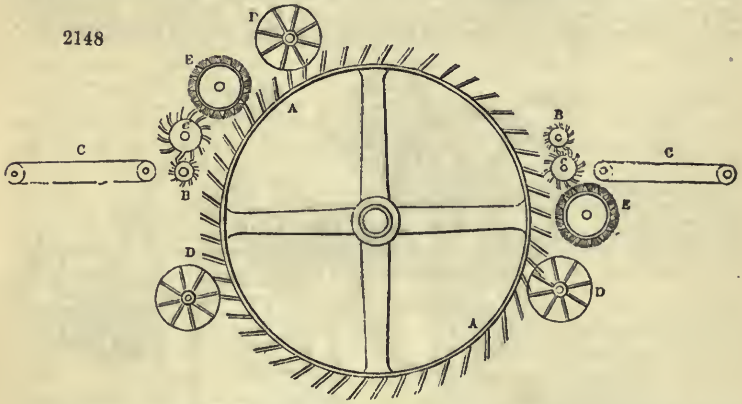




2147

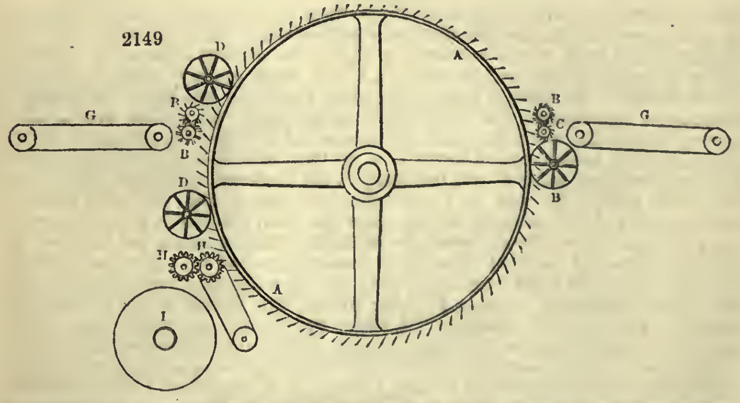
Fig. 2146 is an elevation of a sheeting-machine thus constructed:—F F is the general frame-work upon which the several working parts of the machine are mounted. A is the main or sheeting-drum or cylinder, which is studded with rows of comb or 'porcupine' teeth *a*, *a*, *a*, the length and fineness of which are varied according to the length of the staple of the wool or other material to be operated upon. Instead of the rows consisting each of a single set of teeth, two, three, or more sets may be combined together. The number of wires which may be placed on one line should vary with the quality of the wool or other material. In long-staple machines, the number may vary from four to ten or more, and in short-staple machines from five to twenty and more per inch. B, B, are two fluted feed-rollers; C, C, two porcupine combing-rollers, by which the wool is partly combed while passing from the feed-rollers to the surface of the sheeting-drum; an end elevation of the porcupine combing-rollers on an enlarged scale is given at *fig.* 2147. The teeth *c*, *c*, are set in rows, and the rows of one roller take or gear into the spaces between the rows of the other. D is a grooved guide-roller for preventing the wool or other material escaping the combining action. The wool or other material is laid by the attendant evenly upon the upper surface of an endless web G, which works over the under feed-rollers, and a plain roller H, which is mounted in bearings on the front of the machine. The feed-rollers gradually supply the wool thus spread upon the endless web to the two porcupine combing-rollers, where it is partly combed and separated, and being so prepared, it is laid hold of by the teeth of the sheeting-drum, by which it is still further drawn out on account of the greater velocity with which the surface of the sheeting-drum travels. When a sufficient quantity of the wool or other material has been thus collected on the surface of the drum, it is removed by the attendant passing a hooked rod across the surface of the drum, and raising up one end of the sheet, when the whole may be easily stripped off and removed, being then in a fit state for being supplied to the comb-filling machine, next to be described.

2148



A modification of this sheeting-machine is represented in *figs.* 2148, 2149, which differs from it in this, that it is fed from both ends. In this modification a double set of feeding rollers is employed, so that the machine may be fed from both ends.

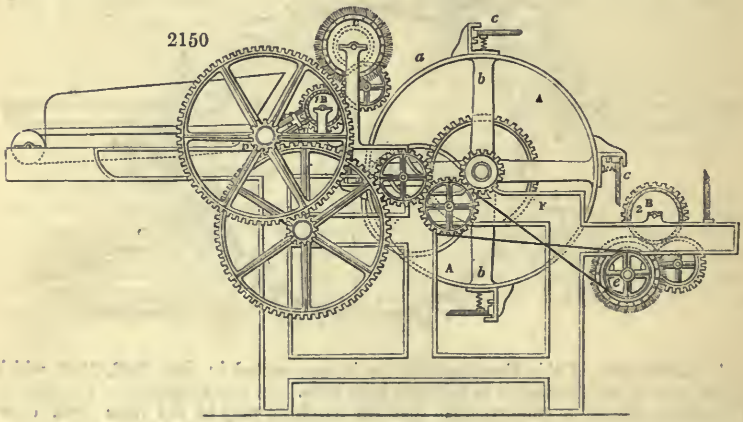
2149



These rollers are grooved and gear into porcupine combing rollers, similar to those before described, which are followed by brush-cylinders or grooved guide rollers. A is the sheeting drum as before; B, B, the fluted feed-rollers; C, C, the porcupine combing-rollers, which gear into the fluted ones; D, D, are the grooved guide-rollers; F, F, are brush-cylinders, which may in the case of long work be dispensed with; G, G, are the endless webs upon which the wool is laid. The framing and gearing by which the several parts are put in motion are omitted in the drawings, for the purpose of clearly exhibiting the more important working parts of the machine. The arrangement of sheeting machines just described, so far as regards the employment of a fluted feed-roller in conjunction with a porcupine combing-roller, and grooved guide-roller, is more especially applicable to sheeting fine short wool, but may also be applied with advantage to wool or other material of a longer staple. In the case of fine short wool, the sheet may be drawn off by means of rollers, in the manner represented in *fig.* 2149. H, H, are the drawing or straightening rollers, and I the receiving roller. During the operation of drawing the wool and winding it on the receiving roller, the sheeting cylinder must have a motion imparted to it in the reverse direction.

The next head of Mr. Ross's specification embraces several improvements in comb-filling machines, which have for their common object the partial combing of the wool while it is in the course of being filled into the combs. We select for exemplification what the patentee regards as the best of these arrangements: *fig.* 2150 is a side elevation of a comb filling machine as thus improved. A, A, is a skeleton drum, which is composed of two rings *a a*, affixed to the arms *b*, *b*, which last are mounted upon the main shaft of the machine, which has its bearings upon the general frame F, F; B^1, B^2 are the porcupine combing rollers, and C^1, C^2 brushes by which the porcupine combing rollers are cleansed from the wool that collects upon them, and by

2150



which the wool is again delivered to the combs *e*, *e*; D, D, are the feed-rollers, and F an endless web which runs over the lower feed-roller and the plain roller G, which is situated at the front of the machine; H, H, are the driving pulleys, by which the power is applied to the machine, and I, I, I, the wheel gearing by which motion is communicated to the different parts. The wool which has undergone the process of sheeting in the machine first described is spread upon the endless web E, and in passing between the feed-rollers, and between or under or over the porcupine combing rollers, is taken hold of by the combs *e*, *e*, as they revolve, and, being drawn under the first porcupine roller B^1 and the brush C^1, the continued revolution of the drum and combs causes the wool to be brought into contact with the other porcupine combing roller B^2 and brush C^2. As the combs get filled, the wool is thus continuously being brought under the action of the porcupine combing rollers and brushes; and each new portion of the wool taken up is instantly combed out. For some purposes the combing will be found carried so far by this operation that the wool will require no further preparation previous to being formed into slivers in the machine just described, and which is calculated for filling the combs and combing the wool or other fibrous material, when the staple is some considerable length (say from 4 to 16 inches), there are two porcupine comb rollers with their brushes employed; but the patentee did not confine himself to that number, as in some cases a single porcupine combing roller and brush will be found sufficient for the purpose of facilitating the process of combing and filling the combs; three or more rollers and brush cylinders may be used with advantage; such as where the staple is short, or where the fibrous material operated upon is very close, and separated with difficulty.

Mr. Ross next describes some improvements in the combing machine of his invention patented in 1841, and now extensively used. The following general description will indicate with sufficient distinctness to those familiar with the machine, the nature of the improvements:—

'First, I give to the saddle combs in the said machine a compound to-and-fro and up-and-down movement, whereby they recede from and advance towards the comb gates, and simultaneously therewith alternately rise and fall, so that each time the comb gates pass the saddle combs, they do so in a different plane, and thus the position of the combs in relation to each other, as well as to the hold they take of the wool or other material, is constantly being changed. Secondly, I employ a fan to lash the wool in the comb gate or flying comb up against the saddle comb, which renders it impossible for the wool to pass by the saddle comb without being acted upon by it. Thirdly, I attach the springs by which the gates are actuated to the lower arms of the combing gates, instead of their being placed parallel to the upright shaft of the machine as formerly, whereby a considerable gain in space and compactness is effected; and fourthly, I use breaks to prevent the sudden jerk which is caused when the wool in the comb gate leaves its hold of the saddle comb or incline plane, and also to counteract the sudden recoil of the springs by which the comb gates are pressed in when these springs are released from the grip or pressure of the incline plane.'

Mr. Ross concludes with a description of an improved method of heating the combs which has for its object 'the economising of fuel, the better heating of the combs, and the prevention of mistakes in removing the combs before they have been a sufficient time exposed to the heat.'

The body of the heating box or stove is divided by a partition into two portions, which communicate together at the back or further end of the stove, so that the flame and heated vapours, after having circulated under and along the sides of the two lower comb chambers, ascend into the upper portion of the stove, where they have to traverse along the sides and over the top of the two upper chambers, ultimately escaping into the chimney through a pipe. The length of the heating box, or the chambers, should be about double the length of the combs. The cold combs are inserted at one end, and on being put into their places push the more heated combs towards the other end of the chambers, from which they are removed. See ALPACA; MOHAIR.

Few of our manufactures have been more stationary than that of woollen goods. Our ancestors appear to have given much attention to the weaving of woollen cloth, and to have produced a fabric of much excellence. All that the moderns have done is to quicken the process of production by the application of steam-power to the machinery employed, and they have introduced, in consequence of this application, a few new and ingenious machines. The sophistication of many woollen fabrics, especially carpets, with the fibre of jute, is destructive of one branch of our woollen manufacture.

WOOTZ, is the Indian name for Steel. The Indian wootz is prepared in very rude furnaces, in a most primitive manner, from hæmatite and magnetic iron ore; charcoal being the fuel employed. See STEEL.

WORMWOOD (*Artemesia Absinthia*). An intensely bitter herb, used medicinally; and it is said to be sometimes employed as a substitute for hops, in brewing inferior kinds of beer.

WORSTED. Yarns made of long wool drawn out into long filaments by passing it, when oiled, through heated combs, as described under WOOLLEN MANUFACTURE. Numerous machines have been introduced for combing wool, and may now be said to have entirely superseded the old fashion of hand-combing.

X

XANTHINE, the name given by Kuhlmann to the yellow dyeing-matter of madder. See MADDER. The name has also been applied to an animal product.

XANTHORRHŒA. Several species of this genus of *Liliaceæ* are known in Australia as 'grass trees.' They yield 'Botany-Bay resin' and 'Black-boy gum.'

XYLOÏDINE—*Nitramidine.* By acting on starch with fuming nitric acid, a transparent jelly is formed, and on adding water, xyloïdine is precipitated as a white granular substance.

This name has been given to some preparations of collodion which have been prepared by acting on some variety of woody fibre with nitric acid, until it became susceptible of solution in sulphuric ether. Many photographers are of opinion that collodion thus prepared is in many respects superior to that obtained by dissolving gun-cotton in ether. Our own experience does not enable us to pronounce on this, but we have heard some very intelligent operators express a very opposite opinion. Chemically the collodions will be the same, but it is possible that there may be a physical difference, and few, except those who have had much experience in the changes produced by light on chemical compounds, can form any correct idea of the differences in actinic power of producing change in bodies physically different, though chemically the same. Xyloïdine, or rather sawdust treated with a mixture of nitric acid and sulphuric acid, until rendered explosive, has been proposed for use in blasting rocks. Another modified form of the same kind of blasting powder has been made by saturating deal sawdust with nitrate of potash, and then mixing the preparation with some sulphur and yellow prussiate of potash. Neither of these explosive powders has, however, come into use. They are dangerous, as being liable to spontaneous combustion. See COLLODION; GUN-COTTON.

XYLOL. A hydrocarbon found in coal-naphtha and in the oils which separate when crude wood-spirit is mixed with water.

Y

YARN. (*Fil*, Fr.; *Garn*, Ger.) Wool, cotton, or flax, spun into thread.

YEAST. See Beer, and Fermentation.

YEAST, ARTIFICIAL. Mix 2 parts by weight of fine flour of pale barley-malt, with 1 part of wheat-flour; stir 50 lbs. of this mixture gradually into 100 quarts of cold water, with a wooden spatula, till it forms a smooth pap. Put this pap into a copper over a slow fire: stir it well till the temperature rise to fully 155° to 160° Fahr., when a partial formation of sugar will take place, but this sweetening must not be pushed too far; turn out the thinned paste into a flat cooler, and stir it from time to time. As soon as the wort has fallen to 59° Fahr., transfer it to a tub, and add for every 50 quarts of it 1 quart of good fresh beer yeast, which will throw the wort into brisk fermentation in the course of 12 hours. This preparation will be good yeast, fit for bakers' and brewers' uses, and will continue fresh and active for three days. It should be occasionally stirred.

The German yeast imported into this country in large quantities, and employed by our bakers in baking cakes, and other *fancy* bread, is made by putting the *Unterhefe* (see Beer, *Bavarian*) into thick sacks of linen or hempen yarn, letting the liquid part, or beer, drain away; placing the drained sacks between boards, and exposing them to a gradually increasing pressure, till a mass of a thin cheesy consistency is obtained. This cake is broken into small pieces, which are wrapped in separate linen cloths; these parcels being afterwards enclosed in waxed cloth, for exportation. The yeast-cake may also be rammed hard into a pitched cask, which is to be closed air-tight. In this state, if kept cool, it may be preserved active for a considerable time. When this is to be used for beer, the proportion required should be mixed with a quantity of worts at 60° Fahr., and the mixture left for a little to work, and send up a lively froth; when it is quite ready for adding to the cooled worts in the fermenting back.

YEAST, PATENT. Boil 6 ounces of hops in 3 gallons of water 3 hours; strain it off, and let it stand 10 minutes; then add half a peck of ground malt, stir it well up and cover it over; return the hops, and put the same quantity of water to them again, boiling them the same time as before, straining it off to the first mash; stir it up, and let it remain 4 hours, then strain it off, and set it to work at 90°, with 3 pints of patent yeast; let it stand about 20 hours; take the scum off the top, and strain it through a hair-sieve; it will be then fit for use. One pint is sufficient to make a bushel of bread.

Dried Yeast Imported in 1873.

Dried yeast *Imported* in 1874: 153,808 cwts.; value 396,067*l.*

YELLOW COPPER ORE. See Copper Pyrites.

YELLOW DYES. (*Teintures jaunes*, Fr.; *Gelbfärben*, Ger.) *Annotto, dyer's-broom* (*Genista tinctoria*), *fustic, fustet, Persian* or *French berries, quercitron bark, saw-wort*, (*Serratula tinctoria*), *turmeric, weld*, and *willow-leaves*, are the principal yellow dyes of the vegetable kingdom; *chromate of lead, iron oxide, nitric acid* (for silk), *sulphide of antimony*, and *sulphide of arsenic*, are those of the mineral kingdom. Under these articles, as also under Calico-Printing, Dyeing, and Mordants, ample instructions will be found for communicating this colour to textile and other fibrous substances. Alumina and oxide of tin are the most approved bases of the above vegetable dyes. A nankin dye may be given with *bablah*, especially to cotton oiled preparatory to the Turkey-red process. See Madder.

YELLOW, KING'S, is a poisonous yellow pigment. See Arsenic and Orpiment.

YELLOW METAL. See Muntz's Metal.

YEW. *Taxus baccata*, the common yew, yields a durable timber, and was the favourite wood for the old long-bows.

YTTRIA is a rare earth, extracted from the minerals gadolinite and yttrotantalite. It is an oxide of the metal *yttrium*.

Z

ZAFFRE. See COBALT.

ZEA. Indian corn or maize is obtained from an American grass, the *Zea mays*. It is now largely cultivated in the East Indies and in Northern Africa, and is grown to some extent in the south of Europe. 'Popped corn' is prepared by heating the grains on a hot metal plate, when they open and expose their starchy contents; sweetened and coloured, they form a sweetmeat known as 'cornball.'

ZEDOARY. (*Zédoaire*, Fr.; *Zittwer*, Ger.) The root of a cucurbitaceous plant imported from Ceylon, Malabar, and Cochin-China, employed sometimes medicinally. It occurs in wrinkled pieces, externally ash-coloured, internally brownish-red; possessed of a fragrant odour, and of a pungent, aromatic, bitterish taste.

ZEOLITES. A group of minerals consisting of hydrous silicates of alumina and other bases. They gelatinise with acids, and intumesce when heated, whence their name (ζέω, *zeo*, to boil). They are found in the cavities of amygdaloïdal rocks, and a few also occur in mineral veins. None of them is of any use in the arts.

ZINC (*Atomic weight*, 32·5; *symbol*, Zn) is a metal of a bluish-white colour, of considerable lustre when broken, but easily tarnished by the air; its fracture is hackly, and foliated with small facets, irregularly set. It has little cohesion, and breaks in thin plates before the hammer, unless it has been previously subjected to a process of lamination, at the temperature of from 220° to 300° Fahr., by which it becomes malleable and ductile. On this singular property a patent was taken out by Messrs. Hobson and Sylvester, of Sheffield, many years ago, for manufacturing sheet zinc for covering the roofs of houses, and sheathing ships; but the low price of copper at that time, and its superior tenacity, rendered their patent ineffective. The specific gravity of zinc varies from 6·9 to 7·2, according to the degree of condensation to which it has been subjected. It melts under a red heat, at 773° Fahr. When strongly heated with contact of air, the metal takes fire, and burns with a brilliant bluish-white light, while a few flocculi of a woolly-looking white matter (*nil album*) rise out of the crucible and float in the air. The result of this combustion is a white powder, formerly called 'flowers,' but now oxide of zinc.

The principal ores of zinc are, the sulphide called *blende*, the carbonate called *calamine*, and the silicates of zinc.

1. *Blende* crystallises in rhombic dodecahedrons; its fracture is highly conchoïdal; lustre, adamantine; colours, black, brown, red, yellow, and green; transparent or translucent; spec. grav. 4. It is a simple sulphide of the metal (ZnS); and, therefore, consists in its pure state, of 32·5 of zinc and 16 of sulphur. It dissolves in nitric acid, with disengagement of sulphuretted hydrogen gas. It occurs in beds and veins, accompanied chiefly by galena, iron pyrites, copper pyrites, and heavy spar. There is a radiated variety found at Przibram, remarkable for containing a large proportion of cadmium. Blende is found in great quantities in Derbyshire and Cumberland, as also in Cornwall and many other localities. It is frequently termed 'black jack.'

2. *Calamine* is a mineral occurring usually in concretionary forms and compact masses, yellowish-white when pure, but frequently brown through the presence of iron. It crystallises in rhombohedra, and has a spec. grav. of about 4·4. It is a normal carbonate of zinc ($ZnO.CO^2 = \mathbf{ZnCO^3}$) containing, when pure, about 52 per cent. of zinc. It is an abundant ore in Derbyshire, Cumberland, Belgium, Sardinia, Silesia, &c. The carbonate is termed by some writers Smithsonite, a name applied by others to the hydrous silicate. See CALAMINE.

3. *Smithsonite* or *Electric calamine* is an ore occurring in compact masses, and in mammillated, botryoïdal, and fibrous forms. It is found in Carinthia, Hungary, Belgium, New Jersey, &c. It is a hydrous silicate, containing $2ZnO.SiO^2 + HO$ ($\mathbf{Zn^2SiO^4 + H^2O}$). Many writers term this ore calamine.

4. *Willemite*. An anhydrous silicate of zinc, containing $2ZnO.SiO^2$ ($\mathbf{Zn^2SiO^4}$). It is found at Vieille Montagne, near Aix-la-Chapelle, and at Franklin and Stirling, in New Jersey.

5. *Zincite*, *Spartalite*, or *Red zinc ore* occurs at Mine Hill and Sterling Hill in New Jersey, where it is associated with franklinite. It is an oxide of zinc (ZnO) containing a little oxide of manganese. An artificial oxide of zinc is sometimes found crystallised among blast-furnace products.

The zinc ores of England, like those of France, Belgium, and Silesia, occur in two geological positions. The first is in the carboniferous or mountain limestone. The blende and the calamine most usually accompany the veins of galena which traverse that limestone; though there are many lead mines that yield no calamine; and, on the other hand, there are veins of calamine alone, as at Matlock.

In almost every part of England where metalliferous limestone appears, there are explorations for lead and zinc ores. The neighbourhood of Alston-moor, in Cumberland, of Castleton and Matlock, in Derbyshire, and the small metalliferous belt of Flintshire, are peculiarly marked for their mineral riches. On the north side of the last county, calamine is worked in a rich mine of galena at Holywell, where it presents the singular appearance of occurring only in the ramifications that the lead-vein makes from east to west, and never in those from north to south; while the blende, abundantly present in this mine, is found indifferently in all directions.

The second locality of calamine is in the magnesian limestone formation. The calamine is disseminated through it in small contemporaneous veins, which, running in all directions, form the appearance of a network. These veins have commonly a thickness of only a few inches; but in certain cases they extend to 4 feet, in consequence of the union of several small ones into a single mass. There were formerly explorations for calamine in the magnesian limestone, situated chiefly on the flanks of the Mendip Hills, a chain which extends in the north-west and south-east direction, from the Canal of Bristol to Frome. Calamine was chiefly worked in the parishes of Phipham and Roborough, as also near Rickford and Broadfield-Doron, by means of a great number of small shafts. The miners paid for the privilege of working a tax of 1*l.* sterling per annum, to the Lords of the Treasury; and they sold the ores, mixed with a considerable quantity of carbonate of lime, at Phipham, after washing it slightly in a sieve. Very little is at present worked in this district. Calamine is now largely imported into this country from Spain and the United States of America.

Metallurgy of Zinc.

Roasting of Ores.—Blende, or sulphide of zinc is, previous to its treatment for metal, carefully roasted in a reverberatory furnace, over the bottom of which it is spread in a layer of about 4 inches in thickness. A strong heat is necessary for this purpose, and during the operation the charge is frequently stirred with a strong iron rake, with a view of exposing fresh surfaces to the gases of the furnace. The apparatus most commonly employed in this country for roasting sulphide of zinc consists of a reverberatory furnace about 36 feet in length and 9 feet in width, provided with a fireplace of the usual construction. The sole or hearth of this apparatus is divided into three distinct beds, of which that nearest the fire-bridge is 4 inches lower than that which is next it, which is again 4 inches lower than that nearest the chimney. In addition to the heat derived from the fireplace, the gases escaping from the reducing furnaces are usually introduced immediately before the bridge, and a considerable economy of fuel is thereby effected.

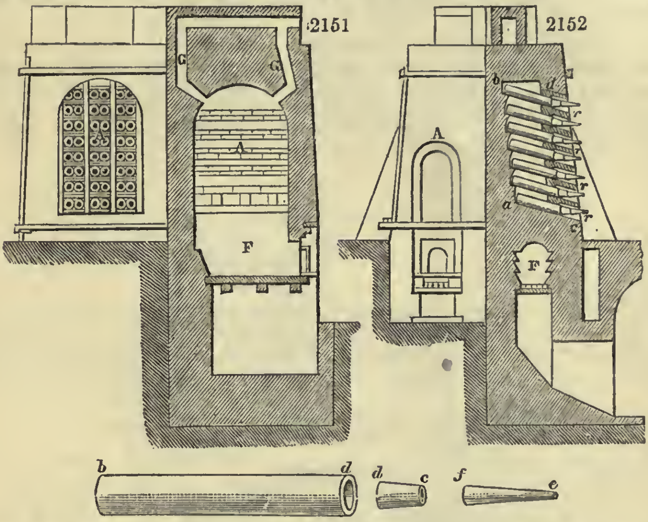
When the furnace has been sufficiently heated, a charge of 12 cwts. of raw blende is introduced into the division nearest the chimney, and equally spread over the bottom, care being taken to stir it from time to time by means of an iron rake, as before described. After the expiration of about eight hours this charge is worked on to the floor of the compartment forming the middle of the furnace, and a new charge is introduced into the division next the chimney. About eight hours after this charging the ore on the middle bed is worked on to the first, whilst that on the hearth next the chimney is equally spread on the middle one and a new charge introduced into the division next the stack. After the expiration of another period of eight hours the charge on the first hearth is drawn, the ore on the middle and third hearths moved forward, and a fourth charge introduced as before. In this way the operation is continuous, and each furnace will effect the calcination of about 36 cwts. of ordinary blende in the course of 24 hours.

Calamine is usually prepared for smelting by calcination in a furnace resembling an ordinary lime-kiln, the heat being often supplied by means of four fireplaces arranged externally, and so placed that the heated gases may be drawn into it, and regularly distributed through the interstices existing between the masses of ore. Calamine subjected to this treatment commonly loses about one-third of its weight, and is at the same time rendered so friable as easily to admit of being reduced to fine powder by an ordinary edge-mill.

Belgian Process.—When this method of treating zinc ore is employed, the furnace represented in *fig.* 2151 is commonly used.

Fig. 2151 represents, on the left hand, a front elevation of the furnace, and on the right a sectional elevation through the ash-pit and fireplace. F is the fireplace, whilst A is the cavity into which are introduced the retorts destined for the distillation of the metal. The products of combustion escape by the openings G into a flue, by which they are conducted into the calciner for the purpose of economising the waste heat. These furnaces are either arranged in couples, back to back, or in groups of four, for the purpose of rendering the structure more solid, and economising heat.

In the arched chamber A are placed 48 cylindrical retorts, 3 feet 6 inches in length from *b* to *d*, and 7 inches internal diameter. These are made of refractory fire clay, well baked and supported behind by ledges of masonry *a*, *b*, *fig.* 2152, whilst in front, at *c d*, they rest on fire-clay saddles let into an iron framing. Short conical fire-clay pipes, 10 inches in length from *d* to *c*, are fixed in the mouths of these retorts by means of moistened clay, and project for a short distance beyond the mouth of the furnace. To these are adapted thin wrought-iron cones 18 inches in length from *e* to *f*, tapering off to the smaller extremity to an orifice of about three quarters of an inch in diameter. The inclined position of the retorts, the method of adjusting the pipes, and the general arrangement of the apparatus are shown in *fig.* 2152, in which *r*, *r*, *r*, *r*, represent the nozzles of thin wrought iron. When a new



furnace is first lighted the retorts are introduced without being previously baked, but care must be taken that they be perfectly dry and seasoned, and for this reason it is necessary to keep a large stock constantly on hand, in a storehouse artificially heated by means of some of the flues of the establishment. The heat is gradually increased during three or four days, at the end of which period charges of ore are introduced, the clay cones are luted in their places, and the furnace is brought into full working order. The charge of a furnace consists of 1,680 lbs. of roasted blende, or calcined calamine, and 840 lbs. of coal-dust. The ore and coal-dust, after being finely divided and intimately mixed, is slightly damped and subsequently introduced into the retorts by means of a semi-cylindrical scoop, by the aid of which an experienced workman will effect the charging without spilling the smallest quantity of the mixture.

In this country the retorts in the lower tier are usually not charged, as they are extremely liable to be broken, and are therefore only employed to moderate the heat of the furnace. On the Continent, however, the fireplace is frequently covered by a hollow arch, and in that case every retort requires a charge of ore.

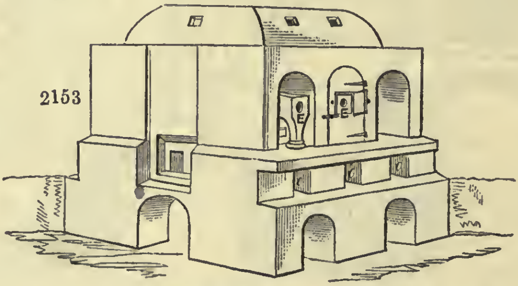
The mixture introduced into the retorts varies, to a certain extent, with their position in the furnace, for in spite of every precaution to prevent inequality of temperature, it is found impossible to heat the whole of them alike, and those next the fire, therefore, from being the most strongly heated, are liable to work off first. As soon as the retorts have been charged the clay cones are luted into their places, and carbonic oxide gas, which burns with a blue flame at the mouth of the cones, quickly makes its appearance. The quantity of this gas gradually diminishes, and as soon as the flame assumes a greenish-white hue, and white fumes are observed to be evolved, the sheet-iron cones are put on, and the furnace at once enters into steady action. From time to time, as the iron cones become choked with oxide, they are taken off and gently tapped against some hard substance, so as to remove it, and then replaced. The oxide thus collected is added to the mixture prepared for the next charge. After the expiration of about six hours from the time of charging the wrought-iron tubes are successively removed, and the metallic zinc scraped from the clay-pipes into an iron ladle. This, when full, is skimmed, and the oxide added to that obtained from the nozzles, whilst the pure metal is cast into ingots, weighing about 28 lbs. each. At the expiration of twelve hours from the time of charging, the zinc is again tapped, and the residue remaining in the retorts withdrawn. The retorts are immediately recharged, and the operation of reduction is conducted as above described.

The residues obtained from the retorts, after the first working, are passed through a crushing-mill, mixed with a further quantity of small coal, and again treated for the metal they contain. The earthen adapters or cones, when unfit for further service, are crushed and treated as zinc ores.

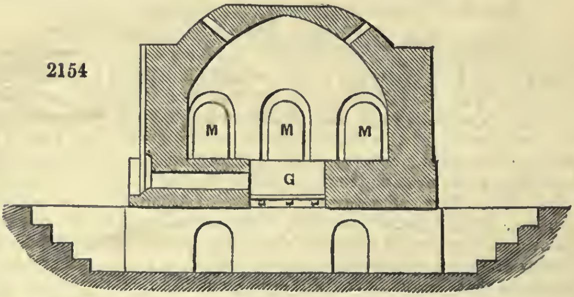
In order to work these furnaces with economy, it is of the greatest importance that they should be constantly supplied with a full number of retorts, since the amount of fuel consumed, and the general expenses incurred for each furnace, will be the same if the apparatus has its full complements of retorts, or if one half of them are broken and consequently disabled.

It is therefore necessary, in all zinc-smelting establishments, to keep a large stock of well-seasoned retorts, which, before being introduced into the furnace, to make good any deficiency caused by breakage, are heated to full redness in a kiln provided for that purpose. The Belgian process of zinc smelting is that which is at present most employed in this country. The principal localities in which zinc ores are treated are Swansea, Wigan, Llanelly, and Wrexham.

2153



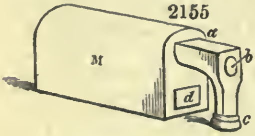
2154



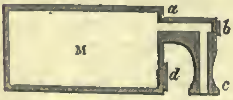
Silesian Process.—In the zinc works of Silesia the furnaces employed differ considerably from those used in the Belgian process.

Fig. 2153, represents an elevation, and *fig.* 2154, a vertical section of the Silesian furnace. The distillation is effected in a sort of muffle of baked clay, M, *figs.* 2155 and 2156; these are each about 3 feet 3 inches in length, and 20 inches in height. The front of this muffle is pierced with two apertures. The lower opening, *d*, serves to remove the residues remaining in the retorts after each operation, and is closed during the process of distillation by a small door of baked clay, firmly luted in its place. In the upper opening is introduced a hollow clay arm, bent at right angles, *a*, *b*, *c*, and which remains open at *c*. An opening at *b*, permits of charging the retort by means of a proper scoop, and this, during the operation, is closed by a luted clay-plug. From six to ten of these muffles or retorts are arranged in rows, on either side of a furnace provided with suitable apertures for their introduction. They are securely luted in their places, and the openings closed by sheet-

2155



2156

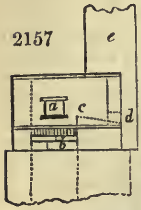


iron doors, by which the too rapid cooling of the pipe *a, b, c*, is prevented. The fuel employed is coal, which is burnt on the grate G, situated in the centre of the furnace. The retorts are charged with a mixture of calamine and small coal, or more frequently coke-dust, since, when coal is employed, the products of distillation are found to be liable to choke the pipe *a, b, c*.

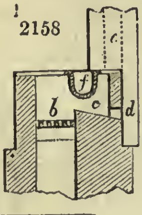
The zinc escapes by the opening *c*, of the adapter, and is received into the cavities *o*, of the furnace.

The furnace shown in *figs.* 2157, 2158, 2159, is for remelting the metallic zinc. *Fig.* 2157, is a front view; *fig.* 2158, is a transverse section; *fig.* 2159, a view from above: *a*, is the fire-door; *b*, the grate; *c*, the fire-bridge; *d*, the flue; *e*, the chimney; *f, f, f*, cast-iron melting-pots, which contain each about 10 cwts. of metal. The heat is moderated by the successive addition of pieces of cold zinc. The inside of the pots is sometimes coated with loam, to prevent the iron being attacked by the zinc.

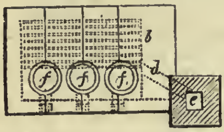
2157



2158

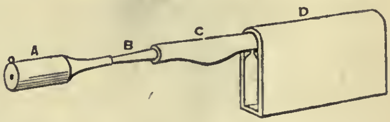


2159



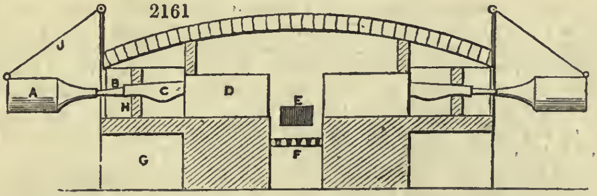
In some establishments, and particularly those

2160



at Stolberg in Prussia, the retorts have the form represented by D, *fig.* 2160, C is an adapter also of fire-clay; B a cone of wrought iron, and A a small vessel of the same material for the collection of the oxide, and furnished in the bottom with an aperture for the escape of the gases generated.

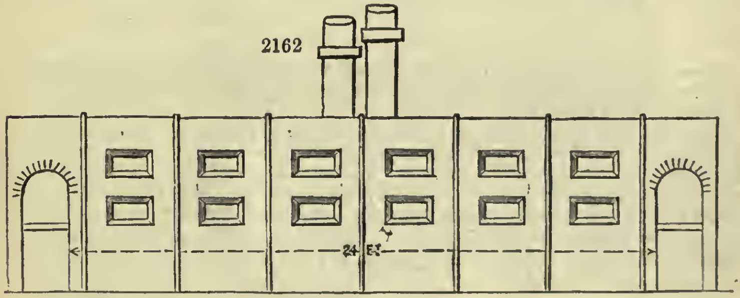
2161



These are arranged on either side of a grate as represented, *fig.* 2161; an internal opening serving for two retorts, and of which there are usually twelve in each furnace. E is the fire-door; F grate; G chamber in masonry of furnace; H diaphragm of fire-brick supporting adapter, in the depressed part of which the metallic zinc is collected and subsequently removed by a scraper, as in the case of the cone of the Belgian retort. The wrought-iron vessel A, is supported by a chain or wire J.

Fig. 2162 represents a longitudinal elevation of the roasting furnace employed.

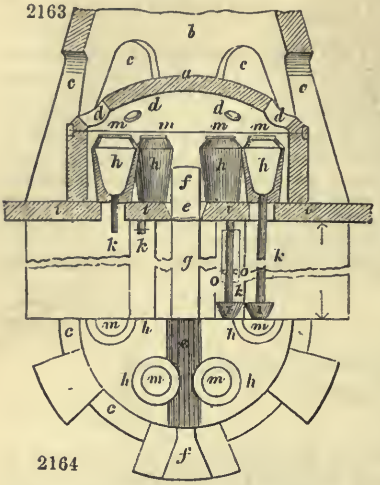
2162



Old English Process.—The English furnaces formerly used for smelting zinc ores were sometimes quadrangular, sometimes round; the latter form being preferable.

They were mounted with from 6 to 8 crucibles or pots (*figs.* 2163, 2164), arched over with a cupola *a*, placed under a conical chimney *b*, which served to give a strong draught, and to carry off the smoke. In this cone there were as many doors, *c*, *c*, *c*, as there were pots in the furnace; and an equal number of vents *d*, *d*, *d*, in the cupola, through which the smoke might escape, and the pots be set. In the surrounding wall there were holes for taking out the pots when they became unserviceable; after the pots were set, these holes were bricked up. The pots were heated to ignition in a reverberatory furnace before being set, and were put in by means of iron tongs supported upon two wheels, as is the case with glass-house pots. In *figs.* 2163, 2164, *e*, is the grate; *f*, the door for fuel; *g*, the ash-pit. The pots, *h*, *h*, *h*, have a hole in the centre of their bottom, which is closed with a wooden plug, when they are set charged with calamine, mixed with coal; which coal prevents the mixture from falling through the orifice, when the heat rises and consumes the plug. The sole of the hearth *i*, *i*, upon which the crucibles stand, is perforated under each of them, so that they can be reached from below; to the bottom orifice of the pots, when the distillation begins, a long sheet-iron pipe, *k*, is joined, which dips at its end into a vessel, *l*, for receiving in drops the condensed vapours of the zinc. The pot is charged from above, through an orifice in the lid, which is left open after the firing until the bluish colour of the flames indicates the volatilisation of the metal, immediately whereupon the whole is covered with a fire-tile, *m*. The iron tubes are liable to become obstructed during the distillation, and must therefore be occasionally cleared by means of an iron bar. When the operation is terminated the pipes must be removed, and the carbonaceous and other residual matters extracted from the pots. In this figure, 1, 2, is the level of the upper floor; 3, 4, level of the lower ceiling of the lower floor. *Fig.* 2164 is a ground plan on the level of 1, 2; only one half being here shown.—J. A. P.

2163



2164

The general consumption of Spelter throughout the world is about 67,000 tons per annum; of which about 44,000 tons are made to take the shape of rolled sheets, and these are estimated to be applied as follows, each quantity being somewhat below the truth:—

	Tons.
Roofing and architectural purposes	23,000
Ship-sheathing	3,500
Lining packing-cases	2,500
Domestic utensils	12,000
Ornaments	1,500
Miscellaneous	1,500
	44,000

Five-and-twenty years ago the quantity used for roofing did not exceed 5,000 tons; none was employed for ship-sheathing or lining packing-cases; and stamped ornaments in zinc date only from 1852.

From the low temperature at which zinc fuses, and from the sharpness of impressions possessed by castings in this metal, it is much employed on the Continent for the production of statues and statuettes. The uses of this metal in the preparation of alloys has already been noticed under the head of ALLOYS. It is also employed like tin for coating iron, producing what is known as 'galvanised iron.' (See GALVANISED IRON.) The *disinfectant liquor* of Sir W. Burnett is chloride of zinc, and the oxide of this metal is much employed as a pigment in place of white lead. (See BURNETT'S FLUID, and ZINC WHITE.)

Imports of Zinc in the Year 1873 *and three previous Years* (*as per Board of Trade Returns*).

Years	Crude Zinc		Zinc manufactures	
	Quantities	Value	Quantities	Value
	Tons	£	Tons	£
1870	19,921	366,461	9,360	220,394
1871	20,968	431,309	8,792	207,855
1872	14,874	302,329	12,417	340,827
1873	20,038	478,628	12,470	367,935

Zinc Imported in 1874.

	Quantities	Value
Crude, in cakes . .	22,216 tons	£492,874
Manufactures . . .	252,607 cwts.	372,176

British Zinc or Spelter Exported in the Year 1873 *and four previous Years* (*as per Board of Trade Returns*).

Years	Quantities	Value
	Tons	£
1869	10,145	207,840
1870	7,345	141,281
1871	6,452	115,281
1872	5,047	101,812
1873	3,439	85,739

ZINCING OF IRON. Iron may be conveniently coated, in the humid way, by a solution of sulphate of zinc, or one of the double salts of chloride of zinc and sal-ammoniac, as now used in soldering and welding. To secure success, the zinc solution should be weak, and only a weak galvanic current should be used, otherwise the zinc precipitated will again separate from the iron in scales. With proper precautions, the deposit may be made as thick as strong paper. The article must be well cleansed before undergoing the operation. See Galvanised Iron.

ZINC PRINTING. If this art be not calculated to supersede wood engraving, it can be applied with great advantage for certain purposes in the etching style, for maps, plans, drawings of machines, &c. A zinc plate is covered with an etching ground, the drawing etched in the usual manner with the needle, and bitten in. The etching ground is now removed, the deep lines cleaned with acid, and then the whole plate, in a warm state, covered with an easily fusible metal, with which, of course, the lines of the drawing are filled up. When the metal thus laid on is cold and firm, the whole plate is planed until the zinc appears again, and only the lines of the drawing remain filled with the fusible metal, which is easily distinguished by its white colour from the gray of the zinc. The whole plate is now etched several times; the former lines of the drawing, filled with easily fusible negative metal, are not affected by the acid, while the pure zinc is eaten away. In this manner a drawing for printing in the copper-plate press can be converted into one in relief for use in ordinary printing press.

ZINC WHITE. Under this name oxide of zinc is now largely used as a substitute for white lead. For this purpose it is prepared by heating metallic zinc in earthenware retorts, and bringing the zinc-vapour into contact with a current of air, whereby it becomes oxidised. Instead of using metallic zinc, the reduction of the ore and oxidation of the metal may be performed at one operation. Thus, at the New Jersey Works and the Lehigh Zinc Works a mixture of ore and charcoal is treated in muffle-furnaces, and the oxide obtained is blown into chambers, in which it is collected in large muslin bags. In some Continental works the metallic zinc is exposed to the action of superheated steam, when oxide of zinc is formed, whilst hydrogen is liberated, the gas being applied in some cases to illuminating purposes.

ZIRCON. See Hyacinth and Gems.

ZIRCONIA is a rare earth, extracted from the mineral zircon, which is a silicate of zirconia. Zirconia itself is an oxide of zirconium. It has lately been proposed to employ zirconia, instead of lime or magnesia, in the preparation of cylinders for the oxyhydrogen light.

ZIRCONIUM may be prepared in an amorphous form by passing the vapour of chloride of zirconium over heated sodium, or by heating the double fluoride of zirconium and potassium with an alkaline metal, and treating the product with dilute nitric acid. Thus prepared, it appears as a dull brown powder, combustible in the air at a temperature below redness.

M. Troost wished to determine whether zirconium, already found in this amorphous state by Berzelius, was a metal similar to magnesium, or aluminium, or a metalloïd not unlike carbon, boron, or silicon. He obtained crystallised zirconium by heating the fluoride of zirconium and potassium with excess of aluminium, and removing the aluminium by solution from the insoluble residue. The zirconium thus obtained appears in hard brittle crystalline laminæ, of specific gravity 4·15.

Zirconium in its chemical properties approaches near to silicium, and perhaps even nearer to titanium. Crystalline zirconium withstands the action of oxygen at a red heat, becomes slightly oxidised at a white heat, and burns only when subjected to the oxyhydrogen-flame. It burns in chlorine, however, at a dull heat. Cold acids have no action upon it, and warm acids affect it but slightly. Its true solvent is hydrofluoric acid. Like silicium, zirconium presents three different physical conditions, viz. the amorphous, graphitoïd, and crystallised. Zirconium forms only one oxide, known as *zirconia.*

ZIZANIA. It has recently been suggested to employ Canada Grass (*Zizania aquatica*) as a paper-making material. This plant grows abundantly on the shores of Lakes Erie, Ontario, and St. Clare, and is known to the Indians as *Tuscarora.* The fibre is said to be easily bleached and comparatively free from silica, while it yields a paper of good colour and texture, well adapted to the printer's use. It is asserted that a supply of 100,000 tons per annum may be readily obtained from Canada.

ZIZYPHUS. Several species of this genus of the Buckthorn order (*Rhamnaceæ*) yield edible fruits. *Z. Jujuba*, and some others, furnish the fruit known as *jujube.*

ZORGITE. A selenide of lead and copper, from Zorge and Tilkerode in the Hartz.

ZOSTERA. The Grass-wrack (*Zostera marina*) is a marine plant common on the coast of Britain. It is collected and dried for use as a substitute for hay in packing.

THE END.
