Comparison of the international filter-tube method and the official hide-power method, H. W. WILEY and W. H. KRUG (*Leather Manufacturer, 12, pp. 9–10; abs. in Jour. Amer. Chem. Soc., 23 (1901), No. 6, Rev., p. 107*).—In a comparison of the 2 methods with various tanning extracts it was found that the filter method gave lower non-tannins and correspondingly higher tannins than the official method.

Comparative hide-powder tests, W. H. KRUG (*Leather Manufacturer, 12, pp. 10–11; abs. in Jour. Amer. Chem. Soc., 23 (1901), No. 6, Rev., p. 107*).—Tests were made with acid hide powder and the same neutralized with sodium carbonate. The results show close concordance, but the neutralized powder lost in absorptive power while the filtrate was turbid and contained tannin.

The volumetric determination of zinc, P. H. WALKER (*Jour. Amer. Chem. Soc., 23 (1901), No. 7, pp. 468–470*).—From the application of Stolba's method, modified by Handy, the author obtained fairly good results with zinc in the presence of iron, calcium, and magnesium. Manganese must be previously separated.

Classification of acid and alkali indicators, J. WAGNER (*Ztschr. Anorgan. Chem., 27 (1901), pp. 138–151; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 464, II, pp. 419, 420*).

Miscellaneous analyses, C. H. JONES and B. O. WHITE (*Vermont Sta. Rpt. 1900, pp. 386–390*).—Analyses are reported of 3 samples of nitrate of soda, 1 of dried blood, 1 of cotton-seed meal, 2 of tankage, 1 of ground fish scrap, 1 of ground bone, 8 of acid phosphate, 4 of muriate of potash, 3 of sulphate of potash, 7 of wood ashes, 3 of mixed fertilizers, 3 of muck, 1 of marl, 14 of feeding stuffs, and 2 of oleomargarine.

Exhibit of the Bureau of Chemistry at the Pan-American Exposition, Buffalo, New York, 1901, H. W. WILEY, E. E. EWELL, W. D. BIGELOW, and L. W. PAGE (*U. S. Dept. Agr., Bureau of Chemistry Bul. 63, pp. 29, pls. 4*).—A detailed description of the exhibit of the Bureau of Chemistry relating to pure and adulterated foods, the beet-sugar industry, and the testing of road-making materials.

BOTANY.

The brome grasses of Wyoming, A. NELSON (*Wyoming Sta. Bul. 46, pp. 21, pls. 3, figs. 9*).—A discussion is given of the forage problems of Wyoming and suggestions for the improvement of the ranges. In this State grasses suitable both for pasture and hay are desirable, but there are comparatively few adapted to this double purpose. Among the most valuable are the brome grasses of which quite a number are native to the region covered by the bulletin. Following the discussion of the forage problems, the author figures and describes a number of the more promising species of brome grass.

Agrostological notes, F. LAMSON-SCRIBNER and E. D. MERRILL (*U. S. Dept. Agr., Division of Agrostology Circ. 35, pp. 6*).—Descriptions and critical notes are given on some species of grasses, published in 1866 by Buckley; notes on the genus Calamovilfa; descriptions of 3 new species of Panicum; a new species of Poa; and some changes in nomenclature.

The comparative anatomy of the foliar organs of Acacia, P. LEDOUX (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 11, pp. 722–725*).—The author reports having examined the leaves, enlarged petioles, and other foliar organs of a number of species of Acacia, in which he found that the flattened petioles, by their persistence, richness in chlorophyll, and numerous stomata are able to perform the ordinary physiological functions of leaves, and at the same time are better adapted to the intense sunlight of tropical regions. These petioles have a thickened epidermis, an abundant sclerenchyma, and a well-developed water conductive tissue, but the thick epidermis prevents too rapid transpiration and the abundant water-conductive tissue supplies the plant with the greatest amount of water possible.

On the relation between the structure of the sugar-beet root and its sugar content, L. GESCHWIND (*Rev. Gén. Chim. Appl., 3 (1900), No. 12; rev. in Bul. Assoc. Chim. Sucr. et Distill., 18 (1901), No. 10, pp. 785–795, figs. 36*).—The author claims in general that there is a relationship between the development of the woody structure of the root of the sugar beet and its sugar content. Usually a high sugar content is associated with a small development of the woody tissue. This conclusion, however, is subject to a number of exceptions, and the small development of woody tissues does not necessarily imply a high sugar content. The attacks of various fungi upon the roots have been shown to influence the development of the woody axis of the root and also to diminish the sugar content. While not an invariable rule, the occurrence of a poorly developed woody area, as shown by a section of the top of the beet, may be utilized in the selection of beets for propagation and breeding purposes.

On the reserve carbohydrates in Arrhenatherum elatius, V. Harlay (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 7, pp. 423–426*).—A study is reported of the reserve carbohydrates found in the enlargements which occur between the lower nodes in the variety *bulbosum* of tall oat grass. The author dried and macerated 200 gm. of these tubercles with a solution of acetate of lead, after which it was filtered, the lead eliminated by oxalic acid, and the filtrate precipitated. The character of the filtrate is described at some length, from which it appears that in its properties it is quite similar if not identical with graminin and phlein. A special study was made of the action of different hydrolyzing agents upon the graminin from the plant under investigation, and it was found that in the presence of saliva and diastase it remained unaltered. The ferments secreted by *Aspergillus niger*, which hydrolyzes inulin, also hydrolyze graminin. This substance is found in considerable abundance in the tubercles of this grass, and is accompanied by reducing sugars. The character of the substance shows that it is undoubtedly of the same nature as levulose.

Investigations on the respiration of olives and the relation between the respiratory quotient and the formation of oil in the fruit, C. Gerber (*Jour. Bot. [Paris], 15 (1901), No. 1, pp. 9–22*).—The author has found that the respiratory quotient of olives increases with the growth of the fruit up to a maximum, which is reached about the time the color begins to rapidly change. This increase is due to the transformation of mannite to oil, which takes place in the fruit. If the fruit remains attached to the tree the leaves continue to elaborate the mannite during the ripening process, and this is transferred to the fruit so that the oil content of the fruit may be in excess of the amount of mannite present in the fruit. As the oil increases the mannite necessarily diminishes, and when the fruit has become a violet or purple color mannite disappears entirely.

The effect of smoke and gas upon vegetation, W. A. Buckhout (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 164–192, pls. 4*).—The author popularly reviews some of the literature on the injurious effect of smoke and gas upon vegetation, particularly the publications of Schroeder and Reuss. He studied the extent of injury to the agricultural and forestry interests of Pennsylvania by pollution of the atmosphere in cokeing and other manufacturing operations, visiting a number of manufacturing centers and noting the condition of vegetation in their immediate vicinity. The injurious effect of the gases, smoke, and soot is shown in the destruction of forests and orchards in the vicinity of these manufacturing establishments. The author collected specimens of leaves in the vicinity of a number of coke ovens and iron furnaces and at chemical works, and determined the amount of sulphuric acid and chlorin in the dry substance, comparisons being made with the same kind of leaves collected in a region far from the injurious effect of such agencies. An analysis of white oak leaves, taken about three-quarters of a mile from a large range of coke ovens, showed 3.6 parts of sulphuric acid per 1,000 of water-free substance, as compared to 1.9 parts in similar leaves taken from the vicinity of the State college. Apple leaves from the vicinity of the same coke ovens gave in 1,000 parts of water-free substance 12.3 parts sulphuric acid and 2.7 parts chlorin. Leaves taken from the vicinity of large chemical works gave 6.4 parts sulphuric acid and 3.6 per cent chlorin, while leaves collected at the State college gave but 1.7 parts sulphuric acid and but a trace of chlorin. The author gives suggestions as to the prevention of some of this injury. The most practicable means are believed to be the erection of tall smoke stacks or chimneys in order to secure the most effectual aid in rapid dilution of the gases; or, if possible, the location of such works in large open plains, instead of in ravines or valleys, as is usually the case.

Action of carbon bisulphid on the growth of trees, E. Henry (*Bul. Soc. Sci. Nancy, 3. ser., 2 (1901), No. 1, pp. 27–33*).—The stimulating action of carbon bisulphid upon the growth of various plants and the results of experiments in which soil about locust trees was injected with carbon bisulphid at the rate of 400 cc. per square meter are shown. The effect of the treatment was soon apparent, and at the end of 2 years the difference in 2 lots was very evident, the treated lot weighing nearly 3 times as much as those not treated.

The factors which influence the size, number, location, and action of the root tubercles of leguminous plants, L. Hiltner (*Arb. K. Gesundheitsamte, Biol. Abt., 1 (1900), No. 2, pp. 177–222, pl. 1; abs. in Mitt. Deut. Landw. Gesell., 15 (1900), No. 45, pp. 268–270; Bot. Centbl., 85 (1901), No. 6, pp. 179–183; Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 5–6, pp. 202–204*).—A critical review is given of the literature relating to the subject of the occurrence and function of bacteria in the root tubercles of leguminous plants, and extensive experiments are reported in which the author investigated the effect of various factors on tubercle development. It is claimed that the quantity of inoculation material does not exercise an appreciable effect upon the number, size, or activity of the tubercles. The proportion between the total development of tubercles and the development of aerial parts of plants is about constant when the other factors, aside from the inoculation material, are the same. This statement applies only where bacteria of similar virulence are employed. When races of root tubercle bacilli of low virulence are compared with more active ones, the greater activity is always with those of the higher degree of virulence. This, according to the author, determines the size, number, location, and action of the root tubercles upon leguminous plants. Active tubercles upon the roots produce in a plant a sort of immunity against other bacteria of equal or lower virulence, and such plants can be stimulated to greater tubercle development only by the use of more powerful inoculation material.

The character of the soil, as influencing tubercle development, is discussed and the dependence between poor soil and abundant tubercle development is again pointed out. Where an abundance of available nitrogen is present, extensive root tubercle development is not to be expected. The effect of moisture in the air and soil, as factors in the distribution and development of root tubercles, is also discussed.

Physiological studies with reference to the germination of certain fungus spores, B. M. Duggar (*Bot. Gaz., 31 (1901), No. 1, pp. 38–66*).—A report is given of investigations to ascertain the influence of certain special factors on germination. Most of the experiments were made with hanging drop-cultures, and comparisons made with spores grown in a standard nutrient solution. The percentage of germination of the spores of about 20 species of fungi is given. The effect of certain stimuli on the germination of spores was investigated, spores of *Aspergillus flavus*, *Sterigmatocystis nigra*, and Phycomyces being treated with various carbon compounds, metallic salts, and mineral acids. In many instances a decided stimulus was given the germination, while in others the stimulus, if any was produced, was slight. The influence of evaporation, surface tension, and other physical agents on spores was investigated, as well as the inhibiting action of various nutrient solutions. The resting stages and drying of spores was a subject of investigation, in which it was determined that the spores of certain fungi have an apparent resting stage, the germination of some increasing considerably from summer to autumn. Spores of some fungi kept dry in the laboratory for 5 years gave no germination, while material 1 and 2 years old germinated readily in nutrient media. The effect of dilution of food materials on germination was examined, and it was found that a tenfold dilution of ordinary culture media would still afford perfect germination. Dilutions below 1,000 times gave no germination except with very sensitive fungi. The spores of Aspergillus and Botrytis were germinated and dried in filter paper, and after drying for some time attempts were made to produce further growth. With Botrytis no further growth could be secured from spores after drying for 24 hours, while with Aspergillus spores grew readily after drying for 20 days, and after 65 days a new growth was produced in about half of the cultures.

The significance of mycorrhiza, E. Stahl (*Jahrb. Wiss. Bot.* [*Pringsheim*], *34* (*1900*), *No. 4, pp. 539–668, figs. 2; Ann. Agron., 27* (*1901*), *No. 3, pp. 113–135*).—The author has made a comparative biological study of the occurrence, distribution, and function of mycorrhiza, reviewing and extending the investigations of Frank, Schlicht, Janse, and others. Schlicht reported the occurrence of mycorrhiza on the roots of 70 out of 105 species of North German plants examined, and Janse states that 69 out of 75 species of plants examined in Java bore mycorrhiza upon their roots. The investigation of the author has greatly extended the knowledge as to the number of plants living in symbiosis with fungi upon their roots. He examined species belonging to nearly every group of the higher plants, as well as vascular cryptogams, and found that symbiosis is of wide occurrence in nearly all groups of the higher plants, except upon those whose roots are submerged or floating, and certain species of Cruciferæ, Cyperaceæ, and Polypodiaceæ. Upon many plants there seems to be a sort of facultative symbiosis, while in others it is obligate. In the course of his observations, tuberous and bulbous plants were examined, and some of those which contained much reserve material in their bulbs were found to live symbiotically under certain conditions.

There appears to be an intimate connection between the substratum in which plants are grown and the presence of fungi upon their roots. In soil poor in mineral matter and rich in humus the conditions are most favorable for the development of the mycorrhiza. If the nature of the soil be so modified that the plant can secure its necessary nutrition directly, the mycorrhiza tends to disappear. The author has adopted the term mycotrophic for plants which bear mycorrhiza, and autotrophic for those capable of directly drawing their substance from the soil. It is claimed that the presence or absence of mycorrhiza may be determined by morphological and physiological characters. The occurrence of a well-developed root system, active transpiration, accompanied by the excretion of much water, and the presence in the leaves of an abundance of starch, oxalate of lime, and nitrates, characterize an autotrophic plant. Those bearing mycorrhiza have reduced transpiration, the carbohydrates in their leaves are in soluble form, and the circulation of the plants is less active. Mycorrhizas convey organic compounds almost entirely to their host plants, as is shown by the lower ash content of such plants. As has been already stated, the symbiosis is more or less facultative with many plants, although obligate with others, and the difficulty attending the cultivation of mycotrophic plants is in inverse proportion to the degree of dependence on the mycorrhiza.

ZOOLOGY.

The relation of sparrows to agriculture, S. D. Judd (*U. S. Dept. Agr., Division of Biological Survey Bul. 15, pp. 98, pls. 4, figs. 19*).—In this bulletin the author reports the results of observations on the feeding habits of the various sparrows found in the United States. As a result of this study the conclusion is reached that sparrows as a class are of greater value to agriculturists than any other group of birds whose habits have thus far been investigated by the Department. They were studied by means of field observations, experiments with captive birds, examination of the stomach contents, and a combination of field work with stomach examination. A detailed description is given of the methods of examination of birds' stomachs in the laboratory and the method of making observations on feeding habits in the field.

The stomach contents of 4,273 sparrows killed in various parts of the country during different months of the year were examined. It was found that mineral matter constituted from $\frac{1}{10}$ to $\frac{1}{4}$ of the total stomach contents. From 25 to 35 per cent of the diet for the whole year consisted of animal matter, chiefly insects, the latter constituting from 10 to 20 per cent of the year's food. The insects eaten included grasshoppers, beetles, and caterpillars, as well as the representatives of various other groups. The main food of sparrows consists of seeds of grasses and weeds. The noneconomic portion of food eaten by sparrows was found to be chiefly insects, spiders, snails, and wild fruit. Sparrows cause some damage to agriculture by destroying useful insects and cultivated crops, such as grain and fruits. Grain and cultivated fruits, however, form no significant part of the food of sparrows, except in case of the English sparrow. Of 19 species of native sparrows only 2 were found to have eaten grain. The sparrows, including the English sparrow, are useful destroyers of weed seeds. As a rule, the weed seeds are cracked or otherwise injured, so that they can not germinate when vented from the body. The principal weed seeds which are fed upon by sparrows are those of ragweed, pigeon grass, smartweed, purslane, crab grass, lamb's quarters, chickweed, and amaranth. This work is done chiefly in the fall and winter and early spring. During this time the seeds of various weeds constitute about three-fourths of the food of 20 species of native sparrows. It is estimated that the native sparrows may destroy 90 per cent of the seeds of pigeon grass and ragweed within 2 months. The benefits derived from the feeding habits of sparrows are believed to be from 5 to 10 times as great as the injuries produced.

Notes are given on the individual habits of different species of sparrows. These observations were carried on especially at a farm near the base of one of the White Mountains; at Marshall Hall, Md.; and in the District of Columbia. In order to determine the possible agency of sparrows in distributing weed seeds, examinations were made which disclosed the fact that comparatively few seeds pass through the alimentary tract without being destroyed.

In the spring of 1898 feeding experiments were made with a song sparrow, a junco, and a white-throated sparrow, in captivity. It was found that these birds were readily induced to eat various beetles and bugs which were provided with volatile irritating fluids for protection. In the winter of 1900, 7 English sparrows in captivity were fed upon the seeds of different weeds, for the purpose of determining how thoroughly these seeds were destroyed. The seeds of climbing false buckwheat, ragweed, lamb's quarters, and amaranth were entirely destroyed. Two sparrows were fed with 100 seeds of crab grass and gravel was furnished to aid grinding power of the birds' gizzards. All of the seeds were destroyed. In another experiment 500 crab grass seeds were fed to the same sparrows without the addition of gravel. The result of this experiment was the same as that of the preceding one. Of 1,600 seeds of crab grass which had passed through the alimentary tract of the sparrows, not a single one was found to germinate.

A large portion of the bulletin is occupied with a special discussion of the feeding habits of the different sparrows which were studied. In the stomachs of 82 English sparrows, insects constituted 2 per cent and seeds 98 per cent of the food. The grain which had been consumed by the birds formed 74 per cent of the entire food for the year. An examination of the contents of the stomachs of 50 nestlings showed that one-third of their food was also grain. The English sparrow was found to feed less on useful insects than any other bird which appears to have been studied, but the injury to grain from attacks of the English sparrow is considered as more than counterbalancing all the benefits which accrue from its presence in the country.

The birds of North and Middle America, R. RIDGWAY (*Smithsn. Inst., U. S. Nat. Mus. Bul. 50, 1901, pt. 1, pp. XVII + 715, pls. 20*).—A description is given of all species, subspecies, and forms of birds found on the continent of North America from the Arctic districts to the eastern end of the Isthmus of Panama, as well as those which are found in the West Indies, other islands of the Caribbean Sea (except Trinidad and Tobago), and the Galapagos Archipelago. Introduced and naturalized species are included, as well as accidental and casual visitors. The system of classification is that of the most recent authorities. Analytical titles for the identification of groups and species are given, and extensive synonymy is presented in connection with the description of each species, together with complete bibliographical references.

Rabbits and their injuries to young trees, H. GARMAN (*Kentucky Sta. Bul. 93, pp. 111–118, pls. 5*).—Notes are given on the prevalence of the common species of rabbits in the State. In some nurseries it is reported that 25 per cent of the apple trees were destroyed by the rabbits. Where the rabbits are hunted extensively their numbers are kept so reduced that their injury is less noticeable. For preventing the injury by the rabbits to nursery stock and orchards, inclosure of the area with a slat fence is recommended. The slats may be bought for from $4 to $7 per thousand, and may be held in place by wires stretched between the fence posts. Several forms of traps and snares for catching rabbits are described. The use of poisoned bait and smearing trees with blood and other offensive materials are not recommended by the author. Wrapping the trunks of trees with cornstalks, straw, paper, and other material is considered very effective. Notes are given on the habits of *Lepus sylvaticus, L. palustris,* and *L. aquaticus.*

Rabbit control and destruction, A. BRUCE (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 7, pp. 751–769, figs. 6*).—The methods of rabbit destruction discussed by the author include rabbit-proof fencing, poisoning, trapping, fumigation, and destruction of rabbit burrows. The use of woven-wire fences in preventing the attacks of rabbits is considered an effective and cheap method. The poisons which have proven most successful are phosphorus, arsenic, and strychnin. Phophorus may be applied with oats, wheat, or other grain. Arsenic may be used in a dry condition, mixed with grain, chaff, carrots, apples, and other substances; or may be used in solution in which these same substances are soaked. Strychnin may be added to jam or placed in carrots, apples, or twigs of trees. A most effective means of applying strichnin and arsenic in the poisoning of rabbits consists in the use of these poisons in tanks of water where rabbits go to drink. Various chemical devices are described by which the rabbits are enticed to visit the tanks in which the poisoned water is contained. The most effective substance for dealing with rabbits in burrows is bisulphid of carbon.

Vermin destruction (*Jour. Agr. and Ind., South Australia, 4* (*1901*), *No. 12, pp. 976–978*).—Detailed directions and formulas are given for the preparation and distribution of phosphorized oats, wheat, and other substances, chaff and arsenic, grain and arsenic, apples or quinces and strychnin, carrots and strychnin, carrots and arsenic, apples and arsenic, and jam and strychnin. These methods are especially adapted for the destruction of rabbits. It is recommended that the poison be distributed along freshly broken furrows where it is claimed the rabbits are much more apt to eat the poison.

Revision of the skunks of the genus Chincha, A. H. HOWELL (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No. 20, pp. 62, pls. 8*).—This bulletin discusses the history, distribution, habits, external characters, and nomenclature of the skunks of this genus, including a description of the specimens of which a study was made. The genus Chincha is subdivided into 2 subgenera, Chincha and Leucomitra. The characters of the genus, subgenera, species, and subspecies are given in detail, together with a list of the species and subspecies of the type, localities, and a key for their identification.

Rat plague, A. EDINGTON (*Centbl. Bakt. u. Par., 1. Abt., 29* (*1901*), *No. 25, pp. 889–894, figs. 4*).—The author investigated an outbreak of disease among rats in Kapstadt, where the bubonic plague was prevalent to some extent among human beings.

It was suspected that the plague had affected rats in this vicinity. An examination of rats which had died of the disease disclosed the presence of a large number of bacteria in the blood, liver, and spleen. These organisms, however, differed decidedly from those of the bubonic plague, and inoculation experiments showed that the disease which was destroying rats was not the same as the bubonic plague. These experiments showed that the disease could be transmitted to guinea pigs but not to rabbits.

Morphological and experimental researches on Trypanosoma of rats (T. lewisi), A. LAVERAN and F. MESNIL (*Ann. Inst. Pasteur, 15 (1901), No. 9, pp. 673–714, pls. 2, figs. 17*).—The literature on the subject is reviewed in connection with bibliographical references. The authors discuss the frequence of natural infection by Trypanosoma and the technique of morphological study of this organism in fresh and preserved conditions. A detailed description is given of the minute structure of the organism, including differences in the structure of various individuals and the methods of multiplication. In studying the phenomena of agglutination of Trypanosoma it was found that normal rat serum exercised no agglutinating action. The serum acquired such power after successive inoculations with blood from infected rats. One of the most striking features in connection with the agglomeration of Trypanosoma is the fact that the organisms remain mobile after agglomeration has taken place. The conclusion was drawn from this fact that the paralyzing and agglutinating properties of blood are due to distinct substances. A detailed description is given of the progress of infection of rats and guinea pigs by Trypanosoma, and the symptoms which characterize the various stages of infection. In studying the problem of immunity to infection by Trypanosoma it was found that the destruction of these organisms begins in the case of rats in the body cavity. The white blood corpuscles of immunized rats surround and devour the Trypanosoma.

Natural history of the Queen Charlotte Islands, British Columbia; natural history of the Cook Inlet region, Alaska, W. H. OSGOOD (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No. 21, pp. 87, pls. 7, fig. 1*).—This report contains an account of the physiography, flora, fauna, and life zones of Queen Charlotte Islands and the Cook Inlet region. A bibliography is given of the literature of these countries, and notes are presented on the birds and mammals which were found during the course of investigations.

Digest of game laws for 1901, T. S. PALMER and H. W. OLDS (*U. S. Dept. Agr., Division of Biological Survey Bul. 16, pp. 152, pls. 8*).—In this bulletin a discussion is given of definitions of game; restrictions as to time of killing game, methods of hunting, purposes for which game may be killed; and shipment of game within a single State or from one State to another. In addition to this general discussion, abstracts are given of federal laws, State laws, Canadian export laws, and provincial laws of Canada regarding the killing and transportation of game. At the end of the report tables are given showing the close seasons for game in the United States and Canada, and especially for game in Maryland, District of Columbia, Virginia, and North Carolina.

WATER—SOILS.

Investigations on the action of various calcium and magnesium compounds, D. MEYER (*Landw. Jahrb., 30 (1901), No. 4, pp. 619–631, pls. 2; abs. in Chem. Ztg., 25 (1901), No. 74, Repert., p. 266*).—In continuation of previous investigations (E. S. R., 12, p. 1020), the author made a series of experiments in pots of 6,000 gm. capacity containing mixtures of sand and peat ($2\frac{1}{2}$ per cent) and of sand and loess loam (10 per cent). The plants grown were oats, potatoes, horse beans, vetch, and a mixture of equal parts of perennial rye grass (*Lolium perenne*) and alfalfa. Lime was applied in form of gypsum, carbonate, and phosphate, and magnesia as carbonate, in various combinations with each other and with potash (sulphate and phosphate) and nitrogen salts (nitrate of soda and sulphate of ammonia). In case of the oats and of the grass and alfalfa mixture applications of gypsum furnishing more than 1 gm. of lime (CaO) per pot caused a decided reduction of yield. With larger applications the reduction in yield was proportional to the amount of the application. Potatoes were not thus affected by applications of gypsum. In case of this crop the effect of gypsum and of calcium carbonate was the same. The injurious effect of the gypsum was overcome by applying calcium or magnesium carbonate in connection with it. The effect of the gypsum was also reduced to a minimum by admixture of the loam soil with the sand, thus indicating that in general practice where gypsum is used in small amounts on ordinary soils the injurious effect would not be observed. Only when applied in small amounts did the magnesium carbonate increase the yield of the grass-alfalfa mixture. With larger applications of this material there was a reduction in yield. Horse beans and vetches were not thus affected by the larger applications of magnesia. The magnesium carbonate was apparently capable of almost completely replacing lime. The highest yields, however, were obtained when the carbonates of lime and magnesia were used together. It was also observed that even when lime had been applied in excess the magnesia was still capable of producing a considerable increase in yield. This is of great practical importance as indicating that dolomitic marl is of at least equal value with calcareous marl.

The plant food capital of the soils of western Germany, with especial reference to their geological nature, taxable value, and fertilizer requirements, F. Wohltmann (*Das Nährstoff-Kapital west-deutscher Böden, mit besonderer Berücksichtigung ihrer geologischen Natur, ihrer Katasterbonität und ihres Düngebedürfnisses. Bonn: Carl Georgi, 1901, pp. 63, figs. 3. Ber. Inst. Bodenlehre u. Pflanzenbau Landw. Akad. Bonn-Poppelsdorf, 1901, No. 1*).—This is a memorial prepared on the occasion of the dedication of the new institute for soil study and plant culture of the agricultural academy of Bonn-Poppelsdorf during the summer of 1901, and summarizes previous work on soils at this institution, giving in addition a brief description of the building and equipment of the new institute and a list of publications of the author from 1894 to April 1, 1901. A general discussion is given of the geological and mineralogical character of soils, their mechanical composition and physical properties, their chemical composition and plant food capital, their absorptive power with reference to salts and gases, the kind and amount of bacteria present, and the relation of soils to climatic conditions. The methods used in the soil analyses reported are described in detail[1] and the results of mechanical and chemical examinations of 66 samples of typical soils taken to a depth of 1 meter are reported and discussed. In most cases analyses were made of each soil at 4 different depths, 0 to 25 cm., 25 to 50 cm., 50 to 75 cm., and 75 to 100 cm. The results show wide variation in the composition of the same soil at different depths, this variation frequently being greater than that observed between different soils, as is shown in the following table:

Variations in the composition of soils of Western Germany.

	Variations in different soils.	Variations in the same soil at different depths.
	Per cent.	*Per cent.*
Nitrogen	0.055– 0.498	0.007– 0.498
Calcium oxid	Trace–22.067	Trace–35.600
Magnesium oxid	0.019– 0.659	0.011– 8.610
Phosphoric acid	.018– .253	.060– .305
Potash dissolved by treatment with cold acid	.026– .212	.019– .188
Potash dissolved by treatment with hot acid	.056– .504	.056– 1.133

[1] The methods here described are a revision of those given in Jour. Landw., 44 (1896), No. 5, pp. 211–234 (E. S. R., 8, p. 573).

The author claims that chemical soil analysis is of the highest value and may be safely used as a guide in determining whether a soil is so poor that it is entirely dependent upon the application of plant food for the production of crops, or only requires the return of the plant food removed by crops, or is so fertile that it may be cropped for a series of years without requiring any addition of fertilizing material. The following classification of soils, based on chemical composition, is given:

Classification of soils based on chemical composition.

Character of soil.	Constituents in air-dry fine earth (particles less than 2 mm. in diameter).				
	Nitrogen. *a*	Calcium and magnesium oxids. *a*	Phosphoric acid. *a*	Potash. Soluble in cold hydrochloric acid.	Potash. Soluble in hot hydrochloric acid.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Very rich (may be cultivated without return of fertility removed)	Over 0.3	Over 3.0	Over 0.25	Over 0.2	Over 0.5
Rich (requires partial return of phosphoric acid removed by cropping)	0.2 -0.3	1.5 -3.0	0.15-0.25	0.15-0.2	0.4 -0.5
Good (requires return of phosphoric acid removed)	.1 -0.2	.5 -1.5	.10-0.15	.10-0.15	.2 -0.4
Medium (requires return of phosphoric acid and potash removed)	.06-0.1	.25-0.5	.07-0.1	.06-0.1	.12-0.2
Poor (requires general increase in fertility)	.03-0.06	.1 -0.25	.04-0.07	.03-0.06	.08-0.12
Very poor (very much in need of increase in fertility or periodical rest)	.02-0.03	.05-0.10	.02-0.04	.02-0.03	.05-0.08
Of little value for cultivation (best suited for meadows and pastures)	Less than 0.02	Less than 0.05	Less than 0.02	Less than 0.02	0.05

a Soluble in cold hydrochloric acid.

As regards humus content the author classifies soils as follows: With 0 to 2 per cent of humus in the air-dry fine earth, soil is considered slightly deficient or poor in humus; 2 to 3 per cent, of medium humus content; 3 to 5, of good humus content; 5 to 8, well supplied with humus (humous); 8 to 10, very well supplied with humus (very humous); 10 to 15, rich in humus; 15 to 20, very rich in humus, approaching moor soil, and over 20 per cent, moorlike or peaty.

Humus substances as a nitrogenous constituent of the soil, A. Doyarenko (*Izv. Moscow Selsk. Khoz. Inst.* [*Ann. Inst. Agron. Moscou*], *6* (*1900*), *No. 4*, *pp. 440–483*).—The object was to ascertain the way in which humic acids absorb nitrogen, and in what form the latter is retained after absorption. As a preliminary study the chemical nature of the nitrogenous constituents of the humic acids of the soil was investigated. For the latter purpose the humic acids of 7 different soils was extracted with a 10 per cent solution of sodium carbonate. In order to remove the slimy impurities which always accompany the extract the latter was filtered through a porous clay filter. In the pure humic acid the total nitrogen was determined by the Kjeldahl method, the amido-acid nitrogen by Böhmer's method, the amid nitrogen by Schultze's method, and lastly the ammoniacal nitrogen. The analyses gave the following results: Amido-acid nitrogen, 22.01 to 70.27 per cent of the total nitrogen; amid nitrogen, 5.47 to 12.13 per cent of the total nitrogen.

For the study of the absorption of nitrogen by humic acid, 2 series of experiments were made with both artificial and soil humic acid. The humic acid was used either in jelly-like condition or quite dry. The absorption of nitrogen from ammonium carbonate and ammonium sulphate was attempted. The experiments were conducted as follows: Three to 5 gm. of dry humic acid (or an equivalent amount of the gelatinous preparation) was mixed in a flask with 100 cc. of a 10 per cent solution of ammonia salt and allowed to stand for a certain number of days with frequent shaking. One series of flasks of each kind of mixture was examined after 24 hours, another at the end of 7 days, and another after a month. In these examinations the unchanged ammonia salt was first removed and then determinations were made of the total and the amid nitrogen. The author sums up the results of his experiments as follows: (1) Absorption proceeds most energetically when the humic acid is soluble in the ammonia salt used, somewhat less energetically when freshly precipitated humic acid is used in connection with an ammonia salt in which it is not soluble, and least when dry humic acid reacts with an ammonia salt in which it is not soluble. (2) The energy of absorption is expressed solely by the rapidity of the reaction, the amount of absorbed nitrogen being the same in all cases. In the first case the absorption attains its limit in a short time, while in other cases the same limit is reached after a longer period of time. (3) In cases where the humic acid is not soluble in the ammonia salt the concentration of the solution of the latter is of importance, the rapidity of absorption varying with the concentration. (4) The absorbed nitrogen gives rise to the formation of amids almost exclusively. The absorption was approximately 1 to $1\frac{1}{2}$ per cent when soil humic acid was used.—P. FIREMAN.

The nitrifying capacity of normal soils and the loss of nitrates through drainage, A. V. KLUCHAROV (*Izv. Moscow Selsk. Khoz. Inst.* [*Ann. Inst. Agron. Moscou*], *6* (*1900*), *No. 2, pp. 132–166*).—In order to overcome the effect on nitrification of the stirring and aeration of soils, which, in the opinion of the author, has led to too high results in many of the investigations reported on this subject, a study of soils in their natural state was attempted as follows: Thin-walled steel cylinders open at both ends, 11 cm. in diameter and 20 cm. in height, sharpened at the lower end, were carefully pressed into the soil to the top and then withdrawn with the inclosed soil. A zinc funnel was slipped on the lower end of the cylinders and luted to the latter. The percolating water was collected in a separatory funnel. The cylinders with the inclosed soil were lowered into thin-walled iron cylinders, 50 cm. high, sunk in the ground. The steel cylinders were made to fit tightly within the iron ones and precautions were taken to prevent the rain water from getting in between the soil and the walls of the cylinders and between the steel and iron cylinders.

In the experiments reported there were determined (1) the amount of nitrates in a control cylinder of the soil at the beginning, (2) that percolating through the soil during a definite period of the experiment, and (3) the amount in the soil at the end. Observations showed that the temperature, humidity, and porosity of the soil in the cylinders were the same as in the normal soil.

Investigations were made in 1895 with 6 soils: No. 1.—Soil from the experiment field of the Moscow Agricultural Institute, a very rich clay soil which had been frequently manured with large quantities of barnyard manure, upper layer strongly colored by humus substances. No. 4.—Soil from a turf meadow on the Zhabinka River, brown in color, passing not infrequently into red yellow. No. 6.—Soil from the farm of the institute, of the same type as No. 1, but less liberally manured. No. 7.—Soil from a field in the viciniy of the institute, a clayey, light yellow, poor soil which had been little manured and badly cultivated. No. 5.—Soil of the podzol type from the forest of the institute, light gray in color, except a thin layer on the surface, which was somewhat darker in color. No. 9.—A sandy, slightly coherent soil.

The chemical composition and absorptive power of these soils were as follows:

Chemical composition and absorptive power of soils.

Number of soil.	Nitrogen.	Humus.	Absorption capacity.	Loss on ignition.
1	0.186	3.86	45.8	5.47
6	.141	3.05	45.6	5.36
5	.143	3.09	38.6	4.98
7	.121	2.61	a 51.3	4.92
9	.119	2.21	38.7	4.06
4	1.476	29.35	98.9	48.16

a The accuracy of this determination is doubtful.

The experiments were begun on May 15 and concluded on October 17. The whole time of the experiments was divided into 2 periods, (1) from May 15 to August 16, and (2) from August 17 to October 17. On August 16 the soils were removed from cylinders and analyzed, being replaced by new samples. The latter were removed October 17 and analyzed. The drainage water was removed after each rain which resulted in percolation.

The following table gives the results of the experiments in 1895:

Formation and loss of nitrates in bare soils in 1895.

Number of soil.	Amount of water percolated from May 15 to October 17.	N_2O_5 in a liter of drainage water.	N_2O_5 formed in 1 kilogram of soil—From May 15 to Aug. 16.	From Aug. 17 to Oct. 17.	Total.	Ratio of the water percolated to that of the rainfall.
	Cc.	*Mg.*	*Mg.*	*Mg.*	*Mg.*	
1	594.0	232.4	51.21	11.05	62.26	1 : 4.4
4	645.0	86.3	30.39	4.17	34.56	1 : 4.1
5	622.0	42.6	16.31	7.03	23.34	1 : 4.2
6	672.0	78.0	5.02	23.67	28.69	1 : 3.9
7	702.0	103.1	35.77	24.99	60.76	1 : 3.7
9	753.0	69.2	19.93	10.45	30.38	1 : 3.4
Mean	664.6	101.5	26.45	13.56	39.99	1 : 4.1

The above data show that with reference to the energy of nitrification the soils arrange themselves in the order indicated by the chemical and mechanical analysis as indicated above. Soil No. 1, rich in nutritive substances and mellow, gives the largest amount of nitrates, while soil No. 5, the poor podzol, difficultly pervious to water and air, gives the least amount. Soils Nos. 6 and 7 appear to be exceptions. In the opinion of the author, an error was made in the experiments with soils Nos. 6 and 7. Nitrification was more energetic in the first period than in the second, obviously on account of higher general temperature. On an average approximately one-fourth of the rainfall percolated through a layer of soil 20 cm. in thickness.

In 1896 similar experiments were made with 3 of the above-described soils, Nos. 1, 4, and 7. With the last soil 2 experiments were made. One was carried out in the usual way, while in the other the soil was taken from the cylinder in layers, pulverized, mixed, and returned to the cylinder, introducing the layers in the same order as in the normal soil. The object of the last experiment was to study the influence of stirring the soil upon the energy of nitrification.

The results show that (1) the energy of nitrification in 1896 was much greater than in 1895, which was undoubtedly due to a higher temperature prevailing in 1896; (2) as in 1895, the better soils formed larger quantities of nitrates; and (3) soil No. 7, mixed, gave more nitrates than the same soil in normal condition, the increase being 9.8 per cent. On the other hand, the difference in the amount of nitrates washed through was very great, the increase for the mixed soil being 84.5 per cent, the soil losing more nitrates than was formed during the period. As in the previous year, the poorer soil lost a smaller percentage of nitrates than the better soils.

Calculating the results for the 2 years to kilograms per hectare, the following data are obtained:

Nitric nitrogen washed out of one hectare of different soils.

Number of soil.	Nitric nitrogen in drainage water of 1 hectare.	
	1895.	1896.
	Kilograms.	*Kilograms.*
1	45.58	77.31
4	18.39	24.61
5	8.75	....
6	17.31	....
7 (normal)	23.90	12.03
7 (mixed)	....	22.18
9	17.21	....
Mean	21.85	34.03

In 1896 an experiment was also made to compare the nitrifying capacity of the soil No. 1 and its accompanying subsoil. The samples were taken as follows: First, the soil layer was cut out by a cylinder, then the opening was enlarged, and a layer of subsoil was removed by means of another cylinder. Both cylinders were fixed in the ground in the way described above. The experiment was begun at the end of June and finished at the end of October. During that period the nitrate contents in the water percolated through a kilogram of the soil was for the soil 59.95 mg., for the subsoil 9.04 mg.

The author also carried out in 1896 a series of experiments in which various plants were cultivated on the soil. The cylinders used in these experiments were of a wider diameter, viz, 20 cm. One cylinder remained without plants, for control. In 3 others were placed germinated seeds of oats, barley, and black vetch. Of the 15 seeds sown originally in each cylinder only 10, the strongest, were allowed to develop. The experiments were begun June 15 and were discontinued September 25 on account of cold weather, although the oats and barley had only reached the milk stage and the vetches, though of normal size, were still green.

As was to be expected, the control soil allowed the largest quantities of water to percolate (1,402 cc., containing 373.7 mg. of nitric nitrogen per liter). The least amount of water percolated through the soil under oats (467 cc., containing 6.1 mg. of nitric nitrogen per liter), which agrees with the experiments of various investigators (Haberlandt, Hellriegel, Sorauer, etc.), showing oats to be a plant consuming large quantities of water per unit of dry matter as compared with other cereals. Oats also consumed the largest amount of nitrates, then follows barley, under which the percolation was 534 cc. of water, containing 6.2 mg. of nitric nitrogen per liter, and lastly, vetches, under which the percolation was 616 cc., containing 103.2 mg. of nitric nitrogen per liter.

The results indicate that the amount of nitric nitrogen lost by soils covered with plants is inconsiderable.—P. FIREMAN.

The humidity of the soil and denitrification, E. GIUSTINIANI (*Ann. Agron., 27* (*1901*), *No. 6, pp. 262–285, fig. 1*).—An account is here given of 3 series of experiments to test the influence upon nitrification and denitrification of (1) temperature, in a liquid medium; (2) proportion of water, in an artificial solid medium; and (3) humidity in the soil. In the earlier experiments of the first series the medium used for observations on nitrification was made up as follows: Ammonium sulphate 94.5 mg., potassium phosphate 20 mg., calcium carbonate 1 gm., water 100 cc.; that used for the denitrification experiments contained sodium nitrate 121.5 mg., potassium phosphate 20 mg., calcium carbonate 1 gm., starch 1 gm., and water 100 cc. In later experiments the medium used in the study of nitrification consisted of ammonium sulphate 3 gm., potassium chlorid 2 gm., potassium phosphate 2 gm., magnesium sulphate 1 gm., ferrous sulphate 0.8 gm., in 1,000 cc. of water; for the study of denitrification it was the same as that used in the nitrification tests except that 3.86 gm. of sodium nitrate was substituted for the ammonium sulphate. In the culture tests 25 cc. of water was added to 25 cc. of these solutions, 0.5 gm. magnesium carbonate being also added, and in case of the denitrification medium, 2 gm. of organic matter. The temperatures employed in the experiments were 22 to 25° C., 24 to 32°, 35 to 37°, and 40 to 42°. Qualitative tests for ammonia, nitrates, and nitrites were made at frequent intervals during the experiments and quantitative determinations of these substances were made at the end.

The solid medium used was made up as follows: For the study of nitrification dry quartz sand 4 kg., ammonium sulphate 2.5 gm., potassium phosphate 0.2 gm., water 500 cc.; for the study of denitrification the medium was the same except that 3.5 gm. of sodium nitrate was substituted for the ammonium sulphate. These mixtures were brought to dryness on a water bath and 100 gm. of magnesium carbonate added. The sand containing nitrate received in addition 200 gm. of organic matter prepared from dry peat soil. The proportions of water used varied from 0 to 16 per cent.

Nitrification and denitrification were also studied in 2 soils, one rich in carbonaceous matter, the other poor in this substance. In one series of experiments the soils were used without addition of any kind; in the second series ammoniacal nitrogen was applied at the rate of 19.6 mg. per 150 gm. of soil; in the third series nitric nitrogen was added at the rate of 18.15 mg. per 150 gm. of soil. The humidity in the different experiments ranged from 0 to 16 per cent. The experiments were continued from 2 months to 70 days, the gain or loss of nitric nitrogen being determined at their close.

Among the conclusions drawn from these investigations are the following: In a liquid medium the denitrifying organisms act most energetically at a temperature which very perceptibly retards the action of the nitrifying organisms. The rapidity of nitrification of ammonium sulphate in solid media was directly proportional to the quantity of water present. Perceptible denitrification occurred in such media only when the percentage of moisture was small. In similar experiments with soils the results were more decided, especially when the proportion of sodium nitrate was increased. Denitrification took place to a marked extent only when the proportion of humidity was less than 6 per cent, an amount insufficient to promote the activity of the nitrifying organisms. The latter became decidedly active when the humidity rose to 10 per cent. In soils containing a small amount of moisture denitrification is proportional to the amount of organic matter present.

The results thus show that water is an important factor in controlling the action of the oxidizing and reducing organisms in the soil and in transforming and conserving the nitrogen compounds present.

Reclamation of salt marsh lands, T. H. MEANS (*U. S. Dept. Agr., Bureau of Soils Circ. 8, pp. 10*).—This is a report of a preliminary investigation of the character of the soils of the tide marshes around Oyster Bay, Long Island, and of the possibilities of reclaiming them for agricultural purposes. Among means of reclamation the circular briefly discusses the exclusion of the sea water and removal of excess of water by ditching, underdrainage, and pumping; the washing out of the salt; and the adoption of a system of cropping and cultivation adapted to the conditions. Mechanical and chemical analyses of several samples of tide marsh soils from the locality named are given, with a discussion of the agricultural value of such soils. It is stated that—

"Salt marsh lands have long been considered the most fertile and valuable of lands. Practically no reclamation has been attempted in America, and that which has been attempted has in many cases been a failure or has been abandoned. There are well-established methods in use in the reclamation of salt marshes, and if these were used the work should be successful. There has never been a known case of failure to effect complete reclamation, in which all proper precautions were taken. After reclamation the lands are very fertile and should repay the expenditure of reclaiming them. It is generally conceded that 1 acre of reclaimed salt marsh land is worth 4 or 5 acres of upland, and, according to the well-substantiated figures quoted from Shaler earlier in this article, the cost of reclamation should not exceed one-fifth of the final value of the land."

List of soil types established by the Division of Soils in 1899 and 1900, with brief description, M. WHITNEY (*U. S. Dept. Agr., Division of Soils Doc. 40, pp. 11*).—This includes all soil names authorized for use on the soil maps of the Division to December 31, 1900.

FERTILIZERS.

The action of kainit and high-percentage potash salts, M. GERLACH (*Fühling's Landw. Ztg., 50 (1901), Nos. 11, pp. 377–388; 12, pp. 409–416*).—The author reviews the work of other investigators and reports experiments of his own, which show that where the material has to be transported long distances kainit is more expensive than the concentrated salt. The kainit, on account of its large content of soda salts, tends more than the concentrated salt to form a crust on the soil, especially in compact soils, although this tendency may be beneficial in loose soils. The concentrated salt is preferable to kainit on soils rich in soda. Kainit is not well suited for use in connection with nitrate of soda because of the excess of soda which will thus be added to the soil. It is also not suited to plants which are sensitive to chlorids, such as potatoes, sugar beets, etc. Cereals, grasses, forage plants, and leguminous plants, however, are apparently not affected.

It appears from the data reported that the use of soda salts resulted in a saving of potash, *i. e.*, partially replaced it, especially when potash was not present in large amounts. The soda salts also set potash free in the soil, but it is doubted whether this was of benefit to the plant, because it is believed that the solvent power of the roots was greater than that of the weak solution of soda salt present.

On the assimilation of nitrogen and phosphoric acid by different crops (3 cereals and 2 Cruciferæ) in three vegetation periods, K. BIELER and K. ASŌ (*Bul. Col. Agr. Imp. Univ. Tokyo, 4 (1901), No. 4, pp. 241–254*).—Experiments with wheat, barley, oats, rape, and mustard grown in porcelain pots containing 6.4 kg. of soil in a glass house during the winter of 1899 are reported. Phosphoric acid in the form of double superphosphate, potash in the form of potassium carbonate, and nitrogen in the form of ammonium sulphate were each applied at rates of 0.25 gm. per pot, or 50 kg. per hectare, with calcium carbonate at the rate of 1 gm. per kilogram of soil. Analyses were made of the plants with reference to nitrogen and phosphoric acid at periods of $2\frac{1}{2}$ months and 4 months after planting and at the blooming period. The data thus secured are tabulated and discussed in detail. The cereals and the Cruciferæ took up nearly the same amounts of nitrogen during their period of growth. The cereals assimilated less phosphoric acid (as well as total ash) than the other plants. The largest amount of phosphoric acid was taken up by rape, followed by mustard. Of the cereals wheat showed the greatest absorptive capacity for phosphoric acid, oats standing between wheat and barley in this respect. With wheat and oats the assimilation of plant food was distributed throughout the different periods of growth, but with barley it was confined mainly to the earlier stages. The greatest assimilation occurred in case of rape after the earlier stages were passed and continued until the plants bloomed. After that period there was no further assimilation.

Analyses of commercial fertilizers, C. A. GOESSMANN (*Massachusetts Sta. Bul.*

75, pp. 24).—Analyses are reported of 220 samples of fertilizing materials, including wood ashes, lime-kiln ashes, cotton-hull ashes, muriate of potash, nitrate of soda, sulphate of ammonia, cotton-seed meal, castor pomace, tankage, bone, mineral phosphate, acid phosphates, mixed fertilizers, barnyard manure, and muck.

Fertilizer analyses, R. C. KEDZIE and L. H. VAN WORMER (*Michigan Sta. Bul. 192, pp. 175–193*).—This bulletin contains the actual and guaranteed composition of 96 samples of fertilizing materials examined during 1901, with text of the State fertilizer law and notes on valuation, explanation of terms, etc.

Analyses of commercial fertilizers, H. J. WHEELER ET AL. (*Rhode Island Sta. Bul. 79, pp. 12*).—"This bulletin contains analyses [48] of such samples of bone, tankage, and of commercial fertilizers designed for potatoes, or for potatoes and vegetables, as have been collected in Rhode Island during the present year [1901]."

Analyses of commercial fertilizers, J. L. HILLS, C. H. JONES, and B. O. WHITE (*Vermont Sta. Bul. 87, pp. 147–192*).—The results of inspection of 134 brands of fertilizers, the output of 9 companies, are reported, with a discussion of the quantity and quality of plant food furnished by the fertilizers, the selling prices and valuations, and the average composition of the brands examined as compared with that of fertilizers examined during 4 previous years. Six-sevenths of the brands were up to or above guaranty. As a rule the quality of the crude stock used was good. The average selling price approximated $28.75 and the average valuation $19.44. Selling prices have remained unchanged notwithstanding an advance in the price of crude stock. The average composition of the brands was a little higher than that of the previous year.

FIELD CROPS.

Report of the agriculturist, E. R. LLOYD (*Mississippi Sta. Rpt. 1901, pp. 12–17*).—Experiments with cotton, broom corn, Indian corn, sorghum and cowpeas, and wheat are briefly discussed. The grade of cotton grown on thin hill land was improved by the use of barnyard manure and commercial fertilizers, the improvement being most marked in the cotton from the land which had received the barnyard manure. One-half acre of Evergreen broom corn yielded at the rate of 1,600 lbs. of uncleaned heads per acre. Sorghum and cowpeas grown together for hay were sown broadcast and in drills. Notwithstanding the 2 cultivations given the drilled plats, the crop of hay was largest from the plats sown broadcast. When grown in the proportion of ¾ cowpeas and ¼ sorghum they were found ready to cut for hay about the same time. The objection to the mixture is that the peas cure much faster than the sorghum. The yield of shredded corn fodder was about 1 ton per acre. The cost of handling the fodder per ton was 75 cts. and its value, as compared to peavine hay, $5. The waste in feeding shredded corn was 12½ per cent. Twenty-five varieties of wheat, including 17 from foreign countries, and 2 varieties of winter and 1 of spring oats were tested, and the yields are here recorded. Brief notes on each variety are also given.

Systems of cropping with and without fertilization, W. C. LATTA and J. H. SKINNER (*Indiana Sta. Bul. 88, pp. 27–38*).—The experiments here reported, in progress since 1889, were conducted to study the effect of various systems of cropping on the yield and quality of the crop and on the soil. The different systems ot cropping were as follows: Series 1—corn and oats; series 2—corn, oats, and wheat; series 3—wheat, grown continuously; series 5—corn, oats, wheat, and clover; series 6—corn, sugar beets, oats, wheat, grass, and grass; and series 7—corn grown continuously. In connection with the crop rotations, a study was made of light and heavy applications of commercial fertilizers and barnyard manure. The results for 10 years are given in tables and briefly discussed. With the exception of the series in which crops were grown continuously, the effect on the quality of the crops was not marked.

Continuous wheat culture proved detrimental to both yield and quality. In series 1, commercial fertilizers produced a large increase in the yield of wheat, but they did not have much effect on the yield of corn, while barnyard manure was equally beneficial to both crops. All fertilizers produced a good effect on the yield of corn and oats in series 2, but the effect on the yield of wheat was less marked. Barnyard manure gave a larger increase in the yield of corn and wheat than the commercial fertilizers, but for oats the increase was about the same for both methods of fertilization. In continuous wheat growing the effects of commercial fertilizers and barnyard manure were comparatively small. The use of fertilizers in series 5 showed a large increase in the yield of oats and a small increase in the yield of corn. Heavy applications of commercial fertilizers largely increased the yield of wheat straw and of clover, although the clover crop was not fertilized directly. In series 6, where a 6-course rotation was followed, a heavy application of commercial fertilizers produced a marked increase in the yield of sugar beets, clover, and timothy. In general, light applications of barnyard manure gave better results than heavy applications. With the exception of the oat crop the large applications of commercial fertilizers were much more effective in this series than the large applications of barnyard manure. The light applications of both fertilizing materials gave about equal results, in the case of commercial fertilizers the effects being more pronounced on beets, wheat, and timothy, and in the case of barnyard manure on corn, oats, and clover. In continuous corn growing in series 7, the results from both kinds of fertilizers were about the same, and the authors conclude that the smaller applications of commercial fertilizers and barnyard manure were sufficient for the crop under the existing conditions. The cost of the fertilizers used in these experiments is considered, and the financial results of each series and the average gains and losses per acre with corn, oats, and wheat in the several series, are tabulated.

The influence of rolling land on the stand of grain, von Seelhorst (*Jour. Landw., 49* (*1901*), *No. 1, p. 5*).—This article is a report on experiments in rolling grain in the spring. In 1898 oats were rolled May 1, when the plants were about 15 cm. high, and in 1900 a roller was used on a wheat field May 15, when the wheat was 20 cm. high. In both cases top-dressings were applied in connection with the experiments, and in every instance the results were compared with the results of check tests. The author concludes that rolling grain before it has begun to head has a tendency to prevent lodging in 2 ways, namely, by retarding the growth of the crop at that period, due to the decrease in nitrification in the compressed condition of the soil, and by giving the roots a better chance to take hold. The compression of the soil may interfere with the growth of the plants to such an extent that the yield is materially decreased, but it was found that depression in yield due to this cause might be counteracted by a top-dressing of nitrate of soda, which, owing to the compressed condition of the soil, becomes active gradually and does not cause an unfavorable, sudden, and rapid growth.

Harrowing, rolling, and cultivating cereal crops (*Semaine Agr., 21* (*1901*), *No. 1039, p. 117*).

Experiments in the culture of leguminous plants, L. Malpeaux (*Ann. Agron., 27* (*1901*), *No. 2, pp. 65–81*).—The work here reported is a study of the effects of nitrate of soda on the development of leguminous plants grown in pots. It was found that nitrate of soda brought in contact with the seeds, especially in the case of clover and alfalfa, had an injurious effect on germination. On ordinary soils rich in nitrogen the use of nitrate of soda seemed superfluous. Inoculating with soil on which leguminous plants had been grown did not always bring about a better development of the plants. The fact that nodules almost always appear on the roots of leguminous plants when the soil has been inoculated tends to indicate, according to the author's views, the truth of the hypothesis that these bacteria are distributed by the wind and the birds, and that when a species is absent in a soil it is due to conditions preventing its development. The nitric nitrogen appeared to be assimilated directly and caused in this case a total or relative absence of nodules on the roots. The experiments are to be continued under field conditions.

Further researches on the inoculation of soil with Alinit, L. Malpeaux (*Ann. Agron., 27 (1901), No. 4, pp. 191–206*).—Experiments were conducted with oats, corn, and mustard grown on different kinds of soil inoculated with Alinit. The plants in each case were grown in the open soil and in pots. The results confirm the conclusions of previous work in this line, namely, that Alinit is active only in mediums rich in organic matter. The author attributes this influence of Alinit to the active rôle bacteria play in breaking up insoluble nitrogenous substances and rendering them soluble.

A new problem in soil inoculation, J. Stoklasa (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 1, pp. 10–29, pls. 9, fig. 1*).—The author reports a series of experiments on the decomposition of bone meal by various soil organisms, laboratory and greenhouse trials having been made with a number of the more common soil bacteria. Plants were grown in pots which received fertilizers, after which they were inoculated with pure cultures of a single species of bacteria. All the pots, except one which was given superphosphate and sodium nitrate, were given bone meal in the same amount. This contained 19.8 per cent phosphoric acid, 5.26 per cent nitrogen, and 1.5 per cent fat. The inoculation material was accompanied by glucose or xylose. The effect of the different inoculation materials upon the growth of oats is shown in the following table:

The effect of soil inoculation on the growth of oats.

Inoculation material.	Fertilizer added.	Yield.		Total.
		Grain.	Straw.	
		Grams.	*Grams.*	*Grams.*
Not inoculated	Bone meal	161.32	213.81	375.13
Do	Superphosphate and sodium nitrate.	213.98	260.13	474.11
B. megatherium	Bone meal	246.79	267.85	514.64
Do	Bone meal and glucose	285.88	306.11	591.99
Do	Bone meal and xylose	320.52	398.04	718.56
B. fluorescens liquifaciens	Bone meal and glucose	165.26	272.26	437.52
B. proteus vulgaris	do	235.26	289.03	524.29
B. butyricus	do	230.79	285.99	516.78
B. mycoides	do	263.66	350.20	613.86
B. mesentericus vulgatus	do	283.21	353.77	636.98

Observations on leguminous plants to determine the correlation of their parts, C. Fruwirth (*Jour. Landw., 48 (1900), No. 4, pp. 305–316*).—Data were collected on the percentage relation (by weight) of the different parts of the plants to the entire plant and to each other of *Vicia faba*, *Pisum sativum*, *Phaseolus vulgaris*, *Lupinus albus*, *L. angustifolius*, *Lens esculenta*, *Lathyrus sativus*, *Ervum ervilia*, *Cicer arietinum*, and *Ornithopus sativus*. The results indicate that a heavy weight of the entire plant is correlative with a high total weight and increased number of seeds and pods together, and of seed alone. The correlation of the heavy weight of the entire plant with a greater height of the plant, a thicker stem, higher weight of pods alone, higher average weight of single seeds, higher weight of straw, and the relatively higher proportion of pods with many seeds was not indicated so generally as in the other cases mentioned. The relation between the weight of the entire plant and the percentage of the weight of the seed and of the pods alone, calculated on the weight of the entire plant, could not be established from the data. The number of seeds increased more with the increase in weight of the entire plant than the average weight of single seeds, and consequently, in general, heavy plants had relatively light seeds. The rate of increase in the weight of straw of heavy plants was less than the rate of increase in the total weight of the seeds.

Seeding down to grass in New South Wales, P. Quirk (*Agr. Gaz. New South Wales, 12 (1901), No. 3, pp. 361–362*).—A popular discussion on the preparation of the land for grass and the kinds of grasses to sow.

Seeding down pastures and meadows, V. Grandjean (*Semaine Agr., 21 (1901), No. 1039, p. 117*).

Nitrogenous fertilizers for meadows, Kuhnert (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 12, p. 183*).

Experiments in the improvement of pasture and range grasses, J. T. Willard (*Industrialist, 27 (1901), No. 30, pp. 369–372*).—This article is a discussion of experiments with grasses on cultivated land and on native sod injured by excessive pasturing, which were conducted by the Kansas Station in cooperation with the Division of Agrostology of this Department, in the extreme southern part of Kansas.

Agaves in Algeria, Trabut (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 6, pp 121–130, figs. 7*).—This article discusses the culture of the agave in Algeria, with special reference to *A. univittata.*

Fall seeding of alfalfa, H. M. Cottrell (*Kansas Sta. Bul. 104, pp. 4, pls. 2*).—A brief popular bulletin giving directions for seeding alfalfa in the fall. Notes are given on the preparation of the land, time and method of sowing, and the soils adapted to alfalfa culture.

Alfalfa culture (*Queensland Agr. Jour., 8 (1901), No. 3, pp. 163, 164*).—Popular directions for growing alfalfa.

Increasing the food value and dry matter of forage beets, P. Assarson (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 14, pp. 210, 211*).—A brief report on the progress made in the improvement of several varieties of fodder beets since 1897. The results for 3 years show an average increase of 1.22 per cent in the dry matter.

Beet culture in Algeria, G. Cureyras (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 4, pp. 82–87*).—An article on the favorable conditions for beet culture in Algeria where the beet occurs in a wild state.

Chemical study of seed beets, M. Gerbidon (*Ann. Agron., 27 (1901), No. 3, pp. 135–144*).—The results of a chemical investigation on forage beets for the purpose of determining the amounts of plant food these plants remove from the soil, what fertilizing value their residues represent, and whether the roots after the grains have been harvested have any feeding value, are presented in tabular form and discussed at some length.

The chlorin requirement of the buckwheat plant, A. Mayer (*Jour. Landw. 49 (1901), No. 1, pp. 41–60, pl. 1*).

Prussic acid in sweet cassava, P. Carmody (*Trinidad Bot. Dept. Bul. Misc. Inform., 1901, No. 27, pp. 319–323*).—The author's results, although somewhat lower, fully confirm those of his predecessor, Francis, as to the presence of hydrocyanic acid in sweet cassava. Francis found that the so-called sweet or harmless cassava, not only yielded prussic acid, but the quantity obtained from it was nearly equal to that from the bitter, so that no line of distinction could be drawn between them. While the author's analytical results were very similar, he found that in sweet cassava the prussic acid is largely in the skin and outer cortical layer. The hydrocyanic acid content of sweet cassava ranged from 0.005 to 0.019 per cent, and averaged 0.010. The author draws the general conclusions that in sweet cassava the prussic acid is not uniformly distributed throughout the tuber, while in bitter cassava its distribution is uniform, or nearly so; and that this affords an analytical means of distinguishing between sweet and bitter cassava. Attention is called to the methods of preparing cassava for food, and especially to the fact that with local methods cassava is prepared by removing the skin of the sweet kind before cooking, the inner portion alone being eaten. There appears to be no ground for the common belief that the hydrocyanic acid in sweet cassava increases with age, nor that the locally grown sweet cassava of Trinidad is a degenerate growth, resulting from many years' association with the bitter variety.

Studies in clover, G. Martinet (*Ann. Agr. Suisse, 2 (1901), No. 1, pp. 6–19*).—The author reports upon a number of studies made with clover and clover seed at the federal seed control station at Lausanne. Comparative tests were made of clovers grown from seed of different origin, in which seed of Swiss growth was compared with that from other countries. In all, about a dozen samples were grown, covering a period of 3 years. The season of 1900 was very hot and dry, and seriously injured some varieties. In general the varieties of clover developed in the vicinity of the station proved best adapted to growth at that place. Studies were made in the relative weight, production, and value of clover seeds of different color. Considerable variation was noted in the relative weight of different colored seeds, and the author believes it possible to obtain by selection a very vigorous and productive variety of clover which will be fairly constant in the character of its seed.

Experiments on cotton at Ghizeh, G. P. Foaden (*Jour. Khedir. Agr. Soc. and School Agr., 3 (1901), No. 1, pp. 13*).—This is a brief discussion on cotton culture under Egyptian conditions, including a report on experiments with different fertilizers made by the Khedivial Agricultural Society. The general conclusions are that the cotton crop in Egypt is benefited by the judicious use of commercial fertilizers. Suitable manuring increased the proportion of the crop obtained at the first pickings, but the use of nitrate of soda alone rather counteracted this effect. Applications of superphosphate on good soil gave a beneficial result. Kainit and basic slag did not increase the yield as much as superphosphates. On poor soils fertilizers containing no nitrogen were not effective. Nitrate of soda gave much better results on poor than on good land, but the author advises its use always in connection with other fertilizers. Guano increased the yield, but proved an expensive manure. Barnyard manure and poudrette were very effective manures, but heavy applications of barnyard manure have been found detrimental to the quality of the crop. Poudrette applied by hand to the plants after thinning gave better results than any other method of application. On good land wide planting gave greater yield and a higher proportion of the crop at the first picking than close planting.

Eragrostis brownii, A. Morrison (*Jour. Dept. Agr. West. Australia, 3 (1901), No. 3, pp. 206–209, fig. 1*).—This article gives a description and the distribution of this summer forage grass.

Flax culture in Belgium, Kuhnert (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 12, pp. 62–67, figs. 2*).

The Philippine hemp industry (*Hawaiian Planters' Mo., 20 (1901), No. 2, pp. 82–85*).—A brief description of the methods of growing hemp (*Musa textilis*) and its preparation for export.

Sisal hemp and its cultivation (*Jour. Dept. Agr. West. Australia, 3 (1901), No. 2, pp. 112, 113*).—Brief cultural notes.

Manurial experiments upon hops, A. D. Hall (*Jour. Southeast. Agr. Col. Wye, 1901, No. 10, pp. 33–40*).—This is a report on several cooperative experiments in progress from 1 to 6 years. The results show that the typical hop soils are not specially deficient in any one constituent, but require a general manuring. Soils such as clays, sands, and others to which hop culture has been extended, were found deficient in phosphoric acid, others in potash, and some in lime.

The manuring of mangels, J. Leslie (*Agr. Gaz. [London], 53 (1901), No. 1417, p. 116*).—This is a report on fertilizer experiments with mangels, from which the author draws the conclusions that in the absence of barnyard manure a complete commercial fertilizer including common salt and kainit or potash in some other form should be used, and that when barnyard manure is applied it is equally advisable to add common salt, but to omit the kainit.

Oat experiments, C. L. Newman (*Arkansas Sta. Bul. 66, pp. 23*).—This bulletin is a concise presentation of the results of culture, fertilizer, and variety tests with oats. It was found that cowpeas, Spanish peanuts, soy beans, sorghum, corn, Kafir corn, German millet, sweet potatoes, and second crop Irish potatoes gave profitable results when sown after oats had been harvested. Thorough preparation of the soil increased the yield of oats from 50 to 100 per cent as compared with poor preparation. Plowing the soil 8 and 10 in. deep gave better results than plowing 6 in. deep or less. Plowing in the fall and replowing in the spring gave larger returns than a single plowing either in fall or spring. Harrowing and disking after plowing and just before sowing, and covering the seed with a double-shovel cultivator, seemed to be the best method of putting in the crop.

Report on variety tests with oats in 1900, G. Martinet (*Jour. Soc. Agr. Suisse Romande, 42 (1901), No. 1, pp. 3–48, pl. 1*).

Cooperative variety tests with oats in North Germany, Clausen (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 16, pp. 237–239*).—A report on varieties of oats grown on marsh and sandy soils.

The culture of oats, V. Grandjean (*Semaine Agr., 21 (1901), No. 1027, pp 101, 102*).—This article is a popular discussion on the culture of oats in France.

Harvesting the pea crop (*Farming World, 18 (1901), No. 26, pp. 590–592, figs. 6*).—A popular discussion on harvesting field peas by means of pea harvesters.

Composition of potatoes at various stages of growth, C. H. Jones and B. O. White (*Vermont Sta. Rpt. 1900, pp. 374–382*).—This report describes experiments with potatoes, conducted in 1898 and 1899, to determine the chemical differences which might exist in marketable and small tubers when dug at different stages of growth. The analyses of the different samples are shown in tables. In 1898, 2 varieties, White Star and Delaware, were grown, and in 1899 the Delaware variety only was used. The results showed that quite marked differences in composition existed between the 2 varieties. The variations between samples dug at different dates were not marked. There was a rather gradual gain in protein as the season advanced. The proportion of ash in the marketable tubers remained quite constant throughout the season, but in the small tubers there was a greater tendency to vary. Crude fiber, although present in small amounts, was very variable. The average phosphoric acid content was 0.06 per cent greater in the small than in the large tubers. The yields increased considerably as maturity advanced, showing that the ripening of the tubers affects the yield much more than the composition. In 1899 it was found that in general the percentage of dry matter and nitrogen-free extract decreased, while that of the protein, ash, and crude fiber increased as the tubers approached maturity. These results were in accordance with those of 1898.

New varieties of potatoes, E. Schribaux (*Jour. Agr. Prat., 1901, I, No. 16, pp. 496–500*).—This article describes a number of varieties of potatoes and classifies them as potatoes for the table and for feeding and industrial purposes.

Variety tests with potatoes at Calvörde, conducted by the German Potato Experiment Station, Vibrans (*Braunschweig Landw. Ztg., 69 (1901), No. 14, pp. 63–65*).—A report with tabulated results on tests made in 1900.

Variety tests of potatoes in Hungary, J. Gyárfás (*Fühling's Landw. Ztg., 50 (1901), Nos. 5, pp. 187–191; 7, pp. 247–253*).—A report on a cooperative test, making a special comparison of the variety Professor Maercker with a number of others. In a number of cases Professor Maercker gave the best results and the variety ranked well in every instance.

Exposing seed potatoes to light and air before planting (*Deut. Landw. Presse, 28 (1901), No. 22, p. 185*).—A brief note showing why the practice is to be recommended and giving directions for exposing tubers to obtain the best results.

Sainfoin as a meadow plant (*Semaine Agr., 21 (1901), No. 1038, pp. 110*).

The soy bean (*Orgaan Ver. Oudleer. Rijks Landbouwschool, 13 (1901), No. 153, pp. 77–79*).—This article is a general discussion on the soy bean.

The growth of sugar-beet culture (*Braunschweig Landw. Ztg., 69 (1901), No. 11, pp. 47, 48*).—A brief note on the increase in sugar-beet culture in various countries.

The growth of the sugar beet in England, A. D. Hall (*Jour. Southeast. Agr. Col. Wye, 1901, No. 10, pp. 3–8*).—A discussion of the crop, yield, and cost, and a report of a test with 6 varieties of sugar beets, all of which showed a high percentage of sugar and a high coefficient of purity.

Sugar cane and sugar beets, C. Daniel (*Rev. Agr. Ile Maurice, 15 (1901), No. 2, pp. 35–37*).—A historical note on the manufacture of sugar from sugar cane and sugar beets.

Tobacco culture in Ireland (*Farmers' Gaz., 60 (1901), No. 8, pp. 119, 120*).—A brief report on experimental tobacco growing in Ireland.

Influence of wheat farming upon soil fertility, H. Snyder (*Minnesota Sta. Bul. 70, pp. 247–266*).—The experiments here reported are in continuation of work previously noted (E. S. R., 9, p. 641). This work has now been in progress for 8 years, and has been conducted for the entire period as described in the previous abstract. The chemical composition of the soil, the physical composition of the subsoil, and the yields of the different plats for the years 1893 to 1900, inclusive, are reported in tables, together with the moisture condition of the soil under several systems of cropping on different dates. The results are discussed with special reference to the loss of nitrogen and humus under the several methods of cropping. It was found that the plat on which wheat had been grown continuously for 8 years lost 1,700 lbs. of nitrogen per acre, of which only 300 lbs. was used by the crop, the rest being lost by the decay of organic matter and the liberation of the nitrogen as gaseous or soluble compounds. On this plat there was a loss for the 8 years of over 21 per cent of the total nitrogen of the soil, or an annual loss of 175 lbs. per acre over the quantity used as plant food. Continuous wheat growing also caused an annual loss of over 2,000 lbs. per acre of humus, due to the fermentation and decomposition of organic matter in the soil. On the plat where wheat was grown in rotation with clover and oats, 5 crops of wheat were produced during 8 years. In this case the loss of nitrogen in excess of the quantity used by the crops was reduced to about 450 lbs. and the loss of humus from the soil was very small. Where oats and barley were grown continuously on the same soil the loss of nitrogen was nearly as large as in the case of continuous wheat growing. Corn growing from year to year on the same land caused a loss of nitrogen less than one-half the quantity lost in growing wheat continuously. The total loss of nitrogen from the soil for 8 years on the plat where corn was grown in rotation with clover and oats and barnyard manure was applied was less than 100 lbs. in excess of the quantity utilized by the crops. It is stated that corn introduced into a rotation decreases the loss of nitrogen as compared with wheat. It was found that bare summer fallowing gave rise to a heavier loss of nitrogen from the soil than continuous wheat growing. Summer fallowing also favored the decay of humus.

"The loss of humus changed the physical properties of the soil, causing it to be less retentive of moisture, lighter in color, and heavier in weight per cubic foot. During times of drought the soil from the continuous wheat cultivated plat contained less water than the soil from the plat which produced wheat in rotation with clover. Humus conserves the moisture of the soil, while the rotation of crops, the use of farm manures, and the growing of clover conserves the humus of the soil."

Winter wheat, A. M. Soule and P. O. Vanatter (*Tennessee Sta. Bul., Vol. XIV, No. 2, pp. 35–64, figs. 13*).—These experiments are in continuation of work formerly reported (E. S. R., 12, p. 1035). The best yields of grain among 45 varieties tested in 1901 were made by Blue Ridge, Kansas Mortgage Lifter, and Dawson Golden Chaff, the yields being 40, 36.66, and 36.33 bu. per acre, respectively. In the average yields for this and the preceding year, Fulcaster leads with a yield of 37.08 bu., followed by Improved Fulcaster, Poole, Improved Poole, Niger, Kansas Mortgage Lifter, and Mediterranean, yielding 36.45, 36.01, 35.97, 35.21, 35.10, and 35.05 bu. per acre, respectively. Fulcaster, Poole, Mediterranean, and Harvest King are considered as among the most satisfactory varieties tested. The best milling wheats so far grown are Fulcaster, Niger, Mediterranean, Improved Fulcaster, and Dietz Amber; while White Golden Cross, Early Genesee Giant, and Fultz were the poorest. The average yield of 13 bald varieties was 31.70 and of 26 bearded varieties 28.18 bu. per acre. Rice, Egyptian, and Mediterranean were the only varieties which equaled or surpassed the standard weight per measured bushel. Most of the foreign varieties proved unsatisfactory.

The results in seed selection with Mediterranean and Poole wheat show an average yield for the large grains of 29.4 and 27 bu. and for the small grains of 25.6 and 22.6 bu. per acre, respectively. The experiments in seed selection indicated further that the largest and choicest grains are found in the large heads, and it is concluded that they contain the largest supplies of plant food and should for this reason produce the best plants.

The results of fertilizer experiments with winter wheat after bare fallow show that the cost of the increase per bushel was 19 cts. with 250 lbs. of acid phosphate per acre in 2 applications, 26 cts. with 10 tons of barnyard manure applied in 1900 and 5 tons in 1901, and 32 cts. with an application of 50 bu. of lime in 1900; while accompanied by a crop of cowpeas plowed under, 50 bu. of lime applied in 1900 reduced the cost of increased yield per bushel to 16 cts., 250 lbs. of basic slag to 17 cts., and the same amount of Tennessee and South Carolina acid phosphates to 19 and 20 cts. Where bare fallow was followed for 2 years, the cost of the increase with these phosphates was 42, 39, and 34 cts. per bushel, respectively. The phosphates gave good results in all cases, but the applications of muriate of potash alone, of blood and bone, and of 100 bu. of lime alone were unsatisfactory. The complete ready-mixed fertilizers were unprofitable, and the complete home-mixed fertilizers were not as economical as either phosphates, lime, or barnyard manure. On impoverished soil a home-mixed application of 50 lbs. nitrate of soda, 100 lbs. acid phosphate, and 25 lbs. muriate of potash gave the best results. Cowpeas gave the best returns when pastured off on the land, and the next best when made into hay. Plowing under cowpeas on poor soil is considered as always profitable.

Wheat on thin and impoverished land suffered most from attacks of the Hessian fly. From the results obtained in sowing winter wheat on different dates "it is apparent that the date of seeding wheat determines, to a considerable degree, the amount of injury done by the fly, and it is further evident that if wheat is sown on carefully prepared land of good quality where there is an abundant supply of available food that it will stool out and in a measure make up for the original shoots destroyed by the fly. These shoots, however, will not be so vigorous, nor will they fill so well as those first thrown up."

Spelt is considered as of little utility for Tennessee.

Experiments in wheat culture, L. Foster and W. H. Fairfield (*Wyoming Sta. Bul. 48, pp. 49–69*).—This bulletin reports in tables the results of culture experiments conducted at the station, and of variety tests made at Laramie and the substations at Lander, Sheridan, and Wheatland. The culture experiments—a comparison of intertillage and field culture, begun in 1897—have not been completed, but the results so far as obtained are given. A large proportion of the varieties tested gave satisfactory results. Those recommended as among the best are Velvet Chaff, Scotch Fife, Scotch of Scotch, Saskatchewan Fife, Nox, and Pride of America. The comparison of intertillage during the growing season and of ordinary field culture seems to indicate that under existing conditions intertillage did not sufficiently increase the yield to pay for the additional labor. Results of previously reported experiments relating to wheat growing are reproduced as follows: Quantity of seed per acre (E. S. R., 10, p. 947); subsoiling *vs.* plowing (E. S. R., 11, p. 1026); wheat after alfalfa (E. S. R., 12, p. 427); and profit of wheat growing (E. S. R., 7, p. 578). Several methods of treating seed wheat for the prevention of smut are reported from other sources.

Wheat growing and general agricultural conditions in the Pacific Coast regions of the United States, E. S. Holmes, Jr. (*U. S. Dept. Agr., Division of Statistics Bul. 20, misc. ser., pp. 44, pls. 8, maps 4*).—This bulletin embraces discussions of the economical conditions of the wheat growing sections of the Pacific Coast region, a presentation of considerable statistical data with reference to the region and its wheat industry, and descriptions of the methods of wheat growing and farming generally. The monthly and annual normal mean temperature and rainfall at certain stations throughout these States are shown in tables. Owing to difference in methods of preparing the soil and harvesting the crop the region is divided into 4 sections, namely, California, Oregon, the Big Bend country of Washington, and the Palouse country in Idaho and Washington, and each of these sections is described separately. The tabulated statistical data include the total and agricultural population in 1890 and 1900; farm wages from 1866 to 1899; acreage and production of winter and spring wheat in Oregon and Washington from 1894 to 1900; acreage, production, value, and average yield of wheat per acre in California, Oregon, Washington, and Idaho; and quantity and value of wheat and wheat flour exported from this region from 1868 to 1900 inclusive.

Wheat culture in Australia (*Mitt. Deut. Landw. Gesell., 16 (1901), Sup. to No. 14, pp. 85–88*).—This article reviews the development of wheat culture in Australia, and describes the practices and methods in vogue in connection with the industry.

Experiments on wheat manures, Simons (*Agr. Jour. Cape of Good Hope, 18 (1901), No. 3, pp. 119–124*).—A report on a series of fertilizer experiments on wheat and of analyses of the soil on which the experiments were conducted.

Wheat pasture, A. B. McReynolds (*Oklahoma Sta. Rpt. 1901, pp. 150, 151*).—The value of growing wheat for pasture is briefly noted, and a table compares the analyses of 2 samples of green wheat made at the station with the analyses of several of the most common grasses obtained from other sources. Wheat pasture as a source of winter forage in Oklahoma is discussed.

The silo and silage, J. Withycombe (*Oregon Sta. Bul. 67, pp. 87–110, pls. 4*).—This bulletin discusses primarily the construction of the silo and the method of making silage. A number of analyses of silage made for the purpose of determining its acidity are given in tables. It was found that the liquid constituents of immature clover containing 79.14 per cent of moisture were lost, to a certain extent, by oozing out at the bottom of the silo. A chemical analysis of this exudate showed a protein content of 1.13 per cent. In one experiment water was added to clover silage approximately at the rate of 1 gall. per 100 lbs. of material, to determine its influence on the acidity and the protein content. The loss of dry matter and the degree of acidity were greatest in the moistened silage. It is considered that acidity and loss of dry matter, which occurs in carbohydrates and allied substances, go hand in hand. The application of water did not wash out protein compounds to any appreciable extent. The results further indicated that immaturity of the plants and extreme compactness of the silage favor the development of organic acids.

Shrinkage of farm products, C. D. Smith (*Michigan Sta. Bul. 191, pp. 159–172*).—This bulletin reports some of the observations made at the station and elsewhere on the gains or losses in the weight of stored farm products. The various experiments on this subject made at different experiment stations and the observations in this line by practical men are briefly described. The data and conclusions given in this abstract are taken from the author's summary of the bulletin. It was shown that the fluctuation in the weight of wheat under ordinary conditions does not exceed 6 per cent, but that when taken from a very dry climate to a moist region the gain may amount to 25 per cent. Oats were much less subject to fluctuations. The heaviest loss observed was 3.4 per cent in oats stored from fall until May. In one instance there was a loss of only 7 lbs. in 100 bu. The loss of weight in corn when the entire plant is stored in the silo is quite marked. Four tests showed an average loss of 8.32 per cent. In some instances the loss varied from 14.57 to 20.36 per cent. When the entire corn plant was cured in the field the variations during subsequent storing depended upon the dryness of the air. In one case 4.8 tons of cured fodder which had been cut September 1, weighed 7.5 tons on the 8th of the February following; and in another, 25.5 tons of green corn weighed 5.2 tons after curing on November 11 and 8.5 tons by February 8. Corn husked when very damp and cribbed early in October lost 30 per cent in weight by the middle of February, while dry corn cribbed October 21 lost 11 per cent by the last of January. Other cases on record show a shrinkage of less than 3 per cent by January 1. Losses of 9 and 20 per cent during an entire year are recorded for ear corn which was quite dry when put in the crib. At husking time the cob represents fully one-fourth of the total weight of the ear, but when properly stored until spring the weight of the cob decreases to less than one-fifth of the weight of the ear. The results of experiments made at Houghton Farm showed a loss of about 7.45 per cent in the weight of shelled corn from October to March, while the loss in the cobs was fully 36 per cent. Results on record show that 2 tons of fairly dry and well-stored Hungarian grass seed lost 96 lbs. in weight from November until the following July. Very dry timothy hay put in the mow from the field on June 27 lost only 7 per cent in 6 months. In other instances timothy hay lost 13.8, 15.7, and 21.7 per cent during storage. A case is reported where early and late cut timothy lost in the barn between fall and spring 29 and 21.5 per cent respectively. It is stated that clover, from the time it is mown until it is perfectly cured loses about 60 per cent in weight. Well-cured clover hay lost in one instance 9 per cent and in another only 3.6 per cent by November. In still another instance the loss amounted to 11.2 per cent between July and February. A crop of clover sown in March and cut in August had lost 22.6 per cent in weight by spring. Observations on the shrinkage of cord wood have been previously reported (E. S. R., 10, p. 195).

Grain elevators, N. A. Cobb (*Agr. Gaz. New South Wales, 12 (1901), No. 2, pp. 255–301, figs. 29, pl. 1*).—This is a comprehensive discussion of the elevator and bag systems of handling grain. Special attention is given to the American, European, and Australian elevator systems, and different appliances and apparatus are described and figured.

HORTICULTURE.

Some results obtained in crossbreeding plants, B. D. Halstead (*Proc. New Jersey State Hort. Soc., 26 (1901), pp. 144–150*).—Some results obtained in crossbreeding corn, dwarf Lima beans, tomatoes, eggplants, cucumbers, and salsify are noted. With the Lima beans the cross was made between Henderson and Burpee varieties, the idea being to combine the prolificacy of the former with the large size and good quality of the latter. The Burpee was used as the mother plant in each instance. The crossed plants were remarkably vigorous and productive. Some closely approached the Henderson and others the Burpee. It is believed that by further crossing or inbreeding, profitable new sorts may be secured. A hybrid was also obtained by crossing the ordinary cultivated salsify, having violet-purple flowers, with the wild species, having yellow flowers, which promises to be more resistant to blight and mold than the ordinary salsify.

Composition of artichokes, C. H. Jones and B. O. White (*Vermont Sta. Rpt. 1900, pp. 382–386*).—Improved French white artichokes, a variety of *Helianthus* *tuberosus*, was grown at the station, and the tops and roots analyzed with reference to food and fertilizing constituents, on 20 different dates between August 4 and November 17. These data are tabulated in detail. The average composition of the mature tubers was as follows: Water 79.59 per cent, dry matter 20.41 per cent, crude ash 7.38 per cent, protein 10.41 per cent, crude fiber 3.62 per cent, nitrogen-free extract 78.19 per cent, ether extract 0.4 per cent, phosphoric acid 0.683 per cent, and potash 2.644 per cent. The variations in composition which both the tops and roots undergo at different stages of growth, are discussed in some detail. In summing up the data the author states that the dry matter in artichokes is about the same as in potatoes, protein and nitrogen-free extract being lower, and ash, crude fiber and ether extract higher. The main constituent of the nitrogen-free extract of artichokes is inulin.

Composition of different varieties of cucumbers at different stages of growth, HEINZE (*Landw. Versuchsw. u. Thät. Landw. Vers. Stat. Preussens, 1898, pp. 249, 250*).—Bismarck, Oppelner Lokal, and Cebulla varieties of cucumbers were analyzed when a little more than a finger long, at a little older stage when ready for pickling, and when the cucumbers were ripe for seed. The following average figures were obtained:

Composition of cucumbers.

	About 1 finger long.	Older pickling cucumbers.	Ripe seed cucumbers.
	Per cent.	*Per cent.*	*Per cent.*
Water content	96.63–96.75	95.40–96.04	95.12–95.23
Dry matter	3.25– 3.37	3.96– 4.60	4.77– 4.88
Total sugar	.05– .13	.16– 1.12	.66– .69
Grape sugar		.11– .98	.55– .57
Cane sugar	.05– .13	.03– .14	.11– .12
Nitrogen-free extract	.69– .98	.56– .94	.69– .71
Fat	.08– .10	.08– .10	.22– .27
Fiber	.55– .64	.58– .68	.72– .76
Ash	.32– .34	.38– .53	.40– .43

The classification of American muskmelons, F. W. RANE (*New Hampshire Sta. Tech. Bul. 2, pp. 83–114, figs. 12*).—For the past 8 years the author has been studying the characters and general behavior of muskmelons. As a result of this work he presents an original scheme of classification based simply on the fruits. All muskmelons are grouped into 8 types, according to the size and shape of the fruit. Each type is named after the most widely known and characteristic variety within the type. Beginning with the smaller melons, the types are designated as follows: (1) Jenny Lind, (2) Rockyford, (3) Hackensack, (4) Montreal, (5) Cosmopolitan, (6) Acme-Osage, (7) Long Yellow, and (8) Bay View. After the type is distinguished, the varieties within it are subclassified as to whether shallow ribbed, deep ribbed, or not ribbed; whether netted or not netted; and whether the color of the flesh is green or salmon. With regard to color, whenever the melons had any yellowish tinge whatever they were classified as salmon fleshed, and all other varieties as green-fleshed melons. Illustrations are given of different type melons, including in all 91 varieties. The characteristics of the different types as given by the author may be briefly noted as follows:

(1) *Jenny Lind type.*—Small size (1 to 2 lbs.), flattened at ends and usually larger in diameter than in depth; mostly shallow ribbed, netted, and green fleshed, except Emerald Gem (tending to be smooth and salmon fleshed) and Christiana (salmon fleshed). Varieties included: Captain, No. 88 J. & S., Jersey Belle, Newport, Earliest Ripe, Jenny Lind, Shipper's Delight, and True Jenny Lind.

(2) *Rockyford type.*—Melons of this type closely resemble those of the Jenny Lind type, but all the fruits are oval in shape, 1 to 2 lbs., netted, shallow ribbed, green fleshed, except Paul Rose. This type of melons usually averages 10 or more matured

fruits to the hill when well grown, and is well adapted to either local markets or for shipment. "If anything this type is preferred to that of the Jenny Lind on account of its standing shipment better. The oval shape withstands pressure and handling perhaps better than the more flattened." Varieties included: Golden Gem, Rose Gem, Pineapple, Golden Netted Gem, Bird Cantaloupe, Netted Gem, Oval Netted Gem, Round Netted Gem, Rockyford, Strawberry, and Paul Rose.

(3) *Hackensack type.*—Fruits similar in appearance to the Jenny Lind type, but larger, 3 to 6 lbs., flattened at the ends, usually as broad as deep, or broader. The shallow and deep ribbed, netted and smooth, and yellow and green fleshed varieties are about equally divided in this group. The fruits average less per hill than the smaller varieties, but their increased size balances the weight in yield. Varieties included: Ironclad, Early Nutmeg, Chicago Nutmeg, Missouri, Improved Jenny, Six Oaks Cantaloupe, Satisfaction, Shumway Giant, Irondequoit, Ivy Gem, Kinsman Queen, Hackensack, Market, Long Island Beauty, Extra Early Hackensack, Arlington Nutmeg, Nutmeg, Carmes, Surprise, and Perfection.

(4) *Montreal type.*—Medium size, oval, smooth or nearly so, netted, 3 to 6 lbs. Correspond in appearance to Rockyford type. About equally divided between green and salmon fleshed varieties. Varieties included: Green Fleshed Osage, Montreal Nutmeg, New White Japan, Skillman Fine Netted, Ward Nectar, Giant Chicago Market, Miller Cream Nutmeg, Tip-top, Citron, McCotter Pride, Golden Eagle, and Nectar of Angels.

(5) *Cosmopolitan type.*—Medium size, 3 to 6 lbs., oval, netted, strongly ribbed. About equally divided between green and salmon color of flesh. Varieties included: Cannon Ball, Cosmopolitan, Netted Beauty, Columbus, Superior, Perfected Delmonico, Banquet, Blenheim Orange, Conqueror of Europe, and Buckbee No. 555.

(6) *Acme-Osage type.*—Oblong, medium size, 3 to 6 lbs., mostly shallow ribbed. The Osage, which is a dark melon with salmon flesh, and the Acme, a light skinned, green fleshed variety, are used to designate the varying characters of the fruits of this type. Varieties included: Extra Early Cantaloupe, Champion Market, Casaba, Netted Nutmeg, Anne Arundel, Atlantic City, Acme, Southern Beauty, Princess, Extra Early Grand Rapids, Osage, Delmonico, Queen of All, Honey Drop, Triumph, Lone Star, and New Hybrid.

(7) *Long Yellow type.*—Fruit over 6 lbs., 2 to 3 times as long as broad, includes both netted and ribbed sorts. Varieties included: Banana, Cassabah, Granite State, Long Yellow, and Improved Cantaloupe.

(8) *Bay View type.*—Fruit over 6 lbs., oval to oblong. Varieties included: Bay View, Large Black Paris, Montreal Market, and Large White French.

A wall supplement illustrating the different groups of melons accompanies the bulletins.

Melons under glass, F. Brunton (*Amer. Gard., 22 (1901), No. 343, pp. 505, 506, fig. 1*).—Cultural directions are given for the growing of muskmelons under glass, with suggestions as to suitable varieties.

The cultivation of onions at Antigua, W. N. Sands (*West Indian Bul., 2 (1901), No. 2, pp. 163–166*).—The adaptability of this industry to the island is pointed out. The varieties found to give the best returns are the Red and White Bermuda kinds. The principal method now adopted of growing the onions is to transplant them in land banked for cane, the young canes being planted in the furrows during the time the onions are growing.

Rates of charge for transporting garden truck, with notes on the growth of the industry, E. G. Ward, Jr., and E. S. Holmes, Jr. (*U. S. Dept. Agr., Division of Statistics Bul. 21, misc. ser., pp. 86*).—This report discusses briefly the origin and progress of the garden-truck industry in this country, and the development and present status of the trucking industry in each of the different centers of truck gardening in the country, information being given in each case in regard to the cost of production of different crops and cost of transportation to the different markets, the transportation of fruits and vegetables from southern truck farms to northern markets, the California fruit industry, and the movement of California fruits to interior points and Atlantic seaboard cities. The report also contains a schedule of freight rates and refrigerator charges on perishable products in all important sections of the country.

Report of manager [Missouri Fruit Experiment Station], J. T. STINSON (*Missouri Fruit Sta. Rpt. 1900, pp. 8–15*).—During the first year's operation of this station about 40 acres of land were brought under cultivation, 20 of which were planted in test orchards. Experiments in crossing strawberries have been undertaken, and some spraying experiments on a commercial scale for the control of apple scab and bitter rot carried out in a neighboring orchard. Eighty varieties of apples, 108 peaches, 41 grapes, and 36 strawberries were set out. Apple scab on the varieties Ben Davis and Huntsman was almost entirely prevented by spraying with Bordeaux mixture. Bitter rot was more difficult to control with Bordeaux mixture. In one experiment on Ben Davis sprayed 5 times, 60 per cent of the fruit was free from bitter rot, while on control trees only 1¼ per cent was free from it. In another part of the orchard 78 per cent of the fruit sprayed 4 times was free from rot, while on unsprayed trees all but 14 per cent was affected. The variety Huntsman, which was sprayed 3 times during the season, "gave 83 per cent free from bitter rot and 92 per cent free from apple scab, while on the unsprayed trees but 48 per cent was free from bitter rot and 69 per cent free from apple scab."

Orchard notes, F. GARCIA (*New Mexico Sta. Bul. 39, pp. 99–130, pls. 4*).—Results of observations and experiments are here given on the growth at the station and elsewhere in New Mexico of apricots, cherries, plums, quinces, and figs. The cultural data given include the results of thinning experiments with plums, and experiments in severely pruning back old peach trees that had become bare of fruiting wood at the base and had grown so tall that it was difficult to pick the fruit. The varieties of fruits grown are described, and data as to the blooming and ripening period and comparative yields given. The summarized information on the growth of the fruits in different parts of the Territory obtained by correspondence is also incorporated. The data obtained go to show that "the apricot is of no commercial importance in New Mexico, because it blooms too early to escape the late spring frosts, though the trees are perfectly adapted to the climate."

Of the cherries grown in New Mexico, the sour varieties predominate and seem better adapted to the dry, sunny climate of the Territory than sweet varieties. At the station the sweet varieties blossom late enough in most cases to escape frost injury, but as a rule set little or no fruit. The northern part of the Territory seems best adapted to cherry growing. "In the station orchard, Esel Kirsche (a sweet variety), Early Richmond, Ostheim, and an unknown sour cherry have given the best results."

Both European and native plums succeed at the station and throughout the Territory. The European varieties bloom latest and for the most part are sure bearers. The Damson is the most widely distributed plum in the Territory. Japanese plums have proved almost worthless in New Mexico for commercial purposes, owing to their early blooming habit and the consequent killing of the blossoms by late spring frosts. These varieties may be planted in private orchards where the owner is satisfied with a crop once in 5 or 6 years. The data given in regard to thinning plums show that the percentage of marketable plums is considerably increased by thinning and that the percentage is higher when thinned to 6 in. apart than when thinned to only 3 in. apart.

In cutting back old peach trees, 3 methods of pruning were used: In the first case branches 5 and 6 years old were cut back to stubs 4 to 5 ft. high; in the second, only wood 3 to 4 years old was taken off; and in the third, only 2-year-old wood was removed. "The new shoots on all the trees made a vigorous growth during the season, and on the more closely pruned trees the bearing wood was considerably nearer the ground. The following season, 1900, there were plenty of fruit buds on the new wood, and the fruit was larger and in every respect nicer on the pruned trees than on the unpruned trees of the same variety. No material difference was observed in the fruit of the differently pruned trees, except that in some cases the less severely pruned trees had more fruit, seemingly due to the larger amount of bearing wood. By the end of the second season most of the trees had made a low, dense, and vigorous growth. . . . This experiment shows that the peach tree will stand very severe pruning, and where the tree has been allowed to grow without being 'headed in' this method of pruning may prove very beneficial, and comparatively old trees can be renewed. Such pruning, to produce the best results, should not be put off until the tree is on the rapid decline."

Quinces grow well in the Territory and do best on a light soil. Figs are too tender for successful culture in the climite of the Territory.

The orchard, O. M. Morris (*Oklahoma Sta. Rpt. 1901, pp. 129–146*).—Complete directions for the location, planting, and care of orchards in Oklahoma, including methods of cultivation, pruning, and spraying the trees. Lists are also given of the different varieties of orchard fruits which are most likely to succeed in the Territory.

Fertilizing orchard fruits, Rudorf (*Fühling's Landw. Ztg., 50 (1901), Nos. 4, pp. 169, 170; 5, pp. 194–198; 6, pp. 232–235; 7, pp. 253–259; 8, pp. 288–292*).—The elements required in the fertilization of orchard fruits on different soils and the principles and methods of their application are set forth in this paper.

Variety tests of fruits, O. M. Morris (*Oklahoma Sta. Rpt. 1901, pp. 147, 148*).—A list is given of the varieties of apples, pears, cherries, plums, apricots, and peaches which set fruit at the station in 1901.

Origin and development of the apple blossom, E. S. Goff (*Amer. Gard., 22 (1901), Nos. 332, p. 330; 333, pp. 346, 347*).—The author states that "there is abundant evidence that leaf buds and flower buds are not structurally distinct. Every bud on the apple tree is formed as a leaf bud; and it is also true that every bud on the apple tree has power to become a flower bud." Leaf and flower buds are, in a measure, interchangeable. By proper pruning a flower bud may be converted into a leaf bud, and by ringing a leaf bud may become a flower bud. Flower buds may be 1, 2, or many years old before they form flowers. Factors which tend to the formation of flower buds are any restriction to the movement of prepared food in the branches, such as is caused by ringing or a wrinkling of the bark formed by the union of the fruit spur with the branch which supports it. Dry weather is also conducive to the formation of flower buds, since during such periods evaporation through the leaves is rapid and the sap becomes concentrated and rich in prepared food. Flower buds are then formed in portions of the tree where there may be no restrictions to the movement of the sap, as at the end of young shoots, etc. Whenever the water supply is increased the tendency is to wood growth and the formation of leaf buds. A decrease in water supply tends to make flower buds. A normal growth is accompanied by a normal formation of flowers. When the fruit spurs of healthy trees push into growth or sap sprouts start freely from the old wood, growth is abnormal and fruit production is postponed.

The author's investigations show that as active wood and leaf growth ceases the formation of flower buds begins and may continue until cold weather sets in. Contrary to the writings of some horticulturists, the same fruit spur has been found to fruit annually in some instances, instead of biennially. During very favorable seasons for the formation of flowers all the 1-year, 2-year, and 3-year-old buds, many older buds, and some buds formed during the year, may form embryo flowers. This explains why an excessive fruit crop is always followed by a scanty one.

On the whole, the production of flower buds on the apple tree is largely controlled by climatic conditions, but a number of other factors also enter in, over which the orchardist has control. The temperature may be modified by planting on north or northeast slopes. Early plowing prepares the ground for absorbing the spring rains, and this moisture may be preserved for the use of the tree by fine level surface cultivation. A good supply of moisture will favor the growth of healthy leaves and buds which are essential. If rains are too abundant the ground may be left rough to hasten evaporation. Since early leaf and wood growth is desirable, manures should be applied early in the season. Cover crops should be relied upon for furnishing sufficient nitrogen to the soil, while wood ashes will furnish the potash and phosphoric acid required. Where cover crops are not grown, well-rotted barnyard manure applied early in the spring may be used.

Wood growth should come to an end about July 1 in the climate of Wisconsin in order to give flower buds an opportunity to develop. A comparatively warm and dry fall is most favorable. Should growth continue much after this date it may be checked by a moderate root pruning. "If the trees are large plow a 'middle furrow' midway between the rows in both directions and follow with the subsoil plow. A slight root pruning at this season will generally start the formation of flower buds if they are backward." The plowing should be followed by a cover crop to evaporate any excess moisture in the soil. The cover crop will also serve the purpose of keeping the ground cool and of forming a winter protection. On poor soils leguminous cover crops only should be used.

Changes in the chemical composition of apples by storing, R. Otto (*Gartenflora, 50 (1901), No. 12, pp. 318–321*).—Changes during storage in the specific gravity and the acid, sugar, starch, and extract content of 8 varieties of apples were investigated. Some of the apples were in cellar storage nearly 3 months. They were analyzed on being put into the cellar and again when taken out. The data secured are tabulated and are summarized by the author as follows: With 6 of the varieties there was a constant and considerable increase in the specific gravity of the apples and in the acid, sugar, and extract content following storage. With the 2 other varieties there was a decrease in the starch and acid content and a slight increase in the specific gravity and the sugar and extract content. On the average the decrease in acid content was about 0.25 per cent and in the sugar content 1.7 per cent. The increase in sugar content with the 2 varieties was scarcely 0.1 per cent.

Cold or cool storage, Kemp (*Garden, 59 (1901), No. 1533, pp. 329–331*).—This refers particularly to the storage of apples in England.

Further contribution to the chemical composition of different varieties of apples at the Government Pomological Institute at Proskau, R. Otto (*Gartenflora, 50 (1901), No. 10, pp. 259–263*).—A table is given showing the chemical composition with reference to sugar, acid, starch, specific gravity, etc., of 26 varieties of apples.

Pollination of apples, F. A. Waugh (*Vermont Sta. Rpt. 1900, pp. 362–366*).—The self-fertility or sterility of apple blossoms to their own pollen was investigated. Thin paper bags were tied over clusters of blossoms during the blossoming season. From 10 to 30 blossoms were covered by each sack. They were thus protected from the visits of insects and all foreign pollen. After the blossoming season the bags were removed and the clusters examined. A record is given of the fruit set, of the clusters which failed to set fruit, and of the crops set on the tree by the uncovered blossoms. The record includes the data obtained with 18 varieties. It shows that only 3 apples set out of 2,586 blossoms covered. These were of the Baldwin, Esopus, and Fameuse varieties. The practical conclusion is reached that "large blocks of apples of a single variety should never be planted, no matter what the variety may be. Mix 2 or more varieties together in alternating rows."

Other considerations are that the varieties which stand next to each other in the apple orchard should blossom at the same time and that "in planting trees to secure cross-pollination, the habits of the bees are to be chiefly considered, and not the prevailing winds. Not more than 3 rows of any one variety should be planted together—better only one or two—with which some other variety or varieties should alternate."

Growing prize peaches (*Agr. Gaz. New South Wales, 12 (1901), No. 4, pp. 527–529*).—The method followed by Mr. Charles Wright, of Delaware, in growing peaches is outlined. Peaches sent by Mr. Wright to the Paris Exposition secured second prize in competition with European house-grown peaches. Mr. Wright selects buds from trees with fruit on them, using the healthiest specimens. The land is prepared as for wheat. The trees are set in the fall 22 ft. apart each way. In the spring they are pruned to a whip about 20 in. high, with 4 or 5 limbs left for a top. Clean cultivation is practiced until August 15, some hoed crop, like tomatoes, potatoes, or corn, being grown between the rows. The orchard is planted on well-drained, rather stiff land.

The peaches shipped to Paris first were picked green, wrapped in tissue paper, then in heavier paper, and packed in a 6-basket carrier. In the next shipment the peaches were first wrapped in tissue paper, then in cotton, and finally in blotting paper. They were packed and shipped in 6-basket carriers, as before, and arrived in Paris in considerably better condition than the first shipment. The first shipment occurred on August 8, and consisted of Bishop Early, Gen. Taylor, Powell Mammoth, Lady Ingold, Foster, and Carman varieties. The second shipment occurred September 12, and was made up of Reeve Smock, Garey Hold On, White Heath, Dr. Corsa Heath, Prize, Townsend, Jowell Late, Newington Free, Walker Variegated, Cowper Late, and McCollister. None of the peaches shipped were considered really first-class varieties.

Peach-tree culture, C. M. Harrison (*Proc. New Jersey State Hort. Soc., 26 (1901), pp. 167–177, pl. 1*).—A popular article on this subject, including notes on the history of peach culture in New Jersey and on renovating old trees.

Plum culture, Skillman (*Proc. New Jersey State Hort. Soc., 26 (1901), pp. 150–157*).—The selection of varieties and the culture of plums are discussed. The author tested the Stringfellow method of root pruning plums, and out of 1,000 trees thus root pruned and planted, 800 died and the remainder are making so poor a growth that they will have to be dug up. Barnyard manure has been found a very satisfactory fertilizer for plums in the author's experience. Japanese plums should be picked as soon as they begin to color.

Propagation of plums—preliminary report, F. A. Waugh (*Vermont Sta. Rpt. 1900, pp. 333–354, figs. 13*).—A brief summary is given of our present knowledge of plum stocks and their combinations with different kinds of scions. In all, 15 kinds of stocks have been used. On these the numerous varieties of 15 distinct groups of plums have been propagated.

In the author's experiments 5 varieties of plums, viz, Stoddard of the Americana group, Green Gage of the Domestica group, Chabot of the Japanese group, Milton of the Wildgoose group, and Newman of the Chicasaw group, were propagated on each of the following stocks: Americana, Wayland type, Marianna, and Peach. Each variety was propagated on each of the different stocks, thus making 20 lots in the experiment; and each lot was made up of 30 grafts. The whip-grafting method was employed. Scions were made about 5 in. long and the piece root-stocks 4 to 5 in. long. The grafts were made in winter, packed in sawdust, and set out, at Denton, Md., in nursery rows in the spring. The growth made by each variety on the different stocks is illustrated and discussed in detail.

"Stoddard gave the largest average number of trees in each lot; Chabot gave the greatest average height, considering either extremes or averages; while Newman gave the largest average number and percentage of merchantable trees. Green Gage gave the lowest average in every column. These figures indicate that Green Gage is comparatively very difficult to propagate; whereas Newman and Chabot are comparatively easy."

In the comparison of stocks, Americana gave the largest average total of trees in each lot, the tallest trees, and considerably the largest number of merchantable trees. This is considered the most striking feature brought out by the experiment. Heretofore Americana stocks have come into use only in the Northwest, and there because they are believed to be extremely hardy. Marianna gave much the smallest number of either total or merchantable trees. Going behind the averages in the tables, the author summarizes as follows:

"Stoddard—an Americana—did better on Americana roots than on any other, though the Wayland stocks gave equal results as regards number of merchantable trees and a greater average size. Green Gage seems to have done best on Wayland stocks, and to have been a failure on Marianna—a stock on which it is often propagated commercially. Chabot gave by far the best result on Americana roots, though it has generally been supposed that Marianna and Peach stocks were specially congenial to the Japanese plums. Milton made the best showing on Wayland stocks, while it was practically a failure on Peach. This last point was very striking, and came much in the nature of a surprise. Peach stocks have been supposed to be suitable for all the plums of the Wildgoose type. Newman did best on Peach, which is according to current opinion; but it gave second best results on Americana, which is not in agreement with the nursery notions commonly held. It was poorest of all on Marianna roots, though Marianna has often been specially recommended for propagating all the Chicasaws. We therefore arrive at this important notion: That a given variety does not do equally well on all stocks, and, *vice versa*, that a given stock is not equally adapted to all varieties."

Three of the best trees from each lot in these experiments were selected and planted out in permanent form at the Vermont Station. Stoddard did best in every respect on Americana roots, Green Gage on Wayland, Chabot on Marianna and Wayland. Milton made a splendid growth on all stocks but Peach, and every tree on Peach roots died. Newman did best on Wayland roots and second best on Americana roots. For the whole lot of trees, the general statement is made that every lot on Peach was inferior to the same variety on any other stock whatever.

Further work in plum pollination, F. A. WAUGH (*Vermont Sta. Rpt. 1900, pp. 355–362, figs. 3*).—In continuing this work (E. S. R., 12, p. 238), the results secured in microscopic examinations and germination tests of the pollen of 44 varieties of plums are recorded and discussed. The germination tests of the pollen were made in sugar solutions varying in strength from 3 to 20 per cent. There seemed to be little difference in pollen germination following the variations in strength of the different solutions, but on the whole the 5 per cent solutions gave the most uniform results. The quantity of pollen produced and its germinating power were found to vary greatly with the different varieties, as did also the size and plumpness of the pollen grains. Pollen grains which to the eye presented a normal appearance were sometimes lacking in protoplasmic contents. These irregularities appeared to be unusually frequent with varieties of hybrid origin. No cause for the fluctuations of the pollen grains in quantity, size, or viability could be assigned. It was concluded that the germination of plum pollen is not readily influenced by ordinary external conditions. The author summarizes briefly as follows:

"From the standpoint of the practical plum planter, there seems to be only one conclusion of consequence to be drawn from the study of pollen and pollen production; namely, that certain hybrid varieties, notably Wickson and Excelsior, probably also Gonzales and others, cannot be relied on for the pollination of other varieties, even though other conditions of simultaneous blossoming, etc., be fully met."

Some drawings and notes are given on certain curious malformations occurring in plum blossoms.

A further study was made of the agency of the wind in distributing plum pollen. Glass slips, such as are used with microscopes, were labeled at one end and the remainder painted with a mixture of vaseline and lampblack. These slips were then exposed for 2 to 24 hours in various parts of the plum orchard at the height of the pollinating season and under the most favorable conditions of wind and weather. The vaseline caught whatever pollen was carried against the slips while it was the purpose of the lampblack in the mixture to make the grains more visible. These slips were afterwards examined for pollen grains. A few grains were found on some of the slips but the amount of pollen transported even the short distance the trees were apart (10 ft.), and in direct line with the wind, was considered far too small for effective pollination. The conclusion is again reached that these fruits are pollinated chiefly, if not exclusively, by insects, and that the wind plays an inconsequential part in this work.

The myrobalan plums, F. A. WAUGH (*Vermont Sta. Rpt. 1900, pp. 366–370*).—This is a short monograph with historical notes on these plums. Their present status is given and 9 varieties described.

Summer pruning of wall plums, A. PETTS (*Garden, 59 (1901), No. 1538, pp. 332, 333*).—Details of methods of pruning wall plums throughout the summer.

Pomelos, H. H. HUME (*Florida Sta. Bul. 58, pp. 385–421, pls. 7, figs. 4*).—Notes are given on the botany and history of the pomelo.

Shaddock and grape fruit are given as synonyms of pomelo. The term pomelo is preferred to grape fruit. The term shaddock, while referring to a fruit botanically the same as pomelo, is stated by the author to be horticulturally distinct from it, this name being applied more especially to the large pyriform or necked varieties of pomelos. It is only within the past 15 years or so that the pomelo has come into commercial importance in Florida. With regard to its culture, the author states that trees in Florida bear heavily, are no harder to propagate and care for than orange trees, and come into bearing early. The following varieties, which include all those listed by nurserymen, are described, and notes given on their origin: Aurantium, Duncan, Excelsior, Hall, Marsh, Pernambuco, Tresca, Triumph, Royal, and Walters.

The weight, size, and proportion of pulp, rind, and seeds are given for 10 ripe fruits of each of 6 varieties, together with analyses of the separate parts of the fruit. The following table summarizes the physical analysis:

Physical analysis of pomelos.

Variety.	Average weight.		Average diameter.	Average number seeds.	Pulp.	Rind.	Seeds.
	Grams.	*Ounces.*	*Inches.*		*Per cent.*	*Per cent.*	*Per cent.*
Royal	541.48	19.1	3.20	46.4	69.32	27.23	3.45
Pernambuco	742.77	26.2	3.75	61.0	68.52	28.05	3.43
Manville	487.62	17.2	3.10	67.2	74.72	20.93	4.35
Aurantium	430.92	15.2	3.00	37.3	68.60	28.29	3.11
Walters	721.34	25.4	3.75	56.0	68.64	28.22	3.14
Triumph	534.60	18.8	3.15	43.3	65.16	31.82	3.02

The average weight of the different varieties, it will be noted, varied from 15.2 to 26.2 oz., and the diameter from 3 to 3.75 in. The percentage of pulp ranged from 65.16 to 74.72, of rind from 20.93 to 31.82, and of seeds from 3.02 to 4.35. The trees producing the fruits were not of the same age and had not been given the same treatment, therefore the relative amounts of pulp and rind in the different varieties are not entirely comparable.

The percentages of phosphoric acid, potash, and nitrogen were greater in the seeds in every instance than in the pulp or rind. The percentage of phosphoric acid in almost every instance was higher in the pulp than in the rind, and the potash was invariably higher in the rind. Except in one variety, the nitrogen was higher in the rind than in the pulp. The fertilizing constituents in the whole fruit was as follows:

Fertilizing constituents in pomelos.

Variety.	Phosphoric acid.	Potash.	Nitrogen.
	Per cent.	*Per cent.*	*Per cent.*
Royal	0.040	0.250	0.119
Pernambuco	.056	.213	.111
Manville	.054	.251	.102
Aurantium	.053	.239	.085
Walters	.049	.233	.129
Triumph	.050	.237	.117
Average	.050	.237	.110

On the basis of this table it is estimated that the fertilizing constituents removed in 10 boxes of pomelos, each containing 80 lbs., would be as follows: Phosphoric acid, 0.4 lb.; potash, 1.9 lbs.; nitrogen, 0.88 lb., which would be replaced by an application of 2.85 lbs. of acid phosphate, 3.8 lbs. of high grade sulphate of potash, and 5.86 lbs. of nitrate of soda. Commercial fertilizers are believed by the author to be more satisfactory for fertilizing pomelo trees than barnyard manures. "Where large amounts of organic fertilizers are used, 'dieback' will almost surely affect the trees, and ammoniated fruit or fruit containing a large amount of 'rag' and of poor shipping and keeping quality is the result." In fertilizing pomelos, the author considers it advisable to make at least 2 applications, one just before or at the time of the commencement of growth, and the other in summer, about the month of July. In some portions of the State, where the roots of citrus trees continue to grow during the winter, it is thought advisable to make a third application in the fall.

"If nitrate of soda be used as a source of nitrogen it is best to apply it in 3 separate dressings, in March, May, and July, and the phosphatic and potash fertilizers twice, as recommended above."

A new banana in the Kongo Free State (*Queensland Agr. Jour., 8 (1901), No. 5, pp. 367, 368*).—A botanical description is given of a new banana in the Lower Kongo. It has been given the specific name of *Musa gilletii*. The plant grows from 1½ to 2 meters high, is not stoloniferous, and completes its cycle of growth in 3 years. During the first year it remains low and forms only a few leaves, the second year it makes its height growth, and the third it produces fruit. The leaves are 40 to 50 cm. long, the flower spike about 40 cm. long. The plant is believed to belong to the group of *M. enseta*. Its seeds approach in size those of *M. livingstonia* and *M. proboscidea*, and like the first of these are rough; but the new banana is much lower in height than *M. proboscidea*, and in other ways widely distinct from it.

Coffee culture; influence of different manures, M. KOCH (*Rev. Cult. Coloniales, 8 (1901), No. 77, pp. 294-296*).—A review of some Brazilian fertilizer experiments with coffee, which seem to show that nitrogen is of value only when it is applied in quantities proportional to the phosphoric acid and potash in the soil. A complete fertilizer produced larger berries and grains than potash manures. Nitrogenous manures, on the contrary, diminished the size of the berries and grains.

The cultivation of cocoa in the West India Islands (*Sci. Amer., 84 (1901), No. 23, p. 360, figs. 2*).—A popular account of present methods of growing and harvesting cocoa beans, with remarks on the possibilities in the industry for investment.

Trenching and subsoiling for American vines, R. DUBOIS and W. P. WILKINSON (*Victoria Dept. Agr., Vit. Sta. Rutherglen, 1901, pp. 171, figs. 110*).—The necessity for subsoiling or deep trenching in the reconstruction of European, Californian, and

Victorian vineyards on American vines is pointed out, and the use of various mechanical appliances for this purpose noted. The work is compiled and translated from various sources for the benefit of Victorian vineyardists. Chapters are given on the use of horsegins, steam winding drums, and portable wind motors as applied to trenching and subsoiling, and these implements are described and illustrated.

Observations on some new direct producers, GRANDCLEMENT (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 17, pp. 516–525*).—The value of a number of new hybrid vines as direct producers, and their characteristics as regards resistance to Phylloxera, fungus diseases, etc., are noted.

Artificial pollination of grapes, P. PACOTTET (*Rev. Vit., 15 (1901), No. 391, pp. 658–660*).—For collecting and distributing pollen in the greenhouse culture of some varieties of grapes the following method is outlined: A smooth paper is spread in the warm sunny part of the day under a variety which produces a large amount of pollen, and the vines shaken. Pollen mixed with débris falls on the paper. The pollen is then separated out by sifting through a silk sieve. The pollen thus obtained may be preserved dry for several months. It is applied to flowers which require artificial pollination 2 or 3 days in succession, or until all the flowers on the bunch are opened, by means of a small specially arranged bellows.

Preserving grapes in bottles (*Queensland Agr. Jour., 8 (1901), No. 5, pp. 365, 366, fig. 1*).—The method here outlined is to take the bunches when perfectly ripe, allowing 3 to 6 in. of stem to each shoot below the bunch; remove all diseased berries, and put the shoot in a bottle of water, set or hung at such an angle that the berries will not touch the bottle. The storing room should be dry and have a constant temperature of 40 to 45° F. Darkness, while not essential, is considered very desirable. If the grapes are to be kept long a teaspoonful of not too finely powdered charcoal in each bottle will be advantageous. The bunches should be examined every week and all decaying berries removed. About the second or third day after the bunches are put in the bottles it will be found necessary to refill the bottles with water, since the shoots will have absorbed a considerable amount. No further refilling will be required. It is claimed that grapes have been thus preserved fresh for exhibition purposes for 8 months.

Top-working pecans, H. H. HUME (*Florida Sta. Bul. 57, pp. 360–373, pls. 3, figs. 7*).—The author suggests top-working as the most satisfactory means of improving the many pecan groves now in Florida, which produce small and inferior nuts. Directions for top-working pecan trees are given, accompanied by illustrations of methods of work, and of the appearance of successfully top-worked trees. The practice of taking scions or buds from young trees which have never borne fruit is strongly condemned. These should be secured only from thrifty, vigorous, and prolific bearing trees. Grafts should be selected from well-matured 1-year-old stock while it is in a dormant condition. They are usually cut 5 to 6 in. long, with a thickness of $\frac{1}{4}$ to $\frac{3}{8}$ in. From the middle of February until the middle of March is considered the best time for grafting pecans in northern and western Florida. If the trees are small, grafts may be made on the trunk of the tree; if of medium size, on the main branches a little way from the trunk; and if large, on the main branches still further up from the trunk. Only a few branches should be worked each year, as any sudden shock to the tree, such as the removal of all its branches, is liable to kill it. Whip grafting is suitable for limbs less than an inch in diameter, but for the larger branches cleft grafting, or a modification called cleft-sap grafting, may be employed. By the latter method the cleft for the insertion of the scion is made on one side of the center. It is preferred for working very large stocks. The author deems it inadvisable to graft stocks over $2\frac{1}{2}$ in. in diameter, since an exposure of so large a surface of wood is apt to form a starting place for rot and decay.

August and September is considered the most suitable time for budding the pecan in the Gulf States, and a modification of the annular method of budding known as Veneer shield-budding is thought preferable. The new grafts in top-worked trees grow rapidly and should, therefore, be supported until they become firmly attached. The top-worked trees begin to bear when the tops are about 2 years old.

The same methods used in top grafting trees may be employed in nursery work, though tongue grafting is usually employed. In the nursery the "scions are inserted just at the small fibrous roots and the earth heaped up so as to leave only one bud exposed. Buds may be inserted anywhere from 5 to 6 in. to 3 ft. above the crown."

The evolution of American floriculture (*Amer. Florist, 17 (1901), No. 687, pp. 1–3; Gardening, 9 (1901), No. 214, pp. 346–349*).—An account of the historical development of floriculture in this country.

Carolina bulbs, W. T. MASSEY (*Gardening, 9 (1901), No. 212, pp. 314, 315*).—The results secured by the author in growing various bulbs in North Carolina are noted.

Progress in cultivation of carnations and varieties, F. C. GOBLE (*Proc. New Jersey State Hort. Soc., 26 (1901), pp. 185–190*).—Improvements in houses for carnations and methods of carnation culture are noted, with mention of some of the more prominent varieties of carnations.

Cyclamen for seed, P. KOPANKA (*Florists' Exchange, 13 (1901), No. 21, p. 570*).—A general article covering the details of the subject.

Culture of Persian cyclamens (*Garden, 59 (1901), No. 1540, pp. 375–377*).—The various cultural operations from sowing the seed to potting and housing the plants, and the second year's treatment of the same are discussed.

California lilies and their habitats, J. P. DAVY (*Gard. Chron., 3. ser., 30 (1901), No. 760, pp. 46–48*).—This article deals with the habitats and descriptions of California native lilies.

Existence of Lilium auratum in Japan as a species, A. UNGER (*Gard. Chron., 3. ser., 29 (1901), No. 752, p. 327*).—The author believes that *L. auratum* is a native Japan species and not of hybrid origin as supposed by some.

The origin of Lilium auratum (*Amer. Gard., 22 (1901), No. 336, p. 392; Rev. Hort., 73 (1901), No. 10, p. 246*).—Some theories as to the probable origin of *L. auratum* are advanced.

The peony and its cultivation, W. A. PETERSON (*Amer. Gard., 22 (1901), No. 339, pp. 441, 442*).—The outdoor culture and forcing of peonies and their place in the border are discussed.

Growing Primula sinensis for exhibition, J. HOBSON (*Amer. Gard., 22 (1901), No. 336, p. 397, fig. 1*).—The author outlines his plans for growing Chinese primrose.

Classification of hardy primulas from the cultural point of view, H. CORREVON (*Rev. Hort., 73 (1901), No. 10, pp. 242–245*).

Culture of Perle des Jardins rose, J. F. AMMANN (*Amer. Florist, 16 (1901), No. 680, pp. 1611, 1612*).—Paper on this subject read before the St. Louis Florists' Club.

Rose stocks for grafting, H. A. SIEBRECHT (*Gardening, 9 (1901), No. 212, p. 314*).—On account of the rapid and strong growth of roses on Manetti stock, this stock is considered the most practical for forcing where the plants are wanted for only one season. For budding or grafting roses outdoors *Rosa multiflora japonica* is considered far superior to Manetti.

Tree planting on rural school grounds, W. L. HALL (*U. S. Dept. Agr. Farmers' Bul. 134, pp. 37, figs. 17*).—Popular directions are given for the planting of trees on rural school grounds for the purpose of beautifying them and protecting them from the cold of winter and heat of summer. Before planting the grounds a careful plan should be drawn up showing accurately the location of the different groups of trees to be planted and an account taken of the soils on which they are to be planted. The general plan should be under the supervision of the district authorities who should be aided and supplemented in the work by the teacher and pupils of the school. The bulletin contains many suggestions on the kinds of trees to plant, methods of obtaining and planting trees, and the care of trees.

FORESTRY.

Forest conservation in Kentucky, J. B. ATKINSON (*Forest Leaves, 8* (*1901*), *No. 2, pp. 22, 23*).—The distribution of the principal forest trees in the State is briefly indicated, and estimates made of the area of forests and the yield and value of the product which has been lumbered. The present forest area of the State is said to be about 13,000,000 acres, producing yearly lumber, fuel, etc., at the present valuation of $7,340,000.

A brief account is given of an attempt made in planting walnuts since 1888. This began with the planting of a 4-acre tract in which the ground was prepared and the walnuts planted in autumn 4 ft. apart, allowing 16 square feet of growing space. The tract has been divided into different plats in which the effect of natural and artificial thinning is shown. Where the trees have been thinned about 70 per cent have been removed, and the largest of the remaining trees are about 6 in. in diameter and 20 to 28 ft. high. On the tract left to natural conditions the trees are smaller in diameter but nearly the same height. This experiment has been continued, a few acres being planted every year or two, until now the reforested area amounts to about 30 acres.

Tree planting, O. M. MORRIS (*Oklahoma Sta. Rpt. 1901, p. 149*).—A brief summary is given of the tree planting which was conducted during the year covered by the report. In February, 1900, yearling seedlings were set out on a piece of rough land unsuitable for farm crops. The species planted and the number of trees were as follows: White elm, 9,000; soft maple, catalpa, black locust, and box elder, 5,000 each; white ash and honey locust, 3,000 each. Of these plantings on June 1, 1900, the living trees were 85, 96, 95, 97, 80, 27, and 33 per cent, respectively, of those planted. The elms were in poor condition when set out, and under normal circumstances a larger percentage would probably have survived. The black locust made the strongest growth, with catalpa and maple about equal. Box elder is third, elm fourth, honey locust fifth, and ash least of all. Black locust thrived best in mixed plantations, while the others did best in pure plantings.

Report of the forestry commissioner, J. T. ROTHROCK (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 98–116*).—The author reports substantial progress made in forestry management by the Commonwealth of Pennsylvania during the past year. Under the laws establishing the office of commissioner of forestry, there have been purchased and added to the State forest reserves since 1898, 98,402 acres which are now under the control and management of the Division of Forestry, as a part of the forestry reservation system. These lands are briefly described, and the subject of forest fires in relation to forestry is discussed at some length. The acts of the legislatures of Pennsylvania and Indiana relative to forest management are quoted, and the text of proposed laws which have been presented to the legislatures of Michigan, Wisconsin, and Minnesota are given.

Forest fires and lumbering during the year 1899, R. S. CONKLIN (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 116, 117, 880–884*).—During the season covered by this report the number and extent of forest fires was considerably greater than those of previous seasons. In all, 214,061 acres were burned over, entailing a loss of $406,581. In seeking the origin of these fires, it was found that most of them were started by the careless burning of brush on land that was cleared or being cleared, the fire escaping and running into the timber. The lumbering operations conducted during the year showed some increase over those reported for the previous year. About 14,000,000 ft. B. M. more pine were cut, about 39,000,000 ft. more of hemlock, and 146,000,000 ft. more of other woods. There were cut-over 126,626 acres, only 28,859 of which are to be used for farming purposes.

Studies on the coast redwood, G. J. PEIRCE (*Proc. California Acad. Sci., 3. ser., Bot., 2 (1901), No. 3, pp. 83–106, pl. 1*).—Attention is called to the habit of *Sequoia sempervirens* of reproducing itself vegetatively by means of suckers from the roots or stumps. This power is possessed by comparatively few coniferous plants. The author takes exception to the statement by Gannett (E. S. R., 11, p. 456) that "with the clearing away of the present forests the end of the species as a source of lumber will be at hand," and states that so far as the region south of San Francisco, in the vicinity of the Santa Cruz Mountains, is concerned, the redwood is reproduced in sufficient abundance and has attained profitable size, and that it still occurs in profitable quantity. The growth of the sprouts from the stumps and underground parts appears to be considerably faster than that of plants from seed. The sprouts or suckers are not wholly dependent upon themselves for the food required, and for this reason the young trees attain a considerable height and diameter in a few years. If allowed to grow and reasonably protected against drought, there appears to be no reason why valuable redwood timber should not continue to be produced. The author believes that by the method of vegetative reproduction, even under present climatic conditions, it will be possible to secure the continuance of the redwood forests in the regions where they now occur, provided lumbering operations are so conducted that the production of suckers and sprouts is not interfered with by destructive fires.

In the second part of this paper the author discusses some peculiarities noted for the vegetative shoots of young redwoods. Fasciation appears to be quite common and is probably due to external injuries producing wounds which form suckers in so great abundance as to insure the fusion of adjacent parts of the very young branches.

An interesting feature described is that of albinism, which is a peculiarity of some sprouts which come from stumps or old roots. These sprouts are sometimes perfectly white and may attain a height of 30 cm. in the course of the season. This growth is about one-third that of normal shoots and the increase in diameter is reduced in about the same proportion. While specimens of albinos that are several years old are reported, it appears that the tissues are less able to withstand the winter than those produced from green shoots, and as a result the white forms are frequently frozen to the ground. Microscopical examinations made of the 2 forms of shoots showed considerable differences, the most marked being in the leaves. In the albino forms there was little differentiation of the cell contents in the leaves, and in most cases there was no indication of the formation of plastids or chromatophores. According to the author, the albinos are probably the result of growth at a temperature too low for the production of chlorophyll, and the protoplasm of the cells is so interfered with that its normal functions are not performed. The white redwoods live parasitically upon the old roots, being dependent entirely upon the elaborated material found in the old stumps. There appears to be no tendency on the part of the leaves to form chlorophyll when the temperature is sufficiently high for its production, and the author believes that the environmental conditions are stronger than the hereditary tendency of the plant to produce chlorophyll. A single experiment, in which a plant was removed from its attachment to the roots and transplanted, is reported, the plant dying, but not until a slight coloration was noticed in some of the leaves. This phase of the subject is to be investigated further.

The Pennsylvania hemlock output (*Forest Leaves, 8 (1901), No. 2, p. 30*).—The forests of Pennsylvania are said to have yielded annually about 1,000,000,000 ft. of hemlock lumber. In addition large amounts of hemlock bark were obtained for use in tanning. Recent changes in tanning methods will, it is believed, bring about a heavy decrease in the demand for hemlock bark and as a result logging operations will be diminished. This will tend to conserve the timber and supply of bark for a much longer period than has seemed possible under the previous consumption.

The black pine, J. HUBERTY (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 1, pp. 1–18, pls. 2*).—A description is given of the black pine, which it is claimed is a variety of *Pinus laricio*, indigenous to the Styrian Alps. The tree has been successfully introduced into sylvicultural operations, being especially adapted to calcareous soils. Notes are given of a number of artificial plantations of this pine near Rochefort, in which the annual increment and general condition of the trees are described. It is especially recommended for planting with Scotch pine as a mixture.

The relation between sap and heart wood of the oak (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 1, pp. 30–40*).—The anatomical characteristics of heart and sap wood are described and their chief differences pointed out. The heart wood is recognized by the resorption of starch, ligneous cells, presence of tannin in these cells and their walls, and the formation of thyllæ in the larger cells. The occurrence of starch and tannin in the wood and their effect upon insect borers are discussed. In the oak there seem to be periods of maximum and minimum storing of starch, and in order to prevent attacks of fungi and insects upon the timber the trees should be cut when the starch content is at its lowest. In the case of spruce, fir, linden, etc., no starch is present during the winter, and trees should be cut at this time. With many other species starch disappears in late summer or autumn, while with others there seems to be a relation between the time of the formation of growth rings and deposition of starch.

The teak industry of Siam, H. KING (*U. S. Consular Rpts., 1901, No. 1041, pp. 1–6*).—Descriptions are given of the teak forests of Siam, that country furnishing about one-fourth of the world's supply of this timber. The annual shipments of teak from the 3 ports are given.

The fixation of sand dunes, J. DEMORLAINE (*Fixation des dunes. Paris: Assoc. Francais Avanc. Sci., 1900, pp. 14; noted in Rev. Eaux et Forêts, 40 (1901), No. 13, pp. 408, 409*).—Gives a review of sand dune fixation and reclamation, and on account of their adaptability and the demand for their timber and other products, recommends plantings of pedunculate oak and of *Pinus maritima*.

SEEDS—WEEDS.

The force exerted by swelling seeds, D. T. MACDOUGAL (*Jour. New York Bot. Gard., 2 (1901), No. 15, pp. 39–42, fig. 1*).—The author describes a series of experiments with peas in which an attempt was made to measure the force exerted by their swelling. The seeds were inclosed in an iron cylinder to which was attached a form of manometer, which is described. At the expiration of 30 hours the air pressure indicated a pressure of 120 lbs. to the square inch. This was maintained for 2 days, when it began to decrease slowly. At the end of a week it had fallen to 18 lbs. per square inch.

Seed studies, W. VON PETERY (*Bol. Agr. y Ganadería, 1 (1901), No. 16, pp. 1–50, pls. 5*).—A general report is given on the objects, methods, and standards of seed testings with special reference to Argentine conditions; together with the results of investigations conducted at the seed-testing station, organized under the direction of the minister of agriculture. Illustrated descriptions are given of the principal grass and forage plant seeds and the foreign seeds commonly associated with them.

Report of seed testing, G. VALDER (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 956, 957*).—A tabular report is given of the germination tests made at the Hawkesbury Agricultural College of about 100 varieties of seed, and the germinations are compared with the germination standards which have been adopted.

A cooperative investigation into the agricultural seed supply of Pennsylvania, G. C. BUTZ (*Pennsylvania Dept. Agr. Bul. 76, pp. 50, fig. 1*).—This bulletin gives the results of cooperative investigations conducted by the Pennsylvania Station and the department of agriculture of that State. In all 243 samples of seed were collected from 57 dealers in different parts of the State, and subjected to examination for their purity, vitality, and genuineness. They included timothy, Kentucky blue grass, orchard grass, clover (red, crimson, and alsike), onion, cauliflower, and sweet corn. So far as known they were grown in Pennsylvania, New York, Ohio, Maryland, Indiana, Illinois, Michigan, and California. The results of the tests are tabulated, comparisons being made with seed of standard purity, and the relative cost of the pure germinable seed in each sample shown.

The clover seeds as a rule were found quite pure. For example, only 3 samples of red clover seed out of 33 examined fell below the standard of purity and 5 below the standard of germination. The 18 samples of mammoth red clover examined were in general fully up to the required standards in purity and germination. The crimson clover seed was all up to the standard of purity, but some of the seed was old and did not germinate well. Among 39 samples of timothy seed, only 3 fell slightly below the required standard of purity, but several samples were low in germinative ability owing to the seed being old. There was great variation in the germinative power of orchard grass, the range being from 33 to 96 per cent. The greatest extremes in quality were met with in the samples of Kentucky blue grass, and only 4 of the 23 samples examined reached the required standard in germination. The author concludes that "there are farm seeds placed on sale that are exceedingly poor and even worthless;" and he advocates the passage of a pure-seed law.

The weeds represented in foreign seeds are briefly described, and the laws of several States relating to seed inspection are quoted.

Report of the section of seed control for 1899-1900, A. Voigt (*Bot. Mus. u. Lab. Waarenkunde Hamburg, Abt. Samencontrole, 1900, IX, pp. 15*).—During the year covered by this report 1,603 samples of seed were examined, 2,169 tests being made. Of the samples received 1,101 were red clover, 103 alsike, 99 white clover, 78 alfalfa, 42 timothy, 39 blue grass, 31 orchard grass, 29 bird's-foot clover, and 21 sheep fescue; the others of the 55 species of seed examined ranging from a single sample to 15 or 20. Among some of the impurities mentioned were old alsike clover seed colored with analin, sand lucern substituted for alfalfa seed, seed of *Brassica juncea* for mustard seed, etc. A specimen of African oil seed proved to be the seed of *Guizotia abyssinica*, and one called Brazilian oil fruit proved to be the fruit of a species of Araucaria. The examination of 967 samples of clover and forage plant seed for dodder showed 66 per cent pure and 11 per cent additional containing but a single dodder seed per hundred grams of the sample. A slight decrease in the total number of samples containing dodder seed is reported. The seed harvest of Germany for the year covered by this report is said to have been a poor one, and as a result numerous sophistications and substitutions are mentioned. The purity and germination tests showed a decided falling off from the percentages previously obtained for many varieties.

An experiment is reported with hard seed of red, white, and alsike clover, alfalfa, yellow clover, and kidney vetch. Five thousand seed of red clover, 1,800 of white, and 1,100 of alsike, and considerably less of the others, were soaked in distilled water, after which they were placed to germinate in the laboratory window. The germinations at the end of the different months are shown in tabular form. At the end of 6 months 60 per cent of the red clover and alsike and 50 per cent of the white clover had germinated, while all of the others had germinated within this time. The mass weight of a number of samples was determined, and observations on the origin, purity, germination, etc., of the different samples are given.

Impurities of grass and clover seeds, L. R. Jones (*Vermont Sta. Rpt. 1900, pp. 287-299*).—The station sent out a request for samples of seed to a number of farmers throughout the State, and received more than 200 samples of alsike and red clover, timothy, and other grass seeds. The seeds of timothy and red clover were examined as to purity, and the character and extent of impurities in the different samples are shown in tabular form, and a discussion is given of the results shown in the tables. In general, it appeared that low priced seed always contained a greater amount of impurities than were found in good seed, although a high price did not necessarily mean that pure seed was supplied the purchaser. In the case of timothy seed, only 9 out of 85 samples fell below 98 per cent purity; while of the red clover, out of 74 samples examined, only 29 were up to the standard of 98 per cent of purity.

Killing weeds with chemicals, L. R. Jones (*Vermont Sta. Rpt. 1900, pp. 282–286*).—The value of salt applied broadcast for the destruction of the orange hawkweed, as shown by a previous investigation (E. S. R., 8, p. 987) is stated. Sulphuric acid, diluted to 1 part of acid in 40 of water, has been claimed as more efficient than salt for the destruction of this weed. The author repeated his experiments with salt, making comparisons with a dilute sulphuric acid. The results obtained indicate that sulphuric acid is not to be compared with salt as a remedy for the hawkweed, and the author states his belief that salt is the best chemical yet tried for killing the orange hawkweed.

Experiments were conducted with copper sulphate solution for killing charlock, or "kale" as it is known in the State. In addition to the charlock 3 other species of Brassica are known as kale, but these have a smooth, glaucous foliage and are but little injured by chemicals. Sprayings were made in oat fields in which 3 and 5 per cent solutions of copper were applied. The first application was given when the plants were quite small. During the following night heavy showers fell which doubtless influenced the results. This application resulted in the injury or destruction of fully ¾ of the plants, about ¼ seeming to be uninjured. About a week later other plats were sprayed, no rain falling for several days. In this case nearly 70 per cent of the plants were killed outright and others injured. Practically every plant of charlock was killed by the last spraying and most of those by the earlier one. The oat plants were slightly injured but soon recovered. The use of copper sulphate at the rate of 1 lb. to 4 gal. of water when sprayed upon young plants is said to be efficient for their destruction, but the author believes that the best way to deal with these weeds, where it is possible, is not by the use of chemicals but by frequent rotation and clean cultivation.

DISEASES OF PLANTS.

Phytopathology and its service to agriculture, E. Marchal (*Jour. Soc. Cent. Agr. Belg., 48 (1901), No. 7, pp. 242–247*).—A brief résumé is given of the present status of our knowledge relating to plant diseases and the means of combating them.

Notes on plant diseases, E. M. Wilcox (*Oklahoma Sta. Rpt. 1901, pp. 116–128, pls. 2*).—Descriptions are given of the apple-leaf rust, and rusts and smuts of cereals. The author describes the hot-water treatment for the stinking smut of wheat and oats and the loose smut of wheat and barley, and recommends its more extended use. The corn and sorghum smuts are described at some length and references given to literature relating to the smuts and rusts of cereals in general.

Notes on some species of Helminthosporium, and the diseases of barley and oats occasioned by them, F. K. Ravn (*Ztschr. Pflanzenkrank., 11 (1901), No. 1, pp. 1–26, pls. 2, figs. 8*).—Studies are given on the morphology and physiology of *Helminthosporium gramineum*, *H. teres*, and *H. avenæ*. These fungi are parasitic, the first 2 on barley and the last on oats. The author, following Rostrup, refers to these diseases as the striped diseases of barley and oats, the name being derived from long discolored stripes occurring on the leaves, leaf sheaths, stems, etc. Prillieux has given the name Helminthosporiosis to these same diseases. Inoculation experiments with the different fungi showed that those occurring upon the barley would affect that host only, and not oats, rye, or wheat. The other species (*H. avenæ*), while most abundant upon oats, gave a few infections on barley, but none upon the other cereals. The time of seeding and temperature, during the first few days of germination, were found to have an important bearing upon the amount of disease; plants seeded in the cool months of spring or autumn were much more affected than those seeded when the average temperature was higher, July and August seedlings being almost wholly without disease. Differences in susceptibility of varieties are noted, and it is claimed that soaking the seed in hot water or in a solution of potassium sulphid prior to sowing will greatly reduce the disease.

The growth of ergot on rye and various grasses, NOFFRAY (*Mem. Soc. Nat. Agr. France, 139 (1900), pp. 501–555*).—From experiments conducted by the author it is claimed that in the germination of the ergot the sclerotia must not be more than 1 year old and the climatic conditions must be mild and humid. The occasional almost total disappearance of ergot from crops is explained by the unfavorable atmospheric conditions which prevailed at the time of the germination of the fungus. In addition to the rye, the author enumerates 30 species of grass which are subject to attacks of ergot, among them are the dog-tooth grass, couch grass, meadow foxtail, various species of brome grasses, timothy, fescue grasses, rye grass, orchard grass, and several species of Poa. For the eradication of ergot the author recommends careful screening of all seeds, and care to avoid distributing the infected material from one field to another by means of hay or stock. In case of pastures which have become seriously infected, it is recommended that some cultivated crop should be employed for a few years until the danger from propagation has passed.

Potato diseases and their remedies, L. R. JONES (*Vermont Sta. Rpt. 1900, pp. 268–281, fig. 1*).—In the season covered by this report the atmospheric conditions were, on the whole, favorable to the potato crop. The yields were somewhat reduced by dry weather, but on this account there was less disease than usual. Experiments were conducted to test the comparative value of several fungicides and insecticides when applied to potatoes. Standard Bordeaux mixture to which Paris green was added, Bug Death, Laurel green, and gypsum and Paris green were applied under similar conditions. At the time of the first application and for nearly 2 weeks thereafter but little difference could be distinguished in the condition of the several plats. By the time of the second application marked differences began to show themselves, which increased as the season advanced. In all cases the plants receiving the Bordeaux-Paris-green mixture were more flourishing and the leaves larger and of darker green color. The effect of the different fungicides, as shown by the yield of the various plats, is given in tabular form. The results are especially significant since there was no fungus whatever on any of the potatoes. Bordeaux mixture was again shown to be a valuable remedy against insect attacks. The amount of gain due to the use of this mixture when applied to experimental plats was almost exactly duplicated upon the main field of the farm, the sprayed plants yielding 223 bu. per acre as compared with 150 bu. from unsprayed rows.

The number and dates of applications to secure the best results were investigated, 3 applications being made of the Bordeaux-Paris-green mixture on July 26, August 17, and September 8. The yields of potatoes sprayed at different times showed that the first application was the most important one, and that about one-half the entire gain was attributed to that. The second and third applications were about equal in importance, each of which added about 25 bu. per acre to the entire crop.

Experiments are reported on the prevention of potato scab, in which comparative trials were made of corrosive sublimate, formalin, formaldehyde gas, sulphur, sulphur fumes, and insolation. Where the soil was free from the scab germs and scabby seed was used, a scabby crop resulted, but where the soil was clean and the seed properly disinfected a clean crop was secured. Where the soil was badly infected no method of treatment was entirely effective. Corrosive sublimate and formalin in solution both proved excellent disinfectants, and either may be depended upon in practice. Sulphur proved decidedly inferior. Exposure to the sunlight of tubers designed for seed greatly reduced the amount of scab. In this case the seed tubers were exposed for 4 weeks previous to planting and a fairly clean crop was given, even when very scabby seed was used. This treatment has the additional advantage of hastening the growth of the tubers and is often practiced for this reason alone. The exposure of seed potatoes to sulphurous gas, which has been strongly recommended by some investigators, was less efficacious than soaking, either in corrosive sublimate or formalin or exposing to formaldehyde gas. The formaldehyde gas, although the experiments are not as conclusive or satisfactory as is desirable, gave results that seem to indicate its superiority over both the formalin and corrosive sublimate solutions.

Concerning the fungi occurring in the beet-seed capsules, F. BUBAK (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 477, 478*).—The author reports a series of studies in which cultures were made from the capsules of beet seed, the fungi being cultivated in various sterile media. He found present as parasitic fungi *Sporidesmium putrefaciens*, *Cercospora beticola*, *Phoma betæ*, and *Entyloma betiphilum*, n. sp.; and as saprophytic fungi, numerous species of Penicillium, Aspergillus, Sterigmatocystis, Verticillium, Mucor, Rhizopus, Chætomium, as well as *Eurotium repens*, *Thamnidium elegans*, *Stachybotrys atra*, *Alternaria tenuis*, *Hormodendron cladosporioides*, *Trichothecium roseum*, *Sordaria fimicola*, *Stysanus stemonitis*, etc.

A disease of mangolds and sugar beets, R. H. BIFFIN (*Dept. Agr. Cambridge Univ. Rpt. 1901, pp. 87–89*).—The first symptoms of disease consist of the brown and dead outer leaves, while the inner leaves become yellowish green and much wrinkled. The disease usually makes its appearance on the edges of the leafstalk. When examined the roots externally show but little evidence of disease except that the affected ones are somewhat drier and harder. When cut across, the fibrovascular bundles of the diseased root are deeply stained a purplish black color, and the leafstalks are marked in a similar manner. Specimens removed from the field to a greenhouse were not destroyed by the disease but made a slow, stunted growth. Further examination showed the vessels of the fibrovascular bundles plugged with a mucilaginous mass containing large numbers of bacteria. Sugar beets have been noticed as affected in the same manner and the bacteria present are believed to be the cause of the disease, which is to be a subject of further investigation.

A soft rot of carrot and other vegetables, L. R. JONES (*Vermont Sta. Rpt. 1900, pp. 299–332, figs. 11*).—A detailed report is given on the soft rot of carrot and other vegetables caused by *Bacillus carotovorus*. The occurrence and character of the disease, morphological and physiological character of the organism, and its various relations are described at length. This disease has been the subject of a previous paper, which has already been noted (E. S. R., 13, p. 362).

A bacteriosis of kohl-rabi, L. HECKE (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 469–476, pl. 1*).—A preliminary note is given on the occurrence of a bacterial disease of kohl-rabi, which is due apparently to the same organism as that causing the brown rot of cabbage and turnips, which has already been noted (E. S. R., 9, p. 847).

A serious disease in the cherry orchards of Kent, W. CARRUTHERS (*Jour. Roy. Hort. Soc. [London], 25 (1901), No. 3, pp. 313–316, figs. 2; also Gard. Chron. 3. ser., 29 (1901), No. 742, p. 172*).—A brief account is given of a serious disease of cherries which simultaneously attacks the leaves and fruit, rendering the fruit unfit for market. The diseased leaves remain attached to the branches, and a further characteristic is the shortening of the branches which bear the diseased leaves. The internodes between the leaves do not appear to have been developed. Dwarfing of the branch is said to be not directly due to the fungus, but is attributed to a lack of food as a consequence of the early death of the leaf. The author reports marked differences in the susceptibility of different varieties to attacks of this disease. What is believed to be the same trouble has been described in Germany as due to the fungus *Gnomonia erythrostoma*. The rapid spread of this disease is attributed to the overcrowding of fruit trees and too much moisture. As a remedial treatment it is suggested that all diseased leaves should be gathered and burned. If this should be continued for a few years the disease would doubtless cease to be troublesome, as has already proved the case in Germany.

Plum-tree canker, F. A. WAUGH (*Vermont Sta. Rpt. 1900, pp. 370–373, fig. 1*).—Attention is called to a canker of plum trees which is distinguished from gummosis as following and often being the result of that disease. If a wound of a peach or plum tree remains unhealed for some time, either as a result of gum flow or other cause, the surrounding tissues become blackened as if corroded, so that the usual processes of healing do not take place. While the surrounding parts continue to grow the cankered portions remain dead, blackened, and sunken below the green adjacent portions. In extreme cases the branch is finally killed. It is to these blackened, unhealed, and unhealing spots that the term canker is specifically applied. Thus far, neither fungi nor bacteria are known to definitely cause the disease. It frequently begins, however, in the attacks of such fungi as brown fruit rot and the fungus causing plum pockets. Some varieties are much more susceptible than others to injury from this cause. As this disease is not known to be directly of fungus origin, spraying can not be expected to serve as a remedy and the only way to rid the tree after the canker appears is by pruning. Preventive treatment of the canker in arresting the spread of the brown-rot fungus and the plum-pocket fungus may be given by spraying with Bordeaux mixture, which should be applied early in the spring before the buds start.

Leaf scorching of trees by the wind, L. R. JONES (*Vermont Sta. Rpt. 1900, pp. 281, 282*).—About July 1, 1900, there was noticed a sudden and peculiar blighting of the leaves of many trees and shrubs. This was first noticed on elderberry. A further observation revealed similar trouble upon a number of other shrubs and trees. The blighting was begun at the tips and margins of the leaves, although in broad leaves like maple dead spots occurred irregularly between the larger veins. Considerable injury was done by this leaf scorching. A line of maple trees appeared as if scorched by fire upon one side, while the other was not harmed. The cause of injury is attributed to a peculiar combination of weather conditions. Hot, clear, dry weather was associated with heavy winds, and excessive loss of water through transpiration is believed to be the cause of the trouble. Trees that were sheltered from the wind escaped, as did many others which were in soil conditions especially favorable. With the exception of trees recently transplanted, it is believed but little permanent injury will be done.

Spot diseases of mandarins, TRABUT (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 5, pp. 112, 113*).—The author describes the causes of a number of different kinds of spots occurring upon the mandarin. One in which the spots are very numerous and quite small is said to be caused by the orange black scale (*Parlatoria zizyphi*). A second form of spot is described in which the spots become several millimeters or a centimeter, or more, in diameter, followed by a complete destruction of the skin of the fruit. This is due to the fungus *Septoria glaucescens*. This disease is sometimes quite destructive to the fruits. Another form of spot described is due to an acarid. This produces lesions in the skin and makes it possible for the easy attack by the fungus causing the previously described trouble.

Gooseberry mildew (*Jour. Bd. Agr. [London], 8 (1901), No. 1, pp. 1–4, pl. 1*).—A brief popular desciption is given of the gooseberry mildew (*Microsphæria grossulariæ*). This mildew is said to be less destructive than the American gooseberry mildew (*Sphærotheca mors-uvæ*) and its occurrence may be prevented by repeated sprayings with potassium sulphid solution. All the dead leaves should be collected and burned in the autumn and the ground under and around the bushes dug so as to bury any stray spores which may be lying upon the ground.

Leaf cast of pine, C. VON TUBEUF (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901), No. 1, pp. 1–160, pls. 7, figs. 32*).—A review is given of the literature relating to this disease, and the various theories as to its cause are discussed. Leaf cast is a very troublesome disease in nurseries where seedlings of *Pinus sylvestris* are grown, not infrequently causing the complete destruction of all the young plants. The principal cause of the injury, according to the author, is to be attributed to *Lophodermium pinastri;* and the systematic relationships, morphology, biology, and pathological effect upon the host plant are described at some length. Numerous infection experiments are reported in which the parasitism of the fungus was clearly established.

Various methods are described for the prevention of the disease. It appears to be of unusual occurrence and of little importance upon seedlings grown among grass, weeds, or other plants; and it is recommended that mixed sowings should be made in the nursery in which some protective species are introduced. Hedges and walls along the west side of plantations are also protective to a considerable degree. The seed bed for young pines should not be placed near pine forests. As there seems to be evidence that the disease may be communicated through infested seed, special care should be given seed selection, and the young seedlings should be made as resistant as possible by promoting their rapid growth through cultivation and the use of fertilizers. A report is also given of experiments conducted at a number of different stations and covering several years, in which various fungicides were tested to determine their value as a means for the prevention of the leaf cast. The best results were obtained with fungicides containing some form of copper. Thorough and repeated applications of Bordeaux mixture, with or without sugar, or a copper-soda mixture, protected the young seedlings from serious injury.

Notes are also given of a disease resembling leaf cast caused by the larvæ of *Diplosis* (*Cecidomyia*) *brachyntera*, and statistics as to the distribution and injury caused by leaf-cast diseases are presented.

A disease of spruce twigs (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 2, pp. 63–74, pls. 2, fig. 1*).—An account is given of a disease of spruce caused by attacks of *Septoria parasitica.* The disease usually makes its appearance in May or June, when the young shoots are rapidly growing and are quite tender. The leaves turn brown and fall away, leaving the extremities of the limbs dead and bare. The fungus seems to attack plants in the seed bed, as well as trees 20 to 50 years old. The disease ordinarily begins in the tips of the branches, where growth is rapid and the water requirements the most pronounced, spreading from this point downward. The fungus seems more prevalent in trees grown at considerable elevation or where there is a diminution of the water supply and where the circulation of air and the light are intense. The development of the parasite seems to be greatly favored by dry seasons. In addition to the disease caused by Septoria the spruce trees are quite susceptible to attacks of *Botrytis douglasii.*

The cacao disease (*Trinidad Bot. Dept. Bul. Misc. Inform., 1901, No. 27, p. 328*).—A brief account is given of the occurrence on the branches of cacao trees of growths known as witches' brooms or hexenbesens. The cause of these growths is said to be *Exoascus theobromæ.* The disease so far has been observed only in Surinam, and it is recommended that wherever observed the deformed growth should be cut out and the trees sprayed, as far as possible, with dilute Bordeaux mixture.

Hexenbesen of cacao trees in Surinam, J. RITZEMA BOS (*Ztschr. Pflanzenkrank., 11 (1901), No. 1, pp. 26–30, figs. 2*).—A technical description is given of hexenbesens or witches' brooms occurring upon cacao trees in Surinam. The author finds they are caused by a new species of Exoascus to which the name *E. theobromæ* is given.

The carnation in health and disease, A. F. Wood (*Florists' Exchange, 13 (1901), No. 8, pp. 188, 189, figs. 4; Amer. Florist, 16 (1901), No. 664, pp. 990–993, figs. 10*).—The author popularly describes the stigmonose of carnations, and briefly mentions stem rot, leaf spot, and fairy ring spot as sometimes proving serious diseases of carnations.

An injurious fungus of orchids, P. Hennings (*Notizbl. K. Bot. Garten u. Mus., Berlin, 3 (1901), No. 25, pp. 97–99*).—A brief account is given of a hitherto undescribed fungus which has been observed upon the pseudobulbs of *Maxillaria rufescens*. The fungus, to which the name *Nectria bulbicola*, n. sp., is given, is technically described. The fungus seems to be indigenous in Venezuela or Trinidad, but has been observed to cause serious injury in other localities.

A new method of combating nematodes, H. Wilfarth (*Ztschr. Ver. Deut. Zuckerind., 1900, No. 529, pp. 195–204; abs. in Centbl. Bakt. u. Par., 2 Abt., 7 (1901), No. 12, p. 445*).—On account of the excessive cost and impracticability of catch crops and chemicals for the destruction of nematodes, the author was led to investigate other means for their destruction. He reports having observed in beet fields that here and there individual specimens occurred which had not been attacked by the nematodes, and suggests the possibility of breeding a race of sugar beets which will be resistant to nematodes.

On the preventive spraying of green plants, L. Mangin (*Rev. Hort., 73 (1901), No. 4, p. 86*).—The occurrence of fungus diseases and insect enemies on palms and other plants in hothouses, especially where the atmosphere is humid, is commented upon. Palms in particular are subject to attack of *Graphiola phœnicis*, which attacks the leaves, and if conditions are favorable for its rapid propagation the plants, unless unusually vigorous, are weakened by it. Another serious trouble in the greenhouse is the fumagine which follows the presence of certain insects. For the prevention of the fungus diseases, the author recommends spraying the plants with a one-half per cent solution of copper sulphate, or a solution of naphtholbeta, 5 gm. to 10 liters of water. For the destruction of insects, tobacco extract may be added to the naphthol solution.

A calcium sulphid or a sulphur-copper fungicide, A. Seignouret (*Rev. Vit., 14 (1900), p. 437; abs. in Ann. Agron., 27 (1901), No. 6, p. 290*).—The author describes a fungicide which has been successfully used for the prevention of grape diseases. It is composed of 25 kilos of lime and 50 kilos of triturated sulphur, which are mixed with 100 to 200 liters of water and boiled for 2 to 3 hours. To this mixture 50 kilos of copper sulphate in solution are added and the volume diluted to 25 or 50 hectoliters, depending on whether a 1 or 2 per cent solution is desired. This mixture gives a complex precipitate of sulphate of lime, sulphate of copper, and sulphur. In practice it has been found that 2 applications of the fungicide—the first made in May and the second about the end of June—will protect the grapevines from mildew. The fungicide adheres very readily to the leaves, and the copper sulphate decomposing slowly retains its efficiency for a considerable time.

ENTOMOLOGY.

Notes on troublesome insects, F. M. Wilcox (*Oklahoma Sta. Rpt. 1901, pp. 112–116, figs. 3*).—*Aphis cucumeris* is reported as doing considerable damage to melons during the season of 1900. For controlling the ravages of this insect it is recommended that the ground be thoroughly cleared of all rubbish at harvesting. Badly infested plants may be sprayed with kerosene emulsion. The harlequin cabbage-bug is reported as producing 5 broods in Oklahoma. The last brood is said to winter over as nearly mature adults. It is urged that leaves and other refuse should be collected into heaps to serve as hiding places for the bugs, and that this rubbish should be burned late in the winter. For controlling *Myzus cerasi* it is recommended that infested cherry trees be sprayed with kerosene emulsion or whale-oil soap. The false chinch bug (*Nysius angustatus*) is reported as injuring turnips, rape, beets, cabbage, potatoes, and flax. The destruction of wild species of the mustard family is recommended as a means for checking this insect.

Report of the botanist and entomologist, G. W. HERRICK (*Mississippi Sta. Rpt. 1901, pp. 26–28*).—Observations have been made on insects injurious to pecans, including *Catocala viduata, Oncideres texana*, and *Sesia scitula*. The author made a study of the mosquitoes of the State, and carried out some experiments in combating the horn fly. It was found that by spraying the cattle with a 20 or 25 per cent mixture of kerosene and water nearly all the flies were killed. Even a stronger solution than this can be used without bad effect on the cattle. It was found that kerosene and water evaporated too quickly in dry weather where it is not convenient to spray the cattle oftener than twice per week. By spraying with undiluted crude petroleum it was found that one treatment was effective for from 2 to 4 days, and all the flies were killed. Even a 50 per cent solution of crude petroleum in water was equally effective. No harm was caused to the cattle.

Notes on injurious insects, E. FLEUTIAUX (*Agr. Prat. Pays Chauds, 1 (1901), No. 1, pp. 110–115*).—The seeds of a custard apple (*Anona muricata*) were found to be badly infested with an insect belonging to the genus Dryocœtes. In some cases as many as a dozen specimens of the insect were found in a single seed. The insect was found in all its stages in the same seed, and it is believed that the period of egg laying is interrupted and extends over a considerable period. A description is given of the method of egg laying and of the appearance of the various stages of the insect.

Notes are given on a number of insects which were found injuring coffee grains. The species most abundant and injurious were *Cathartus advena, Lophocateres pusillus*, and *Silvanus frumentarius*. A number of other insects, including *Chrysobothris chalcophana* and *Agrilus areolatus*, are reported as causing injury to the branches or stems of coffee plants.

Report on economic entomology for 1900, G. H. CARPENTER (*Reprint from Rpt. Council Roy. Dublin Soc. 1900, pp. 92–108, figs. 9*).—The author presents descriptive biological and economic notes on a number of injurious insects, including carrot fly, pea beetle, *Thrips physopus, Lecanium ribis, Hylurgus piniperda, Hyponomeuta cagnagellus, Psylla buxi, Tinea granella, Tenebrio molitor*, and *Tenebroides mauritanicus*.

Diseases of nursery stock, H. GARMAN (*Kentucky Sta. Bul. 93, pp 99–111, pls. 5*).—Notes are given on the fumigation of nursery stock with hydrocyanic-acid gas. The author gives formulas of materials to be used in generating the gas. It is stated, however, that where trees are exceptionally large or where only a few trees are infested it is cheaper and more convenient to spray with soap solution or kerosene preparations. Apple trees sprayed for San José scale with a 50 per cent mechanical mixture of kerosene and water were not injured in the least, while nearly all the scales were killed. In 2 orchards crown gall was found to have infested about 50 per cent of the apple trees. A brief description is given of the appearance and position of the gall. It is recommended that infected trees should be at once removed and burned. A knot disease of apple trees, similar to black knot of plums, is reported. At the base of the main branches and some times on the trunk itself smooth olive-green warts appear, which increase in size and become rough. These warts may be removed with a knife and the affected parts sprayed with Bordeaux mixture, or the whole tree may be dug out and destroyed. Attention is called to the fact that by double-working Northern Spy apples, as recommended in South Africa and Australia, a stock may be secured which is reasonably resistant to the attacks of the woolly aphis. Certain nurseries in the State have advertised trees for sale without guaranty, with the knowledge that the nurseries from which they are sold are infested with the San José scale. A vigorous protest is entered against such business.

An enemy of alfalfa, R. GAVOTY (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 28, pp. 44–46*).—The author reports serious injury to alfalfa from the attacks of *Colaspidema atrum*. The larvæ appear in April, and when occurring in large numbers cause almost total destruction of the alfalfa. Numerous experiments with different insecticide materials were made without great success. These experiments included the use of sulphate of iron in the proportion of 500 gm. to 100 liters of water, kerosene emulsion, Bordeaux mixture, tobacco decoction, and sulphur. These remedies proved to be rather expensive and were too ineffective to be recommended for further use.

The Hessian fly; its ravages in New York in 1901, I. P. ROBERTS, M. V. SLINGERLAND, and J. L. STONE (*New York Cornell Sta. Bul. 194, pp. 237–260, figs. 5*).—A general discussion is given of the occurrence and injurious attacks of the Hessian fly in New York during the season of 1901. Detailed notes are given on the relative abundance and injurious action of the insect in various localities. Cooperative experiments were carried out by several farmers of the State for the purpose of determining the most suitable varieties of wheat for growth in their locality. Some differences were noted in the resistant power of different varieties of wheat to attacks of the Hessian fly. It appears from these experiments and from the observations of others that varieties which prove highly resistant in one State or one locality may not be resistant when planted in another locality. It is believed that the Hessian fly causes more injury on dry poor land than on moist well-drained rich soils, and that thick seeding and vigorous growth assist in warding off the attack of the fly. The most resistant varieties, according to the experiments of the authors, are Dawson Golden Chaff, Prosperity, No. 8, Democrat, Red Russian, and White Chaff Mediterranean. Notes are given on the appearance, habits, and life history of this insect. It is not considered possible to give a date which will be a safe guide for sowing wheat in New York for any series of years. In general, however, wheat sown after September 20 is less injured by the Hessian fly than that which is sown earlier. Attention is called to the desirability of cooperation among the farmers, and of thorough tilling of the soil, together with the use of trap crops.

The Hessian fly in Ontario, W. LOCHHEAD (*Ontario Agr. Col. and Expt. Farm Bul. 116, pp. 16, figs. 10*).—A brief historical account is given of the Hessian fly in Ontario, and the losses caused by its depredations. The insect is described in its various stages, and brief notes are given on its life history. There are 2 broods a year in Ontario, and the eggs are ordinarily laid during the last week of August and the first week of September. Occasionally, however, the eggs are deposited as late as September 20. Brief notes are presented on the natural enemies of the Hessian fly and on the various insects which are most frequently mistaken for this pest. A list of the common food plants is also given. In a discussion of remedies against the Hessian fly, reference is made to the methods which are in common use in combating this insect. It is suggested that fall wheat should be sown in Ontario about the middle of September. It is urged that special care should be exercised in the preparation of the seed bed before sowing. Where summer fallowing is not excluded by considerations of economy this method of preparation yields the best results in the preparation of the soil for wheat. Attention is also called to the desirability of planting trap crops and burning stubble and refuse. In order that any methods against this insect may be generally successful it is necessary to secure cooperation of all farmers in any given locality.

Biological and economic notes on the bollworm, G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 143–159, figs. 6*).—The author describes the species in all stages and gives notes on its habits and life history. A number of the host plants for this species in Italy are enumerated, the most important of which are said to be tobacco, hemp, cotton, tomato, and pepper. Corn is also attacked, but this crop is not so important in Italy as in the United States. A brief account is given of the natural enemies of the bollworm and of the remedies which have been recommended for combating the insect in the larval, pupal, and adult stages. The use of arsenites against the larvæ in Italy is said to be attended with more danger than in the United States. The author recommends, therefore, tobacco decoction.

The grain lantern fly (Tettigometra obliqua), G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 135-142, figs. 4*).—The author describes this insect in all its stages and gives tables showing variation in size of various parts of the body. The damage caused by the species is probably greater than usually supposed, since some of its injury is attributed to other insects. Injuries are especially marked on the tender portions of the food plants. After the grain becomes larger and the epidermis more firm, the injury is less pronounced. In preventing damage from this insect the author recommends planting early varieties of grain and early in the season, in order that the grain may be well developed before the insects begin their attack. The use of fertilizers is also recommended for the same purpose. Stubble should be burned over in order to destroy the insects which have collected on green radicle leaves and on grasses which may grow in the grain fields.

The grain lantern fly fastens itself to the stems of grain by means of its beak and does not move until ready for its final transformations. After the grain harvest the species migrates to grasses of various sorts.

Some insects injurious to stored grain and the cereal products, B. F. MACCARTNEY (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 83-90, figs. 8*).—Brief descriptive economic and biological notes are given on Angoumois grain moth, granary weevil, saw-toothed grain beetle, bean weevil, pea weevil, Mediterranean flour moth, Indian-meal moth, and confused flour beetle.

Species of Calandra and other injurious insects, P. BIOURGE (*Rev. Gén. Agron. [Louvain], 10 (1901), No. 7, pp. 289-294*).—Brief notes on the habits, life history, and means of combating *Ephestia kuhniella*, and common species of grain beetle.

Scale lice on the sugar cane in Java, L. ZEHNTNER (*Meded. Proefstat. Suikerriet West Java, 1901, No. 52, pp. 18, pls. 2*).—The author describes in detail an undetermined species of Aspidiotus and one of Planchonia. Notes are given on the life history and habits of these insects. The first species was found parasitized by a member of the family Encyrtinæ, while a parasite of the family Aphelinæ was bred from the second species.

The life history of two species of plant lice inhabiting both the witch-hazel and birch, T. PERGANDE (*U. S. Dept. Agr., Division of Entomology Bul. 9, tech. ser., pp. 44, figs. 23*).—The stem mothers of *Hormaphis hamamelidis* are hatched from winter eggs in early spring and make their appearance about a week before the leaves of the witch-hazel unfold. This generation causes the development of conical galls on the leaves. In each of these galls from 100 to 120 larvæ are produced by the stem mother. These larvæ reach maturity within from 16 to 20 days and are all possessed of wings constituting the migratory generation. The migratory period extends from May until July. There is only one generation of migrants in each gall. The migrating forms fly to birch trees, where they deposit larvæ on the underside of the leaves. The third, fourth, and fifth generations on the leaves of the birch are very similar in appearance and life history. The fifth generation becomes mature about the middle of August and produces larvæ which resemble Aleurodes in form. The sixth generation, after passing through 4 molts, acquires wings and migrates back to the witch-hazel. From these fall migrants another generation of males and females is developed and the eggs are deposited, in which form the species passes the winter.

The life history of *Hamamelistes spinosus* resembles that of the species just mentioned except for the fact that the galls on witch-hazel are developed in the flower buds rather than on the leaves, and the species hibernates on birch, requiring, therefore, more than a year for a complete life cycle. The winter eggs are deposited from the middle of June to the first of July and hatch during May and June of the following year, remaining dormant, therefore, nearly a whole year. The stem mothers upon hatching attack the young flower buds, and cause a rapid and peculiar development of these structures, so that the insects are soon inclosed within a hollow gall which later is covered with conspicuous spines. In these galls the second or migrating generation is developed. The migrants appear in July or about a month after the hatching of the first generation, and continue to issue until late in the fall. They migrate from witch-hazel to birch. The third generation of this species assumes a form which closely resembles species of Ctenochiton. About the middle of April, or at the time when the leaf buds of the birch begin to open, the females of this generation which have hibernated on the birch deposit their larvæ on the underside of the leaves in the folds between the transverse veins. The irritation caused by the presence of the insects induces the leaves to curl down, and finally the leaf becomes much changed in appearance by the formation of corrugations. The attack of this generation is sometimes a serious drain upon the health of birches. The winged form, or the return migrant, belongs to the fifth generation and migrates back to the witch-hazel during June.

San José scale, A. H. Benson (*Queensland Agr. Jour., 8 (1901), No. 6, pp. 451–454, pl. 1*).—The author gives a general account of this insect, with notes on its distribution, habits, and extent of injury in Australia. It is believed that the scale was introduced into Australia from California. A list of food plants upon which the insect has been found is given. The author considers the best winter spray to be lime, sulphur, and salt wash. Other artificial remedies which have been found effective are whale-oil soap, tobacco extract, sulphid of soda, and whale-oil wash and kerosene sprays. The author prefers the other insecticides to kerosene. In making the sulphid of soda and whale-oil wash, 6 lbs. of sulphur and 3 lbs. of concentrated lye are boiled in 2 gals. of water. At the same time 30 lbs. of whale-oil soap is to be dissolved in 48 gals. of water, and the sulphid of soda is to be added to this mixture. The whole is then boiled and water added to make 120 gals. in all.

A new means of combating the olive fly, A. Brian (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 28, pp. 55-57*).—According to the experiments of Prof. C. Parona, it is believed that the ordinary methods of combating *Dacus oleæ* in olive orchards are too expensive. Since it is well known that the insect prevails to an enormous extent in storehouses where olives are collected for extraction of the oil, it is suggested that special attention be given to destroying the insect in such situations. Experiments conducted for this purpose showed that the insects may be readily destroyed. It is recommended that the walls of storehouses be made of smooth lumber and that the larvæ and chrysalides be collected by hand and destroyed.

The almond bagworm (*Bul. Bot. Dept. Jamaica, n. ser., 8 (1901), No. 9, p. 141*).—The insect is considered to be *Oiketicus abbottii*, and is reported for the first time as injurious to orange trees.

Currant aphides (*Bd. Agr. [London], Leaflet No. 68, pp. 5*).—Considerable injury to currants is reported from the attacks of *Rhopalosiphum ribis* and *Myzus ribis*. In some localities the currrant bushes were entirely ruined by these insects, the leaves turning brown and the fruit falling off. Notes are given on the habits and life history of the two species. It is recommended that black currants be severely pruned in the fall following an attack of the insects, and that the pruned branches be burned. Spraying with kerosene emulsion and quassia is recommended. It is desirable that the first application be made early in the year.

Some insects injurious to shade trees, B. F. MacCartney (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 91–97, figs. 4*).—Brief notes on imported elm-leaf beetle, white marked tussock moth, wood leopard moth, and bagworm.

The imported elm-leaf beetle, H. T. Fernald (*Massachusetts Sta. Bul. 76, pp. 8, fig. 1*).—Notes are presented on the occurrence, distribution, life history, and food plants of this insect. The most approved remedies are outlined and formulas are given for the preparation of suitable insecticides for use against this beetle, such as arsenate of lead, Paris green, kerosene emulsion, and a mechanical mixture of kerosene and water. It is recommended that trees should be sprayed when the leaves are about half grown, and that the application should be repeated during the first week in June. Loose bark on the trunk should be scraped off, and the grubs and pupæ at the base of the tree may be destroyed by spraying with boiling water or kerosene emulsion.

Tent caterpillars (*Bd. Agr.* [*London*], *Leaflet No. 69, pp. 5*).—Descriptive and biological notes are given on *Clisiocampa neustria* and the brown-tail moth. Both species are injurious to various fruit trees, especially apple, plum, and pear, but the first-named species is most common and most destructive. Besides fruit trees, it feeds on oak, elm, hawthorn, and various other trees and shrubs. The brown-tail moth has a somewhat local distribution, but occurs in great numbers wherever it is found. The egg bands of *C. neustria* should be collected in winter and burned. The tent of the brown-tail moth may be easily detected in winter and cut off and burned. Spraying with Paris green, London purple, or arsenate of lead is also effective against both these insects.

Observations on the South African locust fungus, G. Lindau (*Notizbl. K. Bot. Garten u. Mus., Berlin, 3 (1901), No. 26, pp. 119–126, pl. 1*).—The author describes in detail the growth and morphological characters of this species of fungus, which is described under the name *Mucor locusticida*. Culture experiments with this fungus indicated that it can be successfully grown on any of the usual media, and if it proves to be as effective as already suspected its culture on a commercial scale will be an easy matter.

Spraying calendar (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 890–906*).—Brief directions are given for the preparation and application of insecticides and fungicides in the case of the common insect pests and fungus diseases of various cultivated crops.

Insect powders (*Agr. Jour. Cape Good Hope, 19 (1901), No. 4, pp. 266–270*).—Brief compiled notes are presented on the history, cultivation, preparation for use, and active principles of a species of pyrethrum which is used in the preparation of insect powders.

The new law concerning insect pests, W. E. Britton (*Connecticut State Sta. Bul. 134, pp. 6*).—A law concerning insect pests was passed by the Connecticut legislature on June 4, 1901, and approved by the governor on June 10. A copy of the law is given in the bulletin, and a brief statement is made by the author concerning the purpose of the law and the manner in which it is proposed to carry out its provisions.

How to keep white ants from a building (*Queensland Agr. Jour., 9 (1901), No. 2, p. 279*).—Directions are given for preventing the entrance of white ants into frame buildings in countries where these insects are a serious menace to such structures. The stumps on which the framework rests should be solid wood, without cracks or rotten places. All such stumps should be treated with hot coal tar so that this substance may penetrate as deeply as possible. Veranda steps should be connected with the ground by pillars treated in the same manner, and no lumber or rubbish should be allowed to accumulate under the building.

Directions for collecting and preserving insects and plants, E. M. Wilcox (*Oklahoma Sta. Circ. of Inform. 3, pp. 15, figs. 10*).—In this bulletin a request is made for observations and specimens from voluntary observers throughout the Territory. Directions are given for collecting, preserving, mounting, and shipping specimens of insects and plants to the station.

An annotated catalogue of the butterflies of New Hampshire, W. F. Fiske (*New Hampshire Sta. Tech. Bul. 1, pp. 80, figs. 55*).—This bulletin contains a brief general account of the distribution of butterflies in New Hampshire and notes on the habits and life history of 92 species which are reported as occurring in the State.

Bee culture, C. C. Miller (*Pennsylvania Dept. Agr. Bul. 77, pp. 103, figs. 12*).—This bulletin was prepared for the purpose of giving practical information on the various subjects connected with apiculture. Among the subjects which are treated by the author mention may be made of the biology of bees, bee products, varieties of bees, beehives and apiary apparatus, feeding of bees, management of queens, drones, and workers, methods of transferring, use of comb foundation, supers, extraction of honey, regulations of swarming, rearing of queens, introduction of queens, dividing of swarms, rendering of beeswax, robbing of bees, the enemies and diseases of bees, moving bees, honey plants, care of bees in winter, and a brief account of literature relating to apiculture.

Bees, and how to manage them, A. Gale (*Agr. Gaz. New South Wales, 12 (1901), No. 6, pp. 698–701*).—The author discusses the fluctuations in the honey market and calls attention to the necessity of putting up honey in an attractive form in order to secure a good price for the same. At a recent exhibition of bee products at the Royal Agricultural Show it was noticed that special interest was shown by visitors in those exhibits which were most attractively presented, and that the exhibitors secured large and profitable sales, beside giving a demonstration of the possibilities of bee raising.

The management of bees, A. Gale (*Agr. Gaz. New South Wales, 12 (1901), No. 7, pp. 840–845*).—The author discusses the collection, manufacture, and use of propolis by bees. An investigation was made of the possibility of obtaining honey from corn. The author examined many samples of honey which were reputed to be made from corn, but these samples did not agree in aroma, flavor, or color, and the idea that bees can obtain honey from corn is entirely discredited by the author.

Bee keeping in the West Indies, W. K. Morrison (*Imp. Dept. Agr. West Indies, Pamphlet No. 9, 1901, pp. 73, figs. 15*).—This pamphlet is in the nature of a manual of apiculture, and treats of the following subjects: Management of bees, breeds of bees, individuals of the colony, hives, queens, swarming, honey and wax production, comb foundation, robber bees, relation of bees to fruit growers, uses of honey, and the natural enemies and diseases of bees. A list is given of the more important literature on the subject of apiculture and of hive manufacturers, breeders of Italian bees, dealers in honey and wax, and manufacturers of comb foundation. A list is also given of the honey plants of the West Indies.

A glass observing super, H. R. Stephens (*Queensland Agr. Jour., 9 (1901), No. 2, p. 216*).—This contrivance obviates the necessity for the use of a smoker in observing the condition of colonies of bees. The observing super has one-half the depth of an ordinary hive, with a two-pane glass slide fitted into the top. It is to be placed gently and quickly in position on the top of the hive and allowed to remain as long as observations are required. A few bees fly against the glass for a short time, but the colony soon becomes quiet.

Foul brood in Tunis, P. Robinet (*Bul. Dir. Agr. et Com., 6 (1901), No. 20, pp. 251–257*).—The existence of foul brood in Tunis was first made known in 1900. Since, the disease appears to be well established in the country and rapidly spreading among the various apiaries. The author gives a general account of the disease, including the symptoms, microscopic appearance of diseased bees, the means of dissemination of the disease, and the principal methods of treatment which have been found effective in checking it.

Action of different colored rays of light on silkworms, C. Flammarion (*Bul. Min. Agr [France], 20 (1901), No. 3, pp. 493–496*).—The author continued the experiments which he had already instituted along this line and obtained results which in general confirm the results of previous experiments. The maximum production of silk took place under a clear violet-purple glass, and minimum production under a pale blue. The influence of different rays of light upon the determination of sex was somewhat marked. The number of females was reduced to 40 per cent under clear blue glass.

FOODS—NUTRITION.

On the so-called gluten and diabetic foods of commerce, H. C. SHERMAN and H. M. BURR (*Reprinted from New York Med. Jour., 1901, Oct., pp. 8*).—A number of commercial gluten foods were examined. Such goods are frequently recommended as food for diabetics, and it is usually claimed by the manufacturers that they contain only a small amount of carbohydrates.

"Of the 11 samples examined, which are believed to fairly represent the so-called glutens generally found on the market, not half are noticeably higher in protein or lower in carbohydrates than ordinary whole wheat, or Graham flour, and many are scarcely better than ordinary white flour or bread. Only 3 samples show any really material increase in the proportion of gluten, and all of these contain at least three-fourths as much carbohydrate as ordinary baker's flour. The best sample examined contained twice as much carbohydrate as protein. . . . "[Products containing much less carbohydrates in proportion to protein are on sale in England, and] there can be no doubt that equally good products will be offered by American manufacturers whenever they are seriously demanded. The sale under the name 'gluten' of such breadstuffs as those here described is certainly a most serious imposition upon both physicians and patients."

Analyses of miscellaneous food materials, C. D. WOODS and L. H. MERRILL (*Maine Sta. Bul. 75, pp. 89–112*).—Analyses are reported of the eggs of turkeys, geese, ducks, and guinea fowls, several samples of desiccated eggs, egg substitutes, prepared pancake flours, pea flour, gluten foods, condensed foods or emergency rations, acorns, Italian chestnuts, malted nuts, and 3 tropical fruits, namely, alligator pear, rosella or Jamaica sorrel, and Surinam cherry.

Analyses of buffalo butter, sheep butter, lard, and walnut oil from Bulgaria, N. PETKOW (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 18, pp. 826–828*).—Analyses made at the Government Laboratory in Sofia, are reported.

Analysis of banana flour, H. H. COUSINS (*Jour Jamaica Agr. Soc., 5 (1901), No. 8, p. 322*).—The analysis of a flour of local manufacture is reported.

Fruits, nuts, and vegetables, A. BROADBENT (*Manchester, England: Author, 1900, pp. 103*).—The nutritive value of a considerable number of fruits, nuts, and vegetables is discussed, as well as the medicinal properties attributed to many of them.

Concerning the composition of certain fruit juices which are used in the preparation of confectionery, sirups, etc., TRUCHON and MARTIN-CLAUDE (*Ann. Chim. Analyt., 6 (1901), pp. 85–89; Jour. Pharm. et Chim., 6. ser., 13 (1901), pp. 171–176; abs. in Ztschr. Untersuch. Narh. u. Genussmtl., 4 (1901), No. 15, pp. 703, 704*).—A chemical study of the composition of the juice of cherries, strawberries, raspberries, currants, peaches, pears, quinces, and apples.

Glycerin content of dried fruits containing sugar, A. SCHMID (*Jahresber. Chem. Untersuch. Lab. Augsburg, 1901, p. 16; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 15, p. 702*).—After keeping for a time, apparently owing to fermentation, glycerin is found in different dried fruits, such as plums, apricots, and cherries, the amount being dependent upon the age of the fruit. Dried plums, 2 years old, contained 0.18 per cent glycerin. Alcohol was not found, though an abundance of compounds resembling aldehydes was present.

Deterioration of artificial foods, C. H. LAWALL (*Amer. Jour. Pharm., 73 (1901), No. 10, pp. 477–481*).—The changes brought about in food products by fermentation, putrefaction, and oxidation are spoken of, as well as deterioration due to the absorption of odors.

Preservation of chopped meat and the number of spores of micro-organisms in it, A. STROSCHER (*Arch. Hyg., 40 (1901), No. 4, pp. 291–319*).—The composition of a number of commercial preservative salt mixtures is given and the value of such mixtures is discussed as well as the possibility of rendering meat preserved with them harmful on account of the presence of sulphurous acid and salts.

Concerning the chemical composition and sanitary valuation of certain meat preparations, F. KESTNER (*Inaug. Diss. Pharm. Inst., Dorpat, pp. 88; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 14, pp. 646, 647*).—A study (including analyses) of a number of meat preparations.

Annual report of the progress of examination of food and condiments, 1899, H. BECKURTS and G. FRERICHS (*Jahresbericht über die Fortschritte in der Untersuchung der Nahrungs- und Genussmittel. Göttingen: Vandenhoeck and Ruprecht, 1901, pp. 138; noted in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), Nos. 13, p. 624; 18, pp. 863, 864*).—A reprint from the *Jahresbericht der Pharmacie* for 1899.

Reports upon food and drug inspection, microscopical examination of food, and arsenic and other poisons in manufactured goods (*Reprint from Massachusetts State Bd. Health Rpt. 1900, pp. 86, pls. 15*).—This report embraces statistical matter and investigations carried on by A. E. Leach under the State pure-food law.

Diet during training, H. LICHTENFELT (*Arch. Physiol. [Pflüger], 86 (1901), No. 3–4, pp. 177–184*).—The nitrogen elimination of 2 athletes was studied. The conclusion was drawn that the long-continued severe muscular work of athletes requires more protein than ordinary work, the amount ranging from 2 to 3 grams per kilogram body weight.

Observations in China and the tropics on the army ration and the post exchange or canteen, L. L. SEAMAN (*New York: Wynkoop, Hallenbeck, Cranford Co., 1901, pp. 18; reprinted from Med. Rec., 60 (1901), No. 1, pp. 1–4*).—A paper read at the annual meeting of the Association of Military Surgeons of the United States, St. Paul, Minn., June 1, 1901.

On the effect of alcohol on metabolism in man, A. CLOPATT (*Skand. Arch. Physiol., 11 (1901), No. 5–6, pp. 354–371*).—The author was himself the subject of experiments in which alcohol was added to a simple mixed diet during part of the investigation. The principal conclusions follow: Alcohol acted as a protector of nitrogen-free nutrients and, after the body had become accustomed to it, as a protector of protein also. It has no observable effect upon the resorption ot nutrients in the intestines.

The influence of alcohol on the metabolism of protein, R. ROSEMANN (*Arch. Physiol. [Pflüger], 86 (1901), No. 7–10, pp. 307–503*).—On the basis of original experiments and the results of other investigators, which are cited in detail, the author discusses the effect of alcohol on metabolism. The conclusion is reached that alcohol is a protector of protein, but that the effect is not manifest until the body cells become able to tolerate the alcohol.

When alcohol forms part of a ration, does its potential energy serve for the production of muscular work? A. CHAUVEAU (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 2, pp. 65–70*).—Experiments were made with a dog for a period of 389 days. The principal feature was the determination of the respiratory quotient during periods of work and rest, with a diet containing sugar and one in which sugar was replaced by alcohol. According to the author the results show that alcohol is not used to any extent, if at all, for the production of muscular work.

Influence of the substitution of alcohol for an isodynamic quantity of sugar in the diet; its effect on muscular work, maintenance, and waste, A. CHAUVEAU (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 3, pp. 110–114*).—The experiments which were made with a dog led to the following conclusions: When an isodynamic quantity of alcohol was fed in place of a part of the sugar in the ration of a working subject a short time before the performance of the work, unfavorable results were obtained.

Concerning metabolism in adult man with special reference to the amount of protein required, V. O. Sivén (*Skand. Arch. Physiol., 11 (1901), No. 5–6, pp. 308–332*).—Continuing previous work (E. S. R., 11, p. 1067) the author reports a number of experiments, in which he was himself the subject, to determine the possibility of bringing the body into nitrogen equilibrum with a diet containing a very small amount of protein. The experiments led to the following conclusions: It is possible to bring the body, at least for a short time, into nitrogen equilibrium when the diet contains, per kilogram body weight, from 0.7 to 0.8 gm. nitrogen, of which only some 0.3 gm. is necessarily albuminoid nitrogen. When the amount of nitrogen consumed is so low the energy requirement of the body is not increased, but is as great as under ordinary conditions with a diet rich in protein. When the protein in the diet is increased, after the body has lost a large amount of nitrogen, there is at once an effort to attain nitrogen equilibrium and it appears that any gain of nitrogenous material is a comparatively slow process. This apparently indicates that living substance must be slowly formed from the protein supplied in the diet. The data are also recorded for the sulphur and phosphorus balance, and results obtained are discussed at some length.

Concerning the utilization of protein in the food, H. Lichtenfelt (*Arch. Physiol.* [*Pflüger*], *86 (1901), No. 3–4, pp. 185–193*).—A summary of experiments on the digestibility of animal and vegetable protein led to the conclusion that the assimilation of this nutrient must be regarded as a body function and not a property of the protein itseif.

The amount of protein cleavage in fasting, E. Voit (*Ztschr. Biol., 41 (1901), No. 2, pp. 167–195*).—Experiments with fasting subjects are summarized and the conclusion drawn that the cleavage of protein during fasting depends not alone upon the amount of material broken down at a given time, but also upon the relation of protein to fat in the body.

Effects on digestion of food prepared by the use of alum baking powders, E. E. Smith (*New York Med. Jour., 72 (1900), pp. 719–721*).—As a means of judging of the heathfulness of bread made with alum baking powder the author conducted experiments with a healthy man in which bread made with such baking powder was compared with bread leavened with sodium bicarbonate and hydrochloric acid. The alum baking powder had approximately the following combination: Sodium carbonate, 1 part; desiccated soda alum, 1 part; starch, 3 parts. When the stomach contents were examined after eating test meals consisting of the 2 sorts of bread and water no marked differences were observed in total acidity, total, free and combined hydrochloric acid, or the pepsin test. The slight differences, in the author's opinion, were all within the limits of experimental error. The digestibility of the 2 sorts of bread was tested in the usual way with a healthy man. Meat, milk, and butter were eaten in addition to the bread, the amounts being the same in the two cases. Corrections were not made for the metabolic products in the feces, and the digestibility (which the author terms "availability") of the bread made with alum baking powder was as follows. Total solids, 95.9; protein, 90.9; fat, 94.63, and carbohydrates, 98.05 per cent. The digestibility of the control bread was: Total solids, 95.9; protein, 89.9; fat, 94.4, and carbohydrates, 98.4 per cent. As pointed out by the author, the agreement is as close as could be expected even in duplicate experiments. The volume, specific gravity, nitrogen, indican, and combined sulphate in the urine was determined in the tests, practically the same results being obtained in both cases.

"The composition of the urines in the two periods, as regards the constituents indicating the degree of absorption of such aromatic products of putrefaction as are formed in the intestines, are so nearly the same that we must conclude that they do not indicate a greater degree of the putrefactive process in one or the other period. In fact, the evidence of the experiment is that the dietaries in periods 1 and 2 are physiologically identical, and, since the dietary in each instance was composed to the extent of two-thirds of the breads described, the evidence of the experiment is that the two breads are physiologically the same.

"There are certain criticisms of this experiment well worth considering. The point is raised that the metabolic nitrogen is not subtracted from the total nitrogen of the feces, in other words, that the figures obtained represent not the actual digestibility, but rather the availability, of the diet. It would be interesting to subtract the metabolic nitrogen and obtain actual figures of digestibility, but that is not usually attempted in such experiments, since the methods of determining the metabolic nitrogen at present known are quite inaccurate. It is, after all, the gain to the body in each period which we seek to establish, and that is, of course, indicated by the availability, and not by the digestibility.

"The question whether the diet was full and nutritious, including that of whether the subject was in nitrogenous equilibrium, is not to be given the same consideration here as in metabolism experiments in which the question of the balance of income and outgo is all-important. Of course, the diet should contain a fair amount of food, but no effort need be made to establish an equilibrium; on the contrary, to diminish the monotony of a fixed diet, investigators usually administer a little less than sufficient to establish an equilibrium. This does not put the subject in an unhealthy or in any way abnormal state. In fact, individuals vary their diet in this way in everyday life, and even some athletes, in training, for a time do precisely this thing to attain perfect health. The body adapts itself to certain variations that we must recognize as physiological, and the fact that to-day we eat less and to-morrow more is not an evidence of ill health.

"In conclusion, then, the evidence of these experiments is that food prepared by the use of a so-called alum baking powder does not interfere with secretion in the stomach; and, even when it makes up the major part of the diet, it is utilized by the body in the same way and to the same extent as an acceptable control diet. The investigation does not reveal any reason for believing such food at all injurious or unwholesome."

Concerning the digestion of starch in the mouth and stomach of man, Müller (*Med. Woche, 1901, p. 80; Chem. Centbl., 1901, I, p. 637; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 13, p. 605*).—Experiments by a method which is described led to the following conclusions: When flour porridge and bread were eaten, 50 to 100 per cent of the starch was found in the stomach in soluble form, usually a short time after it was consumed. The effect of chewing on digestibility is marked; that of acidity, slight. Saliva is only slightly inferior to pancreatic juice as regards its power to digest starch.

Strength from eating, B. McFadden (*New York: Physical Culture Publishing Co., 1901, pp. 194, fig. 1*).—This book, which is written from a vegetarian standpoint, contains statements of a general character, including some not in accord with the views commonly accepted by phyiologists and physiological chemists.

Investigations on the excretion of carbon dioxid during muscular labor, J. E. Johansson (*Skand. Arch. Physiol., 11 (1901), No. 5–6, pp. 273–307, figs. 6*).—An apparatus of special construction for measuring positive, negative, and "static" work is described, as well as a number of experiments in which the amount of work performed and the carbon dioxid excreted were measured, the author himself being the subject.

The chemical composition of perspiration, W. Camerer (*Ztschr. Biol., 41 (1901), No. 2, pp. 271–274*).—The composition is reported of perspiration induced in a young man by different sorts of baths.

ANIMAL PRODUCTION.

Contribution to the subject of the decomposition of feeding stuffs and foods by micro-organisms which attack fat, J. König, A. Spieckermann, and W. Bremer (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), Nos. 16, pp. 721–744, fig. 1; 17, pp. 769–780*).—The authors summarize their investigations as follows: The 3 sorts of cotton-seed meal examined generally contained in considerable quantity the mycelium of different molds and different hay and potato bacteria. The molds increased when the water content was over 14 per cent. With a water content of from 14 to 30 per cent the molds predominated. When over 30 per cent was present the bacteria were more numerous. The sorts of molds varied with increased moisture content. The first mold noticed was *Eurotium repens* and this was soon followed by *E. rubrum.* When the moisture content was about 20 per cent, different species of Oidium were found, and when 25 per cent water was present, *Penicillium glaucum.* The growth of the molds is always accompanied by a loss of organic material and an increase in water content, the latter, without doubt, due to their respiration. In the first stages of molding, when the water content is about 20 per cent or less, the loss is chiefly fat in the case of cotton-seed meal, which is rich in this constituent. With a higher moisture content, especially when *Penicillium glaucum* is present, fat and nitrogen-free extractives (raffinose, etc.), are violently attacked and the pentosans in lesser degree. Proteids are broken down only in small quantity to nitrogenous compounds soluble in water but are not broken down to ammonia. A small part of the nitrogenous material present is apparently decomposed with the formation of free nitrogen.

The bacteria obtain the necessary carbon generally from nitrogen-free extractives (raffinose, etc.) and pentosans, and in a small measure from fat. On the other hand, they induce a deep-seated cleavage of proteids, which sometimes results in the production of ammonia. Experiments with pure cultures of the molds on cotton-seed meal and of other sorts on sterile cotton-seed meal, as well as on artificial culture media containing fat, have shown that these micro-organisms readily derive the necessary carbon from fat and the higher fatty acids, both liquid and solid. The growth of molds on fatty substances is always accompanied by a cleavage of fat, which varies in intensity with the species present. From the cultures of *Aspergillus flavus* and *Eurotium repens* on sterile cotton-seed meal, enzyms can be separated which produce butyric acid from monobutyrin. According to the authors' investigations this is not the case with cotton-seed oil. Such a cleavage necessitates a previous cleavage of the higher glycerids, and numerous investigations with adipolytic enzyms show that the quantity of free fatty acids produced increases with the amount of fat involved. Apparently the greater part of the fat is broken down directly to carbon dioxid and water.

The preservation and value of mixed molasses feeds, B. Schulze (*Arb. Deut. Landw. Gesell., 1901, No. 59, pp. 26*).—The composition of a number of maize germ molasses feeds and peat molasses feeds is reported. According to the author the keeping quality of molasses concentrated feed diminished with increased water content. Such changes progress more rapidly in summer than in winter. The feeds undergo a loss of sugar and much cane sugar is tranformed into invert sugar. Peat molasses changes little on keeping and has much the same digestibility as molasses itself.

The agricultural value of beet leaves, Hoppenstedt (*Fühling's Landw. Ztg., 50 (1901), Nos. 11, pp. 393–399; 12, pp. 431–438*).—Drying beet forage with special apparatus is recommended as superior to any other method of utilizing this by-product as a feeding stuff. The composition of the dry fodder is given.

Beef making with corn, Kafir corn, and alfalfa, F. C. Burtis (*Oklahoma Sta. Rpt. 1901, pp. 98–101*).—In continuation of previous work (E. S. R., 12, p. 670), the comparative value of corn meal and Kafir corn meal, fed with alfalfa hay and Kafir corn stover, was tested for 151 days with 4 lots containing 5 native grade steers each, averaging 1,026 lbs. in weight. Lots 1 and 2 were fed alfalfa hay, the former receiving Kafir corn meal and the latter, corn meal in addition. Lots 3 and 4 were fed Kafir corn stover, the grain ration of lot 3 being made up of Kafir corn meal and of lot 4, corn meal. The coarse fodder fed to the 4 lots per bushel of grain averaged 6.89, 6.58, 10.15, and 9.90 lbs., respectively. The average daily gain per steer of the 4 lots was 2.72, 2.73, 2.33, and 2.36 lbs., the grain eaten per pound of gain being 7.63, 6.63, 9.95, and 9.50 lbs. The steers were sold for slaughtering, the dressed weight being some 60 per cent of the live weight in every case. The shrinkage per head ranged from 33 lbs. in the case of lot 2 to 51 lbs. in the case of lot 3. The author notes that on an average, in the above test, "a bushel of corn meal produced, when fed to steers, about three-quarters of a pound more beef than did a bushel of Kafir meal. In addition to requiring from a fourth to a third less grain to produce a pound of beef, the alfalfa fed steers made about 16 per cent faster gains than did the Kafir stover fed steers."

Four pigs, averaging 125 lbs. in weight followed each lot of steers. In addition to the food gathered, each lot was fed 360 lbs. of the same kind of grain as the steers followed. The total gains made by the 4 lots of pigs were 272, 183, 410, and 226 lbs.; the grain fed per pound of gain, 1.32, 1.97, 0.87, and 1.58 lbs. respectively.

"Undoubtedly better gains could have been obtained with these pigs if more grain had been fed, but the pigs would not have picked the manure over so closely, and it is a question if it would pay to feed more grain.

"The difference in gains made by the lots can be accounted for largely by the fact that a much larger percentage of the grain passed through the steers getting Kafir stover than those getting alfalfa. Again, a much larger percentage of the Kafir meal passed through the steers than did the corn meal."

Cattle food (*Bul. Bot. Dept. Jamaica, n. ser., 8* (*1901*), *No. 10, pp. 153, 154*).—An analysis of gungo bean or saman pods and seeds (*Pithecolobium saman*) is quoted and its value as cattle feed discussed.

Concerning "kalf room" [calf cream], F. W. J. Boekhout (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4* (*1901*), *No. 17, pp. 781, 782*).—The author believes it probable that this calf food is made from peanut oil and sugar. The opinion has been previously advanced that this material was made up of cotton-seed oil, freshly precipitated casein, and sugar.

Breeding for beef in Trinidad, C. W. Meaden (*West Indian Bul., 2* (*1901*), *No. 2, pp. 169, 170*).—A brief discussion of the industry as affected by local conditions.

Zebu cattle in Trinidad, C. W. Meaden and J. H. Hart (*West Indian Bul., 2* (*1901*), *No. 2, pp. 166–169*).—A history of the introduction of Zebu cattle from India into Trinidad and neighboring colonies for crossing with native cattle.

Lamb feeding experiment, L. Foster (*Wyoming Sta. Bul. 47, pp. 47, pls. 4*).—Lamb feeding in general is discussed, and a test reported of the comparative value of alfalfa and native hay, combined with a grain ration for fattening lambs for market, the special object being to determine whether lambs can be profitably fattened under local conditions. One hundred grade lambs of rather inferior quality were divided into 2 lots of 50 each. After a preliminary period of 1 week the test began December 28 and continued 95 days. Lot 1 was fed native hay of medium quality and lot 2, first and second crop alfalfa hay. In addition, both lots were fed corn and oil cake, the amount of grain being increased as the experiment progressed. The average daily gain in the 2 lots was 0.253 and 0.324 lb., respectively. The sheep in lot 1 consumed per head daily, on an average, 1.07 lbs. native hay, while those in lot 2 consumed 1.47 lbs. alfalfa hay, both lots receiving in addition 0.76 lb. grain and 0.04 lb. oil cake. The cost of food per pound of gain was 4.48 cts. in the case of lot 1, and 3.89 cts. in the case of lot 2. It was observed that the lambs fed alfalfa consumed more water than those fed native hay. A record covering 1 month showed that the former drank 17 per cent more than the latter. The sheep were slaughtered at the end of the trial. The principal conclusions follow:

"Taking the experiment as a whole, the results show a small [pecuniary] loss but the actual gains were made at a fair profit on both the alfalfa and the hay. The indications are that under ordinary conditions lambs will give good returns per ton for either native hay or alfalfa fed in connection with a light grain ration. To produce the quality of mutton in greatest demand by consumers, the feeding period need not include more than 90 days.

"For lamb feeding it is advisable to grow alfalfa in preference to native hay on all lands under irrigation where it can be successfully produced."

Cotton-seed meal as pig feed, F. C. Burtis (*Oklahoma Sta. Rpt. 1901, pp. 102–107*).—Cotton-seed meal is generally regarded as a dangerous feed for pigs. The author had found that a mixture of cotton-seed meal and corn or Kafir corn meal, 1:4, gave excellent results, and few pigs died if the meal was not fed for more than 4 weeks. He also observed that when the pigs had a wide range and green feed unfavorable results did not follow its use. Good results followed the feeding of cotton-seed fed for short periods separated by periods in which none was fed. These points were tested in 2 trials. In the first, 17 pigs averaging 80 lbs. each were fed for 67 days. From the first to the twenty-seventh day, the forty-first to the fifty-fifth day, and the sixty-second to the sixty-seventh day, inclusive, the grain ration consisted of cotton-seed meal with Kafir corn meal (or Kafir corn meal and corn meal), 1:4. At the other times the grain ration consisted of a mixture of Kafir corn meal and corn meal. During the whole test the pigs had the run of a large paddock where they could procure some green food. In the first period on cotton-seed meal the average daily gain per pig was 1.28 lbs., the grain required to produce a pound of gain 3.19 lbs., and the cost of food per pound of gain 1.72 cts. In the second cotton-seed meal period the corresponding figures were 1.21 and 4.39 lbs. and 2.37 cts. In the first period without cotton-seed meal the average daily gain per pig was 1.04 lbs., the grain required to produce a pound of gain 5.71 lbs., and the cost of food per pound of gain 2.55 cts. The data are not recorded for the other periods. The author observes that although the periods are not directly comparable it can be plainly seen that "the pigs made much better gains while receiving the cotton-seed meal, and required much less grain to produce a pound of pork. None of the pigs died, although they had received cotton-seed meal as a part of their ration for 46 days, 27 of which were consecutive."

At the close of the test 13 of the pigs were sold. The remainder were continued on the cotton-seed meal ration for 47 days longer. One of the pigs died on the twenty-first day of the supplementary period; the others were sold at its close as fat hogs.

In the second test, 16 pigs about a year old, in poor condition (averaging 79 lbs. each in weight), were hurdled on wheat and fed a light ration of cotton-seed meal and Kafir corn meal (1:4) for 26 days. They were then shut in a lot and fed the same grain ration for 21 days longer. While hurdled on the wheat the average daily gain per pig was 0.96 lb.; the grain fed per pound of gain, 3.11 lbs. When fed in the lot, the average daily gain per pig was 1.71 lbs.; the grain eaten per pound of gain 3.07 lbs. Five of the pigs were sold. The cotton-seed meal ration was fed to the remainder for 47 days longer. All the pigs lived and were sold as fat hogs.

"Our work has gone far enough to enable us to state that excellent gains may be obtained by adding 1.5 [lbs.] cotton-seed meal to a pig ration, and that it may be so fed that there is but a small chance of any of the pigs dying from the effects of it. We are not ready yet to say exactly how or under what conditions this should be, but under our methods the death rate was so small that the gain from feeding the cotton-seed meal greatly overbalanced it.

Cowpea hay for swine, F. C. BURTIS (*Oklahoma Sta. Rpt. 1901, pp. 108–111*).—Two tests on the value of cowpea hay for pigs are reported. The first was made with 2 lots of 4 pigs each, about 8 months old. Both lots were fed in pens, receiving a grain ration of corn meal and Kafir corn meal, 1:1. In addition, lot 1 was fed cowpea hay. In the 10 weeks of the test the average daily gain in the 2 lots was 1.09 and 0.43 lbs., the grain eaten per pound of gain being 4.46 and 6.95 lbs., respectively. The amount of cowpea hay eaten by lot 1 averaged 2.18 lbs. per pound of gain. The author notes that at the close of the test lot 1 was in a fairly marketable condition while the condition of lot 2 was not so satisfactory.

The second test was made with 2 lots of pigs each about 4 months old. They were fed the same rations and under the same conditions as in the preceding test. The average daily gain per pig in the 2 lots was 0.46 and 0.24 lb., respectively, the grain eaten per pound of gain being 7.1 and 9.8 lbs., respectively. In addition to grain, the pigs in lot 1 ate 1.87 lbs. cowpea hay per pound of gain. In this test also, the best results were obtained with the ration containing cowpea hay.

Pig farming on the paddock system, W. H. CLARKE (*Agr. Gaz. New South Wales, 11 (1900), Nos. 9, pp. 788–792, pl. 1; 11, pp. 993–1000*).—Raising pigs by grazing them on a succession of crops is discussed with reference to local conditions.

The value of barley and pumpkins as horse feed (*Queensland Agr. Jour., 9 (1901), No. 2, p. 187*).—The value of barley and pumpkins is pointed out in a brief note. The latter were found to be especially useful for horses affected with "old man asthma" due to eating corn and chaff.

Improvement of the breeds of horses (*Bul. Agr. [Brussels], 17 (1901), No. 4, pp. 416–465*).—A circular sent to the governors of the different provinces of Belgium regarding an effort to improve breeds of horses.

Points on producing draft horses, W. J. KENNEDY (*Farm Students' Rev., 6 (1901), No. 10, pp. 150, 151*).—Desirable qualities are pointed out and discussed.

Farm poultry keeping (*Oklahoma Sta. Rpt. 1901, pp. 63–85*).—This is practically a reprint of Farmers' Bulletin No. 41 of this Department (E. S. R., 8, p. 428).

Concerning the iron content of hens' eggs and experiments on the increase of iron in the egg when hæmogallol and ferrohæmol are fed, P. HOFFMANN (*Ztschr. Analyt. Chem., 40 (1901), No. 7, pp. 450–459, dgm. 1*).—When hæmogallol and ferrohæmol were fed to hens, the iron content of the eggs produced was increased, the former having more effect than the latter, although it contains less iron. The effect was influenced by outside conditions, for instance, by the diet. When cuprohæmol was fed no copper was found in the eggs.

DAIRY FARMING—DAIRYING.

Feeding trials with cows, J. L. HILLS (*Vermont Sta. Rpt. 1900, pp. 391–443, 461–502, fig. 1*).—Extensive feeding experiments including 48 cows and lasting 28 weeks, in part a continuation of previous work (E. S. R., 12, p. 283), are reported in detail and summarized at some length. The different experiments included from 3 to 11 cows, and covered periods of 4 weeks each.

An experiment was conducted to determine how much grain may be fed with profit. "Four, eight, and twelve pounds of 3 different grain rations were fed at different times with hay and silage to 11 cows, each animal being kept throughout the experiment upon the same grain ration, so far as character is concerned, but a different one as regards its amount. The outcome was essentially as follows: *Quantity.*—The more grain, the more milk, total solids, and fat. *Quality.*—Only slight changes were observed as a result of variation in amounts of grain fed. Such alterations as occurred were in the general direction of better milk on medium than on either low or high feeding. *Economy of production.*—A pound of dry matter produced more on the low than on either the medium or high grain feeding. There was but little difference in this respect between the medium and the high ration. *Live weight.*—Increased feeding usually affected the milk flow only in the first few months of lactation, but from the fourth month on there seemed to be a greater tendency to affect the live weight than to alter the milk flow. *Financial outcome.*—In these trials an increase of grain from 4 lbs. to 8 or 12 lbs. seldom yielded enough more butter to pay the cost of the extra grain. In practically every case, however, there was enough more skim milk and enough better manure made to more than offset the extra expense for grain. . . . The outcome of these trials is in many ways parallel to that of similar experiments lately reported by the Wisconsin Station [E. S. R., 12, p. 81]."

The effect of adding single nutrients—protein, carbohydrates, fat—to standard rations was studied with 9 cows during 3 feeding periods. The results are summarized as follows: "*Protein.*—The addition of about one-fifth more digestible protein to a ration already containing amounts of this nutrient greater than standard requirements was practically without effect as a milk stimulant. *Carbohydrates.*—The addition of about one-fifth more digestible carbohydrates to a ration containing amounts of these nutrients equal to or in excess of standard requirements had little or no effect upon either the quantity or quality of the milk flow. *Fat.*—The addition of a solid fat to a ration already containing digestible ether extract in excess of standard requirements increased its digestible fat content about one-half. It had a slight effect upon the quantity and a pronounced effect upon the quality of the milk flow. The total solid percentage was increased 2 per cent (0.24 per cent) and the fat 7 per cent (0.36 per cent). The increase appears to have been a permanent one."

The feeding value of buckwheat middlings was compared with that of (1) corn meal, wheat bran, cotton-seed meal, and linseed meal, and (2) corn meal and wheat bran. Buckwheat middlings were about equal in value to ration 1 as regards the quantity of milk, total solids, and fat produced, but increased the yield of total solids and fat from 8 to 11 per cent over ration 2. The fat content of the milk was increased about 0.20 per cent when buckwheat middlings were fed in considerable quantities. Buckwheat middlings produced cheaper milk and butter, especially as compared with the corn and bran ration.

A ration containing cotton-seed meal, linseed meal, corn meal, and wheat bran was compared with a ration containing Quaker dairy feed. The nutritive ratios of the 2 rations averaged, respectively, 1:5.3 and 1:7.7. "The medium ration produced 6 per cent more milk, total solids, and fat than did the wide ration. The quality of the milk remained unchanged."

Rations of (1) corn and bran and (2) Quaker dairy feed having practically the same nutritive ratios were compared as in previous years. "The corn and bran and Quaker dairy feed made equal quantities of milk and of butter. If the extra manurial value of the corn and bran ration is reckoned as an offset of its extra cost the outcome was exactly even. If this is not taken into account the dairy feed proved preferable."

In experiments in grooming and watering cows "there was 4 per cent less milk yielded when the cows were groomed than was given when they were left uncarded. The quality of the milk remained unaltered. . . . No more and no better milk was made when the cows drank at will than when they drank twice daily. . . . Warming water from 45 to 70° F. did not avail to improve either the quantity or the quality of the milk yield with cows stabled in barns the average winter temperature of which was 45 to 50° F."

The effect of feed on the quality of butter, J. L. Hills (*Vermont Sta. Rpt. 1900, pp. 443–445*).—The effect of rations made up of hay and silage and different concentrated feeding stuffs upon the quality of butter was studied in connection with the experiments noted above and in continuation of previous work (E. S. R., 12, p. 285). The concentrated feeding stuffs compared were buckwheat middlings and a mixture of wheat bran, corn meal, cotton-seed meal, and linseed meal, alone and with the addition, respectively, of buckwheat middlings, gluten flour, sugar, and palm oil. The average results of analyses of 47 samples of butter are given. Buckwheat middlings made a firmer butter than the ration containing cotton-seed meal and linseed meal, the volatile acid content being higher and the iodin number lower. The addition of sugar increased the volatile acid content of the butter and decreased the iodin number, the melting point remaining practically unchanged. The ration containing palm oil decreased the iodin number and increased the melting point nearly 2° C. without changing the volatile acid content.

Feeding experiments, J. S. MOORE (*Mississippi Sta. Rpt. 1901, pp. 23–26*).—Tests were made to compare cotton-seed meal with wheat bran and Johnson grass hay with cowpea hay for milch cows. Different amounts of cotton-seed meal and wheat bran were fed to 3 lots of 3 cows each in 2 tests of 4 weeks each. The data are tabulated. The results are considered as showing that 4 lbs. of cotton-seed meal are equal to 6 lbs. of wheat bran. Results of feeding cowpea hay and Johnson grass hay in rations otherwise alike to 2 lots of 3 cows each for 4 weeks indicated that the 2 kinds of hay have practically the same feeding value. The results of these and earlier experiments are considered as showing that 1 lb. of cotton-seed meal, 1.71 lbs. of cotton seed, 2 lbs. of corn meal, and 1.5 lbs. of wheat bran have the same feeding value.

A comparative experiment in feeding oil cake to dairy cattle, G. FASCETTI (*Staz. Sper. Agr. Ital., 34 (1901), No 9, pp. 849–864*).

Dairy herd records, G. H. TRUE (*Arizona Sta. Bul. 39, pp. 293–309, figs. 3*).—Introductory notes are given on Arizona as a market for dairy products, cooperative creameries, and on the care of milk. Tabulated records are given of 58 herds in Salt River Valley for the year ended October 31, 1900, and of 43 herds for 6 to 11 months. Of the 58 herds 16 failed to pay what the author estimates as the cost of keeping ($32 a year per cow). The gross returns from the average cow of the best herd was $54.80, and from the average cow of the poorest herd $13.28. The differences in returns from different herds are attributed mainly to differences in the quality of the cows, as methods of feeding are considered practically uniform. Individual records are given of 12 pure-bred Jersey and 30 grade cows belonging to 2 herds ranking among the best for the year. Variations in the fat content of the milk of each cow during the year and between consecutive tests are tabulated. The author believes that the only way of determining the value of a cow involves weighing and testing all of the milk.

Record of dairy herd, J. S. MOORE (*Mississippi Sta. Rpt. 1901, pp. 17–23*).—A record is given of 9 pure-bred Jersey cows for the calendar year 1900. The data are tabulated and summarized as follows: "The record of the herd for the year shows that the average cost of the feed was $33.54, ranging from $30.66 to $36.51. The yield of milk ranged from 3,801 lbs. to 7,045, the average being 5,149 lbs. The average amount of butter was 324.6 lbs., and ranged from 267.6 to 436.2 lbs. The average cost of feed to produce 100 lbs. of milk was 66.4 cts. The cost of producing 1 lb. of butter ranged from 8.37 cts. to 12.29, the average being 10.52 cts."

Records of the station herd for 1898–99 and 1899–1900 (*Vermont Sta. Rpt. 1900, pp. 445–460*).—These records are similar in character to those previously reported (E. S. R., 12, p. 286). The following table summarizes some of the data for 6 years.

Average herd record for 6 years.

Year.	Number of cows.	Yield of milk.	Fat content of milk.	Yield of butter.	Cost of food.	Cost of purchased grain.	Cost of food per pound of butter.	Proceeds from butter sales.
		Pounds.	*Per cent.*	*Pounds.*			*Cents.*	
1895	33	5,633	4.95	325	$50.06	$18.85	16.2	$76.40
1896	37	5,431	5.12	324	42.00	14.22	13.8	74.51
1897	29	5,730	5.06	338	47.45	18.69	15.3	82.04
1898	42	5,296	5.06	313	46.40	15.73	15.6	80.58
1899	47	5,462	5.02	320	45.17	15.57	14.5	83.18
1900	45	5,935	5.15	357	52.43	21.20	15.2	97.15

Lessons from the model dairy tests, E. Van Alstyne (*Amer. Agr.* (*mid. ed.*), *68* (*1901*), *No. 21, p. 518*).—An article from the superintendent of the model dairy tests at the Buffalo Exposition regarding several points brought out.

The sampling of milk, H. Wibbens (*Orgaan Ver. Oudleer. Rijks Landbouwschool, 13* (*1901*), *No. 153, pp. 79, 80*).—The author found that portions taken with a glass tube plunged into a can of milk could not always be depended upon as fair samples for determining the fat content. The two factors that influence the result are the rapidity with which the sampler is plunged into the milk, and the degree to which the cream has risen. The former can be controlled by putting the sampler in carefully, and the latter may be rendered accurate by thoroughly stirring the milk before sampling.

In a series of tests with samples taken from the same can of milk after it had stood for some time and again after stirring, it was found that the percentage of fat was greater in the first case. It is therefore recommended to draw the samples only after the milk has been thoroughly mixed in the can.—H. M. PIETERS.

The influence of high temperatures upon the casein of milk, H. Conradi (*München Med. Wchschr., 48* (*1901*), *pp. 175–177; abs. in Chem. Centbl., 1901, I, No 15, p. 843*).—The author made a study of the effect of sterilization upon the composition of milk, and also the influence of calcium and other salts upon the temperature of coagulation. Milk containing 0.2 to 0.6 per cent of $CaCl_2$ coagulated at a temperature between 45 to 65° C. After heating over 80° the coagulating point fell from 8 to 12°, while milk heated 75 to 80° coagulated at the same temperature as milk not heated. As found by von Freudenreich, no variation was produced by heating one-half hour at 70°. Heating milk containing calcium chlorid above 80° not only lowered the temperature of coagulating, but increased the time required. The results indicate that heating milk above 80° causes chemical and physical changes in its composition.

Treatment of pasteurized milk, Elvira Smeyers (*Lait. Belge, 1901, No. 9, pp. 129–139*).—In a study of pasteurizing milk from 85 to 90° C., cooling one portion rapidly to from 12 to 16°, and preserving both portions at a temperature of from 14 to 20°, it was found that the milk which was gradually cooled kept better than that which was cooled immediatety after pasteurizing and kept under the same conditions of temperature.

Instructions for milk and cream suppliers, G. S. Thomson (*Jour. Agr. and Ind., South Australia, 5* (*1901*), *No. 2, pp. 105–114, figs. 9*).—General instructions, with some rules for the dairy farmer.

An investigation on the value of certain sanitary and other precautionary measures, employed in the protection and marketing of milk, upon the bacterial contents of the milk, D. H. Bergey (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 133–163, figs. 2*).—This investigation was made for the purpose of studying the bacterial content of milk from individual cows and from dairies of different classes, also the estimation of the prevalence of streptococci, and, incidentally, the presence of tubercle bacilli in the milk. The different dairies studied were divided into 3 classes as follows: (1) those in which the utmost care was taken in all details of the management; (2) those in which ordinary precautions were taken in the selection of cows, the nature and variety of food, care and cleanliness of cows, milkers, and utensils, and (3) dairies in which no particular care was observed in the selection and management of the cows, or in the collection, storing, and marketing of the milk. The investigations cover a large number of determinations, which are reported in a series of tables.

From the results the following deductions are drawn: "(1) Milk taken directly from the udder in the ordinary way and collected in sterile test tubes was always found to contain bacteria of the group streptococci. The number in the first milk drawn was usually greater than the latter portion. (2) Where the milk pails were sterilized by steam before and after milking each cow, the number of bacteria was but little higher than when the samples were taken direct from the cows. (3) When the milk pails were not sterilized, the number of bacteria was higher than when the milk was collected directly. The greater the care in milking and the better the hygienic conditions of the cows and surroundings, the lower the bacterial content of the milk. (4) There was an enormous increase in the number of bacteria during shipment. From the large bacterial content of milk collected on depot platforms it is apparent that there is much room for improvement in the methods of collection and shipment. (5) It was found that some bacteria gained access to the milk during the processes of filtering, cooling, and bottling. It is therefore recommended that the apparatus employed for this purpose should be as simple as possible, and so constructed that it can be easily disconnected, cleaned, and sterilized. (6) A few leucocytes were found in practically all the milk examined, and this appears to be an entirely normal condition. (7) The prevalence of pus cells in the milk appeared to be influenced directly by the hygienic condition of the cows. This is also apparently influenced to some extent by other factors, probably by the character of the food. (8) Though no positive evidence was obtained of any pathogenic effect of the streptococci in the milk when inoculated into guinea pigs and rabbits, it is probable that when these organisms are present in large numbers, as in some of the samples, they would be injurious to infants or sick persons when such milk is taken in large quantities."

The presence of tubercle bacilli in market milk, and its diffusion, C. Tonzig (*Arch. Hyg., 41 (1901), No. 1, pp. 46–67*).—A study of the tubercle bacilli content of market milk of Padua, and statistics of various provinces in Italy.

Hydrogen peroxid as a preservative, especially for milk, Jablin-Gonnet (*Ann. Chim. Analyt., 6 (1901), pp. 129–133; abs. in Chem. Centbl., 1901, I, No. 21, p. 1173*).—The author found hydrogen peroxid to be an efficient and harmless preservative for milk. Young dogs and cats thrived upon portions of milk containing 10 to 15 cc. of it. The author himself during 2 months consumed ½ liter of milk daily containing 8 per cent of hydrogen peroxid, without experiencing the least derangement. The hydrogen peroxid employed was neutralized with calcium carbonate; 1 cc. preserved 1 liter of milk 2 days; 2 cc., 4 days; and 3 cc., for 6 days.

Systematic inspection of milk for preservatives, A. E. Leach (*Analyst, 26 (1901), No. 308, pp. 289–291*).—Statements regarding the inspection of milk in Massachusetts, and methods for the detection of preservatives. In 5,169 samples examined, 3.5 per cent were found to contain foreign substances. The most common were formaldehyde, boric acid, and sodium bicarbonate, the former being on the increase and the two latter on the decrease.

Inspection of dairy products (*Chicago Dairy Produce, 8 (1901), No 49, p. 6*).—Rules adopted by this Department covering the inspection and marking of dairy produce for export.

Conditions and methods of making some of the high score butter recently exhibited (*New York Produce Rev. and Amer. Creamery, 1901, Nov. 13, pp. 18–19*).—Statements from different makers of prize-winning butter exhibited at State fairs regarding the methods followed.

Scoring butter, H. E. Alvord (*New York Produce Rev. and Amer. Creamery, 1901, Nov. 6, pp. 12, 13*).—A discussion of improvements in the method of scoring.

Uniformity in Danish butter, M. Mortensen (*Creamery Jour., 12 (1901), No. 146, pp. 8, 9*).—The author states that the position held by the Danish butter in the world's market is due largely to the uniformity of the product. Certain processes prevailing in Danish creameries are cited as being responsible for the uniform high quality of the output.

Butter in China (*U. S. Consular Rpts., 67 (1901), No. 254, p. 454*).—A report from Consul-General Hughes regarding the demands of the Chinese trade in butter, and the form of package best suited for their markets.

The conservation of butter, E. RIGAUD (*Ind. Lait. Belge, 2 (1901), No. 41, pp. 321–323*).—A description of various methods of treatment for the purpose of preserving the quality of butter.

Fishy flavor in butter, H. G. PIFFARD (*New York Produce Rev. and Amer. Creamery, 1901, Nov. 13, p. 20*).—A discussion of the cause of fishy flavor in butter.

A study of butter fat, A. PARTHEIL (*Arch. Pharm., 239 (1901), pp. 358–363; abs. in Chem. Centbl., 1901, II, No. 7, p. 504*).—An investigation of the molecular weight of butter fat and its application in determining the purity of butter.

The determination of margarin in butter, C. ANNATÓ (*Pharm. Ztg., 46 (1901), No. 693, pp. 31–38; abs. in Chem. Centbl., 1901, II, No. 14, p. 836*).—The author made a test to determine the influence of sesame cake upon the butter fat. He fed 3 cows increasing amounts of sesame cake, from 2 to 5 lbs., and examined the resulting milk. In the third period sesame oil was found in the milk by the furfurol reaction. From the results obtained, the conclusion is drawn that the presence of sesame oil in butter from cows fed on sesame cake is not necessarily an adulteration.

Cryoscopic distinction between butter and margarin, W. PESCHGES (*Arch. Pharm., 239 (1901), pp. 358–363; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 468, II, p. 630*).—From his investigations the author found the method of distinguishing between butter and margarin by means of cryoscopic determination of the molecular weight in benzene to be invalid.

Analysis of cheese and butter manufactured at the Queensland Agricultural College, J. C. BRÜNNICH (*Queensland Agr. Jour., 9 (1901), No. 4, pp. 424–428*).

The utilization of skim milk, C. BESANA (*Ann. R. Staz. Spèr. Caseif. Lodi 1900, pp. 19–57*).—A discussion of the various ways in which skim milk is utilized in Italy.

The composition and fertilizing value of the slime from the milk separator, G. FASCETTI (*Ann. R. Staz. Spèr. Caseif. Lodi 1900, pp. 69–71*).

Dairy history of Illinois, A. B. HOSTETTER (*Chicago Dairy Produce, 8 (1901), No. 45, pp. 26, 27*).—A review of the growth of the industry in Illinois and factors that have influenced it.

Report of dairy expert, M. A. O'CALLAGHAN (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 920–923*).—A short report on the progress of the dairy industry in New South Wales during 1900.

Dairy instruction in Alabama (*Chicago Dairy Produce, 8 (1901), No. 49, p. 22*).—Educational work in dairying among the colored people of the institute at Tuskegee.

VETERINARY SCIENCE AND PRACTICE.

Report of the state veterinarian, L. PEARSON (*Pennsylvania Dept. Agr. Rpt. 1900, pt. 1, pp. 118–129*).—During the year 1900 it is reported that glanders and contagious ophthalmia of cattle prevailed to a greater extent than during the past four or five years. The increased prevalence of glanders was directly due to the importation of a carload of infected mules from East St. Louis, Ill. Stringent measures were taken in combating this outbreak, and it is believed that the disease has been exterminated.

A general discussion is given on the prevalence of tuberculosis among cattle in the State, and attention is called to the desirability of continuing strict quarantine regulations against the disease and the thorough application of the tuberculin test. The expense of making this test is considered very small in comparison with the benefits which are derived from it.

Brief notes are also given on rabies, sheep scab, hog cholera, abortion, and forage poisoning.

16275—No. 6—02——7

The mechanism of agglutination, A. Joos (*Ztschr. Hyg. u. Infectionskrank.*, *36* (*1901*), *No. 3*, *pp. 422–439*).—This paper is concerned with the discussion of results obtained from experiments in agglutination with and without the addition of common salt. The experiments were made with the typhus bacillus. The results of the experiments may be briefly summarized as follows: When an agglutinating serum is brought in contact with a substance which is subject to agglutination, no agglutinating process takes place in the absence of salt. When salt is added, agglutination occurs readily. In the absence of salt the agglutinating serum is entirely sterilized by the action of the bacilli, without producing any change in the vitality of the latter. A close connection exists between the relative quantities of the substances which cooperate to produce agglutination and the substances which are to be agglutinated. The process of agglutination may occur in a solution which is free from salt, provided the bacterial cells contain some of this substance.

Coagulation of the blood and anticoagulation serum, J. Bordet and O. Gengou (*Ann. Inst. Pasteur*, *15* (*1901*), *No. 3*, *pp. 129–144*).—During these experiments it was found that the blood plasma of birds is poor in fibrin ferment and serves as a convenient reagent for checking the action of fibrin ferment in the blood sera of several species of mammals. The blood plasma of rabbits can be preserved without undergoing coagulation in a tube sealed with paraffin, but coagulates rapidly in contact with roughened glass. It was found that when one animal was injected with the blood plasma or serum of a second species, a serum was obtained which had the effect of neutralizing the fibrin ferment of the second species.

Experimental vaccine, A. Calmette and C. Guerin (*Ann. Inst. Pasteur*, *15* (*1901*), *No. 3*, *pp. 161–168*).—During the researches reported in this article it was found that an inoculation of rabbits with vaccine was uniformly followed with eruption of small pustules containing large quantities of lymph. The rabbit proved to be a useful animal in this study, since it is possible to verify readily by inoculations into rabbits the relative degree of virulence of vaccines obtained from different sources. By injecting vaccines into the peritoneal cavity of rabbits, the micro-organisms contained in such material are destroyed by the leucocytes without influencing the virulence of the virus.

A study of Bacillol, F. Paszotta (*Monat. Prakt. Thierh.*, *12* (*1901*), *No. 6–7*, *pp. 241–275*).—A description is given of the general properties of this substance. Numerous experiments were conducted in testing its antiseptic power in the treatment of mange, other skin diseases, surgical wounds, and in determining its toxic action. During these experiments it was found that Bacillol is soluble in water and that the solutions are constant. When used on the skin in a concentrated form it is slightly irritant, like lysol. Its antiseptic and deodorizing properties are pronounced. When administered internally, it causes an increased secretion of saliva, the respiration and pulse are increased, but the temperature is lowered. In large doses it causes a motor paralysis. The fatal internal dose of this substance is so large that all danger in its practical application is avoided. A bibliography of the subject is added.

Therapeutic contributions in veterinary science during the years 1898, 1899, and 1900, E. Bass (*Deut. Thierärztl. Wchnschr.*, *9* (*1901*), *No. 12*, *pp. 120–133*).—The author gives a brief digest of the therapeutic literature along veterinary lines and in connection with bibliographical references.

Antitoxic treatment of tetanus, J. Storie (*Vet. Jour.*, *n. ser.*, *3* (*1901*), *No. 16*, *pp. 201–205*).—Six cases of tetanus were treated by this method with a complete recovery in 5 cases. The cases were all severe, and the author believes the most of the animals would have succumbed without this treatment.

The primary effect of the tubercle bacillus, F. Wechsberg (*Beitr. Path. Anat. u. Allg. Path.*, *29* (*1901*), *No. 2*, *pp. 203–232*, *pls. 2*).—This paper is concerned with a discussion of the question of what cells take part in the formation of the tubercle. An elaborate critical review is given of the literature of the subject and a report is made on experiments upon rabbits which were inoculated intravenously. From these experiments it is concluded that the tubercle bacillus by its toxic action destroys the epithelial cells and connective tissue. At first the newly formed cells are affected only in so far as the connective tissue and vascular tissue fail to be formed. Ultimately these cells are completely destroyed and caseified.

The distribution of the lesions in generalized tuberculosis, J. McFadyean (*Jour. Comp. Path. and Ther., 14 (1901), No. 1, pp. 1–11*).—This paper contains a report on experiments with reference to the agency of the blood circulation in the generalization of tuberculosis. Ten cattle were inoculated intravenously with virulent cultures of tuberculosis and careful post-mortem examinations were made after varying lengths of time. In all cases the lungs contained numerous tubercles, while tubercles were found in the liver and kidneys in only 3 cases and in only 1 case in the spleen. The best evidence of generalization of the disease is believed to be the presence of tubercles of nearly equal sizes scattered throughout the entire substance of the lung. The evidence of generalized tuberculosis from an examination of other organs is usually not reliable. In cases of generalized tuberculosis the kidneys, liver, or spleen may be entirely free from tubercular lesions which can be recognized by the naked eye. The tubercles which are found in the liver, spleen, kidneys, and lymphatic glands are, as a rule, due to lymphatic action and not to the agency of the blood circulation. Tubercle bacilli are readily carried in the lymphatic vessels downward from the center of infection. During the post-mortem examinations abundant evidence was noticed of the process of recovery which was taking place in the older tubercles. An infection of the lymphatic system was noted in 4 of the 10 cases.

Tuberculous meningitis in cows and the infection of the fetus, H. Thon (*Deut. Thierärztl. Wchnschr., 9 (1901), No. 11, pp. 107, 108*).—The author gives details of the clinical symptoms and post-mortem findings in a cow infected with tuberculosis. The symptoms indicated an invasion of the brain by the tubercle bacillus, and the post-mortem examination revealed the presence of pathological changes in the cerebral membranes. Tubercles were also found on the surface of the fetal liver.

Cattle inspection and the tuberculin test, G. B. Jobson (*Jour. Comp. Med. and Vet. Arch., 22 (1901), No. 3, pp. 144–148*).—The author discusses the influence of œstrum, stabling in warm weather, age, and other circumstances, upon the temperature of cattle, with reference to difficulties of diagnosis from the tuberculin test. The temperature of 10 cattle under 1 year of age averaged about 0.4° higher than that of 10 other cattle over 3 years of age. All cattle were free from tuberculosis. The author believes that the absence of a reaction to a second test of tuberculin is not conclusive in showing that the animal is free from tuberculosis. Several cases are noted in which there was a failure to react in animals which were known to be tuberculous. A brief discussion is given of the difficulties in arriving at a satisfactory estimate of the value of condemned animals.

Results of seven years' work in testing with tuberculin, F. G. Meyer (*Maanedsskr. Dyrlæger, 12 (1901), No. 11, pp. 409–418*).—The author reports in detail on the condition of cattle in Norway with reference to the prevalence of tuberculosis. The results of tuberculin tests are brought together in tabular form, from which it appears that from 1893 to 1900, 11,686 cattle were tested in 402 herds, and 20 per cent were found to be tuberculous. Brief notes are also given on the prevalence of tuberculosis among calves.

Tuberculosis of cattle and the Pennsylvania plan for its repression, L. Pearson and M. P. Ravenel (*Pennsylvania Dept. Agr. Bul. 75, pp. 262*).—This is a reprint from Pennsylvania Department of Agriculture Report for 1899 (E. S. R., 12, p. 686).

Bibliography of literature on tuberculosis, from January 1 to November 1, 1900 (*Rev. Tuberculose, Paris, 8 (1901), No. 1, pp. 107–162*).—This extensive bibliography is classified according to the subject-matter of the various articles.

Spore formation of anthrax bacillus under anaerobic conditions, R. WEIL (*Ztschr. Hyg. u. Infectionskrank., 36 (1901), No. 3, pp. 451–458*).—The present article is of a controversial nature and largely concerned with a reply to an article on the subject by Klett (E. S. R., 13, p. 92). The author contends that the formation of spores does not take place under strictly anaerobic conditions upon the ordinary nutrient media, while there are a few special media on which the anthrax bacillus forms spores under the same conditions.

The post-mortem diagnosis of anthrax in cattle, H. C. REEKS (*Jour. Comp. Path. and Ther., 14 (1900), No. 1, pp. 11–16*).—A discussion is given by way of answer to the questions whether an opinion may be safely rendered in suspected cases of anthrax from the outside appearance, whether a post-mortem examination shall be made, whether reliance shall be placed upon a microscopic examination of the blood, and whether a sample of blood or spleen shall be sent to an expert. While the careful practitioner will probably diagnose a large proportion of cases accurately from the mere external appearance of the carcass, it is urged that a microscopic examination of the blood be undertaken, or, if the practitioner is not an expert microscopist, that samples be sent to an expert. The practice of making post-mortem examinations is condemned as useless and criminally dangerous.

The anthrax vaccine of Meloni, A. BARBERIO (*Gior. R. Soc. Accad. Vet. Ital., 50 (1901), No. 13, pp. 306–313*).—A detailed description of this method for preparing the vaccine and for making preventive inoculations.

Symptomatic anthrax or blackleg, L. L. LEWIS (*Oklahoma Sta. Rpt. 1901, pp. 88–97, figs. 2*).—On account of the prevalence of blackleg in Oklahoma the station undertook the manufacture and distribution of vaccine for controlling the disease. The vaccine sent out by the station was what is known as the single vaccine. Since March 1, 1900, it is reported that 58,950 doses have been distributed free to stockmen. A general account is given of the symptoms of blackleg, the methods by which the disease is commonly distributed, and the therapeutic measures which are usually recommended. Directions are given for the use of the hypodermic syringe in vaccinating animals for preventing the development of this disease.

Method of making inoculation for the prevention of blackleg, E. B. GRAVENHORST (*Ann. Med. Vet., 50 (1901), No. 3, pp. 132, 133*).—The author gives brief notes on a convenient method of inoculating animals without the necessity of taking antiseptic precaution and without danger of injury to the animal.

Foot-and-mouth disease and its treatment, E. NOCARD (*Rec. Med. Vet., Paris, 8. ser., 8 (1901), No. 7, pp. 222–233*).—The author gives a general account of the extent and seriousness of this disease, of the symptoms by which it may be recognized, and on the means of its distribution. Brief notes are also presented on methods of curative treatment which have been adopted in combating this disease.

Foot-and-mouth disease, J. PEMBERTHY (*Jour. Comp. Path. and Ther., 14 (1901), No. 1, pp. 16–29*).—This article contains a general discussion of the nature of the disease, statistics on the extent of its distribution and on the more noted outbreaks of the trouble, the means of infection, susceptibility of cattle and other animals, the incubation period, diagnosis, medical prevention, and official regulation of the disease.

Conference on the subject of foot-and-mouth disease, E. PERRONCITO ET AL. (*Gior. R. Soc. Accad. Vet. Ital., 50 (1901), No. 15, pp. 347–353*).—A discussion of problems relating to the means of distribution of this disease, and sanitary and therapeutic methods which should be adopted in combating it.

Potassium iodid treatment of milk fever, KAS (*Wchnschr. Thierheilk. u. Viehzucht, 45 (1901), No. 17, pp. 193, 194*).—Notes are given on 4 cases of milk fever which were treated by this method. The author made use of a concentrated solution of potassium iodid with good success. No complications arose and the milk was in all cases of normal color and taste within 36 hours after the animals were able to stand.

Statistics on the treatment of milk fever with potassium iodid, C. HAAS (*Berlin. Thierärztl. Wchnschr., 1901, No. 13, pp. 201–203*).—Statistics are presented in tabular form on 172 cases of milk fever which were treated by this method. Of this number 123 were considered severe, 18 of medium severity, and 31 mild cases. Of the whole number 129, or 75 per cent, were cured. The disease began in from 3 to 16 hours after calving. In almost all cases 10 gm. of potassium iodid was administered and the dose was sometimes repeated as many as 4 times.

Mammitis, W. L. WILLIAMS (*Vet. Jour., n. ser., 3 (1901), No. 16, pp. 205–213*).—A general account of the nature and symptoms of the noncontagious and contagious forms of this disease, with notes on the methods of treatment and prevention.

Abortion in cattle, G. H. WOOLDRIDGE (*Agr. Students' Gaz., n. ser., 10 (1901), No. 3, pp. 83–90*).—A critical discussion of the various causes which may lead to sporadic or infectious abortion. Notes are given on the symptoms and methods of treatment which have been found most effective in combating this disease.

Treatment for roundworms in sheep, goats, and cattle, C. W. STILES (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 35, pp. 8*).—Good success is reported in the treatment of sheep, goats, and cattle for *Strongylus contortus* with a 1 per cent solution of coal-tar creosote. One ounce of this substance is sufficient for 20 adult sheep and the cost is therefore less than ½ ct. per head. Of the 1 per cent solution 6 oz. may be safely given to a sheep. From 5 to 10 oz. were administered to cows from 3 to 8 months old, 1 pt. to young steers, and 1 qt. to adult cattle. If bowel worms, as well as the stomach worms, were present better results were obtained by adding thymol to the coal-tar creosote. From 30 to 100 grains of the thymol may be added to each dose of the creosote for sheep, the amount of thymol depending upon the size of the sheep. Good results were usually obtained from a single dose, but the treatment may be repeated if necessary after one week.

The use of bluestone in combating stomach worms was found quite effective, but the practice is considered somewhat more dangerous than the administrations of creosote. For preparing this remedy 1 lb. avoirdupois of bluestone may be dissolved in 2.4 qt. of boiling water. When the bluestone is completely dissolved 7.8 gal. of cold water, making altogether 8.4 gal. of water, should be added. If smaller quantities are desired, the solution may be made in the proportion of 1 oz. avoirdupois of bluestone to 4.2 pt. of water. The animals should be allowed to fast about 24 hours before administering this remedy and should not be allowed to drink water for several hours after receiving the dose. This remedy is considered somewhat less effective than creosote.

Gasoline was experimented with as a remedy for stomach worms and was found to be effective. The chief objections to its use are that from 3 to 6 doses are required in order to expel the worms, and that the substance may act injuriously upon the stock, especially in animals which are suffering from pleurisy. If an animal should be overcome by gasoline it may usually be revived by administering aromatic spirits of ammonia as a drench. Preference is indicated for drenching by means of a tube, which is inserted into the mouth. It is believed that better results may be expected in the case of sheep if the animal is given the drench in a standing position. As preventive measures against infestation by stomach worms the author recommends isolation of sick animals, establishment of clean watering places in pastures, selection of high sloping ground for pastures, draining of low pastures, annual burning over of pastures, and allowing animals free access to salt.

The removal of Gastrophilus larvæ from young colts by means of carbon bisulphid, W. WESSER (*Berlin. Thierärztl. Wchnschr., 1901, No. 9, p. 156*).—The author administered 6 gm. of carbon bisulphid in capsules every 2 hours to young colts which gave symptons of being infested with bot flies. In all 48 gm. were given to each animal. The remedy was endured well by the colts, although in a few cases slight poisonous effects were noted. After a period of 3 days the bot-fly larvæ passed away in great numbers and the animals recovered their normal condition rapidly.

The susceptibility of hogs to fowl cholera, V. STANG and F. PFERSDORFF (*Deut. Thierärztl. Wchnschr., 9 (1901), No. 14, pp. 139, 140*).—An investigation was made of an outbreak of a disease among hogs, turkeys, and fowls. A bacteriological study was made of the organism, which was isolated from dead animals, and it was found to be that of fowl cholera. All these animals are apparently susceptible to fatal infection from this organism.

Inoculation against hog cholera, J. WEBSTER (*Tijdschr. Veeartsenijk. Maandblad, 28 (1901), No. 6, pp. 260–265*).—The author reports a comparative test of the Landsberg serum, the method of Lorenz, and Susserin in preventive and curative inoculation for hog cholera.

Treatment of glanders, W. C. LANGDON (*Jour. Comp. Med. and Vet. Arch., 22 (1901), No. 4, pp. 246, 247*).—The author gives a brief supplementary report concerning 25 cases of glanders which were apparently cured by repeated injections of mallein. The majority of the treated horses had been quarantined and put to ordinary farm work and had been used in this way from 1½ to 2½ years, without the development of any symptons of the disease. The curative treatment which the author used required from 5 to 8 weeks and cost from \$10 to \$15 per head.

Experimental diagnosis of glanders by means of inoculations into the peritoneal cavity of guinea pigs, V. GALTIER (*Jour. Méd. Vét. et Zootech., 5. ser., 5 (1901), pp. 129–133*).—In addition to other bacteria which were found associated with the glanders bacillus in the nasal discharge of glanderous horses, a round species was found which when inoculated into the peritoneum of guinea pigs along with the glanders bacillus, multiplied to such an extent as to obscure the presence of the glanders bacillus. The glanders bacillus, however, in the experiments of the author ultimately produced the characteristic reaction in male guinea pigs.

A contagious stomatitis of horses in South Africa, THEILER (*Deut. Thierärztl. Wchnschr., 9 (1901), No. 13, pp. 131, 132*).—A description is given of an outbreak of this disease, together with an account of the symptoms. The majority of cases recovered after a few days. The symptoms were those of acute inflammation of the mucous lining of the mouth and tongue, and a discoloration of the tongue which gave the disease the name of blue tongue. The disease was shown to be highly contagious and in many respects resembled foot-and-mouth disease of cattle; but the latter disease did not exist in South Africa at the time.

Serum therapy in gangrenous septicæmia, E. LECLAINCHE and C. MOREL (*Ann. Inst. Pasteur, 15 (1901), No. 1, pp. 1–16*).—The normal serum of solipeds was found to possess very little immunizing power. Occasionally a horse was found from which a normal immunizing serum was obtained. Cattle, which are naturally refractory to the disease, possess a normal serum of considerable immunizing power. The normal serum from goats and sheep showed little active influence upon the septic vibrio. In order to procure an immunizing serum, the authors made use of intravenous injections of small doses of virus. The ass was chosen as the experimental animal. Subcutaneous injections of septic virus were also made on the same animal. Three series of experiments were conducted, one by subcutaneous injection, the second by intravenous inoculation of blood cultures, and the third by intravenous inoculation of cultures in bouillon. The results of these experiments may be briefly summarized as follows: It is possible to obtain a serum which produces immunity against the septic vibrio. The best method of procedure consists in intravenous inoculations of solipeds in series with cultures of the vibrio in Martin bouillon. The serum thus obtained possesses preventive properties, and under certain conditions a curative action. Inoculations with a mixture of the serum and virus are harmless, but do not confer an immunity of long duration. The serum exercises an antibacterial and antitoxic action at the same time. The protection produced in this way is associated with stimulation of the process of phagocytosis.

The rapid diagnosis of rabies, M. P. Ravenel and J. McCarthy (*Jour. Comp. Path. and Ther., 14 (1901), No. 1, pp. 37–44, figs. 3*).—A study was made of the certainty and reliability of diagnosis of this disease from microscopic changes in the nerve ganglia. It was found that the capsular and cellular changes in the intervertebral ganglia, when taken in connection with clinical symptoms, afforded a trustworthy means of diagnosing rabies. These changes, however, were not always present in cases of rabies, and the absence of such changes therefore is not considered as implying that rabies is not present. It was also found that the rabic tubercle of Babes was present sufficiently often to aid materially in the diagnosis where only the central nervous system was obtainable, without any of the ganglia. It is believed that where the ganglia can be had they offer a simpler and easier method of diagnosis than is to be found in the study of the brain and spinal cord.

The Brunswick disease of chickens and turkeys, Jess (*Berlin. Thierärztl. Wchnschr., 1901, No. 12, pp. 191, 192*).—A description is given of an outbreak of a diesase which persisted for 3 months and spread over considerable territory. The post-mortem examination of fowls dead of the disease exposed a brownish red color of the whole alimentary canal, with occasional diphtheritic patches. The trachea was much reddened and the pericardium was distended to a great size by an accumulation of serum. Bacteriological studies on this disease indicated that the trouble was not due to an organism of ordinary fowl cholera, but that apparently this organism was combined in symbiotic relations with another bacillus which needs to be studied further.

Streptothrix infections in the lower animals, A. G. R. Foulerton and C. P. Jones (*Jour. Comp. Path. and Ther., 14 (1901), No. 1, pp. 45–59, pl. 1*).—The authors discuss the nomenclature, classification, morphology, staining, and cultural characteristics, and pathogenic action of these organisms. Detailed description is given of the more common species, including *Streptothrix bovis communis*, *S. nocardii*, *S. capræ*, *S. cuniculi*, and *S. lacertæ*.

TECHNOLOGY.

Sorghum sirup manufacture, A. A. Denton (*U. S. Dept. Agr., Farmers' Bul. 135, pp. 40, figs. 26*).—A revision of Farmers' Bulletin No. 90 (E. S. R., 11, p. 290), covering the growing of sorghum cane and the manufacture of the sirup.

The clouding of white wine, R. G. Smith (*Proc. Linn. Soc. New South Wales, 25 (1900), pt. 4, pp. 650–658*).—A variety of white wine is made in South Australia under the name of Chablis which has a great tendency to develop a turbidity or cloudiness soon after being bottled. A deposit collects at the bottom of the bottle and, while the flavor and bouquet are not affected, the sale of the wine is injured. The author found the trouble to be due to bacteria. Pasteurizing the wine at 43°C. and above destroyed the organism and overcame the difficulty.

Report of the viticulturist, M. Blunno (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 944–949*).—Among other matters relating to wine making, the author discusses the difficulty in the locality indicated of keeping the temperature down during the fermentation of the must. Picking the grapes in the early morning or late in the evening is recommended as affording some relief. Where plenty of cold water is available, it is sometimes employed by passing through coils in the vats until the fermentation is complete. Another method of cooling the must is carried out by pumping it into a small wooden vat fitted with an ingenious contrivance for stirring. A small disk, revolving at a speed of 500 to 600 revolutions per minute, throws the must against the surface of the vessel, and after a few seconds it streams out through a hose placed in the bottom. Besides lowering the temperature, this process frees the juice of a large amount of albuminous substances. This treatment is recommended for white wines, of grapes grown in rich soils, especially those which make coarse and sharp wines.

The acidity of wines, E. KAYSER and G. BARBA (*Rev. Vit., 15 (1901); abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 9, p. 922*).—The chief point investigated by the authors was the effect of adding tartaric acid to must and wine deficient in acidity. The results show the absence of any definite ratio between the acid added and that ultimately found.

Composition and examination of raisin wines, A. SCHNEEGANS (*Arch. Pharm., 239 (1901), pp. 91–95; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 6, p. 599*).—A table is presented showing the analyses of several raisin wines made from different fruits, as currants and sultana raisins. The wines were clear, of various tints, from light yellow to pink, of pleasant taste but no bouquet. The lack of the latter was said to be due to the previous drying of the fruit, which prevented the formation of the higher alcohols and acids which produce the bouquet by esterification.

The results of the study of pure natural wines of the year 1899, K. WINDISCH (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 14, pp. 625–631*).—The results of the analyses of a large number of different kinds of wines are reported in tables.

Analysis of a native Madeira wine, H. THOMS and C. MANNICH (*Ber. Deut. Pharm. Gesell., 11, pp. 91–93; abs. in Chem. Centbl., 1901, I, No. 14, p. 802*).

Cider, F. RIGAUX (*L'Ing. Agr. Gembloux, 11 (1901), No. 11, pp. 455–480*).—A popular article treating of the manufacture, fermentation, preservation, diseases, and adulteration of cider. Tables of analyses are presented showing the composition of cider and the pomace. The utilization of the latter product is discussed.

The clarifying of ciders, V. H. VINCENT (*Rev. Gén. Chim. Appl., 4 (1901), p. 453; abs. in Chem. Ztg., 25 (1901), No. 80, Repert., p. 284*).—In tests with various substances in clarifying apple and pear ciders the author obtained the best results by the addition of citric acid, the color of the cider being preserved and the working of the oxidases eliminated. The addition of 50 gm. of citric acid and 10 gm. of tannin to each hectoliter of apple juice before the fermentation resulted in the clarification after the second racking. With pear cider it was necessary to add only the citric acid.

Rubber preparation (*Trinidad Bot. Dept. Bul. Misc. Inform., 1901, No. 27, p. 333*).—"In pursuing experiments with the view of ascertaining the most economical method of coagulating rubber fluids, some of these were allowed to stand forgotten in a large receptacle where they had been creamed. When again handled the whole mass was putrid, but the rubber was still on the surface and easily coagulated or 'coalesced' on being handled, and the quality produced is stronger and therefore of a higher quality than rubber prepared in other ways. The specimen was shown to a noted American manufacturer of rubber goods, who readily recognized its quality from among numerous other specimens. There were, however, evident signs of loss of weight in rubber material by the decomposition set up by the fermentation of the proteids."

Approximate value of bagasse as fuel, F. N. G. GILL (*Jour. Soc. Arts, 49 (1901), No. 2530, pp. 517–519; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 7, pp. 695, 696*).—The author made a study, from the data at hand, of the actual fuel value of bagasse. This substance is usually regarded as being equivalent in fuel value to from $\frac{1}{6}$ to $\frac{1}{5}$ of its weight in coal. In making the estimates reported the values of Stohmann and Langbein are used for the heats of combustion of sucrose, invert sugar, and cellulose, while for the albuminous and gummy matters the same heating value is ascribed as for cellulose. Three samples of bagasse are taken for making estimations as follows: (1) single and simple milling, giving 66.2 per cent of juice, (2) double and simple milling, giving 70 per cent of juice, and (3) double milling and maceration, giving 75 per cent of juice. Then from 100 tons of cane crushed the actual bagasse will contain in (1), 24.8, (2), 21, and (3), 16 tons of juice. If the calorific power of coal be taken as 14,000 thermal units per pound, bagasse is worth from $\frac{1}{3}$ to $\frac{1}{4}$ of its weight in ordinary coal. A correction must be made, however, as bagasse is burned with an average of 150 per cent excess air as compared with 75 per cent in coal, and this difference causes a loss in the heating value of bagasse of nearly 11 per cent. With this correction, bagasse burned after coming straight from the mill has actually only from $\frac{1}{9}$ to $\frac{1}{8}$ of the value of an equal weight of an ordinary quality of coal.

Employment of the bagasse in the fabrication of paper, N. LEVY (*Bul. Assoc. Chim. Sucr. et Distill., 19 (1901), No. 1–2, pp. 215–217*).—A description of the manner of preparing the bagasse for manufacture of paper, as carried out in Louisiana and Texas.

Manufacture of paper from sugar-cane refuse, F. C. THEILE (*Chem. Ztg., 25 (1901), No. 27, pp. 289–290*).—The method employed for making paper from sugar-cane refuse as followed at a plant in Texas is described.

STATISTICS.

Wages of farm labor in the United States, J. H. BLODGETT (*U. S. Dept. Agr., Division of Statistics Bul. 22, misc. ser., pp. 47*).—Statistical investigations at 11 different times during a period of 33 years (1866–1899) of the wages of farm labor at different seasons are reported. The results of the investigations from 1866 to 1892 have already been published (E. S. R., 3, p. 906), the more important data being here reprinted. In the investigation of 1898 and 1899 data were also collected on the proportion and wages of white and colored laborers, the number and wages of overseers or foremen, the cost of board or rations, and the number of hours of labor per working day. In 1870 farm laborers constituted 48.9 per cent of persons engaged in agriculture; in 1880, 43.6 per cent; and in 1890, 35.8 per cent; these with other statistics indicating a tendency of farm laborers to become farm tenants and farm owners.

The following table summarizes some of the statistics obtained since the previous report:

Wages per month without and with board.

Sections.	Without board.					With board.				
	1899.	1898.	1895.	1894.	1893.	1899.	1898.	1895.	1894.	1893.
Eastern States	$28.76	$27.87	$29.00	$27.02	$29.07	$18.21	$17.63	$17.73	$17.15	$18.45
Middle States	23.91	23.15	23.80	23.64	24.82	15.93	15.33	15.73	15.60	16.51
Southern States	13.80	13.49	12.71	13.04	14.07	9.70	9.45	8.68	9.04	9.92
Western States	23.75	22.44	21.82	21.50	23.12	16.70	15.75	15.21	14.96	16.29
Mountain States	35.15	33.95	30.04	29.95	33.97	25.10	23.94	19.87	19.94	23.37
Pacific States	35.69	33.64	31.68	34.15	36.95	24.97	23.30	20.54	22.60	25.63
Average	20.23	19.38	17.69	17.74	19.10	14.07	13.43	12.02	12.16	13.29

"The following may serve as a suggestive summary of influences that affect farm wages: (1) Intrinsic fertility of the soil, (2) products of the locality, (3) market value of land, (4) latitude, (5) elevation, (6) percentage of woodland, (7) rainfall, (8) water supply in springs, streams, and wells, (9) relations to market—(a) time of transportation, (b) cost of transportation, (10) rates of taxation, (11) economy of public administration, (12) the type of social life, influencing dress, housing for man, beast, and crops, organizations for roads, education, religion, or other associated effort." The influences affecting wages in each State are pointed out.

Twenty-fourth Annual Report of Connecticut State Station, 1900 (*Connecticut State Sta. Rpt. 1900, pt. 4, pp. XV*).—These pages include the organization list of the station, a brief announcement relative to the character of the work done by the station, a report of the board of control reviewing briefly the different lines of station work during the year, and a financial statement for the year ended September 30, 1900.

Fourteenth Annual Report of Maryland Station, 1901 (*Maryland Sta. Rpt. 1901, pp. XXIV+206*).—The report proper consists of a rather detailed account by the director of the history, equipment, lines of work, publications, etc., of the station since its organization. Investigations in progress by the different departments are outlined, as are also a number of cooperative experiments. A subject list is given of station publications. Observations on precipitation and temperature are tabulated. A financial statement is given for the fiscal year ended June 30, 1901. Reprints of Bulletins 68–76 of the station on the following subjects are appended: Fertilizer experiments with different sources of phosphoric acid (E. S. R., 12, p. 930), the influence of feed and care on the individuality of cows (E. S. R., 12, p. 1078), the chemical composition of Maryland soils (E. S. R., 13, p. 28), notes on spraying peaches and plums in 1900 (E. S. R., 13, p. 152), peach growing in Maryland (E. S. R., 13, p. 138), suggestions about combating the San José scale (E. S. R., 13, p. 160), notes on celery blight (E. S. R., 13, p. 257), the effect of hydrocyanic-acid gas upon grains and other seeds (E. S. R., 13, p. 462), and parturient paresis—milk fever, calving fever (E. S. R., 13, p. 492).

Fourteenth Annual Report of Mississippi Station, 1901 (*Mississippi Sta. Rpt. 1901, pp. 30*).—This contains a review of the different lines of station work by the director, a financial statement for the fiscal year ended June 30, 1901, and somewhat detailed reports on station work by the heads of departments. Parts of these reports are noted elsewhere.

First Annual Report of Missouri Fruit Station, 1900 (*Missouri Fruit Sta. Rpt. 1900, pp. 20*).—An account of the establishment and work of the station during the year (see p. 552), with a financial statement.

Tenth Annual Report of Oklahoma Station, 1901 (*Oklahoma Sta. Rpt. 1901, pp. 13–159*).—This includes a report of the director reviewing the different lines of station work; a summary of the press bulletins issued during the year on miscellaneous topics; meteorological observations; several articles noted elsewhere, and a financial statement for the fiscal year ended June 30, 1901.

Thirteenth Annual Report of Vermont Station, 1900 (*Vermont Sta. Rpt. 1900, pp. 246–504*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1900; a report of the director reviewing at some length the work of the station during the year; a subject list of station publications available for distribution; abstracts of Bulletins 72–80 of the station, and departmental reports abstracted elsewhere.

Timely hints for farmers (*Arizona Sta. Bul. 38, pp. 237–296, figs. 9*).—This bulletin is a collection of popular articles issued by the station from October 1, 1900, to July 1, 1901. The following subjects are discussed: The farmer's reading course, stinking smut of wheat and its prevention, the use of chemical preservatives in milk, the open range and the irrigation farmer, the value of a dairy herd record, the use of the Babcock test, plant lice, suggestions concerning date culture, the spring vegetable garden, some trees and plants for barren places, the use of hand separators on the farm, well waters for irrigation, home-made fertilizers, wild barley, the Australian saltbush in Arizona, and millets.

Press bulletins (*Colorado Sta. Bul. 64, pp. 29, charts 5*).—Reprints of press bulletins Nos. 1–11 issued from September, 1899, to April, 1901, on the following subjects: The sugar-beet caterpillar, Colorado sunshine, the beet army worm, the cantaloupe blight, the Russian thistle as forage, a so-called blight cure, the seepage measurements of the experiment station, potato failures, sunshine for 1900, conclusions relative to the culture of sugar beets, and how to fight the codling moth.

Experiment Station Work, XVIII (*U. S. Dept. Agr., Farmers' Bul. 133, pp. 32, figs. 14*).—This number contains articles on the following subjects: The value of stable manure, alfalfa as a fertilizer, effect of lime on different crops on acid soils, celery culture, utilizing the greenhouse in summer, the resistance of strawberries to frost, a fumigator for small orchard trees, foundation in comb building, a device for ridding houses of flies, slop for pigs, profitable crops for pigs, barley as food for horses, water in butter, and losses in the preparation of silage.

Crop Reporter (*U. S. Dept. Agr., Division of Statistics Crop Reporter, Vol. 3, Nos. 4–6, pp. 8 each*).—These numbers contain statistical data on the condition of crops in the different States and Territories on August 1, September 1, and October 1, 1901; trade statistics; and miscellaneous articles of a statistical nature, among which are the following: The crops of France in 1901, Hungarian and Austrian crop conditions, Bureau of Forestry, railway statistics, principal food crops of Denmark, the exportation of cattle and beef, crops of Great Britain in 1901, Hungarian grain crops, estimated wheat crop of the world in 1901, Argentine crop prospects, potatoes in the British Isles, production of spelt and buckwheat in Russia since 1883, and oil seeds crop of India.

List of the publications of the Division of Agrostology (*U. S. Dept. Agr., Division of Agrostology Circ. 36, pp. 8*).

NOTES.

ALABAMA COLLEGE AND STATION.—William Le Roy Broun, president of the college and chairman of the station council, died suddenly January 23, 1902, in his seventy-fifth year. A sketch of Dr. Broun's life and services is given elsewhere in this number.

ALABAMA CANEBRAKE STATION.—H. Benton, director of the station, has resigned and J. M. Richeson has been elected to succeed him.

CALIFORNIA UNIVERSITY AND STATION.—G. W. Shaw, formerly of the Oregon Agricultural College and Station and more recently chemist in the beet-sugar factory at Grand Junction, Colo., has been appointed assistant professor of agricultural chemistry, in charge of beet-sugar industry. F. T. Bioletti, bacteriologist and viticulturist, has resigned to accept a position as instructor in agriculture and viticulture in the Elsenburg School of Agriculture, Cape Colony, South Africa. A. R. Ward, veterinarian of the station, has been appointed instructor in bacteriology. Warren T. Clarke has been appointed assistant entomologist to make a special study of the life history of the peach moth; he entered upon the work January 1 among the orchards of the Foothill region of the State. After ten years' experience the station is now ready to make a final report on the behavior of the northern deciduous fruits at the Southern California Substation near Pomona. These embrace apples (not Russian), pears and plums (European), peaches (Persian), apricots, almonds, and nectarines.

KANSAS COLLEGE AND STATION.—A compromise has been effected with the settlers on the Fort Hays Reservation, ceded to the State of Kansas by the Government for a branch normal school and an experiment station. The compromise gives the settlers leases of from two to five years' duration in exchange for complete relinquishment of claims to the land. This was done in order that work might be commenced there the coming season, and the arrangement renders a considerable tract of land available for experimentation. In the division of the land between the normal school and the agricultural college, the latter obtained about 3,500 acres, including the part most desirable for experimental purposes. The board of regents has made provision for a foreman, who shall carry on the work at Fort Hays under the general supervision of a designated member of the board. The buildings on the reservation are to be repaired so as to make them available for use. The station council has not yet formally decided upon the experiments to be undertaken, but in general there will be tests on a rather large scale with crops and methods, with special reference to the needs of regions having deficient rainfall. As the new station occupies a field different climatically from that of any other station in the country, it is thought that the results obtained there should be applicable to quite a large region.

MAINE STATION.—L. J. Shepard has resigned his position as assistant in agriculture at the station to accept a similar position in the National Farm School at Doylestown, Pa.

MASSACHUSETTS STATION—S. W. Wiley, assistant chemist in the fertilizer control work, has resigned to accept a position in the factory of the Bowker Fertilizer Company at Elizabethport, N. J.

MICHIGAN STATION.—J. D. Towar, agriculturist of the station, has accepted a position as Government professor of agriculture in South Australia. He will be principal of the Agricultural College at Roseworthy, South Australia, and his duties will be (1) to superintend the agricultural college and experimental farm and teach classes thereat, (2) to advise the Government on all points relating to agriculture, and (3) to lecture to agriculturists when required. Professor Towar will assume the duties of this position June 1, 1902.

MINNESOTA COLLEGE AND STATION.—A very attractive class bulletin entitled "Outline of Greenhouse Laboratory Work," by Samuel B. Green and R. S. Mackintosh, has recently been issued by the division of horticulture. The bulletin is intended especially as a guide for the use of the classes in the greenhouse laboratory work of the school of agriculture. It is fully illustrated, and contains plain directions for 47 exercises, arranged in 21 lessons. The range covered is quite broad, including seed testing, propagation, grafting, spraying, pruning, care of orchard stock, etc.

NEBRASKA STATION.—Lawrence Bruner started about February 10 on a trip to Costa Rica, to occupy about three months. He will collect material for his own and other departments in the university and station, and will give some attention to the agriculture of the country. Professor Bruner was accompanied by several young men who have undertaken commissions for a number of other institutions.

NEW MEXICO STATION.—This station has taken up the matter of giving its bulletins wider circulation among its constituents, and of publishing popular bulletins in the Spanish language. The first bulletin of the Spanish edition will be a translation of Bulletin No. 40, entitled "A Southern New Mexico Flower Garden."

OHIO STATION.—A bill has passed the Ohio legislature providing for the reorganization of the board of control of the station. The board is to consist of five members, not more than three of whom shall belong to the same political party, and who shall be appointed by the governor for a term of five years. The duties of the board under this act and of the director of the station are quite clearly defined. The board of control is constituted a body corporate, and to it are assigned the duties of appointing a director, adopting by-laws, rules, and regulations for the government of the station, and fixing the salaries and terms of office of employees, with the power to remove employees at any time for cause sustained by written charges. The director is given control of the affairs of the station in all its departments and made responsible to the board for their efficient management. He is to appoint the chiefs of departments, assistants, and other employees of the station, with the approval of the board, assign them their respective duties, and is given authority to suspend any employee for cause, reporting the matter at once to the board of control for final action. An annual meeting of the board is provided for, with special meetings at the call of the president or upon the written request of two members.

OKLAHOMA COLLEGE AND STATION.—H. G. Beard, of Shawnee, and T. J. Hartman, B. S., of Deer Creek, have been appointed members of the board of regents, *vice* C. J. Benson and J. P. Gandy, resigned. Mr. Hartman, who is a graduate of the college, class of 1898, was elected treasurer of the board at a recent meeting. The short courses in agriculture, horticulture, and mechanic arts are now in progress, and all that can be accommodated are in attendance. Work on the new barn, engineering building, and addition to the library building is progressing, and all will be ready for occupancy by the opening of the fall term.

OREGON COLLEGE AND STATION.—The resignation of President Thomas M. Gatch as director of the station was accepted by the board at its January meeting, and James Withycombe, the vice-director, was appointed to the position. At a previous meeting the chemist, bacteriologist, and entomologist were relieved of all class work in the college in order that they might devote their entire time to station work, and the botanist and horticulturist was relieved to a great extent of station work on account of the heavy teaching duties. Ground has been broken for the erection of a new agricultural hall. The plans provide for a stone building 85 by 125 feet and three stories high. It is to provide laboratories and class rooms for the departments of agriculture, chemistry, zoology and entomology, botany and horticulture, and bacteriology. On the first floor will be a large stock judging room and the dairy department, while the attic is to be finished for the agricultural museum. The building, exclusive of fixtures, is to cost about $40,000.

Porto Rico Station.—The heavy rains and trade winds damaged the experimental crops during the months of December and January. The native crops are doing well, but most northern vegetables are seriously affected by fungus and insect pests. The "changa," a mole cricket, continues to damage all crops in spite of all remedies. It is much more destructive in sandy soils. Among the 80 or 90 experimental crops the following attract considerable attention from visitors: Arrowroot (*Maranta arundinacea*), ginger, llerenes (an excellent root crop), 3 kinds of true yams, tropical varieties of sweet potatoes, 7 varieties of "yautia" (the Hawaiian "taro"), Spanish peanuts, 4 kinds of cassava, the "teyote," teosinte, narcissi, hyacinths, freesias, 5 varieties of Bermuda and Japanese lilies, and palms for the florists' trade.

Annual Report of Office of Experiment Stations.—A new departure has been followed this year with reference to the various Congressional reports of the Office of Experiment Stations. These reports have been combined, and reports of other lines of work added, making an annual report of the Office for the year 1901, which has recently been transmitted to Congress. The volume includes the report of the Office on the work and expenditures of the experiment stations, the separate reports of the stations in Alaska, Hawaii, and Porto Rico, describing the progress of the former and the establishment and inauguration of work at the latter, and reports of the nutrition and the irrigation branches. The report as a whole makes a volume of upward of 400 pages, and is illustrated by 41 plates. It corresponds in a general way to the annual reports of the Bureau of Animal Industry and the Bureau of Soils, and has been suggested by the increased scope and diversity of interests of the Office, which now embrace eight quite distinct lines of work, each in charge of a separate officer. An edition of 6,000 copies has been requested, and it is planned to print separates of the different parts.

Botanisches Centralblatt.—The first number of this journal under the new management has appeared. The *Association Internationale des Botanistes*, organized at Geneva, August 8, 1901, which purchased all rights from the former editors, will issue the *Centralblatt* as formerly—the abstracts in a weekly periodical and original articles in the *Beihefte*. The new editor in chief is Dr. J. P. Lotzy, formerly of Johns Hopkins University, and later connected with the cinchona investigations at Tjibodas, Java. A board of 75 assistant editors from different countries is provided, who are to make especial efforts to abstract all botanical publications appearing in their countries. In this way it is hoped the reviews of literature will be made more complete and appear more promptly. The American editors and their specialties are: Drs. D. H. Campbell, Leland Stanford University, morphology; C. J. Chamberlain, University of Chicago, cytology; D. T. MacDougal, New York Botanic Gorden, physiology; G. T. Moore, U. S. Department of Agriculture, algæ; D. P. Penhallow, McGill University, paleobotany; H. von Schrenk, Shaw School of Botany, fungi and vegetable pathology; and W. Trelease, Missouri Botanic Gardens, systematic phanerogams. In order that delay may be avoided in securing the publication of abstracts of American papers, authors are requested to send marked copies of their publications to the editor in charge of the subject treated, or where separates are not available, to call the appropriate editor's attention to the paper. The place of publication of the *Centralblatt* has been changed from Berlin to Leyden, Holland.

Personal mention.—*Nature*, for January 2, 1902, contains an unsigned article on the life of Sir J. Henry Gilbert. The article mentions the fact that while a school-boy he met with a serious accident which practically cost him the loss of an eye, so that while "his great pluck enabled him to accomplish his life's work with little apparent hindrance, the disadvantage of weak sight was very real." In speaking of his traits the writer says: "He was an indefatigable worker and loved to accumulate an immense mass of results, frequently of a similar kind; and a reader of Rothamsted papers is sometimes so overwhelmed by numerical statements that, to use a familiar simile, 'he finds it difficult to see the wood for the trees.' . . . He enjoyed a very vigorous constitution, and continued actively at work up to the last year of his life. Unfortunately, his disposition forbade his cooperation with any younger colleague, and the institution at Rothamsted is now left without any apparent successor to its historic labors."

Joseph A. Bulkeley, a graduate of the Michigan Agricultural College, and recently experimentalist and assistant professor of agriculture at the Wagga Experimental Farm, New South Wales, has been appointed manager of the experimental farm at Grafton, on the north coast of New South Wales. The farm is in embryo, and Mr. Bulkeley will have charge of organizing and inaugurating the work there. The farm comprises something over 2,000 acres, including soil of poor, medium, and good quality. The lines of work will deal chiefly with grasses and forage plants, with a view to establishing the dairy industry, and with the management and improvement of live stock.

At the recent meeting of the American Society of Bacteriologists Prof. H. W. Conn, of Wesleyan University and the Connecticut Storrs Station, was elected president.

A. P. Bryant, for several years assistant in the nutrition investigations of this Office at Middletown, Conn., has resigned his position to take up work in food chemistry with the Glucose Sugar Refining Company of Chicago. He will enter upon his new duties early in March.

The Paris Academy of Sciences has awarded the Lavoisier medal to Emil Fischer, of Berlin, for his work as a whole and especially that relating to the synthesis of sugars; the Bordin prize to Matruchot and Molliard for their researches on the influence of the external conditions on the protoplasm and nucleus in plants; and the Montagne prize to Mazé for his researches on the mechanism of the fixation of nitrogen by Leguminosæ.

Science notes that Dr. William Somerville, late professor of agriculture at the University of Cambridge, has been appointed assistant secretary of the British Board of Agriculture on the retirement of Sir Jacob Wilson. Dr. Somerville is succeeded by T. H. Middleton, formerly professor of agriculture in the Durham College of Science at Newcastle-on-Tyne.

Prof. U. Kreusler, editor of *Biedermanns Centralblatt für Agrikulturchemie*, retired at the close of the past year, and has been succeeded by Prof. O. Kellner, director of the Möckern Experiment Station, who was one the founders of the journal.

Miscellaneous.—A new feature has been introduced in the *Journal of the Royal Horticultural Society*, which greatly enlarges the usefulness of that publication. It consists of notes on recent research work and short abstracts from current British and foreign periodical literature affecting horticultural and botanical science. The more important articles are reviewed at some length and placed under the heading of "Notes on recent research." In both the notes and the abstracts the material is arranged alphabetically under the name of the plant, insect, disease, etc., as far as the material will lend itself to such arrangement. It is proposed to review 55 of the more prominent horticultural, botanical, and scientific journals of England, Continental Europe, America, and other countries; and 32 members of the society have consented to help in this work. In this first attempt 14 pages of notes on recent research and 50 pages of abstracts are given. Floriculture and ornamental shrubs and plants are given especial attention, as well as the diseases and insect pests of plants.

Articles on irrigation are also abstracted, as well as everything having a bearing on horticulture and botany.

The Royal Agricultural Society of England has discontinued the publication of its *Journal* as a quarterly and will hereafter issue an annual in its place.

The Handbook of Connecticut Agriculture, prepared by T. S. Gold, has been published by the State Board of Agriculture. The pamphlet contains about 100 pages with illustrations. Following a brief statement on the agriculture of the State and its progress are short accounts of the State and Storrs stations, the Connecticut Storrs College, the cattle industry of Connecticut, fruit growing, floriculture, seed growing, tobacco growing, and other industries.

Science for January 17, 1902, prints an abstract of an open letter by B. E. Fernow, replying to severe criticism of the methods practiced by the Cornell College of Forestry in the management of its reserve in the Adirondacks. In his communication Professor Fernow makes it plain that approved forestry methods are being practiced; that thus far 100 trees have been planted for every 4 trees cut, and that the criticisms are due to false rumors and an imperfect understanding of the true condition of the case.

Sir William MacDonald has offered to the Government of Ontario $125,000, to be used in the erection of a building at the Ontario Agricultural College at Guelph, with a view to giving instruction to school-teachers in the elements of nature study and domestic science.

The British Board of Agriculture has appointed a committee to investigate braxy and louping ill of sheep, which are the cause of very great loss to the sheep-farming industry in Scotland. The members of the committee are Professor Hamilton, of Aberdeen University; J. McI. McCall, assistant veterinary officer to the board; E. J. Wheler, and R. B. Greig.

EXPERIMENT STATION RECORD.

Vol. XIII. No. 7.

A review of the world's system of institutions for agricultural experimentation and research has been in process of preparation for some time, to meet the demand for more complete and systematic accounts of the various agencies that are in operation in foreign countries. Such a review is at present not furnished by any known publication or series of publications, and much difficulty was experienced in preparing even a complete list of the foreign stations. As a preliminary step in that direction a list of all known stations has been published in the organization lists for the past three years. This has served as a working basis upon which correspondence could be undertaken and additions and corrections made.

As the work has progressed the dearth of literature describing the foreign stations has become more and more apparent, and has emphasized the need of a publication of this kind. In many countries there is no authorized agency for collating and publishing accounts of the organization and work of the stations, and in very many cases the individual stations have no regular method of publication. In spite of the wide search of literature and extensive correspondence, it has been impossible to secure the necessary data to make the review complete, but so much more has been collated than has ever been published before that it has been thought best to issue it at an early date as a bulletin of this Office.

The total number of experiment stations and similar institutions in the world, as far as our information goes, is about 780. This number includes, however, many institutions which in this country would not be reckoned as stations, such as experimental farms and fields, laboratories for miscellaneous analysis, and cooperative enterprises. The most that can be said is that the list includes the various agencies of different kinds and grades for experiment and investigation in agriculture, and for the protection and information of farmers. Purely as a matter of convenience, these agencies may be referred to collectively as "stations."

The list demonstrates the world-wide extent of the station movement at the present time, embracing nearly all the civilized countries of the globe. The most notable exception in Europe is Greece, where, so far as can be learned, there are no stations or similar agencies in operation. In Asia there are a goodly number of stations, located in Russia, Japan, and British India. The Chinese Empire represents a large territory which appears to be entirely without stations, and the same condition applies to Turkey, Persia, Afghanistan, and Beloochistan. Africa has quite a large number of stations in the English, French, and German colonies. There are no stations as yet in Mexico or in Central America, except in British Honduras, where a botanic garden is located; and of the South American countries no trace has been obtained of any stations in Bolivia, Buenos Ayres, Colombia, Ecuador, Patagonia, Peru, Uruguay, or Venezuela. Australia and New Zealand have a large number of stations of various kinds which are actively studying the practical problems suggested by the agriculture of those countries.

Viewed as a world enterprise, the station movement is spreading quite rapidly year by year, and the systems of different countries are being strengthened in many ways, increasing financial aid being the general rule. Well-supported experiment stations are rapidly coming to be looked upon as a necessary requisite of modern agriculture the world over.

The largest number of separate agencies for investigation and experiment in agriculture is found in Russia, in spite of the fact that the movement is comparatively recent there. There are 102 such establishments and 3 experimental forests. Many of them are small demonstration fields, established for the purpose of instructing the peasants or of introducing new agricultural industries; others serve as centers for the production and distribution of improved varieties of seeds and plants, and some are conducted as institutions for research. There are a number of stations for special crops, such as tobacco, beet sugar, silk, cotton, olive, tea, wines, and other products.

If the same class of institutions were designated as experiment stations in the United States as in foreign countries, this country would without doubt show the second largest number of agencies, and probably the largest number of what we commonly regard as experiment stations—that is, eliminating laboratories which are purely for control or analytical work, demonstration fields, etc. As the list stands, however, Germany is second in numerical order, and France third.

The total number of stations in Germany is given as 80, which includes about a dozen control stations and laboratories for miscellaneous analysis, together with a number of stations for special industries. The only real bond of union between the German stations is the Association of Agricultural Experiment Stations in the German Empire, which was organized at Weimar in 1888 for the purpose of securing uniformity in methods for control work; and this does not include all of the stations.

The agricultural stations and laboratories of France, of which there are 70, are under the general direction of an inspector-general, an officer of the Ministry of Agriculture. Prof. L. Grandeau has held this position since its creation in 1882.

Austria has 40 stations, about one-third of which are of the grade of the control station. These are under the general control of the Ministry of Agriculture, which also issues an official publication (*Zeitschrift für das landwirthschaftliche Versuchswesen in Oesterreich*) containing reports and papers on various phases of the station work.

In Great Britain it is difficult to determine what should be listed as stations, as many of the institutions were not established primarily for agricultural experimentation, but have been subsidized by the board of agriculture for that purpose, or have taken up a certain amount of work which has an incidental bearing. The list enumerates about 30 agencies, including 12 institutions that may be regarded as stations, 10 institutions which are subsidized by the board of agriculture, and 7 botanic gardens. In India there are 10 experiment farms and plantations and 21 botanic and municipal gardens, besides a number of other agencies for the benefit of agriculture.

Belgium has a system of 16 stations, 7 of which are analytical laboratories, all under the supervision of the Belgian Ministry of Agriculture. Hungary likewise has 16 stations, under the supervision of the central commission of experiment stations, which provides an organ for the publication of their work; and Italy has 15 stations and laboratories which receive a portion of their appropriation from the Government, many of them also receiving funds from the province or municipality in which they are located and from local agricultural associations and chambers of commerce.

A feature of the system in Australia, which includes 34 institutions, is the state farms. There are 16 of these scattered over the country, devoted for the most part to culture and similar experiments, demonstrations of good farming, the improvement of live stock, and similar work, but having no real scientific work connected with them.

In the Netherlands there are 7 stations, including a seed-control station and a laboratory of vegetable pathology, besides a system of experimental fields, 11 in number, conducted under the auspices of local agricultural and horticultural societies, but subsidized by the Government.

Sweden has 26 stations, controlled and partially supported by the state department of agriculture, most of which are chemical and seed-control stations. In addition there are 10 agricultural chemical stations, maintained by societies, which are in reality laboratories for analysis and control. Norway has 11 stations, including several control stations, all, with one or two exceptions, under the direct control of the department of agriculture; and Denmark has 10 stations, several of them being among the most liberally supported of the European stations.

In Japan there are 15, including 9 branch stations; in Switzerland a system of 10 stations, all under the control of the department of agriculture, except 1 for brewing; and in Spain 9 stations, 6 of which are œnological and viticultural and 1 for sericulture.

These comprise the principal countries in which experiment stations and similar agencies are most active, with the exception of Canada and the United States. The full list, however, includes Algeria, Bosnia and Herzegovina, Bulgaria, Brazil, Egypt, Java, Portugal, Roumania, and many minor countries and dependencies.

The more we study the foreign experiment stations the more apparent it becomes that the American stations represent a distinct type of institutions, which are the product of their environment. Their exact prototype or counterpart is not found in any other country, either in scope, organization and management, or in relation to the farming community and the promotion of agriculture in general. They are an adaptation of the European stations to the conditions and requirements of this country. As such they present many unique features; and familiarity with their general character makes a study of the foreign systems the more interesting.

The various agencies for agricultural experimentation and research in foreign countries may be classified in a general way under six heads, i. e., (1) experiment stations proper, (2) special stations for particular crops or agricultural industries, (3) control stations and agricultural laboratories, (4) botanic stations and gardens, (5) experiment farms and demonstration fields, and (6) agencies for local or cooperative experiments.

Among those of the first class there are but few which correspond to the American stations in the breadth of their work and in their organization. To a quite large extent the foreign stations have developed in the direction of some particular branch of agriculture, as agronomy, animal production, or dairying, although their field of operation is broader than that of the special stations. As a rule they are dominated by the influence of a single man, who is usually the director, and their energies are bent toward the development of his theories of plant nutrition, or some phase of animal nutrition, or the like. With a few notable exceptions the individual stations do not embrace strong departments in plant production, the feeding of animals, injurious insects and diseases, with experts in these several lines. Indeed, where we find these different branches working side by side, they are usually broken up into as many separate stations, each with its own director. This is partly a matter of finances and largely of custom. The union of a number of departments in a single station seems opposed to the ruling system in Europe, and it is admitted that, as far as advanced work goes the European plan has much to commend it.

The special stations are devoted to such subjects as tobacco, flax, and cotton culture, moor culture, forestry, viticulture, wine making, brewing and distilling industries, milling, sugar and starch industries, indigo, sericulture, butter and cheese making, etc. A number of these special stations are found in Austria, France, Germany, Italy, Russia, Spain, and Switzerland. In some cases they are partially supported by government appropriation, while in others they are entirely under the control and maintenance of local organizations.

The work of the control stations is generally understood. Many of these undertake no investigations but confine themselves to the examination of fertilizers, seeds, feeding stuffs, etc. The agricultural laboratories differ from the control stations in being established primarily for the convenience of farmers who desire analyses made, and frequently have no regular control duties. Systems of such agricultural laboratories are maintained in Belgium, France, Italy, and Sweden.

The botanic stations and gardens, while frequently not established for the direct benefit of agriculture, render considerable incidental aid in the introduction and acclimatization of plants, distribution of seeds, etc., and a considerable number of them have experimental fields connected with them, so that they have developed into stations comparable with many of the experiment stations. In Great Britain and France the botanic gardens constitute one of the features of the experiment station system. The Royal Botanic Gardens at Kew, London, have connected or in cooperation with them a system of 102 botanic gardens and stations distributed through Great Britain and its colonies. In a similar way there are affiliated with the Colonial Gardens at Vincennes, France, a system of 15 gardens and stations located in the various French dependencies. In many instances these gardens constitute the only agencies which have been provided in the newer countries, and their work is quite varied and important to agricultural development.

The experiment farms and demonstration fields are found quite extensively in Australia, New Zealand, India, the Netherlands, and Russia. In a number of countries where the station movement is new these farms and fields represent the initial step in agricultural experimentation. For instance, in Bosnia and Herzegovina, in Brazil, Bulgaria, and Paraguay a beginning has been made by the establishment of a few experimental farms or fields, which for the most part are for the purpose of conducting culture and demonstration experiments.

Among the agencies for local and cooperative experiments various agricultural societies and organizations are prominent, which through their efforts alone or with the assistance of government funds provide for local trials or cooperative experiments of a quite simple order. Such experiments are carried on quite extensively under the county-council system of England and under the department of agriculture in Ireland.

The most extensive series of cooperative experiments which have been brought to light, and they do not belong to the class mentioned above, are those in feeding dairy cows in Denmark, which were begun by Professor Fjord in 1872 and are still being carried on by the laboratory of the Royal Veterinary and Agricultural College at Copenhagen. The same institution also has charge of the butter exhibitions, which in a sense are cooperative. These exhibitions entail an annual expenditure of about $47,000, but they have been instrumental in improving the average quality of the butter and developing a large export trade.

The systems of management and sources of revenue of the foreign stations present a great variety of conditions. In the majority of countries there is a central directing or supervisory agency, by which the government funds are administered. This central control is quite general in Austria, Belgium, Bosnia and Herzegovina, British West Indies, France, Hungary, Norway, Sweden, and Switzerland. In these countries the administrative agencies are the state departments or ministries of agriculture. In parts of Australia, notably in New South Wales, and in New Zealand this system also prevails. In Denmark, the Government directs many of the agencies for the promotion of agriculture through the Royal Danish Agricultural Society; in Holland the stations are under the general management of a committee appointed by the Crown, and in Russia they are in part under the supervision of the Ministry of Agriculture. In Great Britain there can not be said to be any centralizing authority further than that exerted by the board of agriculture, which distributes grants, and the Royal Botanic Gardens at Kew. In Germany there is no central authority for the stations of the whole Empire. The Prussian stations are affiliated with the Ministry of Agriculture, Domains, and Forestry, but there can not be said to exist in Germany any central administrative authority in the sense that there is in France, Belgium, Hungary, and other countries.

Taken as a whole the foreign experiment stations are working in the main independently of one another, there being very little cooperation among the stations of any country or with the central department of agriculture. This cooperation, which is becoming so extensive in the United States, may be regarded as one of the characteristic features of our station system.

The information obtained regarding the revenue of the foreign stations is quite fragmentary. A large number of the stations have no fixed or separate revenue. Many of them are operated in connection with other institutions, while others are maintained jointly by government and local appropriations, together with fees for analysis, some agricultural society supplying the deficit. In most of the control stations and laboratories small fees are charged, and in many cases these constitute quite a large proportion of the revenue of the station.

In a large number of instances the total income reported amounts to only a few hundred dollars, but in such cases the station or laboratory is usually connected with some other institution which probably pays the salaries of the employees. A number of the German and Austrian stations have quite liberal funds for maintenance. For example, the station for moor culture at Bremen received about $16,000 in 1900, the experiment station at Vienna over $20,000, and the Halle station over $30,000, while the moor experiment station in Denmark for several years past has expended over $70,000 annually. The latter is conducted by the Danish Heath Society, which carries on two large demonstration fields and about 40 small fields.

While a number of the German stations receive as high as $15,000 a year from various sources, an income of over $5,000 a year is rather the exception than the rule for European stations, and there are large numbers whose income amounts to only $2,000 or $3,000. These stations, however, are usually at no expense for buildings or for printing, the publication of their work in periodicals often being a small source of revenue; and as their fields are quite restricted in area the expense for labor is reduced to a minimum. By the exercise of rigid economy, and confining their efforts to a few specific lines of work, many of these stations have accomplished a surprising amount of high-grade work, which has contributed materially to the sum of human knowledge in the field of agricultural science.

NEW AGRICULTURAL BUILDING AT PURDUE UNIVERSITY.

The new building for the School of Agriculture of Purdue University, as provided for in the legislature of 1901 by an appropriation of $60,000, will be a worthy and substantial addition to the equipment of the institution.

The structure, which is already under roof, is 65 by 165 feet in outside dimensions, and 2 stories in height above a working basement. The materials are Bedford stone and pressed brick of a light terracotta shade. In appearance the building is plain, but dignified. It will contain, with one or two exceptions, all of the offices, class rooms and laboratories of the School of Agriculture.

The construction of the building is of the most substantial character; the heating and ventilation will be provided for by a system of forced circulation, and a very notable feature of the edifice is the provision for well-lighted class rooms and laboratories, made by the large amount of window space. Both gas and electric lights will be used.

One-half of the basement is devoted to the dairy laboratories, including separator, testing, curing, and home-dairy rooms; constant-temperature rooms for cheese curing and storage, and refrigerating apparatus. Laboratories for the study of soil physics and horticulture occupy the remainder of this story.

On the first floor are class rooms for dairy and live-stock husbandry, and laboratories for agricultural physics, economic botany and entomology, together with the offices of the instructors. The second story contains the laboratories, collections, and class rooms for veterinary science, one or two general class rooms, the agricultural museum, and a handsome lecture hall with seating capacity for about three hundred persons.

The plan and general character of the building are generally commended, and it is expected that its completion will contribute very largely to the efficiency and popularity of the school.

NEW AGRICULTURAL BUILDING, PURDUE UNIVERSITY.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The indirect weighing of quantitative precipitates. A rapid and accurate method for determining the weight of a precipitate without separating it from the liquid from which it was precipitated, R. W. Thatcher (*Jour. Amer. Chem. Soc., 23 (1901), No. 9, pp. 644–668*).—The author discusses at some length the method of determining the weight of a precipitate without separating it from the solution, and cites a number of examples of the application of the method to solutions of chemical salts and reducing sugars. The method is based on the fact that the weight of any substance is equal to its specific gravity multiplied by its volume, and, conversely, that the volume of any substance is equal to its weight divided by its specific gravity. "Briefly stated, the principle upon which this new method for determining the weight of quantitative precipitates is based is that if the weight of a definite volume of a mixture of two substances whose specific gravities are known be determined, the proportion of each which is present in the mixture may be calculated."

While the investigation of this method is not complete, the author believes the results indicate that it is applicable in gravimetric analyses, being of easy manipulation and shortening the time required for the determination.

Simplification of the method of determining phosphoric acid as phosphomolybdic anhydrid according to Meineke-Woy; studies on methods of obtaining a pure precipitate of ammonium phosphomolybdate by means of molybdic solution containing citric acid; the transformation of the molybdic-magnesia method into a strictly molybdic method by the use of the Wagner-Stutzer molybdic solution, A. Seyda (*Chem. Ztg., 25 (1901), No. 72, pp. 759–768*).—This article briefly reviews the work of Meineke (E. S. R., 8, p. 100), Woy (E. S. R., 9, pp. 321, 723), Wagner[1], Stutzer[2], and others, and reports in detail the results of tests of the accuracy of the molybdic method under a variety of conditions. In summing up the results the author states that the only error in the method of determining phosphoric acid by precipitation as phosphomolybdic anhydrid is the simultaneous separation of free molybdic acid, and that this error can not be overcome with absolute certainty by a single precipitation, using an excess of the molybdic reagent. The separation of molybdic acid in case of a single precipitation is best prevented by shaking for one-fourth hour in a rotary apparatus at room temperature and by adding 20 cc. of 10 per cent citric acid. For solutions free from iron compounds the temperature should not exceed 30° C.; for those containing iron, 20° C. In the latter case also, the solution should be filtered within 15 minutes after the shaking. The most practical method of freeing the precipitate from free molybdic acid is to dissolve in ammonia and reprecipitate in hot solution by adding dilute molybdic solution and nitric acid, washing the precipitate with hot solutions (60 to 80° C.). Under some circumstances it may be necessary to repeat this process. The right amounts and concentration of the reagents are of great importance. The transformation of the precipitate into anhydrid is not considered complete until the ignited product is uniformly black and crystalline on both the upper and under surface. Directions for preparing reagents and carrying out the method are given in detail.

The determination of phosphoric acid in superphosphates, mixed fertilizers, and precipitated phosphates by precipitation in the cold as ammonium phosphomolybdate, L. LEDOUX (*Bul. Assoc. Belge Chim., 15 (1901), No. 3, pp. 125–129; abs. in Chem. Centbl., 1901, I, No. 25, p. 1341; Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 15, p. 766*).—The author points out that phosphoric acid may be determined in form of phosphomolybdate by the citro-mechanical method provided the solutions contain a sufficient amount of ammonium nitrate and a sufficiently large amount of molybdic solution be added. The solutions must also be heated with nitric acid to convert all of the metaphosphates into orthophosphates. The molybdic reagent used is made up of 150 gm. of molybdic acid, 600 cc. of 0.96 sp. gr. ammonia, and 1,070 cc. of nitric acid of 1.22 sp. gr. The method of procedure recommended is as follows: Treat 2 gm. of superphosphate or 4 gm. of phosphatic fertilizer in the usual way with water and citric acid; make the solution to 250 cc.; heat 50 cc. of this solution for 5 minutes with 15 cc. of nitric acid (1.4 sp. gr.); cool; add 15 cc. of ammonia (0.92 sp. gr.), and shake vigorously for 30 minutes, adding 100 cc. of molybdic solution. Titrate the yellow precipitate according to Pemberton's method or convert into ammonium-magnesium phosphate in the usual way.

Determination of phosphoric acid as ammonium phosphomolybdate, H. PELLET (*Ann. Chim. Analyt., 6 (1901), pp. 248–251; abs. in Chem. Centbl., 1901, II, No. 7, p. 501*).—The author points out the danger of incomplete precipitation of phosphoric acid in the presence of much iron and other impurities when Ledoux's method (see above) of shaking for one-half hour in the cold is followed. He recommends as more accurate the direct weighing of the ammonium phosphomolybdate without converting it into magnesium pyrophosphate. He claims priority over Ledoux as regards discovery and announcement of conditions under which a pure ammonium phosphomolybdate may be obtained.

Determination of phosphoric acid, DE MOLINARI (*Bul. Agr. [Brussels], 17 (1901), No. 2, pp. 154–157*).—Comparisons of the so-called citro-mechanical method and Pemberton's titration method are reported. Tests of the method based upon titration of the ammonium-magnesium phosphate precipitate according to De Koninck are also reported.

Determination of phosphoric acid by titration of ammonium phosphomolybdate, NYSSENS (*Bul. Agr. [Brussels], 17 (1901), No. 2, pp. 142–146*).—Tests of precipitation in the absence of citric acid and in the presence of a large quantity of this substance are reported. The composition of the yellow precipitate was found to vary with the quantity of precipitant and the manner of adding it to the solution. The author precipitates in the cold, using a shaking apparatus making 100 revolutions per minute. By this method 10 minutes suffices for complete precipitation. With more vigorous shaking 5 minutes suffices, but the precipitate is very fine and difficult to retain on the filter. When citric acid is present it is oxidized by means of potassium permanganate before precipitation. The author is attempting to work out a method by which complete precipitation in the cold may be effected without destroying citric acid. This is based on the use of nitro-molybdate of potash as a precipitant instead of nitro-molybdate of ammonia.

The transformation and purification of magnesium pyrophosphate with the object of weighing as magnesium pyrosulphophosphate, H. PELLET (*Ann. Chim. Analyt., 6 (1901), p. 211; abs. in Chem. Centbl., 1901, II, No. 3, p. 233*).—In order to obtain a perfectly white ignition product the author treats the magnesium

---

[1] Ztschr. Analyt. Chem., 19 (1880), p. 450; 21 (1882), p. 353.

[2] Ztschr. Angew. Chem., 1890, p. 43.

pyrophosphate with sulphuric acid. By this means a new body is obtained, magnesium pyrosulphophosphate, 0.715 gm. of magnesium pyrophosphate yielding 0.2305 gm. of the body. The content of MgO is calculated by the factor 0.265, of P_2O_5 by the factor 0.47.

The determination of lime, magnesia, and phosphoric acid in the presence of considerable amounts of iron oxid, H. PELLET (*Ann. Chim. Analyt., 6* (*1901*), *p. 163; abs. in Chem. Ztg., 25* (*1901*), *No. 58, Repert., p. 208*).—The methods proposed for the analysis of substances containing from 5 to 10 per cent of iron associated with small percentages of lime, magnesia, and phosphoric acid are as follows: For the determination of lime, neutralize a portion of the nitric or hydrochloric acid solution freed from silica, corresponding to 2 to 5 gm. of the substance, with ammonia to the verge of precipitation, and add a few drops of acetic acid, about 20 times the amount of ammonium oxalate required to precipitate the lime, and a little more ammonia. The operation is completed in the usual way. For the determination of magnesia use an aliquot of the solution corresponding to the same amount of substance, and for each 50 cc. of the solution add 70 cc. of Petermann's ammonium citrate solution, 10 cc. of saturated sodium phosphate solution, and 20 cc. of ammonia, and proceed as usual. For the determination of phosphoric acid use ammonium molybdate to which 20 drops of ammonium citrate solution has been added to prevent the separation of molybdic acid. Dissolve the ammonium phosphomolybdate in ammonia and reprecipitate with dilute nitric acid in a warm solution. Dry at 100° C. and weigh. One hundred parts of the precipitate correspond to 3.75 parts of phosphoric acid.

Estimation of magnesium by organic bases, W. HERZ and K. DRUCKER (*Ztschr. Anorgan. Chem., 26* (*1901*), *pp. 347–349; abs. in Jour. Chem. Soc.* [*London*], *80* (*1901*), *No. 463, II, p. 348*).—The method of estimating zinc by precipitation with dimethylamin is applicable to magnesium, giving accurate results. Magnesium salts are also completely precipitated by a solution of free guanidin. This method is especially recommended in the estimation of magnesium in the presence of alkalis and in the analysis of mixed silicates containing magnesium.

The determination of potash, O. SCHUMM (*Ztschr. Analyt. Chem., 40* (*1901*), *pp. 385–389; abs. in Chem. Centbl., 1901, II, No. 4, p. 321*).—The author recommends Classen's electrolytic method, in which metallic platinum is separated from the potassium platinum chlorid in sulphuric-acid solution and weighed. The factor used in calculating potassium chlorid from the weight of platinum is 0.76689 for less than 0.2 gm. platinum and 0.764595 for 0.2 gm. or more.

The relative value and limits of accuracy of various titration methods for determining caustic soda in the presence of sodium carbonate, R. LUCION and D. DE PAEPE (*Bul. Assoc. Belge Chim., 15* (*1901*), *No. 1, pp. 19–23; abs. in Bul. Soc. Chim. Paris, 3. ser., 25* (*1901*), *No. 12, p. 652*).

On various classic methods for the volumetric determination of small quantities of sodium carbonate in the presence of large amounts of acid sodium carbonate, R. LUCION and D. DE PAEPE (*Bul. Assoc. Belge Chim., 15* (*1901*), *No. 1, pp. 23–25; abs. in Bul. Soc. Chim. Paris, 3. ser., 25* (*1901*), *No. 13, p. 703*).

A method for the determination of the availability of organic nitrogen in commercial fertilizers, J. P. STREET (*Jour. Amer. Chem. Soc., 23* (*1901*), *No. 5, pp. 330–338*).—The following method is proposed: To an amount of substance equivalent to 0.075 gm. of nitrogen in a 300 cc. Erlenmeyer flask add 100 cc. of neutral 1.6 per cent potassium permanganate and digest the mixture on a steam bath for 20 minutes with occasional shaking, filter and wash with 125 to 150 cc. of water, and determine nitrogen in the undissolved residue by the ordinary Kjeldahl process. The results of a large number of tests of widely differing fertilizers show that this method places them in about the same rank as that assigned by vegetation tests and agricultural experience.

On the compounds formed in the process of determining nitrogen according to Kjeldahl, V. ANDRLIK (*Věstník III Sjezdu České. Přír. Lék Praze, 1901, p. 290; abs. in Chem. Ztg., 25 (1901), No. 60, Repert., p. 221*).—It is claimed that in the Kjeldahl method not all of the nitrogen is transformed into ammonia, but a portion remains as amin. This was found to be especially true in case of sugar-beet products which contain betain.

Determination of nitrogen in nitrates by the Schulze-Tiemann method, V. STANĚK (*Böhm. Ztschr. Zuckerind., 25 (1901), No. 7, pp. 356–358; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 5, p. 506, fig. 1*).—In the Schulze-Tiemann method the nitric oxid is collected in a graduated tube over dilute alkali solution and the tube is then transferred to a tall cylinder filled with recently boiled water and after a time the volume and temperature of the gas are read off. The author has devised an apparatus that avoids the transfer of the measuring tube containing the nitric oxid. This apparatus is figured and described.

On the determination of nitrates in potable waters with brucin and crystallized formic acid, E. CAZENEUVE and H. DEFOURNEL (*Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 12, pp. 639, 640*).—The method proposed is as follows: When the water contains only a trace of nitrate evaporate 1 liter to dryness, take up the residue in 20 cc. of distilled water, and evaporate to dryness again with 0.05 gm. of brucin in a small shallow dish, remove the dish from the water bath, and while still hot add a few drops of concentrated formic acid and a little distilled water. A yellow coloration appears, which, after standing 12 hours, is, on the addition of a small quantity of hydrogen peroxid, changed to a rose color. By this means one part of nitrate in 100,000 parts of water may be detected. Quantitative determinations may be made by the colorimetric method.

On the occurrence of free iodin in nitrate of soda, F. W. DAFERT and A. HALLA (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 6, pp. 732–734*).—It is stated that free iodin is found in certain samples of sodium nitrate, resulting from the decomposition of iodates present.

A rapid method for the determination of arsenious oxid in Paris green, S. AVERY and H. T. BEANS (*Jour. Amer. Chem. Soc., 23 (1901), No. 7, pp. 485, 486*).—The authors offer the following rapid and accurate method for determining the arsenic in Paris green: The sample is pulverized in an agate mortar and 0.2 to 0.3 gm. placed in a beaker of about 300 cc. capacity. About 25 cc. of water is added, and concentrated hydrochloric acid, drop by drop, with constant stirring until the green suspended is in solution; from 6 to 10 drops are usually sufficient. Sodium carbonate solution is then added until a slight permanent precipitate is formed and at this point 2 to 3 gms. of sodium potassium tartrate in solution added. The tartrate will immediately dissolve the precipitated copper and prevent further precipitation during the subsequent titration. The whole is diluted to about 200 cc., solid sodium bicarbonate and starch solution added, and titrated with iodin in the usual manner. The operation requires about 10 minutes. The end reaction is sharp and is not obscured in the least by the blue color of the solution.

On the elimination and quantitative estimation of water in oils, fats, and waxes, C. B. DAVIS (*Jour. Amer. Chem. Soc., 23 (1901), No. 7, pp. 487, 488*).—In order to avoid loss by foaming and sputtering in drying oils, fats, and waxes, the authors propose the following method: A coil of thick filter paper is placed in a wide-mouthed weighing bottle and dried to constant weight. As much of the oil, fat, or wax is introduced as will be absorbed by the filter paper, the whole weighed, dried to constant weight, and again weighed.

Use of amyl alcohol in the analysis of fats, G. HALPHEN (*Ann. Chim. Analyt. 6 (1901), pp. 133–135; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 463, II, p. 359*).—The following method is given as being rapid and sufficiently accurate for commercial purposes in estimating nonsaponifiable matter in fats: To 5 or 10 gms.

of the fat, dissolved in 10 volumes of carbon bisulphid, twice as much concentrated sulphuric acid as the fat is added drop by drop, with shaking, to avoid rise of temperature. The whole is rinsed into a separatory funnel, the lower layer run out, the upper one shaken with a little animal charcoal to remove tar and traces of acid, then filtered, distilled, and the residue weighed.

A new reaction of saccharin, A. LEYS (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 17, pp. 1056–1058; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 6, p. 622*).—This color reaction with saccharin is given when even very dilute solutions are treated with dilute copper sulphate or ferric chlorid and hydrogen peroxid. Five cc. of the solution containing saccharin, treated with 2 drops of ferric chlorid and 2 cc. of hydrogen peroxid diluted, gives a violet color in 30 or 35 minutes.

This reaction may be used for determining the presence of saccharin in milk and in butter. The milk is treated with potassium bisulphate and absolute alcohol and the clear liquid filtered from the precipitated casein and fat. This liquid is then shaken with ether, evaporated, dried, taken up with boiling water, cooled, and tasted. If sweet, examine for saccharin as above.

Butter is dissolved in equal volumes of chloroform and alcohol, water added, and shaken. The separated chloroform retains the fats; the aqueous-alcoholic solution the saccharin. The latter is tested as described.

Clarification of low-grade molasses for polarization, H. C. LAURENCE (*Beet Sugar Gaz., 3 (1901), No. 5, pp. 109, 110*).—In the laboratory of the Los Alamitos Sugar Company experiments were made of using permanganate of potash in clarifying sugar solutions. After clarifying with lead subacetate the filtrates when dark were treated with a few crystals of permanganate of potash and again filtered, resulting in a bright and much clearer filtrate. In order to test the correctness of this addition 50 cc. portions of the same samples were placed in 200 cc. flasks and treated with a slight excess of lead solution. After 10 minutes 50 cc. of a strong permanganate solution was added, the whole allowed to stand long enough for the air bubbles to escape, brought to the mark, filtered, and polarized. The polarizations were made with ease, and agreed with those obtained with the lead solution alone. The filtrates from the lead alone were dark and hard to read; those from the permanganate were colorless as water.

These results were verified by A. M. Masser, chemist of the Wolverine Company, who also found the method applicable to carmelized sugar.

The action of carbonic acid in sugar solutions saturated with lime, J. WEISBERG (*Bul. Assoc. Chim. Sucr. et Distill., 18 (1901), No. 7, pp. 457–462*).—The products formed in adding carbonic acid to precipitate the lime in the carbonation process in sugar making are described and discussed. In passing carbonic acid into a sugar juice containing lime the alkalinity as denoted by phenolphthalein continues to fall, while the polarization of the filtered juice falls and then rises again to the original value. At the lowest point of polarization there is the greatest thickening of the liquid, the slowest rate of filtering, and this is the point at which the decoloration of the juice begins.

Estimation of sugar in vinous products, A. BERNARD (*Ann. Chim. Analyt., 6 (1901), pp. 89–95; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 463, II, p. 355*).—Ten cc. of the liquid to be examined is diluted in a conical flask, 20 cc. Fehling's solution added, and heated to boiling. The flask is cooled in cold water, the contents filtered, and 15 cc. or more of the filtrate is titrated with a solution of potassium cyanid until colorless. The cyanid solution is made up so that 10 cc. will discolorize 10 cc. of Fehling's solution. The strength of the latter may be determined by means of an accurately made solution of invert sugar.

Estimation of total extract and free acid in wine, F. FREYER (*Oesterr. Chem. Ztg., 4 (1901), p. 129; abs. in Analyst, 26 (1901), No. 303, p. 157*).—Owing to the many sources of probable error in estimating the extract of wine by evaporation, the author proposes getting this figure from the specific gravity of the sample taken before and after distilling, using either the Haas or Windisch tables for making the calculations.

With the "free acid" of wine it is recommended to determine the potassium bitartrate; reduce this (188=75) to free tartaric acid, deduct this value from the total nonvolatile acid obtained by titration, and consider the difference as true free acid. The nonacid extract is then obtained by subtracting both the tartar and true free acid from the total extract.

A new indicator for use in determining total acidity of wines, E. G. RUNYAN (*Jour. Amer. Chem. Soc., 23 (1901), No. 6, pp. 402–405*).—The author employed the mixture of corallin and malachite green, as recommended by Lachaux, in examining dark-colored juices of the sugar beet. Owing to the good results obtained, the mixture is recommended as an indicator in the analysis of wines, vinegars, ciders, and similar products.

A method of determining nicotin in tobacco and tobacco extracts, J. FOTH (*Rev. Internat. Falsif., 14 (1901), No. 1, pp. 12–14*).—A modification of Kissling's method (E. S. R., 5, p. 433). The dried mass is extracted with a mixture of ether and light petroleum. An excess of normal sulphuric acid is added and the liquid titrated with normal sodium hydroxid, 1 cc. of sulphuric acid neutralized being taken as equal to 0.0162 gm. of nicotin.

Three new alkaloids of tobacco, A. PICTET and A. ROTSCHY (*Compt. Rend. Acad. Sci. Paris, 132 (1901), p. 971; abs. in Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 13, p. 698*).

Chemistry of tobacco smoke, H. THOMS (*Schweiz. Wchnschr. Pharm., 39 (1901), No. 27; abs. in Pharm. Jour., 66 (1901), No. 1607, p. 459; Jour. Soc. Chem. Ind., 20 (1901), No. 6, p. 626*).—Tobacco smoke was drawn through absorption tubes containing caustic soda, sulphuric acid, etc., and the contents of the tubes afterwards examined. The smoke was found to contain the bases nicotin and pyridin, and ammonia, carbonic and butyric acids, carbon monoxid, and 2 volatile oils, one of which could be steam-distilled from tobacco. In 15,000 gm. of tobacco there was 6 gm. of this oil of dark color and smell resembling camomile oil. The other oil was extremely toxic, of dark color and narcotic odor. About 75 per cent of nicotin in the tobacco passed over through the smoke, being afterwards partly decomposed. The ash amounted to 20.09 per cent of the tobacco burned, and 18.82 per cent of the ash was carbonaceous. The mineral matter consisted chiefly of carbonates of calcium and potassium, the phosphates of calcium and magnesium, potassium chlorid, silicates, and silica.

Official method for analysis of tanning materials (*U. S. Dept. Agr., Bureau of Chemistry Circ. 8, pp. 2*).—A description of the method adopted at the last convention of the Association of Official Agricultural Chemists (E. S. R., 13, p. 412).

On the determination of formaldehyde, A. G. CRAIG (*Jour. Amer. Chem. Soc., 23 (1901), No. 9, pp. 638–643*).—The author has made an extended study of the methods for the determination of formaldehyde. These methods may be divided into 3 groups: (1) depending on a specific reaction, (2) formation of addition products with elimination of the elements of water, and (3) oxidation and reduction. Of the various methods tested, that of Legler was found the most accurate, with certain modifications. The requisites to the determination are a normal solution of sulphuric acid, an approximately normal solution of ammonia, the exact strength being immaterial, and a methyl orange solution; 3 oz. bottles with smooth sides and close-fitting soft-rubber stoppers, and a boiler in which they may be immersed to the neck. Place 25 cc. of the ammonia solution in each bottle and to one-half of them add a sample containing 0.5 gm. of formaldehyde. Stopper tightly, place the bottles in the boiler, fill with water to the neck, and boil for 1 hour. Cool slowly and titrate carefully with sulphuric acid and methyl orange to the first indication of a color change. The differences between the readings for the blanks and the samples represent the ammonia consumed in normal cubic centimeters; 1 cc. equals 0.0601 gm. of formaldehyde.

The errors in the Legler method do not counterbalance one another, the tendency being toward low results. A blank determination is necessary, and in the titration an accurate end-point is very important. Any acid present must be accounted for.

The oxalic acid in organisms, CIPOLLINA (*Berlin. Klin. Wchnschr., 38 (1901), p. 544; abs. in Chem. Ztg., 25 (1901), No. 44, p. 169*).—A study of the oxalic acid in animal and vegetable products, with some reference to its source.

Improvement of Küster's hydrogen sulphid apparatus, G. FRERICHS (*Arch. Pharm., 239 (1901), pp. 118–121; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 463, II, p. 311*).—Küster's apparatus (E. S. R., 5, p. 728) has the disadvantage that a good deal of acid enters before the steady evolution of gas begins. The author obviates this difficulty by placing a small vessel with a valve to admit air between the large reservoir of acid and the bottle of sulphid. This small vessel is filled from the reservoir and then connected with the sulphid bottle.

Areometer for use with the Reichert-Meissl determination, M. J. VANDERPLANCKEN (*Bul. Assoc. Belge Chim., 15 (1901), No. 4–5, pp. 176, 177*).—A description of an instrument to be used in determining the Reichert-Meissl number is given and its advantages are set forth.

A modification of the Landsberger apparatus for determining the boiling point, C. N. RIIBER (*Ber. Deut. Chem. Gesell., 34 (1901), p. 1060; abs. in Chem. Ztg., 25 (1901), No. 46, p. 174, fig. 1*).

Tables for calculating in quantitative chemical analysis, founded on the basis of the atomic weights as recommended by Landolt, Ostwald, and Seubert, A. SARTORI (*Ztschr. Analyt. Chem., 40 (1901), No. 4–5, pp. 202–376*).—Tables of all the elements are given, together with multiples of the same up to 9, and the logarithm.

The improvement of instruction in technical chemistry, A. LACHMANN (*Jour. Soc. Chem. Ind., 20 (1901), No. 6, pp. 546–551*).—A popular article on chemical education.

BOTANY.

On the origin of new species of plants, H. DE VRIES (*Proc. Sec. Sci. Koninkl. Akad. Wetensch. Amsterdam, 1901, III, pp. 245–247*).—A brief account is given of 15 years' experiments with *Œnothera lamarckiana*, in which the author has established new types which are considered of sufficient stability to warrant description as new species. The author believes that plants undergo long periods of constancy alternately with periods in which new species may be produced. He believes that each species has originated from another at such a time. For this it is held that it is not necessary that the mother species be changed in any way, but that it may continue with all its former characteristics unchanged. His observations have been made from plants growing in natural conditions as well as seed collected and sown in gardens. After an extended research, one species was found which was in what he terms a mutation period. The results of observations on many thousands of seedlings are given, and the author has separated forms which have been constant from their first occurrence after several generations of cultivation. At present he has originated from the original wild species 12 distinct forms which come true to seed. The conclusion is drawn that new species originate suddenly without intermediate forms or any other preparation. From the beginning they remain unchanged during the subsequent generations. No reversion, or atavism, was observed in any of these cases. Mutation seems to take place in various directions, and not in any predetermined manner. In many instances the new species are weakened but sometimes appear more adapted to their surroundings than the original.

The plants of western Lake Erie, with observations on their distribution, A. J. PIETERS (*U. S. Fish Com. Bul. 1901, pp. 57–79, pls. 10*).—This is a contribution to the biology of the Great Lakes, made with a view of studying the possibilities of increasing the stock of fish now existing in those waters. A report is given of the various plants found along the shores and extending into the deeper waters. The different life zones are described, and influence of variation in depth of water is shown. The report enumerates the species of phanerogams, charas, and desmids observed during the investigations made in the summer of 1898.

The flora of the Palouse region, C. V. Piper and R. K. Beattie (*Pullman: Washington State Agr. Col., 1901, pp. 208*).—Descriptions are given of all the Spermatophytes and Pteridophytes known to grow wild within a radius of 35 kilometers of Pullman, Wash. The total number of species described is 663, representing 337 genera.

A contribution to the knowledge of the flora of the Red River Valley in Minnesota, W. A. Wheeler (*Minnesota Bot. Studies, 2. ser., 1901, pt. 5, pp. 569–600, pls. 8*).—The results of a study of the flora of this region show the presence of 325 species of flowering plants. The species are enumerated and general views given of the distribution of the flora in different localities.

A preliminary list of Minnesota Uredineæ, E. M. Freeman (*Minnesota Bot. Studies, 2. ser., 1901, pt. 5, pp. 537–560*).—The occurrence and distribution is noted of 165 species of Uredineæ, and critical notes given on a number of species.

Plants reported to be poisonous to stock in Australia, J. H. Maiden (*Agr. Gaz. New South Wales, 12 (1901), No. 6, pp. 637–666*).—A list is given, arranged in their natural orders, of plants which have been reputed poisonous to stock, and notes added briefly describing the plants, symptoms produced, and remedial treatments suggested. The list contains many plants upon which the evidence of poisonous properties is very doubtful, and others which have been shown to be innocuous. Bibliographies are given of a number of plants.

Crossing of varieties, K. Sajo (*Prometheus, 11 (1901), pp. 209–212, 225–231, 244–251, figs. 9; abs. in Jour. Roy. Micros. Soc. [London], 1901, No. 3, pp. 300, 301*).—The results of crossing varieties of grapes and apples are discussed at some length. The author claims that not only the seeds but the pericarp are influenced by such crossing. It is stated that the pollen of the grape never develops tubes greater than 6 to 7 mm. In the apple and pear orchards wind is said to play a very small part in the dissemination of pollen. Bees, flies, and other pollinating insects, as a rule, visit a large number of flowers in succession on the same tree, and therefore do not bring about true cross pollination. In the case of apples and pears only a small proportion of the flowers are habitually fertilized (5 to 6 per cent in the former and about 13 per cent in the latter case).

The vitality of pollen (*Rev. Hort., 73 (1901), No. 14, pp. 323, 324*).—In a brief note it is stated that experiments have shown that the pollen of roses may retain its vitality for 22 days or more; Clivias at least 3 months and some hybrids for over a year, cannas for 15 days or more, and Aucuba for 10 days.

The double fecundation of maize, L. Guignard (*Jour. Bot. [Paris], 15 (1901), No. 2, pp. 37–50*).—A critical review is given of the recently published papers of De Vries, Correns, and Webber, relating to Xenia, or double fecundation of maize (E. S. R., 12, pp. 421, 717).

Influence of wounds on the formation of proteid material in plants, A. Hettlinger (*Rev. Gén. Bot., 13 (1901), No. 150, pp. 248–250*).—The author reports experiments in which onion bulbs were divided into 4 equal parts and the proteid material determined. Two of the portions were subjected to immediate analysis, while the other 2 were cut in small pieces, retained in darkness for 5 days, after which they were analyzed. The results showed that in the bulbs of the onion there is a considerable increase of proteid material due to wounds.

On the comparative poisonous properties of compounds of nickel and cobalt when applied to higher plants, H. Coupin (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 17, pp. 489, 490*).—Comparisons of the chlorids, sulphates, and nitrates of nickel and cobalt as shown upon the germination of wheat are reported, from which it appears that the toxicity of the same compound of each metal was very nearly the same, and both are quite high.

On the poisonous properties of compounds of silver, mercury, gold, platinum, and palladium, when applied to higher plants, H. Coupin (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 17, pp. 509, 510*).

On the toxic value of mercuric chlorid and its double salts, J. F. Clark (*Jour. Phys. Chem., 5 (1901), No. 5, pp. 289-316*).—The author made an extended study of the influence of various solutions of $HgCl_2$ on fungi. The results are reported in a table and also plotted. The results of the addition of NaCl in varying amounts to the $HgCl_2$ is also noted. In great concentration of these 2 salts, a large increase in the toxic properties of the mixture was obtained by the simple dilution with water to 4 or more volumes. The reason for this would appear from the fact that by the greater dilution the double salts were more readily broken down. Contrary to the usual belief, the addition of NaCl to the mercuric salt lessened, instead of increased the toxic value. This is stated to be because of the fact that the double salts have less affinity for the proteid substances than the pure $HgCl_2$ solution.

Digestive secretion of Nepenthes, Clautrian (*Biol. Centbl., 21 (1901), p. 33; abs. in Jour. Roy. Micros. Soc. [London], 1901, No. 3, p. 290*).—The result of a series of observations on the digestive properties found in the urns of Nepenthes are given. Owing to the comparative scarcity of small insects no great numbers were entrapped. The bodies of those that were captured were found more or less completely digested, and, according to the author's experiments, bacteria had no part in the digestion. The fluid in the urns is ordinarily neutral to reagents, but upon shaking or introducing any foreign substance it becomes acid. The digestive ferment present is considered to be zymase, which is regarded as a pepsin rather than a trypsin.

The oxidases in higher plants, N. Passerini (*Abs. in Ann. Agron., 27 (1901), No. 6, p. 302*).—The author has made a study of the diffusion and localization of oxidases among the higher plants, as shown by the well-known reactions for diastases, such as hydroquinone, pyrogallic acid, and tincture of quaiacum. He found that oxidases are widely distributed among plants, the Solanaceæ, Labiatæ, Compositæ, and Umbelliferæ containing them in considerable abundance. Diastases are most noticeable in the roots of plants, and rarely in the leaves. When present in the leaves it is most often localized along the veins. The pistils and filaments of the stamens are richest in oxidases of the flowering organs. They are also localized in the pericarp of the fruits. Seeds in the process of formation contain oxidases, but they disappear with their ripening. Aquatic plants do not seem to contain oxidases.

Enzyms of fungi, P. Kohnstamm (*Bot. Centbl. Beihefte, 10 (1901), pp. 90-121; abs. in Jour. Roy. Micros. Soc. [London], 1901, No. 3, p. 308*).—An extensive study has been made with enzyms which attack starch, glucosids, proteids, and cellulose in those fungi which are noted for destroying wood, especially in *Agaricus melleus*, *Merulius lachrymans*, and *Polyporus squamosus*. The mode of treatment is described at length and the results summarized. From the 3 fungi enumerated a starch-destroying enzym (amylase) was obtained which apparently is identical with the diastatic enzym of malt. It was found most abundant in *Polyporus squamosus*. Emulsin, a glucosid ferment, was found in *M. lachrymans* and *P. squamosus*, but not in *A. melleus*. A proteolytic enzym was found in small quantity in *A. melleus*, and more abundantly in the others. In *M. lachrymans* a cellulose-decomposing enzym was found, and it was established that these various ferments may act simultaneously. The ferments were found only in the receptacle of *P. squamosus*, while the mycelium of *M. lachrymans* also contained these substances.

Decomposition of glucosids by mold fungi, A. Brunstein (*Bot. Centbl., Beihefte, 10 (1901), pp. 1-50; abs. in Jour. Roy. Micros. Soc. [London], 1901, No. 3, p. 310*).—A series of experiments are reported on the decomposition of different glucosids by species of Aspergillus, Penicillium, and other fungi. It appears that the glucosids employed have very different values for the nutrition of the fungi. In all cases the glucosid is split up into glucose and a benzol derivative. None of the media containing glucosids gave as good growth as those free from them, and some of them produced substances prejudicial to the growth of the organism.

A text-book of plant physiology, D. T. MacDougal (*New York: Longmans, Green & Co., 1901, pp. XIV+352, figs. 159*).—This book, by the director of the laboratories of the New York Botanical Garden, is an important addition to the text-books which have recently appeared for secondary schools and laboratory guides. An attempt is made to place before the student a method whereby a working knowledge of the physiological activities of the plant may be acquired. This entails a study of the functions and properties of the organism in connection with the agencies and forces which influence plant life. The first part of the book is devoted to the consideration of forms of irritability as exhibited by typical organisms, while the second part is taken up with a study of the various phases of plant activity. The discussion of the principles is accompanied with directions for practical demonstrations, the purpose of the author being to present practical directions for the demonstration of the principal physiological phenomena of the plant as well as the details of methods requisite to research work.

Numerous references are given to the literature of the subject, but no attempt is made to make the bibliography exhaustive, only the more important recent publications or those which treat of phases of plant life not touched upon in the present work being cited.

Southern wild flowers and trees, Alice Lounsberry (*New York: Frederick A. Stokes Co., 1901, pp. XV+570, pls. 177, figs. 50*).—This book treats in a popular way of the wild flowers and trees of the Southern States, and is the first work of the kind adapted to that large and interesting region. The text is simply written, and the order of arrangement is that adopted by many of the more recent writers in beginning with those flowers which are structurally simple and progressing to the more complex. In compiling this work the author has given a selected list of more than 1,000 species of plants, the system of names adopted being for the most part that of the so-called Rochester code. Simple keys have been prepared for the plant families and technical terms, so far as consistent with clearness, have been omitted. For such technical terms as are used an illustrated glossary is provided. A special attempt has been made to give something of the history, folk lore, and uses of the southern plants, and their distribution, habits, and surroundings are described in a pleasing style. The illustrations, many of which are colored and all prepared especially for this work, are of a very excellent character, and portray the plants with marked fidelity.

BACTERIOLOGY.

Botanical descriptions of some soil bacteria, O. Gottheil (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 12, pp. 430–435; 13, pp. 449–465; 14, pp. 481–497; 15, pp. 529–544; 16, pp. 582–591; 17–18, pp. 627–637; 19, pp. 680–691; 20, pp. 717–730, pls. 4*).—Attention is called to the difficulty met with in the specific determination of species of soil bacteria, and suggestions are given for a uniform method of description. This embraces not only the morphological characteristics of the organisms, but also their behavior in a large number of media under different conditions. In addition, about a dozen species are described, as follows: *Bacillus ruminatus*, *B. tumescens*, *B. graveolens*, *B. petasites*, *B. ellenbachensis*, *B. mycoides*, *B. subtilis*, *B. pumilus*, *B. simplex*, *B. cohærens*, *B. carotarum*, *B. fusiformis*, and *B. asterosporus*. All of these species were found, probably as saprophytes, upon the underground parts of plants, many of which are of economic importance. A list of about 50 works, relating to the systematic and diagnostic descriptions of species of bacteria, completes the paper.

Notes on Vibrio denitrificans, R. G. SMITH (*Proc. Linn. Soc. New South Wales, 26 (1901), pt. 1, pp. 118–121, pl. 1*).—In studying the bacteria found in the canals used for conveying the Sydney water supply, the author isolated the above-mentioned species and was struck with its resemblance to the organism which produces root tubercles on leguminous plants. In size and character of growth, as well as some other peculiarities, the two are quite similar. The Vibrio, however, differs in its power of growing on ordinary media as well as in media containing little nutriment. Unlike the root tubercle organism, this bacteria is unable to convert free nitrogen into combined forms, but reduces nitrates to gaseous form.

On the value of plating as a means for determining the number of bacteria in drinking water, W. C. C. PAKES (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 11, pp. 386–391*).—The conclusion is drawn that plating upon ordinary gelatin, whether made with distilled or tap water, is no necessary criterion of the number of bacteria present, and so far as possible gelatin should be made without meat extractives with the water to be examined or with a sample of water of the same mineral constitution.

The soluble ferments or enzyms, E. O. JORDAN (*Pop. Sci. Mo., 59 (1901), No. 5, pp. 497–503*).—The author popularly describes various enzyms, grouping them according to their action upon sugar, proteids, etc.

Agricultural bacteriology, H. W. CONN (*Philadelphia: P. Blakiston's Sons & Co., 1901, pp. 412, figs. 40*).—This new book is a study of the relation of bacteria to agriculture, with special reference to the bacteria in the soil, in water, in the dairy, in miscellaneous farm products, and in plants and animals. Different authors have written upon the subject in a restricted sense, but this is one of the first books in the English language that covers the whole range of the relation of bacteria to agriculture in its broadest sense. After discussing the nature of bacteria and fermentation, the author takes up serially the bacteria in the soil and water, showing the transformations caused by bacteria in the soil, manure, sewage, etc., and means of reclaiming lost nitrogen; the relation of bacteria to dairying and the use of cultures of bacteria in butter and cheese making; the fermentations concerned in the preparation of various products, as in vinegar, silage, sauerkraut, tobacco curing, etc.; the preservation of food products; and parasitic bacteria, in which diseases of animals and plants are discussed at some length, the work closing with a chapter on disinfection. As Professor Conn has given much attention to the bacteria of soils, water, and dairying, those subjects are very fully treated, especially those concerned with the ripening and flavor of dairy products. The book is free from unnecessary technicalities and can be as readily appreciated by the lay reader as by the student. Aside from a few minor particulars the work appears to be a good general treatise on the subject, and will be an important addition to our agricultural literature.

METEOROLOGY.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 29 (1901) Nos. 7, pp. 291–340, pls. 2, charts 9, fig. 1; 8, pp. 341–398, pls. 3, charts 8; 9, pp. 399–446, charts 9*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of July, August, and September, 1901, recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 7.—Special contributions on The thunderstorm, a new explanation of one of its phenomena, by B. McFarland; A meteorological balloon ascension at Strasburg, Germany, by A. L. Rotch; Diurnal winds on faint gradient in northwestern New Mexico, by R. E. Dodge; Original memoirs on the general circulation of the atmosphere, by M. Brillouin; Supplementary remarks on the theory of the formation of rain on mountain slopes, by F. Pockels; and Yukon weather (illus.), by U. G. Myers; and notes by the editor on a proposed meteorological commission, university research at Washington, D. C., instructions to the voluntary meteorological observers of the United States Hydrographic Office, lunar influences in meteorology, the red dust of March, 1901, and the Milwaukee, Wis., convention of Weather Bureau officials (illus.).

No. 8.—Special contributions on The island of Porto Rico, by J. L. Cline; The meteorological observatory of Saint Ignatius College, Cleveland, Ohio, by J. Kenealy; The tornado in Hudson County, N. J., on August 24, 1901, by J. H. Eadie; The solar constant, by F. W. Very; Ice caves and frozen wells as meteorological phenomena (illus.), by H. H. Kimball: Our killing heat, by H. L. Abbot; The moon and the weather, by L. W. Meech; and Tornado and waterspout at Norfolk, Va., on August 6, 1901, by J. J. Grey; and notes by the editor on organization of the Philippine Weather Bureau by the United States Philippine Commission, the autumn haze, the moon and the weather, meteorology in Madagascar, popular errors in meteorology and geography, and further explanations desired.

No. 9.—A special contribution on the general circulation of the atmosphere, especially in arctic regions, by H. H. Kimball; and notes by the editor on wind force in tornadoes, a new field for kites in meteorology, climate and crops—a problem with two solutions, seismometers in meteorology, the observation of shooting stars, the south polar expeditions, and answers to correspondents—popular queries about rain, hail, wind, and frost.

Yukon weather, U. G. Myers (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 29 (1901), No. 7, pp. 309–311, fig. 1*).—A discussion based mainly on observations at Eagle from September, 1899, to May, 1901, inclusive. The highest temperatures occurred between June 15 and July 15, sometimes reaching a maximum of 90° F. The lowest temperatures occurred as a rule in January, although not confined to such close limits as the maximum temperature. The minimum temperature recorded at Eagle is −68° F., which occurred in January of 1900 and 1901. A minimum of −70° F. is recorded at Seventymile Creek, 30 miles northwest of Eagle, for February 12, 1901. The mean temperature for March, April, and May, 1900, was 28°; for the same period in 1901, 20°. Rainfall was light, being about 12 in. annually, 75 per cent of which fell during the 6 months April–September. The heaviest rainfall occurred regularly in August. The snow fall was not heavy, averaging between 3 and 3.5 ft. per year. The summers were cloudy. In conclusion, the author says:

"While no one ever expects to see the interior of Alaska become an agricultural country, its possibilities in that line are not so limited as at first supposed. The ground is practically all frozen to a varying depth and covered with soggy moss, and, where level, swamps abound. Almost all localities are capable of furnishing garden spots at least, and the swamps are bountiful sources of native hay which is known to be good fodder for horses and cattle. While the soil is sour and needs cultivation and aeration to render it more productive, hardy vegetables sufficient for all local needs can be grown; radishes, lettuce, turnips, and potatoes do well and are particularly sweet and succulent."

The Island of Porto Rico, J. L. Cline (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 29 (1901), No. 8, pp. 353–355*).—"The climate is not so oppressive as one might expect in the Tropics. A cool, very pleasant, and most welcome breeze generally blows across the island, particularly in the afternoon and at night. . . . Much cloudy weather prevails, with an occasional fog in the mountains. San Juan has an annual mean temperature of 78.5°. The warmest weather prevails from June to October, during which period the normal temperature ranges from 80.4 to 81.4°, with the highest in August, but slightly cooler weather prevails in the mountains. The coolest weather occurs in December, January, and February; during these months the normal temperature ranges from 75.2 to 76.5°, with the lowest in February. . . . Temperatures of 50° or slightly below have been recorded in the mountainous portions, and it is reported that light frost has been noted on some of the highest points, but no meteorological records report frost. The highest temperature recorded at San Juan during the past two years, or since American occupation, was 93.2° on May 2, 1901, and 93° was recorded April 25, 1900; the lowest was 65°, December 26, 1899. The temperatures at San Juan, the only station mentioning continuous self-registers, range generally from 65 to 89° during January, February, March, November, and December, and from 66 to 93° during the other months of the year.

"January, February, and March are the driest months, and during this period the rainfall is less than 3 in. per month. The greatest monthly rainfall occurs in October and November, but the so-called wet season generally commences in April and continues into December. Droughts, very destructive to vegetation, are noted in some years. The average annual rainfall at San Juan is 54.5 in., while at Hacienda Perla, a station in the northeast part of the island, on El Yunque, it is 133.93 in. The greatest annual rainfall at San Juan, from a record of 25 years, was 82.66 in. in 1878, and the least was 36.64 in. in 1893. The greatest monthly rainfall was 17.66 in. in December, 1893, and the least was 0.24 in. in February, 1896."

Guide to the weather, R. Börnstein (*Leitfaden der Wetterkunde. Brunswick: Friederich Vieweg & Son, 1901, pp. VIII+181, pls. 17, figs. 52*).—A popular elementary well-illustrated treatise on meteorology, written, however, almost exclusively from the German standpoint. The general principles involved, the methods and instruments used, and the main facts known are explained. The book also includes a somewhat full explanation of the principles upon which forecasts are made, the results of recent balloon observations, and an account of various weather services of the world. A reference list of 206 works consulted in the preparation of the book is given.

The results obtained in the organized effort to prevent hail in Italy during the years 1899 and 1900, F. Houdaille (*Ann. École Nat. Agr. Montpellier, n. ser., 1 (1901), No. 2, pp. 109–119*).—This is a report of observations made by the author during the summer of 1900 at the direction of the Minister of Agriculture of France. The various stations visited and the apparatus used are described, and the efficiency of the method and the conditions under which it may be applied with advantage in France are discussed. It is stated that the efficiency of the method, despite certain local failures, appears to be established, the principal practical difficulty encountered being that of securing energetic agitation of the air at a sufficient height to reach all hail clouds. The author recommends the establishment of an experiment station in France, like the one already in operation in Italy, to test materials and apparatus and to study the meteorological questions involved.

Weather control, W. S. Franklin (*Science, n. ser., 14 (1901), No. 352, pp. 496, 497*).—The article explains the very small force necessary to cause the falling down or collapsing of unstable states of the atmosphere and how "the trend of the collapse could be controlled, not only by choice of time and place of starting the collapse, but also by starting independent collapses at other times and places. . . . It is hard to think of a better means of starting a collapse of an unstable atmosphere than the smoke ring cannon of Burgomaster Stiger. . . . It seems to be within the range of possibility that Stiger's cannon may be a means for controlling all kinds of storm movements."

Cannonading against hail storms, C. Abbe (*Science, n. ser., 14 (1901), No. 358, p. 738*).—A reply to the article by W. S. Franklin noted above. "The popular faith in cannonading that seems to prevail among the peasantry of southern Europe is a craze that has no scientific basis whatever. . . . Thus far there has not been reported a single case where cannonading has been logically demonstrated to have been effectual.

Modern "weather shooting," J. M. Pernter (*Das moderne Wetterschiessen. Sep.*

from Die Kultur published by Oesterr. Landw. Gesell. Stuttgart and Vienna: J. Roth, 1901, pp. 16).—The history of this method of preventing hail is reviewed, as well as the arguments for and against it. The author concludes that it is possible that cannonading may have an influence in preventing hail.

The third international hail congress (*Grêle, 2 (1901), No. 12, pp. 10–12*).—A brief account is given of the hail congress held at Lyons, November 15, 16, and 17, 1901. It is reported that 1,800 delegates were present at the opening session, representing France, Italy, Switzerland, Spain, Germany, Austria, Greece, Bulgaria, Turkey, Russia, and Argentina, and including government officials, viticulturists, and scientists. The French Ministry of Agriculture was represented by the Subdirector of Agriculture. Resolutions adopted by the congress state that after considering the results obtained during 1901 in Austria, Hungary, Italy, Switzerland, Spain, Russia, and France, it is believed that means of protection against hail merit the attention and study of scientific men and are worthy of trial by agriculturists, and that the method of cannonading has given satisfactory results when properly organized and carried out with sufficient care and vigilance and on not too large a scale. The precautions to be observed to insure success are explained in some detail.

The hail protection congress, J. Dufour (*Chron. Agr. Canton Vaud, 14 (1901), Nos. 22, pp. 559–566; 23, pp. 594–600*).—This is a brief account of the congress held at Lyons in November of the past year and the text of a paper on protection against hail in Switzerland, presented to the congress by the author. It is stated that the results reported to this congress were encouraging in certain cases but doubtful in many others. The cases of unsuccessful trials of the cannonading method have been quite numerous, especially in Italy. Some of these have been ascribed to insufficiency of the cannonading, but others have not been satisfactorily explained.

Storms and hail, I. R. Plumandon (*Les orages et la grêle. Paris: Masson & Co., 1901, pp. 190*).

Clouds and their rôle in the formation of rain, C. Ritter (*Ann. Soc. Météor. France, 49 (1901), pp. 137–141, 203–234*).

Practical experiments in frost protection, J. W. Freeman (*California Cult., 17 (1901), No. 24, p. 374*).—An account is given of an experiment with smudges to protect lemon orchards from frost. The bottoms of the smudge baskets used were covered with dry eucalyptus or palm leaves sprinkled with melted resin mixed with kerosene to the consistency of molasses. A few pieces of kindling were also dipped in this mixture and placed in the basket, followed by untreated kindling. The basket was then filled with coal with the small lumps at the bottom. It is stated that with one basket to 2 trees the temperature of the atmosphere was raised at least 4° in from 4 to 6 hours.

A new field for kites in meteorology, A. L. Rotch (*Science, n. ser., 14 (1901), No. 350, pp. 412, 413*).—This article suggests installing kites on steamships so that observations may be made in calm weather and over the surface of the ocean. A successful trial of this method is reported.

Use of kites in meteorological work (*Jour. Franklin Inst., 152 (1901), No. 4, pp. 313, 314*).—Brief note.

Instructions for voluntary observers (*U. S. Dept. Agr., Weather Bureau Doc. 250, pp. 27, pl. 1, figs. 9*).—This is the second edition of this pamphlet, the object of which is to furnish voluntary observers of the Weather Bureau with "brief instructions for their guidance in taking and recording observations, more especially on temperature and rainfall."

The Blue Hill meteorological observatory, F. Waldo (*Pop. Sci. Mo., 59 (1901), No. 3, pp. 290–304, figs. 11*).—An account of the organization, equipment, and lines of work of this institution, especial attention being given to the subject of the study of the upper atmosphere by means of kites, a line of observation in which this observatory was the pioneer and which "has been pushed with such success that records of atmospheric pressure, temperature, relative humidity, and wind velocity have been secured by means of kites up to a height of 15,800 ft. above the sea."

Work at the station of agricultural climatology of Juvisy during the year 1900, C. FLAMMARION (*Bul. Min. Agr.* [*France*], *20* (*1901*), *No. 3, pp. 497–511, figs. 10*).—This is an account of observations on temperature of the air and of the soil at different depths, the relations between sun spots and temperature, atmospheric pressure, duration of sunshine and solar radiation, rainfall, and underground water in continuation of the work of previous years (E. S. R., 12, p. 918). Summaries covering not only the year 1900, but also long periods prior to that year, are given.

Meteorological observations, J. E. OSTRANDER, C. L. RICE, and H. L. BODFISH (*Massachusetts Sta. Met. Buls. 151, 152, 153, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during July, August, and September. The data are briefly discussed in general notes on the weather of each month.

Meteorology, G. GINESTOUS (*Bul. Dir. Agr. et Com.*, *6* (*1901*), *Nos. 20, pp. 298–301; 21, pp. 407–411*).—These articles record observations on rainfall and temperature during 6 months, March to August, 1901, at a number of places in different parts of Tunis.

Meteorology, P. BONÂME (*Rap. An. Sta. Agron.* [*Mauritius*], *1900, pp. 1–9*).—Summaries of observations on atmospheric pressure, temperature, rainfall, and humidity during 1900 as compared with similar data for previous years are given.

Weather Bureau exhibit, Pan-American Exposition, D. T. MARING (*U. S. Dept. Agr., Weather Bureau Doc. 248, pp. 4, pls. 4*).—This is reprinted from *Monthly Weather Review, June, 1901.*

SOILS.

Alkali and alkali soils, W. H. HEILEMAN (*Washington Sta. Bul. 49, pp. 35, figs. 3*).—The general results of a preliminary study of the alkali conditions in the Kittitas and Yakima valleys are reported. This includes investigation of the origin, nature, and distribution of the alkali, of its effects in the soil, and preventive and remedial measures.

The Kittitas Valley lies a little south of the central part of the State. It "is inclosed almost entirely by basaltic and drift ridges of variable elevation and with rounded general appearance. The ridges along the sides and southern end of the valley are composed largely of basalt rock and débris, while the lower uplifts on the northern side of the valley are composed largely of gravel drift which reach far into the valley southward. Back of these deposits on the north are higher elevations composed of volcanic ash and basalt rock. . . .

"The immediate surface soil of this valley varies somewhat as to texture and origin, though taken generally the soil of the cultivated portions of the valley is composed largely of disintegrated basalt. In some parts of the valley the basalt soil is intermixed with sand and gravel, and again other sections of the surface are covered with sandy or gravelly soils almost entirely. The floor of the valley is of sedimentary origin, as is indicated by the deposits of water-worn gravels and bowlders. These deposits extend many feet in depth in the bed of the valley as has been found by prospects made for artesian water. The presence of lava or volcanic ash soil is perhaps due to the fact that much of such material was deposited during the period in which the other sedimentary deposits were being placed, and also to the fact that the present surroundings of the valley have had an influence upon the immediate surface soil of the valley."

The Yakima River flows through the valley and is the source of supply for irrigation, which is a necessity in this part of the State. Analyses of the water of this river at a time when it was carrying its largest amount of sediment, as compared with similar analyses of the water of the Columbia and Snake rivers, indicate that the water used for irrigating is not the source of the alkali which is found to greater or less extent in the valley, especially where irrigation has been practiced longest. The analyses of the river waters are as follows:

Analyses of sediment in river waters.

[Grains per imperial gallon.]

	Yakima River.	Columbia River.	Snake River.
Sand and silica	4.59	0.72	1.58
Calcium oxid	2.45	3.20	2.08
Magnesium oxid	.82	.68	.66
Ferric and aluminum oxid	3.23	.09	.12
Potassium oxid	.45	.08	.14
Sodium oxid	3.51	.36	.67
Sulphur trioxid	3.59	.28	.86
Chlorin	Trace.	Trace.	.23
Organic solids and carbonates	13.65	3.41	2.37
Undetermined		.18	.29
Total	32.29	8.92	9.00

The analyses of the soluble salts in 56 samples of soil from the region under consideration, generally from fields where alkali is noticeably present, indicate that "the alkali areas in every case have been brought into existence through the action of the soil water on the soluble salts naturally existing in the soil and distributed generally throughout all parts of it; and the position of these areas has been determined by the natural drainage of the land previous to the advent of irrigation, and also largely since irrigation has been introduced." The alkali of the valley is largely of the black variety (sodium carbonate). All of the soils show some alkali, but the smallest amounts are found in the uncultivated and unirrigated soils, and where irrigation was limited there was less surface alkali than where an unlimited amount of irrigation water was obtainable.

"Throughout the whole irrigated section of this valley, and ranging from a few inches to several feet below the surface, is a well-defined layer of hardpan, varying from about 3 in. to 1 ft. in thickness. This hardpan consists of a calcareous layer quite impervious to water, and has much to do with permitting the soil near the surface to become clogged with alkali." The hardpan layer "may be found also above the irrigated sections and the lower bench lands surrounding the valley proper. Below in the valley the stratum is dark gray in color, due perhaps to organic matter and an excessive amount of soil being mixed with it. Those samples found at greater elevations were lighter in color and nearly free from organic matter."

Analyses of hardpan from the valley are given in the following table:

Composition of hardpan from Kittitas Valley.

Numbers of samples.	Calcium carbonate.	Magnesium carbonate.	Water-soluble salts.		
			Total salts.	Black alkali.	White alkali.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
No. 8	21.15	1.72	0.343	0.174	0.018
No. 21	14.93	3.09	.136	.029	.023
No. 43	21.79	2.97	.133	.109	.011
No. 56 *a*	63.22	2.45	.350	.145	.041

a From unirrigated land.

These analyses do not prove the hardpan to be the source of the alkali in the valley, as many suppose. In fact, the water-soluble material from this calcareous stratum is seldom in excess of what is found in the soil overlying it.

A limited study of similar character made in the Yakima Valley and its tributaries, Moxee and Ahtanum, show that the alkali soils of this district "contain both sodium carbonate and sulphate, and often also sodium chlorid. The heavily infected soils show the most sodium carbonate, while in other areas the sulphate is to be found in excess. The greater part of the alkali of the Yakima Valley is sodium sulphate. The soil does not show a high percentage of lime or magnesium carbonates. Other general conditions for this valley are the same as those noted in the Kittitas."

The use of gypsum on black alkali and the introduction of adequate drainage to keep the salts in the soil steadily moving toward water courses are recommended for trial on a small scale. A method of laying wooden drains devised by a farmer of the Kittitas Valley is described. This, "briefly stated, is a process for laying wooden tile in 3 ft. joints by means of a plow so constructed as to draw into the soil after it the wooden tile attached to the heel of the plow by means of a cable." It is stated that the work done by this means is satisfactory.

Tolerance of alkali by various cultures, R. H. LOUGHRIDGE (*California Sta. Bul. 133, pp. 42, figs. 8*).—This is an account of a continuation of investigations of previous years at Tulare and Chico substations (E. S. R., 10, p. 225; 12, p. 221). In previous investigations the examinations of the soil extended, as a rule, only to a depth of 1 ft. "In the past 2 years, however, we have extended the investigations and have endeavored to ascertain, as far as possible, the highest amount of each salt occurring in 4 ft. depth in which the different cultures of all kinds—orchard as well as others—will grow and come to maturity. . . . About 100 varieties of cultures have been studied. These embrace orchard trees, grain and forage crops, grasses, vegetables, and other miscellaneous growths." An improved method used in extracting the alkali from soils is as follows: "A weighed amount [of soil] is mixed with a measured quantity of water and allowed to digest for 24 hours, with frequent shaking. The salts thus dissolved are thoroughly diffused through the liquid, and an aliquot part may be taken for evaporation and examination. If necessary, a portion may be passed through a filter to clear it from sediment, but very often the solution settles perfectly clear."

The data for all of the examinations made are reported in detail and summarized and discussed. The results indicate that "while for the crops in general the maximum tolerance for alkali salts has not yet been definitely found, close approximations are reached with a number, such as the apple, peach, orange, and lemon trees, with respect to carbonate of soda and common salt. In one or two instances alone was the sulphate of soda the apparent cause of distress on the part of a tree. Grapes and olives thus far stand at the head among fruits in their tolerance of each of the alkali salts. Oranges grew in a larger amount of carbonate than did the olive, but that salt was chiefly held below the 2 surface feet. On the other hand, the lemon seems to be the most sensitive to the effects of alkali, especially to common salt, and next to it the orange."

The highest amounts of alkali salts in which apples were found to be unaffected were sodium sulphate 14,240 lbs. per acre (to a depth of 4 ft.), sodium carbonate 640 lbs., sodium chlorid 1,240 lbs., total alkali 16,120 lbs. The limits for peaches were sulphate 9,600 lbs., carbonate 680 lbs., chlorid 1,000 lbs., total alkali 11,280 lbs.; for oranges, sulphate 18,600 lbs., carbonate 3,840 lbs., chlorid 3,360 lbs., total alkali 21,840 lbs.; for lemons, sulphate 4,480 lbs., carbonate 480 lbs., chlorid 800 lbs., total alkali 5,760 lbs.; for grapes, sulphate 40,800 lbs., carbonate 7,550 lbs., chlorid 9,640 lbs., total alkali 45,760 lbs.; for olives, sulphate 30,640 lbs., carbonate 2,880 lbs., chlorid 6,640 lbs., total alkali 45,760 lbs.

"The amount tolerated depends largely upon the distribution of the several salts in the vertical soil-column, the injury being most severe in the surface foot, where under the influence of the unfortunate practice of surface-irrigation the feeding rootlets are usually found. It is therefore important that in alkali regions such methods of culture and irrigation should be followed as to encourage deep rooting on the part of crops.

"The amount tolerated varies with the variety of the same plant, as shown in the grape.

"The amount of alkali tolerated by the various cultures varies with the nature of the soil. It is lowest in heavy clay soils and fine-grained soils, in which the downward movement of plant roots is restricted; and highest in loam and sandy soils, in which the roots have freedom of penetration.

"Some plants, such as the saltbush and alfalfa, are quite susceptible to alkali salts when young, but when the roots penetrate deeply, and the ground is heavily covered with the foliage of the plant, they are immune to a very large extent.

"Lands heavily charged with alkali may often be made productive for certain crops by the application of irrigation water in sufficient amount to leach the salts down to a depth of several (5 or 6) feet, and by preventing their subsequent rise by proper mulching, or cultivation until the foliage of the plant itself will prevent evaporation of the soil moisture from the surface of the ground. Alfalfa culture has thus been made highly profitable in lands once so strongly charged with alkali as to kill all vegetation.

"The reclamation of lands charged with carbonate of soda by neutralization with gypsum often renders possible the profitable planting of such crops as withstand large amounts of common salt or of glauber salt.

"The effects of carbonate of soda are seen in the yellowing of the leaves of the tree caused by its corrosive action on the root-crown, whereby the proper flow of sap and food supply to the leaves is prevented. The effect of common salt is seen in the falling of the leaves from the newer branches, and in the blackening and curling of the leaves of pears.

"Sulphate of soda (glauber salt) is hurtful only when present in very large amounts, most cultures doing well in more than 10,000 lbs. per acre in 4 ft. depth; saltbush, hairy vetch, alfalfa, and sorghum grew well in more than 61,000 lbs.

"Barley is better adapted to alkali land than is wheat, for it will withstand the effects of twice the amount of carbonate of soda and common salt. Of course, the carbonate may be neutralized with gypsum, and in the absence of much common salt will permit of the growth of excellent crops of wheat; but where the amount of common salt exceeds 5,000 lbs. barley should be given the preference over wheat."

The relation of lime and magnesia to plant growth, O. Loew and D. W. May (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 1, pp. 53, pls. 3*).—This bulletin discusses the liming of soils from a physiological standpoint, explaining in detail the physiological rôle of calcium and magnesium in plant growth (E. S. R., 11, p. 1008), and showing the ratio between lime and magnesia in the soils of different countries, and reports water, sand, and soil cultures to determine the proper ratio of lime and magnesia for certain plants, including cowpeas, privet, tobacco, barley, oats, wheat, and beans. The nitrates, sulphates, and carbonates of calcium and magnesium were used in the sand and soil cultures in various combinations and proportions (on the basis of molecular weights). In the water cultures only the more soluble nitrates and sulphates were employed.

The principal results are thus summarized:

"Soil analyses show that lime and magnesia are widely distributed in soils, and generally in sufficient quantities for the direct needs of plants. They are not always in the best proportions to each other, from a physiological standpoint, for favoring plant growth.

"Magnesia in a soil in great excess over lime, in a finely divided or soluble condition, is noxious to the growth of plants. With a great excess of lime over magnesia the physiological action of the plant is hindered, and it exhibits phenomena of starvation. An excess of lime counteracts the poisonous effects of magnesia, while the more favorable proportion of the two bases obviates the poor nutrition of the plant.

"The best proportion of soluble lime to soluble magnesia for the germination and growth of plants is about molecular weight 5 to 4, or actual weight 7 to 4.

"The more soluble forms of magnesia, as nitrate and sulphate, are in excess more injurious to plants than the less soluble, as carbonate, while the more soluble forms of lime, as sulphate and nitrate, are more efficient in overcoming the noxious effects of magnesia than less soluble forms, as carbonate.

"In applying fertilizers containing magnesia, as in the crude potash salts, liming should be carried on in conjunction unless the soil is known to contain an excess of lime. Where the lime content of the soil is about equal to or less than the magnesia content, lime in a finely divided form, as sulphate, should be supplied with the fertilizer in an amount in excess of the magnesia present in the latter.

"In liming soils the amount of lime and magnesia should be first determined in both the soil and the material applied. In this way only can the process be intelligently carried out and the best ratio between the two bases for the promotion of the growth of crops be maintained."

The influence of the moisture of the soil on the growth of plants, D. Prianishnikov (*Zhur. Opuitn. Agron.*, *1* (*1900*), *No. 1*, *pp. 3-20*).—In this article the author gives the results of his experiments with regard to correlation in the development of plant organs. It is usually accepted that with an increase of moisture in the soil the yield of straw increases while the yield of grain diminishes. This is contradicted by the author's experiments with wheat during 2 years, in which there was a steady rise in percentage of grain with an increase in the amount of water in the soil. It has also been claimed that the absolute weight of the grain decreases with an increase of moisture (E. S. R., 7, p. 366), but the experiments of the author show a different result, there being an increase in absolute weight of the grain with the increase of moisture in the soil during 2 years. Similar results were obtained with flax. The absolute yield of straw increased with the moisture of the soil, owing to the increase in both number and size of stems. The author's experiments seem also to corroborate the view of A. Mayer—that the length of the stem has a tendency to reach a maximum sooner than the yield. The length of stem reached its maximum in these experiments with 50 per cent of moisture. Both the length and width of the leaf of beets was found to increase with an increase in the moisture of the soil. It was also observed in the case of beets that there was a decrease of the weight of the dry matter per unit of leaf area and a change of the correlation between the length of the petiole and of the blade, the weight per unit area and the relative length of the petiole decreasing with an increase in moisture. Thus the plant utilizes the same quantity of dry matter in the larger leaf as in the smaller, according as it is obliged to save moisture and lower evaporation, or, on the contrary, has at its disposal an excess of water. The root system in experiments with beets and flax was found not to increase with the increase of humidity in the same proportion as the total yield. Analyses were made of grains of wheat raised with different degrees of moisture, but on the same soil under the same conditions of light and temperature. It was found that with higher degrees of moisture there was a lowering of the nitrogen content in the seed. Analogous results have been obtained by A. Mayer, von Seelhorst, and others. It was found also that the duration of the period of vegetation is somewhat shorter when the moisture is greater.—P. FIREMAN.

Investigations on the temperature and moisture relations of loam soils of various kinds and under different systems of fertilizing, von Seelhorst (*Jour. Landw.*, *49* (*1901*), *No. 3*, *pp. 231-250*, *dgm. 1*).—Observing that plats of soil which had been fertilized with potash appeared to dry out quickest after a rain, while those receiving nitrogen and phosphoric acid dried out more slowly and those receiving no fertililer or only phosphoric acid remained in a moist condition longest, the author undertook to study the relations of these and other fertilizing materials to the moisture of the soil in pot and field experiments. The results of the pot experiments agree with those obtained by Hollrung (E. S. R., 6, p. 60) and Kravkov (E. S. R., 12, p. 620) in showing that the unfertilized soil lost water most rapidly, while the soil fertilized with potash and nitrogen gave off water most slowly, and phosphoric acid generally only slightly retarded evaporation. In the field experiments a large number of determinations were made, not only of the moisture, but of the temperature of the differently fertilized plats which were seeded to spring wheat. The results show that the application of nitrogen resulted in a larger yield and left the soil exhausted to a greater extent of water than the other fertilizers. The deficiency of water under ordinary conditions persisted for a long time. The other fertilizers were apparently without marked effect upon the water content of the soil. The direct influence of the fertilizing on the temperature was apparently of no practical importance.

On nitrate fermentation and its importance in relation to the biological processes of the soil, J. Stoklasa (*Deut. Landw. Presse, 28 (1901), Nos. 79, pp. 666, 667; 81, pp. 683, 684*).—This is a continuation of investigations on denitrification in which the author has attempted to determine (1) the source of carbon most favorable to the denitrifying organisms in the culture media, (2) the nature of the chemical changes which take place, and (3) the importance of denitrification in relation to the soil processes. The results of the first two lines of investigation have been reported elsewhere (E. S. R., 12, pp. 37, 614), and are only briefly reviewed in this article. The author concludes that there are present in soils and in manures two principal groups of bacteria which cause denitrification. The first group contains *Bacterium hartlebii*, *B. fluorescens liquefaciens*, *B. pyocyaneum*, *B. stutzeri*, *B. centropunctatum*, *B. filefaciens*, *B. denitrificans* (*B denitrificans* and *B. coli commune*), *B. nitrovorum*, etc. The characteristic of these organisms is that they reduce nitrates to elementary nitrogen. The second group contains *B. megatherium*, *B. mycoides*, *B. subtilis*, *B. mesentericus vulgatus*, *B. ramosus*, *B. typhi abdominalis*, *B. coli communis*, *Proteus vulgaris* and *P. zenkeri*, *B. radicicola*, *Clostridium gelatinosum*, etc. These organisms as a rule simply reduce nitrates to ammonia without the formation of elementary nitrogen. They also appear to have the power of assimilating the ammonia so formed. This is especially true of *B. radicicola* which is found in the tubercles of leguminous plants and of the alinit bacteria. The nitrogen set free during the process of denitrification appears to be more active than that of normal air and is more readily assimilated by the organisms of the soil.

Pot experiments on the influence of rapid and complete drying of the soil on the growth of sugar beets, J. Vanha (*Oesterr.-Ungar. Ztschr. Zuckerind. u. Landw., 30 (1901), p. 146; abs. in Centbl. Agr. Chem., 30 (1901), No 11, p. 787*).—In connection with experiments in drying the soil to destroy injurious organisms, the author observed the effect of this treatment on the growth and yield of the beets. It was found that neither the total yield nor the quality of the beets was injuriously affected by the drying of the soil.

Is the chemical analysis of soils necessary to determine their fertilizer requirements? (*Deut. Landw. Presse, 28 (1901), No. 93, p. 778*).—An argument to show that chemical analysis is not necessary for this purpose, and is seldom, and only in exceptional cases, a reliable guide to the fertilizer requirements of soils.

The composition of soils as shown by the plant, C. Schreiber (*La composition de nos sols révélée par la plante. Brussels: Louis Vogels, 1901, pp. 52, figs. 19*).

A contribution to the knowledge of marsh soils, J. Struve (*Fühling's Landw. Ztg., 50 (1901), Nos. 21, pp. 758–765; 22, pp. 784–786*).—This is a discussion of the physical and chemical character of different classes of marsh soils found in Germany. The close relation between the productiveness and the proportion of clay and other fine soil particles is pointed out. For the heavier soils marling is stated to be the most effective means of improvement.

Soils, T. S. Dymond and F. Hughes (*Notes on agricultural analyses. Chelmsford: County Technical Laboratories, Essex Technical Instruction Committee, 1901, pp. 5–11*).—

This article gives a description of soils occurring in Essex, their geological and physical characteristics, and their chemical composition. The total amounts of lime, potash, phosphoric acid, organic matter, and nitrogen in 37 samples, and the available lime, potash, phosphoric acid, and nitrogen in 17 samples of soils are reported, with total amounts of lime, potash, phosphoric acid, organic matter, and nitrogen in 5 samples of subsoils.

The banana soils of Jamaica, H. H. Cousins (*Bul. Bot. Dept. Jamaica, n. ser., 8 (1901), No. 10, pp. 145–153*).—Mechanical and chemical analyses of 7 samples of soil are reported. These are preliminary "to a wider survey of the soil conditions of Jamaica and they will receive a more practical interpretation in the light of the field experiments which the board of agriculture has now instituted to cover all the chief cultivations of Jamaica."

Cultivated soils of São Paulo, Brazil, G. D'Utra (*Bol. Agr. São Paulo, 2. ser., 1901, No. 9, pp. 557–562*).—The percentages of moisture, organic matter, and principal fertilizing constituents in a number of samples of soil from different parts of the State analyzed during 1900–1901 are reported.

Exhaustion and abandonment of soils (*U. S. Dept. Agr. Rpt. 70, pp. 48*).—This is the testimony of M. Whitney, Chief of the Division of Soils of this Department, before the Industrial Commission, and deals with the causes of the abandonment of soils and methods of reclamation.

Geological Survey of Canada Report for 1898 (*Ottawa: Government Printing Bureau, 1901, vol. 11, n. ser., pp. 885, pls. 25, maps 7*).—This report contains accounts of studies of the geology and mineral resources of various sections of Canada. The features of special agricultural interest are analyses of natural waters and statistics of the production of salt, gypsum, and phosphate.

FERTILIZERS.

On the fermentation of the nitrogenous matter of manure, P. P. Dehérain and C. Dupont (*Ann. Agron., 27 (1901), No. 9, pp. 401–427*).—In continuation of previous investigations (E. S. R., 12, p. 623) the authors studied the influence of variable amounts of alkaline carbonates on the fermentation of manure, alone and with the addition of liquid manure, the fermentation of urea, uric and hippuric acids, and of various albuminoid substances, including egg albumen, gluten, and legumin from beans. The plan and methods followed were the same as in previous investigations. From the results obtained the conclusion is reached that the nitrogenous substances of manure are of two classes—the amids of the urine and the albuminoids of the litter and animal and vegetable residues. Under the influence of the manure ferments the nitrogen of the urine, uric acid, and hippuric acid are completely transformed into ammonium carbonate, the fermentation of the hippuric acid occurring only in the presence of air, while that of urea and of uric acid takes place in an atmosphere of carbon dioxid. These fermentations, however, are not so rapid that litter impregnated with urine may not be added to the manure each day without danger of loss of ammonia, although the litter so added may not be covered until the following day and does not become charged with carbon dioxid until several days after. In the absence of air the fermentation of the albuminoids was very incomplete and did not occur at all in very alkaline media. During this fermentation the larger part of the nitrogen was transformed into ammonium carbonate, but a small portion escaped in the free state. The nitrogenous substances gave off during decomposition carbon dioxid, hydrogen, methane, and sometimes hydrogen sulphid. It is on account of the fact that the ferments which decompose albuminoids act with difficulty in alkaline media that the larger part of the nitrogen of manure remains in the organic state and only a small fraction is found in form of ammonium carbonate.

Studies on the agricultural value of Damara and Peruvian guano, C. SCHREIBER (*Rev. Gén. Agron.* [*Louvain*], *10* (*1901*), *No. 8–9*, *pp. 373–381*).—Comparative tests of these 2 guanos on different crops grown on clayey and sandy soils are reported. The composition of the guanos used was as follows: Ammoniacal nitrogen—Damara guano, 4.34 per cent, Peruvian guano, 1.62 per cent; nitric nitrogen—Damara guano, 0.26 per cent, Peruvian guano, traces; organic nitrogen—Damara guano, 2.52, Peruvian guano, 0.51; phosphoric acid soluble in water—Damara guano, 5.76, Peruvian guano, 1.21; soluble in alkaline citrate—Damara guano, 3.20, Peruvian guano, 2.82; potash—Damara guano, 3.06, Peruvian guano, 1.05. The results of the experiments show that the Damara guano was a very effective fertilizer and its action in the soil was quite rapid. This was true both of the nitrogen and of the phosphoric acid which it contained, and while it appeared to be suited especially to sandy soils, it also gave good results on clay soils. The Peruvian guano, on the other hand, was almost without effect on the heavy soils, while producing good results on the sandy soils.

Bone products and manures, T. LAMBERT (*London: Scott Greenwood & Co., 1901*, *pp. VIII+162, figs. 17*).—An attempt is made in this book to give "a practical and comprehensive account" of the modern method of fat extraction and the manufacture of glue, size, gelatin, boneblack, manures, etc., from bone. There is also included a discussion of fertilizers in general, with some account of methods of analysis, especial attention being given to bone and its products. Tables of weights and measures, a description of a vacuum pan, and a comparison of French and British gelatins are given in appendixes.

The value of meadow muck, F. W. MORSE (*New Hampshire Sta. Bul. 83, pp. 53–56*).—This bulletin discusses the comparative values of meadow muck and barnyard manure, based on data taken from the work of the experiment stations. Basing this comparison on the fertilizing constituents, it appears that 1 cord (3 tons) of manure is worth $3\frac{1}{2}$ cords of muck, while on the basis of organic matter a cord of manure is equivalent to $1\frac{1}{2}$ cords of muck. The variable character of muck is pointed out and farmers are advised to send samples to the station for examination before undertaking its use.

Green manuring, P. H. GREG (*Jour. Jamaica Agr. Soc.*, *5* (*1901*), *No. 11*, *pp. 436–440*).—In this article the author argues that green manuring is not a profitable practice for the sugar planter in Jamaica.

The agricultural value of the nitrogen in the black substance of the phosphates of the Pyrenees, J. JOFFRE (*Bul. Soc. Chim. Paris*, *3. ser.*, *25* (*1901*), *No. 22*, *pp. 960, 961*).—Pot experiments are reported in which this material (see E. S. R., 10, p. 833) was compared with nitrate of soda, sulphate of ammonia, dried blood, and coal. The phosphate used contained 0.14 per cent of nitrogen. All of the pots received the same amount of potash, and in case of the pots not receiving the Pyrenees phosphate, the proportion of phosphoric acid was made up by the addition of other insoluble phosphates. Under these conditions the nitrogenous organic matter of the Pyrenees phosphate behaved like the coal; that is, there was no increase of crop due to its use.

Fertilizer experiments with 40 per cent potash salts, A. BAUMANN (*Vrtljschr. Bayer. Landw. Rath.*, *6* (*1901*), *No. 2*, *Sup.*, *pp. 461–475*).—Experiments carried out by the Bavarian moor culture station since 1894 on moor soils are reported. In these experiments the concentrated (40 per cent) potash salt was compared with kainit and other potash fertilizers on potatoes. The results are not conclusive.

The use of chemical fertilizers in the Alps, C. DUSSERRE and E. CHUARD (*Chron. Agr. Canton Vaud*, *14* (*1901*), *No. 19*, *pp. 479–484*).—Experiments on hay meadows with Thomas slag alone and mixed with kainit, each 1,000 kg. per hectare, at an altitude of 1,280 meters (4,199.47 ft.) in the Alps are reported. The results indicate the profitableness ot the use of fertilizers under such conditions.

Fertilizing field and garden, F. E. H. W. Krichauff (*Adelaide: Vardon & Pritchard, 1901, pp. 94, figs. 19*).—A summary of the results of scientific experiments and practical experience in different parts of the world on the use of commercial fertilizers for the production of the principal field and garden crops adapted to South Australian conditions.

Practical guide in the use of chemical fertilizers, Maizières (*Guide pratique pour l'emploi des engrais chimiques. Paris, 1901, 3. ed., pp. 185, ill.*).

The use of chemical fertilizers, P. Wagner (*Anwendung künstlicher Düngemittel. Berlin: Paul Parey, 1900, pp. XII+163*).

Manures, T. S. Dymond and F. Hughes (*Notes on agricultural analyses. Chelmsford: County Technical Laboratories, Essex Technical Instruction Committee, 1901, pp. 11–20*).—Analyses of a number of samples of unmixed and mixed fertilizing materials are reported.

Commercial fertilizers, J. T. Anderson (*Alabama College Sta. Bul. 115, pp. 148*).—This is a report of the results of analyses of commercial fertilizers and miscellaneous fertilizing materials collected and examined during the year ended July 1, 1901, with an introduction on the selection and use of fertilizers; the State laws relating to fertilizers; directions for sampling, etc.

Fertilizer inspection, C. D. Woods and J. M. Bartlett (*Maine Sta. Bul. 77, pp. 161–176*).—This bulletin contains the analyses of samples collected by a representative of the station during 1901. A previous bulletin (E. S. R., 13, p. 236) gave the results of analyses of samples furnished by the manufacturers. "A comparison of the results of analyses of the samples collected by the station with the percentage guaranteed by the manufacturers shows that as a rule the fertilizers sold in the State are well up to the guarantee."

The inspection of fertilizers in 1900, F. W. Morse (*New Hampshire Sta. Bul. 80, p. 8*).—Analyses of 60 samples collected by the secretary of the State board of agriculture are reported.

Use of fertilizers in South Australia, W. S. Summers (*Jour. Agr. and Ind. South Australia, 4 (1901), No. 12, pp. 969–971*).—The use of fertilizers in this region practically dates from 1897. It is estimated that 26,400 tons of imported fertilizers and 5,000 tons of fertilizers of local manufacture were used on the wheat crop in 1900. Of this amount 25,500 tons was mineral superphosphate, 2,700 tons bone and guano superphosphate, 1,600 tons Thomas phosphate, and 1,600 tons bone dust and other fertilizers. Of the imported fertilizers Great Britain supplied about 21,500 tons, Germany 2,500 tons, New South Wales 1,300 tons, and Victoria 500 tons.

Mineral resources of the United States (*Ann. Rpt. U. S. Geol. Survey, 21 (1899–1900), pt. 4, pp. 634*).—This contains, among other data relating to mineral resources, statistics of production, consumption, etc., of phosphate rock, salt, and gypsum. The total production of phosphates in the United States in 1899 was 1,515,702 tons, valued at $5,084,076. The statistics show that the phosphate deposits of Pennsylvania were worked during the year to the extent of 2,000 tons.

FIELD CROPS.

Plant breeding, W. M. Hays (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 29, pp. 72, pls. 6, figs. 21*).—This bulletin contains general observations on plant breeding, discussions on methods, and illustrations of work in this line. The work of plant breeding, as practiced by the author at the Minnesota Station, forms the basis of the bulletin. As prominent examples of results of breeding, the Wealthy apple, the Race Horse Messenger, and Minnesota No. 169 wheat are pointed out. Some of the important principles and facts to be observed in improving plants are enumerated as follows:

"The individual plant produced from a seed is the important unit in plant breeding. The 'bud unit,' though of much consequence in case of marked bud variation, is usually of minor importance.

"Heredity, centripetal-like, enables us to produce from certain choice plants many descendants which, on the average, quite resemble their parents.

"Variation, centrifugal-like, causes the production among the descendants, along with very many average plants, of a few very good individuals and a few very poor ones.

"By selecting those best plants which upon trial produce superior progeny, the whole variety may be slightly or considerably improved.

"Since the plants of each succeeding generation also vary, by repeatedly choosing the best, the variety or race is further improved.

"In many cases crossing increases the average vigor of the progeny, but in other cases it decreases the average vigor, size, or other desirable characteristics.

"In all cases crossing increases variation, as a rule, both toward better plants and toward poorer ones, thus giving opportunity for selecting from among the best plants individuals which are superior, as progenitors of varieties, to any individuals which could have been secured without crossing.

"New varieties can best be founded upon one to a dozen superior selected or crossbred seedling plants used as parents.

"Very large numbers of individuals must be used from which to select or breed in order that mother plants may certainly be discovered from which superior varieties will spring.

"In addition to growing large numbers, the breeder of plants should grow all the plants of a given stock under uniform conditions, that they may be accurately compared.

"The testing of the finished variety must include adaptability to the soil and climatic conditions, the quality and value of the resulting crop, and the relative cheapness and practicability of its production."

Under methods of plant breeding the author considers breeding by selection and by hybridization and selection. Discussions on breeding wheat, corn, timothy, potatoes, apples, black walnuts, and flax are presented to illustrate many of the general methods. Views of prominent horticulturists on the subject of hybridizing apples are quoted, and complete descriptions of wheat flowers and the operations of hybridizing are given. The "centgener plats," to which reference is made in the bulletin, are described as follows: "One hundred, more or less, of the seeds, from each of [the selected] . . . plants are planted in separate nursery plats in the wheat-breeding nursery the second season in a manner similar to that under which the seed was grown the first season. These collections of plants are called 'centgeners,' this word having been originated to mean a hundred plants, more or less, springing from the seeds of a single mother plant—that is, a larger number of one generation."

The results so far obtained in breeding wheat at the Minnesota Agricultural Experiment Station are briefly summarized. These results show that the heavy-yielding spikes, as well as the heavy-yielding plants, should be selected. The centgener plan of experimenting has been found expedient in the selection of plants for greater ability to stand erect. "The tendency in the blood of a mother plant to beget a race with stiff straw can not well be judged with the single plant, but it can with the small plat of a hundred or more of the progeny. . . . Recent results from incrosses and outcrosses lead to the belief that hybridizing is of paramount importance to supply the best stocks for the more laborious work of selection. . . . Hybrid wheats vary as to the length of time variation continues under rigid nursery selection, but generally they are reduced to a type in a few generations, this being accomplished with little special effort while selecting for superior yield and other qualities. . . . The selection of large-yielding individual wheat plants is important as a means of securing strong plants to be tested in centgener trials to determine their power of producing plants with large average yield. . . . Extensive trials of new and old wheats show conclusively that wheats must be specially bred for each of several conditions in Minnesota, as well as for each of the several adjoining States. . . . By inspection the choice of 5 per cent of the best-appearing plants nearly always includes the plant which gives the largest weight and superior grade of grain. . . . Records on the rust resistance of 100 progeny of each of numerous parent plants made in percentages promise to aid materially in finding blood lines which resist rust within the standard variety and among the plants of the new hybrid. . . . Wheat hybrids should be grown in quantity during the first 3 to 5 years that variation may have its full opportunity; then the selection of superior plants should be from among large numbers, as from among several thousand in the nursery plats."

The results of crossing and hybridizing further show an increase in variation in numerous characteristics, such as the yield, percentage of protein, etc., and the work as followed out promises to give good results in breeding for strong chaff to prevent easy shelling. Natural crosses have been found to occur, but the percentage is very small. In the work of making a strain or variety of wheat from a single or from several mother plants it has been the experience that numerous strains, each from a single mother plant, and grown for 8 years in field-test plats, have continued to average as much superior to the parent variety as at first, and have so far shown no signs of deterioration. The best of several tried methods of handling the spike in cross-pollinating wheat is described as follows: "Remove the smaller upper and lower spikelets and the smaller florets on the central spikelets, leaving 10 to 20 of the best. Emasculate these early, about the time the first tinge of yellow appears in the anthers. Cover the spike with tissue paper. Twenty-four to forty-eight hours later, when the florets on neighboring spikes of similar age are opening, bring pollen from the plant chosen for the male parent and, removing the covering, apply pollen to each floret."

The fertilizer requirements of cultivated plants and the relation of the composition of the plants to the chemical composition of the soil, E. Godlewski (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 479–536*).—This is a report on a series of experiments begun by Czarnomski, extending over a period of several years. The experiments were conducted with wheat, rye, potatoes, and barley in plats 1 acre in size, 6 plats being devoted to each crop. The results of analyses of the soil and the plants produced under different conditions of soil fertility are given and discussed at some length.

Although a 25 per cent solution of sulphuric acid dissolved about equal quantities of potash and phosphoric acid out of the soil, the application of potash fertilizers was very effective, while fertilizers furnishing phosphoric acid were almost without effect. Rye and barley showed a greater requirement of nitrogen and phosphoric acid than potatoes, but this latter crop needed more potash than the cereals. When potash is lacking in the soil, the life of the stems and foliage of the potato is much shorter than when the soil supply of potash is sufficient, and the dying off of these parts takes place still sooner in the presence of large quantities of assimilable nitrogen and phosphoric acid. The application of nitrogen and phosphoric acid when the supply of assimilable potash was insufficient was not only ineffective but in some cases reduced the yield and injured the quality of the potatoes. The use of potassium sulphate in potato fertilizer applied in the spring had a good effect on the quality. It was found that the surplus of assimilable phosphoric acid in the soil sometimes reduces the yield. Rye seemed to require more potash than barley. An insufficient supply of potash retarded the development of the stems of the barley plant, and under these conditions nitrogen fertilization tends to cause lodging. The author states that the chemical composition of plants bears relation to the chemical composition of the soil on which they were grown, and that the proportion of the different food elements contained in the plants is the chief characteristic in this connection. The insufficiency of potash in the soil narrowed the ratio of potash to phosphoric acid and of potash to nitrogen in the tubers. The ratio of potash to nitrogen was lower than 1 in some instances. The inadequate supply of nitrogen manifested itself in the composition of the tubers by widening the ratio of potash to nitrogen and narrowing the ratio of nitrogen to nearly all ash constituents. A ratio of nitrogen to phosphoric acid in potatoes narrower than 100:50 is considered as an indication of nitrogen poverty of the soil. The results indicate further that the relation of potash to nitrogen in potatoes is influenced by factors other than the chemical composition of the soil, and that the relation of potash to magnesia is only slightly affected by the composition of the soil or its content in potash. The composition of the soil was found to affect the composition of barley straw more than that of the grains. A high nitrogen content in barley straw and potato tubers is not regarded as an indication of a soil rich in assimilable nitrogen, but as showing that more than the minimum amount of nitrogen is present. An inadequate supply of potash in the soil reduced the potash content of barley straw to less than 1 per cent in the dry matter, increased the amounts of nitrogen, lime, and magnesia, and narrowed the ratio of potash to phosphoric acid, magnesia, and lime, and of phosphoric acid to magnesia. The normal relation of potash, nitrogen, phosphoric acid, lime, and magnesia in barley straw is given at 100, 50, 30, 40, and 10. A low nitrogen content of the soil narrowed the ratio of nitrogen to phosphoric acid in barley straw without affecting the relation of the nitrogen to other elements, while an insufficient amount of phosphoric acid widened the ratio of nitrogen to phosphoric acid to 5 : 1, and is considered as indicating lack of phosphoric acid in the soil. It is not thought that the results of chemical analyses of plants show definitely the composition of the soil, but that they aid in determining what element of plant food is lacking in quantity.

Experiments with crops and stock (*Dept. Agr. Cambridge Univ. Rpt. 1901, pp. 89*).—This report presents the results of cooperative experiments on manuring meadows and pastures, laying down land to grass, and rotation experiments combined with fertilizer tests. Each experiment is concisely outlined and the results shown graphically and in tables. In some cases the experiments have not yet been completed. In connection with the reports on the seeding of temporary pasture and on a rotation experiment, the results and analysis of the soil and subsoil are recorded. Nitrate of soda at the rate of 1 to 1½ cwt. per acre applied in conjunction with 1 cwt. of muriate of potash or 4 cwt. of basic slag, gave the best results on grass land as compared with other applications. The nitrate was applied in the spring. Manured and unmanured 3-acre plats were compared for pasturing sheep, with the results in the production of live weight decidedly in favor of the manured plats. A plat receiving ½ ton of basic slag per acre carried nearly 2 sheep more than a plat dressed with half the quantity. Phosphoric acid in the form of superphosphate produced a greater live weight than in the form of basic slag. Grass mixtures consisting of perennial red clover, white clover, Italian rye grass, orchard grass, tall oat grass, yellow oat grass, timothy, Kentucky blue grass, and rough meadow grass, gave good results on a light chalky soil. For heavy soils it was found best to add trefoil (*Medicago lupulina*), perennial rye grass, and fescue grass to this mixture and withdraw Italian rye grass and yellow oat grass, and to double the amount of timothy. The behavior of these different grasses and clovers in the various mixtures grown on different soils is noted. On heavy wet land commercial fertilizers were more economical than barnyard manure.

Field work of the Division of Agrostology, C. L. SHEAR (*U. S. Dept. Agr., Division of Agrostology Bul. 25, pp. 67, pls. 28, maps 8*).—This bulletin is a review and summary of the work done since the organization of the Division, July 1, 1895. The territory covered in field work is described and shown on maps. The principal problems and requirements of the work are discussed, and the work itself is reviewed by regions as follows: The Atlantic coast, the Gulf coast, the Great Plains, the Rocky Mountain region, the Northwest (including western Idaho and the portions of Washington and Oregon east of the Cascade Mountains), the Southwest (including western Texas, New Mexico, Arizona and southeastern California), and the Pacific Coast region, or the country lying west of the Cascade and Coast Range mountains. The conditions and problems of each section are briefly considered and in describing the work done in each region the different native and introduced species of grasses and forage plants are enumerated, with brief descriptive notes concerning their growth, management, and value for forage. In summarizing the bulletin, the author discusses forage plants for alkali soils and the plants adapted to sand and soil binding. A brief account is given of the methods of controlling public grazing lands in Australia, Canada, and Texas.

Drought resistant forage experiments at Highmore, South Dakota, for 1900, D. A. Saunders (*South Dakota Sta. Bul. 70, pp. 57–73, figs. 6*).—This bulletin describes in detail the work with drought resistant forage crops carried on in cooperation with the Division of Agrostology of this Department during 1900. The results have been noted from an earlier report (E. S. R., 13, p. 240).

Fertilizer experiments on meadows, Bachmann (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 24, pp. 361–363*).—In this test, 800 kg. per hectare each of Thomas slag and kainit were applied singly or together on marsh meadows. In one instance, 80 kg. of nitrate of soda per hectare was used. The results favor the use of kainit in conjunction with Thomas slag for an increase in yield and an improvement in the kinds of forage plants. The use of kainit tended to diminish the less desirable grasses and to increase the more valuable kinds, together with the clovers and vetches. The application of Thomas slag and nitrate of soda gave a marked increase in the yield.

Results of fertilizer experiments, F. Hanusch (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 417–420*).—Tabulated results of cooperative fertilizer experiments on clover, barley, and oats.

Field experiments with rye, barley, wheat, and oats, P. Wagner (*Hessische Landw. Ztschr., 71 (1901), No. 20, pp. 213–219, figs. 3*).—In every instance the complete fertilizer applications gave the best returns as compared with incomplete applications, but barley without phosphoric acid gave a little better yield than with it.

Oil yielding plants cultivated in Egypt, G. Bonaparte (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 1, pp. 14–19*).—Brief notes on flax, sesame, cotton, safflower, and lettuce as the chief oil yielding plants now cultivated in Egypt. The product obtained from these plants is also briefly described.

Tillering as an important factor in breeding grain, Rimpau (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 25, pp. 147, 148*).—A brief note comparing results obtained by the author and by Schribaux.

Report on crops at Wagga Experimental Farm, G. M. McKeown (*Agr. Gaz. New South Wales, 12 (1901), No. 4, pp. 451–456, pls. 2*).—A summary of the farm operations for the past year with brief reports on the results.

Culture and fertilizer tests at the experiment station at Lobositz in 1900, J. Hanamann (*Ztchr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 390–394*).—A brief report of work conducted at the station during the year. Hanna and Lobositz barley gave the best results in yield and in quality. Chevalier barley gave good results on good soils and in favorable positions, but it felt the lack of nitrogen in the soil more than other varieties. The results of comparative tests of ammoniacal phosphate and kainit on sugar beets and barley showed that the potash salt had been effective, a fact contrary to the general experience in that region. A cooperative experiment to determine whether clover needs phosphoric acid and potash gave negative results. The author states that under favorable soil and water conditions the clover plant is capable of obtaining these elements from the soil as well as from fertilizer applications. Experiments with Alinit and nitrogen did not show conclusive results.

The effects of sowing barley at different rates, J. Vaňha (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 537–546*).—Barley was grown in pot experiments made in triplicate and sown at the rate of 60, 130, 180, and 240 kg. per hectare. The detailed results are here reported in tables and briefly discussed. The influence of the rate of seeding on the stems, heads, grains, composition of the grains, and the stooling of the plants was determined.

A fertilizer experiment with Vicia faba and barley on heavy marsh soils, Lilienthal (*Fühling's Landw. Ztg., 50 (1901), Nos. 2, pp. 80–84, figs. 3; 4, pp. 141–146, fig 1*).—The experiments were conducted to determine the different effects of lime on marsh soils when applied alone and when applied with different combinations of commercial fertilizers.

Results of an investigation of barleys on exhibition at the Bavarian exposition of barleys and hops, Munich, 1900, C. Kraus (*Vrtljschr. Bayer. Landw. Rath., 6 (1901), No. 1, sup. 1, pp. 187–198*).—The protein and starch content of the barleys grown in different Bavarian provinces was determined and the results, with brief explanations concerning the cultural conditions for the different samples, are given in tabular form.

A study of beet plants produced from seed of a single boll, H. Briem (*Oesterr.-Ungar. Ztschr. Zuckerind. u. Landw., 29 (1900), p. 137; abs. in Centbl. Agr. Chem., 30 (1901), No. 8, pp. 544, 545*).—A study is reported of the plants produced by beet seed taken from the same boll. In the author's experiments 5 seeds weighing from 0.0058 to 0.0027 gm. were grown under similar conditions, the plants being weighed at the end of 20, 50, 118, and 191 days. Throughout the entire period the plants produced were almost in direct ratio to the original weight of the seed. At the end of the experiment the beet plants weighed from 765 to 193 gm., the heaviest plant being produced by the heaviest seed.

Note on the cultivation of cotton in Egypt, E. A. Benachi (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 2, pp. 68–72*).—This note describes briefly 4 important varieties of cotton grown in Egypt, namely, Mit-afifi, Abbassi, Yannovich, and Upper Egypt, and sums up the results of cotton culture the preceding season.

Culture experiments with flax conducted by the German Agricultural Society in 1900, Kuhnert (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 18, pp. 89–91*).—In these experiments flax was sown at the rate of 150, 180, 210, and 240 kg. per hectare, but as in previous years the results were not conclusive.

Ginseng (*Truck Farmer of Texas, 4 (1901), No. 3, pp. 121–123*).—This article discusses the history and distribution of ginseng culture and points out the uses of the plant.

Hop manuring, Wagner (*Württemburg. Wchnbl. Landw., 1901, No. 17, p. 279*).—This article recommends 3 different fertilizer applications for hop growing.

A study of the lupine plant, A. L. Knisely (*Oregon Sta. Rpt. 1901, pp. 30, 31*).—Determinations are given of the nitrogen content of the leaves, pods, stems, roots, and nodules of the lupine plant at different stages of growth. When the plants were in full bloom the water-free substance of the leaves contained 4.02 per cent of nitrogen, the pods which were just forming 3.07 per cent, the stems 1.15 per cent, the roots 0.92 per cent, and the nodules 5.17 per cent.

Maize, H. V. Jackson (*Agr. Gaz., New South Wales, 12 (1901), No. 5, pp. 552–558, pls. 4*).—This article gives a classification of maize, enumerates a number of varieties under each group, and reports the results of variety and fertilizer tests with this crop at Wollongbar Farm.

An experiment on change of seed, W. RIMPAU (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 13, pp. 70-72*).—Probsteir oats from east Germany, where the period of growth is short, was grown in middle Germany, where the season is longer. The results show that the practice was unprofitable.

Culture and selection experiments with potatoes, M. FISCHER *Fühling's Landw. Ztg., 50 (1901), Nos. 9, p. 331; 10, pp. 361-367*).—A test was made of different sized tubers for seed in connection with different fertilizer applications. From the results obtained the author concludes that under ordinary conditions of culture and fertility large tubers should be used for seed, and on soils where these conditions are less favorable smaller tubers with closer planting are recommendable. Where small tubers are used, however, the author advises that they be taken from a crop grown from large tubers on well-cultivated and fertilized land in order to prevent the degeneration of the variety. On good soils with heavy fertilizer applications small tubers and close planting are also recommended.

The influence of whole tubers and cuttings and the position in which they are planted on the yield of potatoes, G. MARTINET (*Chron. Agr. Canton Vaud, 14 (1901), No. 10, pp. 267-276*).—The results of experiments along these lines here presented indicate that the use of whole tubers and sets was indifferent as to the yield, and that placing the seed piece, whether a whole tuber or a set, with the greater portion of the buds down was the preferable practice.

Report on late potatoes at Chiswick, 1900 (*Jour. Roy. Hort. Soc. [London], 25 (1901), No. 3, pp. 378-380*).—Short descriptions are given of 49 varieties of late potatoes.

Variety tests with potatoes, MÜLLER (*Sächs. Landw. Ztschr., 49 (1901), No. 16, pp. 317-319*).—A report on a test of 14 varieties of potatoes. Silesia, a very late variety, produced the largest yield of tubers and starch.

Artificial propagation of potatoes (*Gard. Illus., 23 (1901), No. 1156, p. 136, fig. 1*).—An article describing a method of intense propagation of the potato.

Potato growing in central Illinois, J. H. BROWN (*Rural New Yorker, 60 (1901), No. 2673, pp. 285, 286, fig. 1*).—A general article on the culture, care, and handling of potatoes.

Correlation and transmission of the form of the head and the color of the grain in rye plants (*Deut. Landw. Presse., 28 (1901), No. 36, pp. 137, 138*).—A brief outline of the results of experiments which form the basis of an inaugural dissertation.

Ramie, P. A. HELGUERO (*Bol. Soc. Nac. Agr. [Lima], 4. ser., 3 (1901), No. 11, pp. 635-646*).—A lecture on ramie culture with special reference to Peru.

The culture of ramie and other fiber plants in Japan, M. SCHANZ (*Tropenpflanzer, 5 (1901), No. 5, pp. 227-231*).—Brief descriptions of the culture of 11 different fiber crops grown in Japan.

Sisal, TRABUT (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 9, pp. 193-204, figs. 7*).—This article treats of the sisal industry in different parts of the world and gives a description of the sisal agave (*A. sisaliana*) with directions for its culture in Algeria.

Sugar beets, R. H. FORBES and W. W. SKINNER (*Arizona Sta. Rpt. 1901, pp. 340, 341*).—A brief report is given of experimental sugar-beet culture in 1901. The work was carried on at Pima and Safford, and the results obtained at both places are given in a table. The results show an average of 13.48 per cent of sugar in the beets with a purity of 81.9 and a yield per acre of 19.3 tons. These figures are equivalent to a yield of 5,211 lbs. of sugar per acre.

Sugar beets in alkali soil, H. C. MYERS (*Jour. Soc. Chem. Ind., 20 (1901), pp. 445-448; abs. in Jour. Chem. Soc. [London], 90 (1901), No. 465, II, p. 468*).—Analyses of sugar beets grown on alkali soil at Hooper, Utah, as well as of the soils used, are reported. The results show that beets of good quality may be grown on soils containing amounts of alkali which prohibit the successful growth of most other crops.

It appears also that the beets exhibit a tendency to improve such land by taking up the excess of alkali. By analysis of roots of different shapes and character it was found that small roots contain the highest percentage of sugar, and that long roots show the highest coefficients of purity, thus indicating that small slender roots obtained by deep tillage and a limited supply of water are the best.

Results of comparative variety tests with sugar beets conducted by the Agricultural Society of Bohemia, F. SITENSKY (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 441–457*).—The results obtained with 29 varieties of sugar beets are presented in tabular form. The average yield of beets per hectare was 412.02 quintals, the extremes being 497.20 and 326.83 quintals. Seventeen varieties gave higher results than the average. Thirteen of the 29 varieties tested and 6 of the 17 best sorts were of Bohemian origin.

Breeding of sugar beets, VON RÜMKER (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 25, pp. 148, 149*).—A brief review of the work, given in a paper read before the German Agricultural Society at their meeting in Halle.

The cultivation of the sugar beet in Egypt, G. P. FOADEN (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 2, pp. 56–67, pls. 2*).—This article is a report on the culture of the sugar beet in Upper and Lower Egypt. The conditions indicate that in Upper Egypt sugar beets can be more extensively grown than in Lower Egypt, where cotton occupies the larger portion of the cultivated lands. The results of analyses of 2 samples of beets grown on the experimental farm of the society at Ghizeh, in Lower Egypt, showed an average of 16½ per cent of sugar in the beet and a purity of 85.95. These beets had been sown in July. The use of 2 cantars (about 200 lbs.) of nitrate of soda per feddan (1.03 acres) increased the yield of beets by 50 cantars, or about 5,000 lbs.

Recent progress in sugar-beet culture, HERZFELD (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 25, pp. 144*).—An abstract of a paper presented at a meeting of the German Agricultural Society at Halle.

Tobacco culture in Ireland, M. LECORNET (*Jour. Dept. Agr. and Tech. Instr., 1 (1901), No. 4, pp. 618–622*).—An article describing culture tests with tobacco in 1900.

Tobacco (*Bul. Bot. Dept. Jamaica, n. ser., 8 (1901), No. 3, pp. 33–35*).—A series of brief reviews of work on the fermentation of tobacco and of investigations on tobacco diseases.

Manure experiments with wheat, F. B. GUTHRIE and R. HELMS (*Agr. Gaz. New South Wales, 12 (1901), No. 4, pp. 431–450, pls. 3*).—The method of conducting the experiments is described in detail, the rainfall for the season is given, the results of the analyses of the soils are reported, and the results of the experiments are given in tables and discussed. The work was performed on the government agricultural farms at Wagga and Bathurst. The fertilizer applications used furnished per acre 14 lbs. of nitrogen, 51 lbs. phosphoric acid, and 21 lbs. of potash, the quantity of plant food considered necessary on an average soil for a crop of about 30 bu. of wheat per acre. The results at the 2 farms differed remarkably in some cases. At Wagga superphosphate gave strikingly good results and proved superior to other phosphatic manures. For the soil at Wagga an application of about 3 cwt. of superphosphate, 96 lbs. of nitrate of soda, and 40 lbs. of sulphate of potash per acre are considered effective and economical. At Bathurst the slower acting Thomas slag and rock phosphate gave better results than superphosphate, and the best mixture for that soil seemed to be a combination of sulphate of ammonia with untreated phosphate. At Wagga the use of superphosphate alone nearly doubled the yield of wheat, while at Bathurst it resulted in only a slight increase in yield over the unmanured plats. Both soils, and the Bathurst soil more particularly, are well supplied with humus, and this is considered the cause of the high manurial value shown by the untreated phosphate in these tests. Previous liming produced a healthy growth of the plant and improved the quality of the grain. The authors consider excessive manuring for wheat prejudicial, especially in a dry season.

Manuring wheat crops (*Station, Farm and Dairy, 4 (1901), No. 40, pp. 858, 859*).—This article reviews the results of fertilizer experiments with wheat carried on in different parts of Australia.

Thick and thin seeding of wheat, F. COLEMAN (*Jour. Agr. and Ind., South Australia, 4 (1901), No. 11, pp. 882–884*).—A note on the subject with a report on a test, the results of which favored heavy seeding. The largest quantity of grain sown per acre was 1 bu. 38 lbs. and 7 ozs.

The culture of glutenous wheats, EDLER (*Deut. Landw. Presse, 28 (1901), No. 8, pp. 53, 54*).—A discussion of the culture of glutenous wheat under conditions prevailing in Germany.

Wheats suitable for Queensland, W. SOUTTER (*Queensland Agr. Jour., 8 (1901), Nos. 4, pp. 251–254, pls. 5; 5, pp. 328–331, pls. 5*).—Brief descriptions are given of 26 selected varieties of wheat suitable for Queensland conditions. The list includes a number of hybrid wheats. Illustrations of the heads of the different varieties described are shown.

Notes on wheats at Wagga Farm, W. FARRER (*Agr. Gaz. New South Wales, 12 (1901), No. 5, pp. 548–551*).—White Lammas, Tardent Blue, Nonpareil, Jade, Nutcut and Steinlee wheats are described, and the results obtained with the different varieties reviewed.

Storing seed wheat, VIBRANS (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 19, pp. 96, 97*).—A brief note in which the author recommends leaving the grain in the straw if its germinative power is to be retained for more than one year.

HORTICULTURE.

The book of asparagus, C. ILOTT (*London and New York: John Lane, 1901, pp. 108, figs. 17*).—This is the first of a series of handbooks which it is intended to publish on the different phases of practical gardening. The work takes up the practical details of asparagus culture and describes minutely all the different operations. The use of asparagus as a decorative plant is also treated of. The history of the plant is considered, and recipes given for cooking. In addition to asparagus, the culture, marketing, and cooking of sea kale, celery, celeriac, salsify, and scorzonera are given. While the book is intended primarily for English gardeners, it contains many suggestions which will be of use elsewhere.

Garden beans cultivated as esculents, H. C. IRISH (*Missouri Bot. Gard. Rpt. 1901, pp. 81–165, pls. 10*).—A monograph on this subject, the cultivated garden varieties of Phaseolus, Dolichos, Vigna, Glycines, and Vicia being included. "The classification of varieties is based primarily on the form of seed, which appears as constant as color or plant habit and perhaps more so." General cultural directions for the different sorts are included.

Horticultural monograph on garden peas, DENAIFFE (*Jour. Soc. Nat. Hort. France, 4. ser., 2 (1901), July, pp. 783–803*).—A monograph on the different garden varieties, with cultural directions and notes on composition and food value.

Celery growing (*Florida Agr., 28 (1901), No. 20, pp. 289, 290*).—Suggestions by Northern buyers to Florida celery growers as to desirable varieties for Northern markets and best methods of packing and shipping.

An extremely early corn (*Amer. Gard., 22 (1901), No. 347, pp. 574, 575, fig. 1*).—The variety Peep of Day, planted in the American Gardening trial grounds May 17, gave the first picking of ears July 22, or 66 days after planting. Cory, planted 15 days earlier, did not give a picking of corn until July 25, making a difference in the time of development between these 2 early varieties of 18 days.

The forced culture of cucumbers in the greenhouse, N. SCHNEIDER (*Rev. Hort.*, *73* (*1901*), *No. 14*, *pp. 338–341*, *figs. 2*).—The seed, preparation of the seed bed, cultural care to be given, including pinching, pruning, and training the vines, pollenizing the flowers, choice of varieties, etc., are the subjects popularly considered.

Znaim cucumbers, J. ZAWODNY (*Jour. Soc. Nat. Hort. France*, *4. ser.*, *2* (*1901*), *June*, *pp. 526–540*, *figs. 9*).—An account of the history, development, and importance of the cucumber industry at the town of Znaim, Austria, and of methods of culture and manuring followed by growers in that district. A circular giving similar data upon these cucumbers has been issued by the Department (E. S. R., 12, p. 1043).

Winter muskmelons, S. L. WATKINS (*Amer. Gard.*, *22* (*1901*), *No. 349*, *p. 601*, *fig. 1*).—Brief notes on the value of these melons for late fall and early winter use, with a list of the varieties which the author has successfully grown in California.

Two methods of growing onions, B. C. PITTUCK and S. A. MCHENRY (*Texas Sta. Bul. 60*, *pp. 101–111*, *pls. 5*, *figs. 5*).—The difference in yield, cost of growing, and the profits in cultivating the Red Bermuda and the Creole varieties of onions, by horse cultivation and by hand, and in planting the seed in the field and in beds and transplanting, are here reported upon. Methods of onion culture are also given, some of the finer points upon which success in onion culture in Texas depends being pointed out. The work was carried on by the State station at Beeville without irrigation. The data secured in the test are summarized in the following table:

Yield, cost, and profits per acre in onion growing.

Cultural methods.	Yield of salable onions.	Value at 1 cent per pound.	Cost of growing.	Cost of gathering.	Cost of trimming and sacking.	Total cost of growing and harvesting.	Net profit per acre.
Red Bermuda onions:	*Pounds.*						
Horse culture, seed planted in field	4,551	$45.51	$16.65	$0.38	$3.80	$20.83	$24.68
Horse culture, seed planted in bed and transplanted to field	7,336	73.36	16.00	.61	6.10	22.71	50.65
Hand culture, seed planted in field	13,152	131.52	17.40	1.09	0.95	29.40	102.08
Creole onions:							
Horse culture, seed planted in field	7,842	77.42	16.65	.64	6.47	23.76	53.66
Horse culture, seed planted in bed and transplanted to field	8,257	82.57	16.00	.69	6.90	23.59	58.95
Hand culture, seed planted in field	10,664	106.64	17.40	.89	8.91	26.20	80.44

The table shows but little difference in the cost of growing onions to maturity by horse cultivation whether the seed is sown in the field or in beds and transplanted. The yields and profits, however, from transplanting are nearly double in the case of the Red Bermuda onions, and considerably in excess with the Creole variety. In horse cultivation the onions were grown in rows 30 in. apart and the plants allowed to stand 4½ in. apart in the row. With hand cultivation the rows were but 14 in. apart. The cost of hand cultivation, as seen in the table, was but 75 cts. in excess of cultivating with the horse, while the yield was increased from 36 per cent in the case of the Creole variety to 188 per cent with the Red Bermuda onions. The net profits in hand culture over horse culture are $26.78 with Creole onions and $77.40 with Red Bermuda onions. The opinion frequently expressed that the extra cost of cultivating and handling a crop of onions by hand, as compared with horse cultivation, will offset the increase in yield is shown in this experiment to be groundless.

The securing of good seed is considered one of the most important points in onion culture in Texas. The experiments at the station show that of 23 varieties of onions tested only 2, the Red Bermuda and Creole, can be recommended for extreme south

Texas. Creole seed from either Louisiana or Texas has given good results, but American Bermuda seed has not given nearly as satisfactory results as imported seed. Bermuda onions grown from American seed do not mature well, have a large, soft stem, and keep but a short time after maturing. Imported Bermuda seed grown on the Teneriffe Islands and along the western coast of Africa is considered best.

A study of the markets shows that the best market for Texas onions is just before the Southern crop moves (May), and again after the Southern crop is marketed and before the Northern crop matures (July and August). The Red Bermuda onions are preferable for the early market, while for the late market the longer-keeping Creole is better suited.

Alternation in the varietal characters of the tomato, C. A. White (*Gard. Chron., 3. ser., 30 (1901), No. 763, p. 105*).—The Acme variety of tomato seed was sown by the author in Washington in 1898 and produced plants and fruits similar in character to the authentic Acme variety. Seeds from these were saved and planted the following season, 1899, in the same way. The resulting plants and fruits, while entirely alike as regards each other, differed widely from the original Acme tomatoes of the preceding season. No cross pollination is thought to have taken place. No seed from the plants grown in 1899 was saved, but in 1900, the genuine Acme seed was again obtained from a seed firm and the plants and fruits produced therefrom resembled the true Acme. The seed saved from these, however, and grown in 1901, produced plants and fruits varying much from the mother plants, but entirely similar as regards each other and as regards the tomatoes grown in 1899. From these data the author draws the conclusion that "any lost variety or breed may be reproduced under the same conditions which originally produced it."

Tomatoes on trellis (*Agr. Jour. Cape Good Hope, 18 (1901), No. 11, pp. 784, 785*).—It is especially urged that with tomatoes trained on stakes the fruit clusters should be induced to start fruiting 10 in. or 1 ft. from the surface of the soil instead of higher up. More and better tomatoes are secured.

Nitrate of soda for market garden crops, W. L. Summers (*Jour. Agr. and Ind., South Australia, 4 (1901), No. 12, pp. 972–974*).—Some data are given showing the increase in the yield of cabbages, lettuce, rhubarb, carrots, spinach, and potatoes fertilized with different amounts of nitrate of soda as compared with the yields obtained with these same crops when fertilized with 12½ tons of barnyard manure. In general, the nitrate of soda proved much more effective than the barnyard manure and cost considerably less.

Report of the floriculturist and gardener, G. Coote (*Oregon Sta. Rpt. 1901, pp. 41–45*).—A brief report on culture tests with onions, tomatoes, cabbage, Swiss chard, beans, vegetable marrow, chicory, radishes, lettuce, peas, kale, tobacco, and hops. The author found that onions started in the greenhouse and transplanted to the field gave a more even crop than when the seed was sown in the open field. The onions also kept better. Chicory made an excellent growth at the station, showing that the climate is well adapted to its culture.

Horticulture, E. R. Lake (*Oregon Sta. Rpt. 1901, pp. 36–39*).—The horticultural work of the station for the year is outlined. In the test to ascertain the efficiency of basket veneering and yucca fiber as protecting sheaths for fruit trees only 20 per cent of the veneer sheaths remained intact 4 months after putting in place, while 89 per cent of the yucca sheaths were in place. Temperature observations made inside the sheaths go to show that during the heated term the temperature is slightly higher inside the sheaths and in cooler weather slightly lower than the outside temperature. It is believed that the chief benefits from the sheaths lie in the protection of the trees from the direct rays of the sun, winds, and violent changes in temperature.

As a result of a test of plums it is believed that the Japanese varieties of both pears and plums, and also many of the American hybrids, are unsuited for the Willamette Valley conditions. Tests are being carried on with hardy stocks for both cherries and apples, and varieties of aphis-resistant apples have been imported from Australia. Grapes are practically a failure at the station.

In a test of root pruning orchard trees 24 yearling trees were set out in one row, each alternate tree being root pruned according to the Stringfellow system, while the others were root pruned and the tops cut back 30 in. After 2 years the author states it was impossible to select one set of trees from the other except by taking note of the place of union of new growth. Two trees set out at the same time without either top or root pruning presented a very unthrifty appearance in comparison with the pruned trees.

In the case of whole and piece root grafting with Summer Wafer apples, the whole root and top cut gave considerably better growth than when the scions were grafted on the bottom cut. As between the whole root and top cut there appeared to be a slight advantage in favor of the former.

Quality of nourishment determines flower-bud production, J. M. W. KITCHEN (*Amer. Gard., 22 (1901), No. 338, p. 427*).—The author believes that the flower bud of the apple or any other flower bud has its origin whenever the vegetable cell which starts a new growth receives a sufficient supply of adequately elaborated sap as nourishment. A supply of unelaborated sap tends to wood growth. But when this sap has been elaborated in the leaves and reaches newly starting growths "its special richness in carbonaceous elements and its comparative lack of nitrogenous matter has the effect of modifying the growth from leaf forms to flower forms." The kind and amount of nourishment which a cell receives is governed, among others, by the following conditions: "The location of the embryo cell on the plant; the density and size of the wood tissue conducting sap from the roots; decrease of root absorption following loss of roots and coldness and dryness of the soil; relative high atmospheric temperature conducing superactivity of metabolic processes in the leaves and distance from the roots with intervention of a large area of leafage between the root and the flowering point."

The teaching of orchard fruit culture in the nineteenth century, GUILLOCHON (*Jour. Soc. Nat. Hort. France, 4. ser., 2 (1901), Apr., pp. 348–363*).—A horticultural review of the development of horticultural societies and horticultural literature with reference to fruit-tree culture in France during the nineteenth century. The work includes a bibliography of the publications on orchard fruits, in the French language, since 1850.

Propagating new varieties of tree fruits from seed, C. G. PATTEN (*Amer. Gard., 22 (1901), No. 335, pp. 379, 380; Nat. Nurseryman, 9 (1901), No. 6, pp. 197, 198*).—The author holds that innumerable and serious mistakes have been made all over the Northwest in an endeavor to mingle the little Siberian with our cultivated apple. This he considers a violent cross which is not nearly so likely to result favorably as would be the planting of seeds from the most highly developed fruits that we now have, or by using seed obtained from crosses of these varieties. It is believed that the Concord and Worden grapes, Ben Davis, Winesap, Fameuse, Duchess, Wealthy, and the Patten Greening apples, and the Richmond cherry are the most highly developed forms of fruit we now have. In improving fruits from seed, therefore, it is seed from these varieties rather than from the small, worthless varieties which have not been developed at all that should be used.

Experimental fruit culture at Wye College (*Gard. Chron., 3. ser., 29 (1901), No. 752, pp. 332, 333*).—Experiments were begun at the College in 1897 to test the effect of various fertilizers on apples grown in zinc pots. Complete commercial fertilizers, fertilizers containing but 2 elements, and fertilizers containing normal amounts of 2 elements and the third in excess were used each year from 1897 to 1900, inclusive. The effect of sulphate of iron was also studied in connection with a complete fertilizer. The results in 1900 show especially finely colored apples with an excess of phosphate and a lack of any effect due to either the absence or excess of potash. Sulphate of iron had no effect on the color of the apples.

The commercial value of cider fruits in England since the seventeenth century, A. Truelle (*Mem. Soc. Nat. Agr. France, 139 (1900), pp. 383–431*).—Historical review of prices and varieties.

The date-palm orchard, R. H. Forbes (*Arizona Sta. Rpt. 1901, pp. 315–318, 342*).—Data are given on the condition in July, 1901, of the 405 date palms comprising 27 varieties which were received through this Department in July, 1900, and set out in the station and Tempe orchards. The data show that 71 per cent of the suckers set, including 22 varieties, are now established and for the most part growing vigorously, 11 per cent are still alive but very feeble, while 18 per cent are dead.

Relative to methods of shipping suckers data are given which show "that it is much better to transport the suckers immediately after cutting them from the parent tree than to grow them in tubs or garden before shipment."

Various methods were employed in packing these suckers for shipment from Algiers, and they were 2 months in transit. The author states that "those palms which were shipped with no packing whatever came through as well or better than those carefully bound in wet moss or packed in charcoal. As a precaution, however, against unusual delay in transit it is probably safer to bind coverings of wet moss about the bases of the suckers and provide for renewal of moisture on the road."

Fumigation of the suckers with 0.3 to 0.5 per cent fumigations of hydrocyanic-acid gas was made with scarcely any apparent and no lasting injury, while the scales appeared to be all killed.

Most of the suckers received were planted in the "extremely alkaline" Tempe orchard. These gave about the same percentages of growing and living trees as those which were planted in the fresh soil of the station orchard.

Reliable comparisons could not be made as to the shipping endurance of different varieties, though 82 per cent of the Rhars is now living, as compared with 70 per cent of the Deglet Noor. Some of the largest, as well as some of the smallest, suckers have perished alike during the season. Very small suckers are considered less desirable for field operations. "The main points observed thus far in caring for the suckers have been to plant not deeper than their greatest diameter and to water assiduously after planting."

Date culture, A. J. McClatchie (*Arizona Sta. Rpt. 1901, pp. 321, 322*).—Brief notes are given on the fruiting habits of the date palms at the station, and on packing dates. Full crops are apparently borne only in each alternate season. Dates ripening from September to October could be packed directly from the tree, while those ripening in the cooler and moister weather of late autumn and early winter required some drying before being packed. In order to prevent too rapid drying of the dates after being picked, due to the aridity of the climate, it was found necessary to pack them in boxes surrounded with paraffine paper and keep them well covered. Date seed made the best growth when planted during January or February, though the statement is made that it may be planted any time during winter, spring, or early summer.

Preparation and conservation of dried figs, Trabut (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 11, pp, 241–249, figs. 8*).—Brief descriptions are given of some of the more common varieties of figs used in the Mediterranean districts for drying, with notes on methods of drying and packing for market.

A new fig for drying, Trabut (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 15, pp. 353–355, figs. 2*).—A new white fig which the author has named Isly is figured and described. In taste it resembles the Smyrna and is considered by the author well adapted for drying purposes.

Stoneless prunes, L. H. Bailey (*Pacific Coast Fruit World, 11 (1901), No. 22, p. 6*).—The work of Luther Burbank in breeding stoneless prunes is mentioned. Mr. Burbank has succeeded in breeding out the pits of prunes though the soft kernels still remain. These prune trees are not as yet on the market and may not be put there, though it is stated that Mr. Burbank has many trees which bear stoneless prunes in various sizes and forms.

Self-sterility of Compass cherry, R. S. Mackintosh (*Amer. Gard., 22 (1901), No. 340, p. 455*).—The author reports that experiments with this cherry at the Minnesota Agricultural Experiment Station indicate that the Compass cherry is sterile to its own pollen. The Compass cherry is a cross between the Miner plum and Dwarf Rocky Mountain sand cherry. The fruit is considered desirable for jelly making.

Cultivation of oranges (*Agr. Jour. Cape Good Hope, 18 (1901), No. 9, pp. 547–549*).—Notes on methods of culture in the colony.

Notes on citrus trees and also working over worthless old orange and peach trees, W. J. Allen (*Agr. Gaz. New South Wales, 12 (1901), No. 7, pp. 834–836, figs. 15*).—An illustrated account is given of methods of rejuvenating old orange and peach trees by pruning back the main limbs to stubs, and budding or grafting sprouts that arise from them.

Pineapple growing, J. Rose (*Queensland Agr. Jour., 9 (1901), No. 1, pp. 145, 146*).—A paper on pineapple growing in Queensland.

Clove planting, R. N. Lyne (*Shamba [Zanzibar], 1901, No. 23, Sup., pp. 1–3*).—Details of the cost of laying out and planting a clove plantation of 6,550 trees.

Foxy coffee (*Queensland Agr. Jour., 8 (1901), No. 5, pp. 370–371*).—"This term denotes a reddy-brown appearance of the seed caused by the adhesion of the silver skin into which the coloring matter in the outer skin and fruity portion of the cherry has infiltrated." This appearance indicates that the fruit was picked when quite ripe. It does not injure the quality of the coffee, though it is undesirable from the standpoint of appearance. Some precautions which should be taken to prevent foxy coffee are suggested as follows:

"(1) Avoid, as far as possible, allowing the berries to become dead, or purple, ripe on the trees. They should be picked as uniformly red-ripe as possible. A spot of green on the outside pulp will make no difference, the bean being nearly always matured before the pericarp has been fully colored.

"(2) Pulp the coffee as soon after taking in as possible. The operations of pulping and measuring might go on simultaneously. . . .

"(3) Pulp as cleanly as possible. If pulpers are not working satisfactorily, this must be done with the aid of a sieve, the skins and half-pulped cherry being passed through the pulpers a second time.

"(4) Wash the coffee as soon as the mucilage is ready to be acted on by water. This can be determined by experiment."

Coffee culture in Queensland, H. Newport (*Queensland Agr. Jour., 8 (1901), No. 5, pp. 371–375*).—Popular instructions on pitting, filling in, planting, and shading coffee.

Artificial drying of cacao, G. W. Smith (*West Indian Bul., 2 (1901), No. 2, pp. 171–174, fig. 1*).—The general plans of 2 buildings for drying cacao are given. One cost about $500 to erect and the other $1,500.

The horticultural status of the genus Vaccinium, W. M. Munson (*Maine Sta. Bul. 76, pp. 113–160, figs. 9*).—This paper aims to present as concisely as may be the exact status of the genus Vaccinium at the close of the nineteenth century and to give greater publicity to the horticultural worth of blueberries. The distribution of the species is noted, horticultural notes given on the uses of the fruits, the ornamental value of some varieties pointed out, methods of propagation and cultivation detailed, descriptions given of the blueberry industry in Maine and elsewhere in the United States, and a key to the natural groups of species. The future outlook for the blueberry industry is also discussed. A bibliography of 44 references to literature on blueberries, huckleberries, cranberries, etc., completes the bulletin.

The report on the blueberry industry in Maine has been noted earlier (E. S. R., 11, p. 931). The terms "whortleberry" and "bilberry," which are other names for blueberries, are said to be seldom or never heard in this country, while the term "huckleberry" is very common. "In the Central States the term huckleberry is usually applied to *V. corymbosum*, while blueberry is given to the low growing species, like *V. canadense* and *V. pennsylvanicum*. In New England huckleberry is reserved for species of Gaylussacia, while blueberry is applied to the lower growing species, as above, and high-bush blueberry to *V. corymbosum*."

The propagation of blueberries from seed is stated to be comparatively easy. The seed of ripe fruit is washed free from pulp and sown either at once or stratified in sacks and sown the following spring. On good potting soil, to which leaf mold has been added, they are scattered thickly over the surface of the soil, packed down lightly with a board, and covered with a very slight sprinkling of soil. At the station the seed was stratified, being allowed to freeze during the winter, and sown in the spring. The plants were handled once, and later in the summer transferred to a cold frame, where they were simply covered with litter during the winter.

"The following spring they were transplanted into beds, shaded until established, and made a good growth during the summer. . . . The low blueberry (*V. pennsylvanicum*) will usually fruit in from 3 to 4 years from seed, but *V. corymbosum* requires 4 to 6 years."

Blueberries may also be propagated by division or by grafting. The high-bush blueberry (*V. corymbosum*) and its varieties are considered relatively easy to transplant, either from swamps or upland. The berries are of good size and very prolific. "The variety *amœnum* is a rather dwarf form, with very large berries, and grows freely on the upland. *V. vacillans* is the next best species for cultivation as a 'small fruit.'"

Not much attention has as yet been given to the cultivation and improvement of blueberries, but it is thought by the author that in its wild state this fruit is more worthy of notice than was either the blackberry, raspberry, or currant, and that it is probable that within a few years garden blueberries will rival in importance some of the best of the other small fruits.

Some statistics are given on the blueberry industry in Maine and Michigan. There were 7 factories in Maine in 1900 engaged in the blueberry industry, having a valuation of $50,000. The total canned product from these factories was about 50,000 cases, valued at $100,000.

Strawberry growing at the South, O. W. BLACKNALL (*Amer. Gard., 22 (1901), No. 342, pp. 490, 491*).—The Hoffman is considered by the author the ideal Southern shipping berry. Cotton-seed meal, 500 to 700 lbs. per acre drilled in, is recommended as a fertilizer for fall-set plants.

Strawberries in Ohio for 1901, M. CRAWFORD (*Amer. Gard., 22 (1901), No. 350, pp. 617–619*).—The author briefly describes and notes the value of 29 of the better varieties of strawberries grown by himself during the season.

The adaptation, affinity, and pruning of vines, L. ROUGIER (*Prog. Agr. et Vit. (Éd. L'Est), 21 (1900), Nos. 2, pp. 48–50; 4, pp. 109–111*).—The author has studied especially the adaptation of the principal American stocks to the soils of the Loire region of France, and their affinity for French varieties. Fifteen American species and varieties were used as stocks. The soil of the experimental field was of average physical condition, being made up of débris from granite rock and containing a small proportion of basaltic gravel with a clayey subsoil. The vineyard inclined slightly to the south and was well drained. The soil was poor in phosphoric acid and lime. The plat was planted to vines in 1894 and has been manured but once, so that the soil is of only average fertility. A number of French varieties were grafted on each of the American stocks. A few stocks of each variety were not grafted so that their vigor of growth might be studied. Only the results obtained with the French variety Gamay de Montbrison are here reported upon.

The growth in the above soil of all the American varieties when not grafted left nothing to be desired, but their vigor when grafted with the Gamay variety varied considerably. Certain hybrids of Rupestris stood first in vigor, while the least vigorous were those on the Riparia varieties. The following grouping of the varieties with regard to vigor of growth is given for 12 of the stocks used: (1) Aramon-Rupestris Ganzin No. 1, Gamay Couderc; (2) Rupestris du Lot, Rupestris Metallica; (3) Rupestris Martin, Rupestris Ganzin, Rupestris Fortworth; (4) Riparia tomentose, Solonis; and (5) Riparia Gloire de Montpellier, Riparia Grand glabre, Riparia Martineau.

An examination of the different groups showed that the union of the Rupestris with the Gamay was more intimate than Gamay with Riparia, and the difference in size between scion and stock was scarcely noticeable, while between Riparia and Gamay there was a marked difference in size.

Considered from the standpoint of fruit production, the above grouping of varieties might be just reversed. The Gamay on Rupestris grew luxuriantly but produced little fruit, while on Riparia the growth was much less and the fruit production much greater. In order to increase the fruitfulness of Gamay on Rupestris, the branches were pruned to long arms. On an average 4 arms 50 to 60 cm. long were left on each stock, and these were trained recurved in the form of a circle. As a result the first 3 groups on Rupestris, as noted above, produced from 3 to 4 times as much fruit as the fourth and fifth group on Riparia stock, the second group giving the best returns. The experiment is believed to show that in pruning French vines grafted on American stock the arms and number of buds left on each should be proportional to the vigor of the vine. In soils where the Riparia grows fairly well, but Rupestris develops much more vigorously, it is advisable to grow the latter and prune properly rather than the former.

On the adaptation and affinity of Riparia, L. ROUGIER (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 35, pp. 266–269*).—The earlier work of the author (E. S. R., 13, p. 649) has shown that grafting French varieties on American stocks diminishes the vigor of the latter, particularly Riparia stocks as compared with Rupestris. This result was reported with the Gamay variety used as scion. Further work in the same vineyard with Syrah and Pinot varieties show like behavior on the American stocks. In order to overcome as much as possible the lack of affinity between Gamay and Riparia, it is urged that the Riparia be planted on soils neither too moist nor too clayey, but that when this stock is used with Gamay it be planted in rich, deep, permeable soil, which does not suffer from either drought or an excess of moisture.

Success in grafting green vines in Roumania, A. SAUGET (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 27, pp. 12–14.*)—In the reconstruction of some vineyards in Roumania, the tongue graft or a modified form of the same has been employed successfully with green wood. According to the author, in grafting the green vines, the stock should not be less than 6 mm. in diameter where the graft is made, and the wood should be hard enough so that it can not be easily compressed between the thumb and finger. The scion should also have reached the same stage of maturity. All the precautions necessary to the successful grafting of the dry wood cuttings must be observed in grafting the green vines. The grafts once made and the scion and stock firmly united by growth, they may be handled like cuttings, or roots may be started on the stock below the graft by layering. The advantages claimed for the green grafting of vines are noted as follows: It simplifies operations by doing away with the necessity of stratifying both scions and stocks; the chance element of success in the nursery is reduced to a minimum; it is cheaper and a larger percentage of grafts succeeds; and it is believed that the system will permit of grafting, with more chance of success, varieties which are difficult to unite when grafted dry. An instance is cited in which 325 grafts of different varieties were made; all of these grafts succeeded, 319 being first-class grafts, and only 6 defective.

Study on shield grafting, C. Clarac (*Rev. Vit., 16 (1901), No. 396, pp. 71–74, figs. 3*).—The advantage of shield grafting over other methods and the physiology of the wound and its healing are discussed.

Thinning out grape bunches, P. Pacottet (*Rev. Vit., 16 (1901), No. 397, pp. 99–103, figs. 5*).—The method followed in thinning out and removing defective berries or a too heavy set of berries in the bunches, for the purpose of securing more attractive and perfect bunches for table use, is outlined. Scissors are used to remove the defective berries.

The culture of nuts in the United States, L. Wittmack (*Gartenflora, 50 (1901), No 17, pp. 468–470*).—Brief report of the author on this subject.

On soils suited to the chestnut tree, L. Piccioli (*Staz. Sper. Agr. Ital., 34 (1901), No. 8, pp. 745–766*).—A discussion of this subject, with analyses of soils and of chestnuts, and a bibliography.

The composition of the horse chestnut (Æsculus hippocastanum), E. Laves (*Pharm. Centralhalle, 42 (1901), p. 33; abs. in Chem. Ztg., 25 (1901), No. 46, p. 117*).—The following composition is given: Albumin, 10.63 per cent; dextrin, 1.7; starch, 64.8; ash, 3.16; phosphoric acid, 0.32; sulphuric acid, 0.13. The ash contains about $\frac{2}{3}$ magnesia, $\frac{1}{3}$ lime, and a trace of iron.

Caoutchouc in Soudan, H. Hamet (*Agr. Prat. Pays Chauds, 1 (1901), No. 1, pp. 23–43, figs. 2*).—This article points out the growth of the world's rubber consumption since 1889, enumerates different species of plants from which rubber is obtained, reports a study of the latex of *Landolphia heudelotii*, the most valuable of the rubber plants here considered, gives a few brief notes on the culture and propagation of this plant, and describes different methods of coagulation employed in Soudan.

The culture of the Castilloa rubber, F. Koschny (*Beihefte Tropenpflanzer, 2 (1901), No. 3, pp. 119–172, fig. 1*).—Complete directions for the culture of *Castilloa elastica*, with figures as to the costs and profits in the industry.

The influence of darkness on the development of flowers, N. Beulaygue (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 11, pp. 720–722*).—A review is given of a number of experiments conducted along this line, and the author presents the results of his own observations with a large number of flowers. In the author's experiments, 2 branches of the same plant as nearly alike as possible were chosen. One branch was then allowed to develop in a box painted black on the inside and so inclosed that no light could penetrate the interior. The effects of the darkness on the time of blooming, color, form, size, and weight of the flowers were determined. In general, darkness prolonged slightly the blossoming period of the flowers. The violet blue color of such flowers as iris was of somewhat lighter color. Similar results were obtained with yellow and red flowers. The size of the flowers was slightly diminished, as was also the weight and volume.

Tuberous-rooted begonias as bedding plants, J. W. Withers (*Amer. Gard., 22 (1901), No. 336, p. 393*).—In exposed sunny positions begonias require an abundance of water. The author has been most successful when the plants have been set in a position where the sun does not shine until afternoon. Peruvian guano is depended upon as a source of manure. The guano is scattered in a thin coating over the surface before digging, and another thin coating given over the surface when raking down and leveling. Later in the season, after the plants are getting well established, a scattering of guano is placed on the soil surface underneath the plant leaves and watered in. For winter storage the tubers are lifted after the first frost has touched the stems. About 3 in. of stem is left on each tuber and the soil is not shaken off too closely. After curing 4 or 5 days under a shed they are stored in the cellar like potatoes. The author's loss has been but 4 per cent by winter storage in a dry cellar.

Carnations; topping plants in the field, A. M. Herr (*Amer. Florist, 16 (1901), No. 680, p. 1610*).—In place of breaking or carelessly cutting the stems, which may furnish conditions for the development of bacteriosis, the use of a sharp knife in topping is recommended. The first top should be taken out when the stem is in danger of toppling over and growing into a crooked plant, the second when the branch is forming a bud at the end. Late-blooming carnations should be topped very sparingly, so that the plant can be taken in with shoots long enough to produce some early flowers. Early bloomers require more constant attention and should not be carried into the house with buds on, since such buds make only third-rate flowers. Continuous bloomers should be handled the same as the foregoing, according to their habit of earliness or lateness. Carnations that bloom in crops require especial attention to topping in order that they may be made to bloom at the season when they are most wanted. "Quick comers" should be topped once or twice in the house in order to get the crop to come up between December 15 and January 10 and a second crop at Easter time.

Benching carnations, C. W. WARD, L. E. MARQUISEE, and J. HARTSHORNE (*Amer. Florist, 16 (1901), No. 686, pp. 1781–1783*).—The best course to pursue in benching carnations, as regards date of planting indoors, proper compost, details of the operation of moving the plants from the field, etc., are considered independently by each of the authors.

The influence of incandescent lights on carnation culture (*Florida Agr., 28 (1901), No. 1436, p. 503*).—It is stated that in experiments conducted at the Michigan Agricultural College incandescent lights in the greenhouse had the effect of increasing the length of the stem and the size and quantity of the flowers.

Carnation hybrids, AMELUNG (*Gartenflora, 50 (1901), No. 17, pp. 449, 450*).—Brief notes and a colored plate are given showing the result of the artificial crossing of *Dianthus chinensis* as mother plant *D. caryophyllus* as pollen plant. The details of this work were noted in an earlier number (E. S. R., 12, p. 752).

Recent chrysanthemum literature, C. H. PAYNE (*Gard. Chron., 3. ser., 30 (1901), No. 765, p. 145*).—The publications on chrysanthemums since 1897 are briefly noted.

Cineraria stellata (*Amer. Florist, 17 (1901), No. 690, pp. 133, 134*).—Notes on the origin of this flower and on methods of culture.

Horticultural monograph of the lilacs, L. HENRY (*Jour. Soc. Nat. Hort. France, 4. ser., 2 (1901), July, pp. 726–759*).—The various species of the genus Syringa and of the subgenus Ligustrina are monographed.

Newer lilies, J. G. BAKER (*Amer. Gard., 22 (1901), No. 350, pp. 620, 621*).—This is a summary of a paper presented by the author at the London lily conference, in which a number of the newer lilies are briefly noted as to species and character of flowers.

Hybrid stock for grafting roses (*Amer. Gard., 22 (1901), No. 339, p. 440*).—The writer considers Manetti stocks, which are so largely used in growing roses, not at all suited to our climate. Where perfect hardiness is required the writer has substituted Michigan or Prairie rose (*Rosa setigera*), *R. wichuraiana*, and sweetbrier (*R. rubiginosa*) for Manetti stocks with good satisfaction. "All make good, deep roots, and are little affected by dry weather when established, and are not at all disposed to sucker." The best of all stocks, however, has been obtained by crossing Crimson Rambler with Clothilde Soupert, both of which are varieties of *R. multiflora*. These stocks are extraordinarily vigorous, show no inclination to throw up sprouts, and for budding purposes the stocks are easily worked. "In hardiness it seems little inferior to the native species." The roots are easily grafted with the splice graft. The stems are not so satisfactory for grafting. For tree-rose effects the writer prefers to bud high up on strong sweetbrier shoots and trim off all other shoots and branches from the stock as soon as the bud has formed a fair top.

Horticultural monograph on roses, J. GÉROME (*Jour. Soc. Nat. Hort. France, 4. ser., 2 (1901), July, pp. 760–762*.—A botanical and horticultural study of genus.

Tecomas, H. NEHRLING (*Amer. Gard., 22 (1901), No. 351, pp. 634, 635*).—Ten species of Tecoma are described.

Wind-breaks and frost, J. Hoffman (*Pacific Rural Press, 61 (1901), No. 21, pp. 325, 326*).—The advantages and disadvantages of wind-breaks as a protection against frosts in lemon orchards are considered.

Growing evergreens from seed, C. Wedge (*Amer. Gard., 22 (1901), No. 351, p. 636; reprint from Minnesota Hort.*).—Detailed cultural directions are given for the growing of evergreens from seed.

Henderson's picturesque gardens and ornamental gardening illustrated, C. Henderson (*New York: Peter Henderson & Co., 1901, pp. 158, figs. 317*).—The effects produced by different methods of landscape gardening, ranging in character from the more natural to the formal gardens of the Italian and French schools, are brought out in an extended series of illustrations. The illustrations give views of gateways and entrances, lawns and decorated parks, fountains and statuary, floral sundials, water pieces, artistic flower beds, topiary work, cactus gardens, subtropical gardens, hedges, and the hardy shrubs, flowers, etc., in landscape gardening.

Gardens old and new—the country house and its garden environment (*London: Country Life [1901], pp. XXIV+295, figs. 470*).—A presentation of methods of English gardening and of garden architecture by the aid of an elaborate series of half-tone reproductions of famous English manors, abbeys, country houses, etc., and the ground attached thereto. The text consists in a large measure of historical and descriptive notes in explanation of the illustrations.

FORESTRY.

Observations on forest meteorology, R. de Drouin de Bouville (*Bul. Min. Agr. [France], 20 (1901), No. 2, pp. 240–270, pls. 9*).—At the National School of Forestry since 1867 observations have continually been made to ascertain the effect exerted by forests upon rainfall and upon a supply of subterranean water. Three stations were maintained, one of which was selected to represent a dense forest of deciduous trees, the second a less heavily timbered region, while the third was an agricultural region of considerable extent which was taken to represent the meteorology of an area free from the influence of forests. The influence of wooded areas on the total rainfall is shown for the three stations. While there was considerable variation from year to year, the relative proportion measured at the different stations was about the same. For the 33 years the relative proportion of water on the 3 different areas above described was 100, 93.9, and 76.7, showing that in general forests increase the amount of rainfall over a given area, and this increase seems to be about in proportion to the extent and density of the forest.

In order to ascertain whether winds exerted any appreciable effect on the amount of rain falling at these different regions, a tabular statement is given showing the rainfall for 11 years under the influence of winds from different directions. The results show that practically the same proportion stated above is shown for the rainfall of the different stations, no matter what the direction of the wind.

The effects of cold and hot seasons and seasons of great and small rainfall are shown by tabular statements, but practically the same relative quantity of water fell at the different places. With slight variation there was no appreciable difference in the action of the forest in winter or summer, the average precipitation being about the same for each season. In dry seasons the relative precipitation over forested areas was little, if any, greater than during periods of heavy rain.

Investigations were conducted to determine the amount of rain water intercepted by the forest cover. These observations were begun in 1867 and continued for 32 years. In the densely covered forest, small areas were cleared of trees and comparisons made between the amount of water reaching the soil in these areas and those where the timber was not removed. In the dense forest the amount of water intercepted by the trees varied from the minimum in winter to a maximum of 14.3 per cent of the total rainfall. At the second station the amount of water intercepted attained a maximum of 16.6 per cent.

The evaporation taking place from the soil in wooded and cleared areas was investigated by means of atmidometers, by which it was found that the evaporation was considerably greater in the open areas than those under forest cover. No estimation appears to have been made of the amount of water transpired through the foliage of the growing plants.

Forestry planting for southern Minnesota, H. W. Poole (*Farm Students' Rev., 6 (1901), No. 9, pp. 142, 143*).—On the high prairie soils of the southern part of the State the author recommends the planting of green ash, boxelder, white willow, white spruce, red cedar, Norway and Scotch pines. For the more moist soils, black walnut, green ash, hard maple, white willow, basswood, soft maple, Norway spruce, Douglas fir, and white pine are more suitable.

Forestry at Coteau Substation in southwestern Minnesota (*Farm Students' Rev., 6 (1901), No. 9, pp. 131–133*).—A review is given of the forestry conditions at the substation, and the necessity for the planting of wind-breaks is shown. For wind-breaks the author recommends the planting of willows, of which the golden willow is considered one of the best. The caragana and buckthorn are both considered good hedge plants for wind-breaks, but are of less rapid growth. After a windbreak is started the permanent trees may then be planted, and in this section boxelder, ash, and elm give the best results, although some of the oaks, particularly bur oak, make considerable growth while young. The presence of underbrush, such as dogwood and buckthorn, is recommended in the planting as a protective measure. After the forest trees become established this undergrowth can be cut out when the plantation is thinned.

Investigations conducted by the Bureau of Forestry in Nebraska, W. L. Hall (*Forester, 7 (1901), No. 8, pp. 188–193, figs. 4*).—Forest investigations are being conducted in Nebraska, in which an attempt is made to study the planted and natural timber. The planted timber is studied to find not only what thrives best in different sections of the State, but also what is most valuable for different purposes. The natural timber is investigated to find what species occur, to what extent timber is increasing, and the conditions under which the increase takes place. In 1890 this Department had a large number of pines planted in the Sandhill region of southwestern Nebraska. The plantation consisted of Scotch, Austrian, Rock, and Banksian pine. The land was very sandy, and the trees were set in furrows run through the sod. Since planting no cultivation has been given. The Scotch and Austrian pines now average 6 to 8 ft. in height, the Rock pine from 4 to 6, and the Banksian pine 12 to 18 ft. This experiment seems to show that they are well adapted to the location and similar regions. The investigations conducted by the Bureau of Forestry will be in that portion of the State which is not adapted to farming or grazing, and will bring together all available information on its adaptability to forest growth and on means of foresting in case it is adapted to the growth of trees.

The forest and water resources of Washington, A. D. Foster (*Forester, 7 (1901), No. 4, pp. 88–91*).—A summary is given of an address in which the forest and water resources of the State are reviewed. It appears that of a forest area of 15,858 square miles formerly covered with merchantable timber, 22.5 per cent has been destroyed by fire, 22 per cent cut over, and the remaining 57.5 per cent is still covered with standing timber. Thus in less than a generation of time about two-fifths of the timber in what is considered the richest merchantable timber region in the world has disappeared.

Tree planting on idle lands in New England, J. D. Lyman (*Forester, 7 (1901), No. 8, pp. 199–201, fig. 1*).—The author states that the great difficulties in the way of forestry are lack of knowledge of the art and science of forestry, and the rate of taxes usually assessed against lands. There is said to be 116,000 acres of idle land in New

Hampshire, much of which is adapted to the growing of forest trees if properly managed. The white pine, spruce, and chestnut will probably be the best trees for culture. An example is cited of a 13-acre plantation of white pine from which, 40 years after planting, the owner cut 40 cords of boxwood logs, valued at $240 per acre. After providing for all expenses there was left a net profit of $128 per acre. If larger timber had been desired, by more prolonged thinnings the production could have been increased still more.

The outlook for forestry in the Philippines (*Forester, 7 (1901), No. 9, pp. 211–215, figs. 5*).—The author quotes Capt. G. P. Ahern, of the Forestry Bureau at Manila, as stating that there are more than 50,000,000 acres of public woodlands in the archipelago. There have been classified up to the present time 665 species of forest trees, and it is believed that the total number will prove to be fully 1,000 after the region has been more thoroughly explored. The plans of the Forestry Bureau of the Philippines are outlined, in which timber testing and forest management are to be given a prominent place. The proceeds derived from the leasing of forest privileges during the first fiscal year amounted to about $200,000, and at the present time the revenues are about $30,000 per month, an increase of about 150 per cent over what they were during the Spanish occupation. The present market for all timber is in Manila. Some of the timber has previously been exported to the Asiatic coast, but at present the demand for timber in Manila and other parts of the island is greater than the ability to supply it.

The forests of New South Wales, J. H. Maiden (*Agr. Gaz. New South Wales, 12 (1901), No. 7, pp. 811–826, map 1*).—The author popularly describes the forests of New South Wales, giving their topography and dividing the forest region into 4 zones, the principal characteristics of which are described. Descriptions and economic notes are given of the principal forest timbers of the country. Statistics are quoted in which the forest area is estimated at 20,000,000 acres, of which in 1900 there had been reserved 6,355,605 acres. These reserves, which are under government control, are mostly occupied under leases for grazing. The forestry operations are described at some length, the annual output of different kinds of timber being shown.

On the improvement and renovation of beech forests in Ardennes, L. Claude (*L'Ing. Agr. Gembloux, 11 (1901), No. 10, pp. 427–446*).—Attention is called to the gradual destruction of the beech forests, and suggestions are given for their restitution. The author recommends the prevention of the removal of the leaves, grass, and other materials constituting the forest floor, protection of the young growth, and the maintenance of plantations from which the trees may be transplanted.

Handbook of German dune protection, P. Gerhardt (*Handbuch des deutschen Dünenbaues. Berlin: Paul Parey, 1900; noted in Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 1, pp. 55, 56*).—This work is a complete treatise on the sand dunes of Germany, and describes the methods that have been adopted for their reclamation, the cost of the improvement, and methods of reforestation. Among the tree species found adapted to planting in such conditions are Scotch pine, *Picea alba*, *P. excelsa*, *Alnus glutinosa* and *Betula verrucosa*, and under certain conditions *Pinus laricio*, *P. rigida*, ash, elm, poplar, etc. For the dunes along the North Sea the author believes it feasible to forest them with mountain pine and black alder, with mixtures of Scotch pine and birch in some places. For the side of dunes next the coast, planting grass and other halophytic plants is recommended to prevent their shifting about.

Durability of timber (*Queensland Agr. Jour., 8 (1901), No. 6, p. 444*).—A discussion is given of the relative durability of seasoned and green timber when used for structural purposes. The application ot coal tar, paint, and other coverings to green timber tends to increase the liability to dry rot, and it is recommended that unseasoned timber should not be painted except at the joints. Where seasoned there will be less shrinkage in timber. It may be finished, tarred, or painted without incurring danger of dry rot, and the timber itself will frequently be found to be stronger.

Wood preserving by painting with or immersing in tar oils, E. P. Schoch (*Trans. Texas Acad. Sci., 4 (1901), No. 1, pp. 88–92*).—Gives results of tests of timbers treated with carbolic acid, high-boiling oils, and tar bases. To protect timber by means of superficial application the best results were obtained with a coal-tar distillate boiling at 270° C. or above, free from low-boiling oils and carbolic acid, and containing a high percentage of tar bases, notably acridine, and free from tarry or insoluble substances that close the pores of the wood.

SEEDS—WEEDS.

On the color and weight of red-clover seed, C. Fruwirth (*Landw. Vers. Stat., 55 (1901), No. 6, pp. 439–452*).—Studies are reported on the color and weight of the different seed found in red-clover heads. The seed in a large number of clover heads were counted and divided according to color, an attempt being made to divide each head as nearly as possible into an upper and lower half. The results are given for 9 heads, showing that the lower half of the head contained 10 dark-violet seed, 30 variegated, 72 deep yellow, and 86 yellow, while the upper half contained 16 dark violet, 54 variegated, 72 deep yellow, and 64 yellow. The total seed production of a number of plants was counted, showing considerable variation as to the color of the seed. Based upon their color, the seed produced by one plant were 160 deep yellow and 445 yellow; a second plant produced 154 violet, 125 variegated, 58 deep yellow, and 11 yellow seed; a third, 177 deep yellow and 366 yellow seed; while still another bore 131 variegated and 47 deep-yellow seed. From these and other investigations reported the author seems to believe there is a predisposition in color of seed found in the red-clover heads. This is particularly true of the yellow seed or the violet. For the variegated seed and those approaching that color there seems to be greater predisposition to the production of dark-violet seed than to variegated. Numerous weighings were made of different classes of seed, and the averages showed that the dark-violet seed were the heaviest, followed by the variegated, and the average of these was still heavier than the lighter-colored seeds.

The seed coats of angiosperms and gymnosperms, and their development, J. J. Attema (*De zaadhuid der angiospermæ en gymnospermæ en hare ontwikkeling. Groningen: P. Noordhoff, 1901, pp. 226*).

A chemical and physiological study of the corneous endosperm of some leguminous seed, M. Goret (*Thesis, Lons-le-Saulnier [Declume], 1901, pp. 85*).

The germination of seed plants, A. J. J. Vandevelde (*Dodonaea, 1900, pp. 141–301*).—Treats of the morphology and physiology of the germination of spermaphytes.

On the action of formaldehyde on germination, R. Windisch (*Landw. Vers. Stat., 55 (1901), No. 4–5, pp. 241–252; abs. in Ann. Agron., 27 (1901, No. 8, pp. 388, 389)*).—A study was made of the action of formaldehyde in strengths of 0.02, 0.05, 0.1, 0.2, and 0.4 per cent upon the germination of lupines, peas, horse beans, soy beans, flax, summer rape, alfalfa, clover, and maize. In general the more concentrated the solution, the more the germination was retarded and the less number of seeds germinated, the action of the formaldehyde generally manifesting itself by a diminution of the germinative energy of the seed. The most dilute solution had little or no injurious effect upon the germination of lupines, peas, beans, or maize, while it retarded slightly the flax, summer rape, alfalfa, and clover, although the total germinations were not diminished. More marked effects were noted as the strength of solution was increased, the 0.1 per cent having an injurious effect upon all but the horse beans and maize. The summer rape and flax were killed and the germination of the alfalfa and clover greatly retarded. The 0.2 per cent solution was injurious to all except the maize, retarding those which had previously not been affected, and completely killing the others; while the 0.4 per cent solution destroyed all seeds except the maize.

Germination of wheat treated with copper sulphate, E. DEMOUSSY (*Ann. Agron., 27 (1901), No. 6, pp. 257–261*).—On account of recently published investigations, which showed the injurious action of extreme dilutions of copper and other salts, the author was led to study the effect of fungicides upon plants and to ascertain the reasons for the comparatively slight injury upon foliage and seeds when treated with fungicides containing an amount of copper far in excess of the minimum toxic strength. In the case of fungicides sprayed upon plants, the injurious action is neutralized by the presence of carbonate of lime, or other alkalis. Where seeds are soaked or wetted with strong solutions, the reason for the limited injury is not so evident.

The author conducted a number of experiments in which wheat was soaked in solutions of copper sulphate and determinations afterwards made of the copper adhering to the seed. In ordinary practice the strength of the solution employed is 1 kg. of copper sulphate dissolved in a hectoliter of water, or 0.253 gm. metallic copper per 100 cc. of water. In the first of the author's experiments, 25 gm. of wheat were immersed in 50 cc. of the above solution, and after 15 minutes' immersion the weight of the copper remaining in the solution was practically undiminished. In a second case, the amount of metallic copper in the solution fell from 0.251 to 0.248 gm. After treatment 25 gm. of seed wheat were dried, incinerated, and the amount of copper adhering was found to be 0.011 gm. After washing treated seed three times, the copper still adhering was 0.009 gm. Other investigations showed that the copper was wholly deposited on the outside of the grain, at least none could be detected by potassium ferrocyanid tests within the seed coats. Germination tests were made of 6 lots of wheat, of 5 gm. each, practically 100 seeds each. Two lots were simply dipped into the copper solution; 2 soaked for 15 minutes; and 2 soaked for the same length of time, after which the grain was washed in 3 waters; and all germinated under similar conditions, with a check lot untreated. A retarding action was noted for all treated lots. If the treated seeds were germinated upon filter paper no injurious action was noted, and similar results were obtained for 6 lots of seed germinated in pots containing soils, some of which contained lime and others without. In explaining this lack of injury, the author claims the capillary action of the filter paper and soils drained the copper from the seed, and as a result the tender radicles did not come in contact with a toxic quantity of the metal. The suggestion often given, that seed treated with copper sulphate should afterwards be limed, he believes to be unnecessary in ordinary practice, his experiments having shown equally well for those lots which received no lime. The physical character of the soil seems sufficient to overcome the injurious action of the salt when used in ordinary strengths.

Stimulating the germination of teak seed (*Trop. Agr., 20 (1900–1901), p. 176*).—It is stated that the usual time required for germinating seed of teak varies from 2 to 3 months. Experiments which have been undertaken show that this time may be greatly shortened in different ways. One experiment was carried out in which the seeds were placed in a shallow pit, which was afterwards filled with water, and subsequently the seeds were kept moist by being watered every 4 days. In the second experiment the seeds were soaked for 24 hours in warm water before planting. In both experiments the time of germination was reduced to a few days.

Deciduous tree seeds, G. W. STRAND (*Florists' Exchange, 13 (1901), No. 14, p. 379*).—Directions are given for the collection and management of the seeds of a number of deciduous forest trees. The seeds of willows, soft maples, poplars, and elms—with the exception of the red elm—should be sown on ground that remains reasonably moist, as soon as possible after gathering, as they lose their germinating power very quickly. The depth to which seeds should be covered varies with different varieties. Elm, poplar, birch, and elder should not be covered more than ½ in.; maple, ash, box elder, and basswood, from ¾ to 1 in.; oak, chestnut, walnut, butternut, and hickory, from 1½ to 2 in. in depth. As a rule, seeds which ripen in the fall should be planted at once, except those which can be kept over without danger of spoiling. Those of a dry nature may be kept until spring if stratified in sand or leaves. They have also been preserved by being mixed with leaves and hung in sacks in a cool, dry place. If kept in this manner they must be thoroughly soaked before planting or many of them will not sprout. Locust seeds should be scalded before planting, and only the swollen ones planted. The seeds of thorn apple or wild thorn, mountain ash, red cedar, juniper, and others as a rule do not germinate until the second season. These may be kept either in a stratified condition or planted and the rows mulched. Seeds which have a fleshy covering, such as cherries and plums, should be separated from their pulp and stratified in moist sand until planted.

On the germination of half-ripe dodder seed, W. KINZEL (*Landw. Vers. Stat., 55 (1901), No. 4-5, pp. 255-256; abs. in Ann. Agron., 27 (1901), No. 8, p. 390*).—A study was made of the germination of immature seed of *Cuscuta lupuliformis*. Capsules containing green seeds were collected, some of which were preserved as collected, while others had the seed removed. In testing the germination of the green seed, it was found that 56 per cent of those which had been removed from the capsules germinated, while 73 per cent of those preserved within the seed balls germinated. Those preserved in the capsules, while germinating more slowly at the beginning, finally gave 92.5 per cent germination. Seeds allowed to ripen normally which were germinated for comparison gave but 5 per cent germination at the end of 26 days.

The sprouting of cocklebur seeds, E. E. MASTERMAN (*Ohio Nat., 1 (1901), No. 5, pp. 69, 70*).

Weeds of Montana, J. W. BLANKINSHIP (*Montana Sta. Bul. 30, pp. 70, figs. 21*).—A general study is given of the weed flora of the State and the characteristics of the different weeds are described. The means of distribution and origin of the weed flora are shown. The classification of the weeds into annuals, biennials, and perennials is made and brief notes given regarding their root systems. The different weeds are classified according to their situations, and methods for eradication are discussed at some length. The weed law of the State is quoted, in which it appears that Canada, Scotch, and Russian thistles are proscribed. An annotated list of the weeds growing in Montana is given, the species being arranged in alphabetical order. Those which are especially troublesome are indicated by having their scientific names printed in black-face type. In all 138 species are enumerated.

An experiment on the eradication of weeds in meadows, R. ADERHOLD (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 17-18, p. 662*).—A brief report is given of experiments conducted with a 15 per cent solution of iron sulphate sprayed upon meadows to destroy weeds. The first application was made on May 11, followed by a second one June 13. The herbicide had but little effect upon such species as Bellis, *Leontodon taraxacum*, Veronica, thistles, or dead nettle. There was some injury done to species of Symphytum and Ægopodium. The second application was made without any injury to the grass, which consisted of a mixture of Lolium and Cynosurus, but the flowering stalks of Leontodon and Bellis and some others were destroyed, thereby preventing the spread of their seeds.

Experiments in the destruction of wild mustard and wild radishes, E. MARRE (*Semaine Agr., 21 (1901), No. 1069, pp. 358, 359*).—In order to popularize the method of weed destruction by means of chemicals, the author arranged, during the summer of 1901, with a number of cultivators in different parts of the department of Aveyron to spray crops with a 5 per cent solution of copper sulphate and a 10 per cent solution of iron sulphate. The results of the experiments are briefly reported. Fields of barley, winter wheat, oats, and maize were sprayed with these herbicides, and where properly applied resulted in the destruction of the wild mustard, the wild radish, and in a number of instances of the field poppy, crowfoot, cardoons, etc. In general, all the treatments were successful, but on account of cheapness the iron sulphate is given the preference. It is believed that by the use of this herbicide it will be possible to destroy these weeds growing in fields of cereals.

DISEASES OF PLANTS.

Notes on fungus diseases of plants, J. RAY (*Rev. Gén. Bot., 13 (1901), No. 148, pp. 145–151*).—The author believes that it is possible, within certain limits, to prevent attacks of fungus parasites through the presence of inimical substances in the tissues of the host plant. Among the external parasites the effect of the host is inappreciable and fungicides must be employed in combating them. For internal parasites a number of alternates are presented. A brief report is given of experiments in which various chemicals were injected into the plants, indicating, the author believes, that the injection of the juices of plants not subject to attacks of a specific organism will secure immunity for the treated plant from attacks of that fungus. The principal part of the paper is taken up with an account of experiments in which immunity to disease was secured by producing a mild form of disease through inoculation with attenuated cultures of the fungi, or by the use of toxins derived from pure cultures of the organisms. The methods of attenuation were those usually employed in such investigations and consisted of heat, light, and cold. Experiments were conducted with wheat, oats, lupines, beans, sunflowers, radishes, and mustard, all of which—with the exception of the mustard—are subject to a bacterial rot caused by *Bacillus putrefaciens.* The experiments with the lupines and beans are reported at considerable length. The bacteria cause a peculiar rotting of the tissues, accompanied by an exudation of viscous gum which has a very characteristic odor. Inoculations with attenuated cultures, or with a solution obtained by dissolving the alcoholic precipitate secured from the cultures, produced a mild form of disease which apparently rendered plants immune to subsequent attack. The author believes that the occasional immunity and resistance of some individuals to disease is largely brought about in this manner.

Result of experiments for the prevention of bunt in wheat, W. FARRER (*Agr. Gaz. New South Wales, 12 (1901), No. 4, pp. 419–430*).—In 1899 and 1900 the author conducted a number of experiments for the prevention of bunt in wheat at Lambrigg, Australia. The results of his experiments in 1899 showed that copper sulphate was not to be depended upon as a fungicide for the prevention of bunt. Repeating his experiments in 1900 the results obtained were much more favorable for the use of fungicides than the previous season. The experiments were conducted by drilling different varieties of wheat in 20-yard rows in which badly infested seed was used or smut balls were broken and mixed with the seed before treatment. The experiments show that formalin was efficient in destroying a considerable portion of the fungus spores, and from the tabular statement but few plants produced any smutty heads which had been treated either with formalin or copper sulphate. The fungicides, however, were in some instances decidedly injurious to the seed. Considerable difference in the susceptibility of varieties to smut is reported. A series of experiments was conducted in which the seed was soaked in hot water and other lots subjected to dry heat, the temperatures ranging from 130 to 180° F., but negative results were obtained. An experiment was attempted in which it was sought to infest wheat through the soil by stirring smut balls in the soil. The seed wheat sown was from plants which showed no indication of disease, and of the plants which grew and came to maturity every one was found to be free of bunt. In a somewhat similar experiment it was shown that plants grown from seed which had been produced on noninfested plants did not show any disease.

Observations on the propagation of apple-tree canker, DESCOURS-DESACRES (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 7, pp. 438, 439; abs. in Gard. Chron., 3. ser., 29 (1901), No. 745, p. 227*).—The author reports on observations made on the apple-tree canker in nurseries containing several thousand trees, and prolonged for a considerable period. He asserts that the appearance of canker, caused by *Nectria ditissima*, is almost invariably preceded by the occurrence of a woolly aphis on the branches or roots of the trees. The presence of the woolly aphis is almost invariably followed by the appearance of canker, if diseased trees are in the immediate vicinity, otherwise there is no canker. The appearance of canker followed punctures of the aphis when the insect had been transferred from a contaminated region, and all the cankers examined on the apple tree contained the fungus *N. ditissima*. Experiments were conducted in which colonies of woolly aphis were transferred from a diseased tree and placed upon a sound one near wounds which had been intentionally made, and soon after the canker growth was observed in these wounds; while colonies taken from sound trees and transferred to other trees, under identical conditions, seldom developed any cankerous growth. These experiments were repeated a number of times with similar results. It seems that the woolly aphis is an active agent in the transmission of apple canker, not only in preparing the way for the fungus, but in actually transporting the mycelium and spores to wounds which had been accidentally made. As means for preventing the occurrence of this disease, nicotin, tannin, and tannic acid have been found very efficient, the solution being employed after thorough cleansing of the diseased part and cutting away the cankerous growth. The use of tannic acid gave particularly favorable results.

The canker fungus (*Jour. Bd. Agr. [London], 8 (1901), No. 1, pp. 12-16, pl. 1*).—A popular description is given of the apple-tree canker of Europe (*Nectria ditissima*). In addition to attacking apple trees, some varieties of which are more susceptible than others, this fungus has also been noted on pear, plum, oak, beech, ash, hazel, alder, maple, and linden. Young branches of trees which are attacked should be cut off as soon as the fungus shows itself, and older branches may have the wounded parts cut away and the cut surface coated with gas tar or some similar substance. If the disease spreads from the original point of infection the branch should be cut off. The fungus may be held in check by applying a strong solution of sulphate of iron to the diseased parts of the trees.

Root rot of peaches, sugar prunes, and apricots, H. VON SCHRENK (*Pacific Rural Press, 61 (1901), No. 21, p. 324*).—A brief account is given of a disease which attacks the roots of peaches, prunes, and apricots. The fungus attacks the younger roots, growing through the bark into the inner bark and the cambium layer. As the disease progresses the newer wood becomes affected, and pockets filled with gum appear here and there. At first these pockets are very small, but rapidly increasing in size and fusing form large cavities separated only by thin layers of pith rays. The gum exudes from the bark, where it can be readily detected in roots still alive. With continued growth of the fungus the cambium layer and inner bark are killed near the point of infection, and the fungus spreads toward the base of the tree. In trees which are in a dying condition the bark readily separates from the diseased roots. In the specimens submitted to the author there were no signs of fruiting bodies, so that the nature of the fungus could not be definitely determined. Root diseases, caused by *Agaricus melleus* and *Peniophora parasitica*, which destroy many fruit trees, are described; and based upon other investigations the author recommends combating the diseases by trenching about diseased trees, sterilizing the soil where possible, and planting resistant varieties.

Pear blight on the Pacific coast, N. B. PIERCE (*California Fruit Grower, 26 (1901), No. 675, p. 4*).—The occurrence of pear blight among the orchards of pomaceous fruits is noted, and the cause of the disease and methods of infection are described, being essentially those given by Waite (E. S. R., 8, p. 796).

A cherry disease, F. CORBOZ (*Chron. Agr. Canton Vaud, 14 (1901), No. 15, pp. 387–389*).—Notes the occasional occurrence of *Gnomonia erythrostoma* upon cherries in Switzerland. The fungus attacks the leaves, sometimes very severely, but is seldom found upon trees where light and air are sufficient.

Fungus and insect enemies of citrus fruits and means for their prevention, G. D'UTRA (*Bol. Agr. São Paulo, 2. ser., 1901, No. 6, pp. 351–363*).—Brief descriptions are given of a number of fungus and insect enemies of the orange, with directions for their prevention. Among the diseases described are gummosis, which it is claimed is caused by *Mycosphærella lœfgreni*, as well as a second form caused by *Aphionectria coccicola*, *Didymella citri*, *Colletotrichum glœosporioides*, *Glœosporium spegazzini*, and *Fumago citri*. Of the insects described most of them belong to the group commonly known as scale insects.

Collar rot in citrus trees, W. J. ALLEN (*Agr. Gaz. New South Wales, 12 (1901), No. 6, p. 728*).—The occurrence of mal-di-goma or collar rot is mentioned and the removal of the diseased bark, after which the wound is treated with carbolic acid, is recommended as a treatment.

A cure for orange root rot (*Agr. Jour. Cape Good Hope, 19 (1901), No. 3, pp. 185, 186*).—Recommends digging up diseased trees, cleaning off all adhering dirt, and exposing the roots for a week or 10 days to the air under shade, after which cut the tree back severely and replant. This method, it is said, has been repeatedly followed with success.

Diseases of pineapples, C. W. MALLY (*Agr. Jour. Cape Good Hope, 19 (1901), No. 3, pp. 171–180*).—The author agrees with Schönland that the mealy bug is neither the originating cause nor an important factor in pineapple diseases.

Report of the agricultural chemical experiment station in Spalato, F. GUOZDENOVIĆ (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 3, pp. 254–272*).—Among the investigations pursued were experiments on the prevention of a number of plant diseases. Grape peronospora, oïdium, and white rot are described, and experiments reported in the use of various fungicides for their prevention. Among the substances used were solutions of various compounds of zinc, cadmium, nickel, and copper. The Bordeaux mixture proved the best suited to use in combating disease. Experiments on the efficiency of sea water as a fungicide were continued and indicated that the use of this substance is not to be recommended, as it has a decidedly injurious effect. A disease of olives, due to *Cycloconium oleaginum*, was decidedly injurious, but experiments with a 1 per cent solution of Bordeaux mixture or with a potassium permanganate solution showed that the disease could be readily controlled. Analyses of a large number of samples of wine are reported, as well as investigations in fertilizers, minerals, oils, etc.

Comparative effects of lightning and gélivure on grapevines, L. RAVAZ and A. BONNET (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 12, pp. 805–807*).—The effect of electricity upon plants, as shown by the shattered trunks of trees when struck by lightning, is described at some length. The authors conducted a series of experiments in which growing grapevines were subjected for a short time to powerful electric currents from a dynamo, after which the plants were replaced in the vineyard, where they were subject to the ordinary conditions. The changes produced by the electric currents were compared with those produced by lightning, as well as those produced by the disease known as gélivure, which has been attributed to freezing and to bacterial agencies. The authors found in the plants subjected to electric currents that there was a drying, beginning at the summit of the branches. The bark was broken and crevices formed to various depths. Within the branches the tissues were dried and more or less destroyed. These conditions are identical with those produced by the disease in question, and the authors believe that what has been attributed to the bacterial disease or to freezing is really due to the effect of lightning upon the vines in the vineyard.

Gélivure, gummosis, etc., P. VIALA (*Rev. Vit., 15 (1901), No. 384, pp. 461–464*).—In a controversial article the author takes exception to the statement of Bonnet and Ravaz that gélivure as a bacterial disease should be no longer recognized, claiming this disease was due to the effect of lightning upon the vines. The effect of electricity on vines, as shown by experiments of these authors, is given above. The author of the present paper recounts his experiments and those of a number of others in which inoculation experiments were conducted with bacteria from diseased vines, in which the characteristic lesions were produced without any appreciable difficulty. The same general condition of vines is produced, the author claims, by the bacterial disease which he has described under the name gélivure, by the injury of hail and possibly by lightning. The different diseases which have been attributed to bacterial agencies, the author says, are probably identical, and maintains that the first name published was gélivure and that gummosis, maladie d'Oléron, and possibly mal nero are identical. While not denying that lightning may cause effects that have been confounded with bacterial disease, the author still maintains that there is a distinctive bacterial disease to which grapevines are subject.

Practical treatment for black rot and mildew, G. CAZEAUX-CAZALET (*Rev. Vit., 15 (1901), No. 392, p. 677*).—The relation between moisture, temperature, and growth of fungi is discussed, and the most advantageous time for spraying said to be during periods of low temperature, accompanied by rain. Spraying immediately after a period of hot, rainy weather is said to be useless.

Black rot and mildew, G. CAZEAUX-CAZALET (*Rev. Vit., 16 (1901), No. 396, pp. 68–71*).—Describes the essential characteristics of these diseases as shown upon the leaves, the object being to enable growers to recognize the diseases in their different stages and to know when to apply preventive treatments.

Gray rot of grapes, J. M. GUILLON (*Rev. Vit., 16 (1901), No. 401, pp. 206–208*).—Describes attacks of *Botrytis cinerea*, which the author considers the cause of most of the injury to vineyards in Charentes.

Concerning gray rot, B. DE CHEFDEBIEN (*Rev. Vit., 16 (1901), No. 402, pp. 236–238*).—Gives methods for the preparation and use of sulphosteatite for combating attacks of *Botrytis cinerea*.

Chlorosis of grapes, B. CHAUZIT (*Rev. Vit., 15 (1901), No. 393, pp. 718–719*).—This disease is said to be most injurious on vines grown upon calcareous soils. It may be wholly prevented by washing vines with a solution of iron sulphate, 400 gm. to 100 liters of water. The salt may also be applied to the soil about the base of the vine with advantage.

Sulphuring grapes during flowering, P. PACOTTET (*Rev. Vit., 15 (1901), No. 388, pp. 582, 583*).—The author concludes that the application of sulphur during flowering is not only not injurious to the setting of fruit, but aids in pollination, the blast of air scattering the pollen to a considerable extent. Applications at this time are said to be very beneficial in reducing mildew.

Sulphur and sulphuring, B. CHAUZIT (*Rev. Vit., 15 (1901), No. 388, pp. 580–582*).—Discusses the use of sulphur as a fungicide when applied as a powder or in various chemical compounds.

Copper fungicides and fine wines, P. PACOTTET (*Rev. Vit., 16 (1901), No. 398, pp. 129, 130*).—The author claims that the use of certain fungicides exerts an unfavorable influence upon the quality of some of the fine wines. This is especially true when resin, molasses, soap, etc., are added to increase the adhesive qualities of the fungicide. The use of verdigris or other clear fungicide for the later sprayings is recommended as not being injurious to the quality of the wine. If copper acetate is used, the excess of acetic acid is eliminated in the processes of fermentation.

Rhizophagus populinus, P. A. DANGEARD (*Botaniste, 7. ser., 1901, No. 6, pp. 285–287, pls. 2*).—In 1896 the author gave a preliminary note on a disease of poplar trees which was attributed to the above-named fungus. Since that time he has continued his investigations and affirms his previous conclusion that the fungus belongs to the order Chytridineæ. The parasite attacks the young roots, shutting off their nutrition and accomplishing their destruction. The roots of diseased trees contain but few root hairs, and young roots are very rare, and as a result the nutrition of the tree is impaired. If an examination be made of the roots the cortex will be found invaded by a nonseptate mycelium, which not only invades the tissues, but often completely fills the cells. The fungus does not extend into the woody tissue of the root. The effect on the tree is generally noticed by the destruction of the higher branches, since the roots are unable to furnish the normal amount of nutrition and the lower roots appropriate what is supplied, leaving the tops of the trees to perish. Some of the morphological phenomena of the fungus are described in considerable detail.

Woodiness of the passion fruit, N. A. COBB (*Agr. Gaz. New South Wales, 12 (1901), No. 4, pp. 407–418, pl. 1, figs. 13*).—Attention is called to a diseased condition of the passion vine, the fruit of which is used to a considerable extent in Australia. The disease, which the author designates as "woodiness," has been known for 10 years or more and is of widespread distribution. The name of the disease is derived from the characteristic appearance of the fruit. The affected vines are unhealthy in general appearance, their color being more or less yellowish green. The leaves are smaller, distorted, and spotted, and the branches more or less twisted and crooked. The rind of the fruit develops abnormally, the fruit frequently falling before maturity, and that which remains on the vines is worthless on account of the absence of edible pulp and the woodiness of the rind. The seeds of diseased fruits are invariably smaller and lighter in weight than sound ones. Just before the time for ripening, the diseased fruits assume an unnatural green color and not infrequently crack.

Various causes have been suggested as producing this disease, among which are exposed position, frosts, poor soils, improper fertilizers, and insufficient moisture. Associated with this disease the author has observed a fungus which is as yet not definitely determined. He believes from his investigations that the fungus is the specific cause of the disease, although as yet there is no direct evidence to substantiate this claim. Various remedies are suggested for the prevention of the disease, the principal of which are fertilizer mixtures by the use of which more vigorous vines are secured. It is claimed that the disease can be communicated through the planting of seeds from infected fruit, and the author recommends propagation by cuttings and layering wherever practicable. It is believed—although no experiments have been conducted to ascertain the fact—that the growth of the fungus may be prevented by spraying the vines with Bordeaux mixture.

Violet rusts of North America, J. C. ARTHUR and E. W. D. HOLWAY (*Minnesota Bot. Studies, 2. ser., 1901, pt. 5, pp. 631–641, pl. 1*).—The occurrence, distribution, and host plants are described of *Æcidium pedatatum*, *Puccinia violæ*, and *P. effusa*. The authors point out the distinctive characteristics of these different species, describing their different phases in detail. Four additional species of violet rusts are known to occur in Europe, and it is thought that they may eventually be found in this country.

Chrysanthemum rust, CHIFFLOT (*Gard. Chron., 3. ser., 29 (1901), No. 753, pp. 351, 352*).—In a translated article the author gives directions for the prevention of chrysanthemum rust. This consists of a winter treatment in which the leaves of affected plants should be collected and burned, and the pots and old stems sprayed with a solution of potassium sulphid. In the spring growers should choose buds not infected with the disease, and before using them they should be carefully examined to see that no pustules of rust are present. Before putting them in the frame it is recommended that they should be plunged in a solution of potassium sulphid. The summer treatment consists of the removal and burning of affected leaves and the spraying of plants with potassium sulphid solution.

When to apply Bordeaux mixture, G. Quinn (*Jour. Agr. and Ind. South Australia, 5 (1901), No. 1, pp. 18–22, figs. 5*).—Gives formulas for preparation of Bordeaux mixture, and for spraying peaches, pears, apples, and similar fruit recommends first application before the buds begin to swell. Later sprayings with more dilute mixtures should follow.

A lime and soap fungicide, Mancheron (*Rev. Vit., 16 (1901), No. 401, p. 208*).—Describes the preparation of a dilute Bordeaux mixture to which soap is added. The lime is said to be held in suspension in very fine particles, and the fungicide does not color fruit to any appreciable extent.

Crystallized and powdered copper sulphate, P. Pacottet and A. Lievre (*Rev. Vit., 16 (1901), No. 400, p. 179*).—The difficulty of dissolving the crystallized copper sulphate is pointed out, and it is stated that 2 forms of powdered copper sulphate are on the French market, one which is evidently crushed crystals, the other apparently crystallized from solutions which are agitated continually. Analyses show the latter varies considerably, some specimens containing as much as 10 per cent iron sulphate.

ENTOMOLOGY.

Some miscellaneous results of the work of the Division of Entomology (*U. S. Dept. Agr., Division of Entomology Bul. 30, n. ser., pp. 98, pls. 2, figs. 29*).—*The differential grasshopper in the Mississippi Delta; other common species, H. A. Morgan (pp. 7–33)*.—In Bolivar County, Miss., a large territory was flooded in 1897, and the flood prevented the planting of this area during that season. Weeds flourished in this locality to an unusual extent, and when the area was planted in 1898 grasshoppers were present in considerable numbers and attacked cotton. In 1899 the grasshoppers attacked cultivated plants in this region to an extent which constituted a plague. An investigation of the conditions surrounding this outbreak was made by the author. It was found that the eggs were deposited from July 20 to October 1, the number of eggs in each sac ranging from 103 to 132. The eggs were deposited in ditch banks, plantation roads, upon levees, around stumps and logs, and even in the logs. It was believed by some of the settlers in that locality that areas which had been flooded and left uncultivated were much frequented by the grasshoppers for the purpose of laying eggs. The eggs began hatching about the middle of April, and the entire life history of the grasshoppers, minus the time required for incubation, was 119 days. The young were observed to remain after hatching for several hours close to the egg pod from which they had emerged. Experiments were tried in perfecting remedies for use against this grasshopper. Thorough cultivation was found by laboratory tests and field observations to be an effective method for breaking open the egg pods and exposing the eggs to climatic changes. Winter cultivation of the soil was therefore advised where practicable. Spraying with a 12 per cent kerosene emulsion at least once a day was very effective when applied upon the egg beds at about the time of hatching. Another effective method was found in damming water in ditches, covering the surface with kerosene oil or kerosene emulsion, and driving the grasshoppers into the ditches. Where hopperdozers could not be used successfully it was found that good effects were secured from dragging tarred sheets over infested country. The young were thus captured and destroyed. Experiments with the South African fungus showed that where a solution of this fungus was spread out, diseased grasshoppers were abundant. Another grasshopper (*Schistocerca obscura*) was not affected by this fungus. Experiments in the use of acid phosphate, lime, kainit, and other substances to check the march of the grasshoppers proved the ineffectiveness of these substances. Among the natural enemies of the grasshopper mention may be made of the locust mite, blister beetle, *Helicobia helicis, Sarcophaga* spp., *Scelio hyalinipennis,* and *S. œdipodæ.* Notes are given also on the occurrence and injurious habits of *Schistocerca americana*, *S. obscura*, *Dictyophorus reticulatus*, *Dissosteira carolina*, *Chortophaga viridifasciata*, *Orchelimum agile*, and other related species. With regard to the relation between flooding and rainfall and the presence of grasshoppers, it was observed that where heavy rains occur in May and June, immediately following a flooding of the land, the grasshoppers do not prevail to any great extent. Where, however, dry summers follow flooding the grasshoppers occur in much larger numbers.

Some insecticide experiments, C. L. Marlatt (pp. 33–39).—Plum, apple, and pear trees were sprayed with crude petroleum on March 22 between 2 and 3 p. m. The day was bright and the weather continued fair for 4 days after the application. Another block of trees was sprayed at the same time with kerosene. After the second day the trees which were sprayed with kerosene showed only a very slight discoloration. The crude petroleum was apparent on the trees, however, for 3 weeks. The grass under the trees seemed at first to be badly affected by kerosene, but later it recovered and showed no permanent injury. No bad effects were produced on the trees by either crude petroleum or kerosene, and the San José scale and *Diaspis pentagona* were apparently all killed. A lime, sulphur, and salt wash, made in the proportion of 30 lbs. of lime, 20 lbs. of sulphur, and 15 lbs. of salt to 60 gal. of water, was applied at a boiling temperature to pear and plum trees infested with San José scale and *D. pentagona*. The application was made on March 23 and repeated on March 24. In order to determine whether the heat of the solution had anything to do with its effectiveness, infested trees were sprayed with boiling water with the result that none of the scale seemed to be injured by such application. The San José scale was completely destroyed by the lime, sulphur, and salt wash. The weather following the application was exceedingly favorable, and it is believed that where such is the case this insecticide may prove as effective in the East as on the Pacific Coast. An application of Bordeaux mixture kerosene emulsion, in the proportion of 5 lbs. Bordeaux mixture to 1 gal. of kerosene, churned together until the oil was emulsified, was sprayed on peach trees infected with *D. pentagona* on April 24. The mixture had little effect on the trees, but did not kill the scales. Kerosene-lime emulsion, in the proportion of 4 lbs. fresh lime and 5 gal. of water to 1 gal. of kerosene, applied on April 14 to peach trees infested with *D. pentagona*, had the effect of destroying nearly all of the scales without causing injury to the trees. Whitewash, prepared by slaking 2 lbs. of lime in a gallon of water, and applied in a thick coat on April 14 to a plum tree infested with *D. pentagona*, had little or no effect on adult scales. It appeared to have a slight value in preventing the settling of young scales. Formaldehyde gas produced in a patent generator to a strength 3 or 4 times greater than that which is necessary for germicide purposes was tested on infested stored products. The Angoumois grain moth was killed if not protected, but the bean weevils were apparently not injured. A test was made of this gas by placing a tent over a peach tree infested with *D. pentagona* and generating the gas under the tent. The tree was badly affected and died soon after the application. Scale insects were destroyed.

The carriage of disease by flies, L. O. Howard (pp. 39–45).—The essential parts of this article have been noted from another source (E. S. R., 13, p. 163).

The green clover worm (*Plathypena scabra*), *F. H. Chittenden* (pp. 45–50).—The larva of this moth feeds on leguminous plants, especially clover, and has been observed as attacking beans, peas, soy beans, strawberries, and blackberries. When attacking strawberries the pupal condition was passed in the rolled strawberry leaf. The species is described in its various stages and brief notes are given on its habits and life history. Poisons can of course not be used on infested pasture lands or on clover fields. The attacks of the insects on lawns, however, can be largely prevented by frequent mowing with a lawn mower.

Report upon an investigation of the codling moth in Idaho in 1900, C. B. Simpson (pp. 51–63).—The codling moth is reported as occurring everywhere in Idaho except in certain localities in the mountains. During 1900 about 50 per cent of the apple crop was destroyed and in some places the damage was as high as 75 per cent. Pears were only slightly infested. The codling moth was first known as an apple pest in Idaho in 1887, and probably came into the northern part of the State by way of the Snake River Valley. According to observations on different varieties of apples, the Pewaukee was most infested, while the Winesap was least attacked. Eggs were found throughout the summer either on the fruit or on the upper surface of the leaves. About 60 per cent of the larvæ of the first brood entered the apple at the calyx end. In later broods only a few entered at this point. A number of larvæ may be found in a single apple, 13 burrows being found in one large specimen. In Idaho the broods overlap to a remarkable extent; all stages of the insect except the adult were found in the field from July 7 to September 1, and larvæ were found under bands on the trees every day during this time. Every tree had at least 3 complete broods and a partial fourth brood during the year. A few of the pupæ are parasitized, but the parasites are not identified. The larvæ are attacked by ants and birds, and bats occasionally capture the moths. According to the author's observations, the chief arsenites are all about equally effective as applied against the codling moth. It is recommended that 2 sprayings be applied while the calyx is open, one immediately after the blossoms fall and the other about a week later. The third application should be made when the second brood is entering the fruit. Windfalls should be destroyed, the easiest method being to allow hogs or sheep to run in the orchard. Banding the trees is also very effective. The bands should be placed around the trunk of the tree from about 1½ ft. above the ground upward. If the tree is large it is best to put a band on each of the branches. Two bands on the trunk are recommended as better than one.

Insects and the weather during the season of 1900, F. H. Chittenden (pp. 63–75).—From observations on this subject the author comes to the conclusion that forms introduced into the North from further south show a tendency to produce one or more generations in excess of the number developed by related species which are native to the region of the adopted habitat. These introduced species are frequently observed to remain later in the field than native species. As a result of these habits, in combination with their greater susceptibility to low temperatures, the introduced species are liable to great destruction every year, and their residence in the northern limits of their range can therefore scarcely be considered permanent.

On the habits of Entilia sinuata, L. O. Howard (pp. 75–78).—This species of leaf hopper is found on a number of plants, especially sunflower. The insect is attended by 2 species of ants, *Camponotus pictus* and *Formica subsericea*. The young leaf hoppers are guarded by the ants and kept in close colonies. It is also observed that the adult female broods over the eggs until they are hatched. When the insect occurs in large numbers on cultivated sunflowers it may be destroyed by an application of kerosene emulsion.

Fumigation with carbon bisulphid, W. E. Hinds (pp. 78–82).—A large room belonging to a tobacco establishment containing about 75,000 cu. ft. and infested with *Lasioderma serricorne* was fumigated with carbon bisulphid. About 145 lbs. of this substance was exposed in 50 or more pans, 3 ft. long by 1 ft. wide and 1 in. deep. The pans were distributed through the room as high up as they could be conveniently placed. The building was carefully locked and left for 22 hours, after which it was opened for ventilation. Nearly all of the beetles were destroyed, and the treatment was considered successful. Special caution is urged in the use of this substance in preventing any fire from coming in contact with the gas, and brief notes are given on the effects of the gas upon human beings.

General notes and notes from correspondents occupy the remaining portion of the bulletin (pp. 82–98). These notes cover a great variety of subjects, including habits and life history of various insects and remedies which have been found successful in various parts of the country.

Proceedings of the Entomological Society of Washington (*Proc. Ent. Soc. Washington, 4 (1901), No. 4, pp. 347–527, figs. 21*).—This number of the proceedings of the society contains many papers on entomological subjects of a technical nature, short notes, biographical notes, and reports of trips in various localities for the purpose of collecting and observing the habits of insects. Special mention may be made of a few articles of more or less economic value.

On the insect fauna of the mistletoe, E. A. Schwarz (pp. 392–394).—In Arizona the mistletoe is much infested by *Lecanium phoradendri*. An undescribed species of snout beetle was found boring into the twigs of mistletoe and finally causing the death of the plant. Twigs thus infected may not be killed at once, but serve as favorable places for the development of bark beetles.

Remarks on the spittle insect (Clastoptera xanthocephala), O. Heidemann (pp. 399–402, pl. 1).—This insect is reported as causing some injury to chrysanthemums. Ragweed is considered as being the original food plant of the species. The habits of the immature forms of the insect are briefly described.

The ant decapitating fly, T. Pergande (pp. 497–501).—*Apocephalus pergandei* is described by D. W. Coquillett as a new species. The insect was found parasitic in the head of the carpenter ant (*Camponotus pennsylvanicus*). The fly is described and brief notes are given on its habits.

A season's experience with figs and fig insects in California, E. A. Schwarz (pp. 502–507).—A historical account is given of attempts to raise Smyrna figs in California and to introduce *Blastophaga grossorum* for the purpose of fertilizing the figs. At Fresno, Cal., in 1900, it was estimated that there were enough female fig insects to inhabit 20,000 figs. At Niles, Cal., early in April, winter figs containing fig insects were received from Fresno and established in a fig arboretum containing a number of Italian caprifig trees. This experiment in establishing a second colony of the fig insects was successful. The insect underwent only 2 generations at Niles during the year.

Insect record for 1900, C. M. WEED (*New Hampshire Sta. Bul. 81, pp. 9–22, figs. 11*).—A striking reduction in the number of the forest tent caterpillars is reported and is considered due to unfavorable weather conditions, especially to a frost which occurred on May 11, and during which the minimum temperature of 16° F. was recorded. The caterpillars of the Antiopa butterfly were also much less abundant than usual, and the cause of this partial disappearance is believed to be the attack of parasites, for instance, *Telenomus graptæ*. The American tent caterpillar occurred in large numbers during 1900. Tarnished plant bug was recorded as injurious to sweet peas. Imported currant borer was abundant on currant bushes in Durham. In some parts of the State considerable damage was done by locusts, especially by *Melanoplus atlanis* and *Dissosteira carolina*. Many of the grasshoppers were destroyed by a fungus disease. Brief notes are given on *Cacœcia cerasivorana*. The eggs are said to be laid on the bark of choke cherries near the ground. Brief popular notes are also given on the occurrence and habits of *Bucculatrix canadensisella*, Hunter's butterfly, monarch butterfly, and walking stick.

Entomological work and notes for 1900, W. W. FROGGATT (*Agr. Gaz. New South Wales, 12 (1901), No. 7, pp. 794–805, pls. 2*).—During the season locust plagues of considerable severity occurred in some parts of the country. Formulas are given for the preparation of mixtures of bran and arsenic, and bran and Paris green. A number of parasites of the locust are described, among which mention may be made of *Masicera pachytyli* and several species of Ichneumon flies.

The weed weevil (*Lixus mastersi*) is usually found feeding upon a species of Amaranthus. During the season, however, the author observed it as an orchard pest. The insect was especially injurious to young grapevines on which it devoured the young buds.

Carrot seeds were found infested with *Sitodrepa panicea*. The insect is reported from nearly all parts of the civilized world, and is a well-known pest in herbaria and drug stores. It may be destroyed in infested seed by fumigation. Complaints were made that orange trees were being attacked by *Bostrychopsis jesuita*. It is believed by the author, however, that this beetle did not attack the trees until after they were dead, or nearly dead. Related species of this genus are known to attack forest trees in a living condition in Germany and elsewhere. Descriptive and economic notes are given on *Mecyna polygonalis*, reported as occurring on broom corn; *Teara contraria*, which is reported as especially injurious to eucalyptus; San José scale: and *Halterophora capitata*. The last-named species was observed crawling over oranges and depositing their eggs in the skin of the fruit.

Report of the entomologist, W. W. FROGGATT (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 915–920*).—Mention is made of the various lines of work undertaken by the entomologist, and of the addition in collections and equipment made to the department during the previous year. Special attention is given to the study of the San José scale, *Plusia verticillata*, *Agrotis suffusa*, and various species of fleas.

Insects injurious to staple crops, E. D. SANDERSON (*New York: John Wiley & Sons, 1902, pp. 295, figs. 162*).—This volume contains a compilation of information concerning the chief insect pests of staple agricultural crops, together with observations from the personal experience of the author. Chapters of the book are devoted to insects injurious to the following crops: Grains and grasses, wheat, Indian corn, clover, cotton, tobacco, potato, sugar beet, and hop plant. One chapter is occupied with a discussion of insects injurious to stored grain. A general discussion of insecticides is given at the end of the volume. In connection with the treatment of each crop for insect enemies, special attention is given to a consideration of various cultural methods which are adapted to preventing injury from the insects by which the crop is naturally attacked.

The Colorado potato beetle, F. V. THEOBOLD (*Jour. Bd. Agr. [London], 8 (1901), No. 2, pp. 147–154, pl. 1*).—This insect recently secured a foothold in England and was found breeding in considerable numbers. All stages of the insect were found in one large field of potatoes. The infested locality at Tilbury was burned over with kerosene, the ground was then saturated with kerosene and dressed with gas lime, which later was plowed under. All surrounding herbage was cut and burned, and an examination of the country for a distance of 3½ miles in all directions indicated that the beetle had been exterminated. The life history and habits of the insect are gone over anew from original observations. A list of food plants is given. At Tilbury the beetle is said to have matured on tomatoes. Notes are given on the natural enemies and means of combating the potato beetle. The author considers that the climatic conditions in Great Britain are favorable to the establishment and development of the Colorado potato beetle, and urges the necessity of keeping sharp outlook to prevent its becoming thoroughly established in the country.

The apple sawfly (*Jour. Bd. Agr. [London], 8 (1901), No. 2, pp. 183–187, fig. 1*).—Injuries from *Hoplocampa testudinea* have been reported for 2 years on apples. The attack of the insect resembles somewhat that of the codling moth. The female appears in the spring at the time when the apple blossoms are opening, and deposits its eggs, usually one in each blossom, below the calyx. Under certain conditions there may be 2 broods of the insect each year. It is recommended that infested fruit should be removed from the trees and destroyed. Some help may be expected from thorough cultivation of the soil underlying the trees, but spraying does not promise much good in combating this insect.

Notes on Coccidæ (*Contrib. Biol. Hopkins Seaside Lab. Leland Stanford Jr. Univ., 1901, No. 25, pp. 387–420, 1–14, pls. 6, fig. 1*).—*Notes on Cerococcus, Rose W. Patterson* (pp. 387–398).—The author gives detailed description and biological notes on *C. ehrhorni*, found on live-oaks; *C. quercus*, reported as abundant on oaks in Arizona and southern California; and *C. corticis*. A black fungus is reported to occur in connection with the last-named species.

Notes on new and little known Californian Coccidæ, S. I. Kuwana (pp. 399–408, pls. 2).—Detailed descriptive notes are given in connection with observations on the food plants and habits of *Eriococcus artemisiæ, Ripersia festucæ, Lecanium adenostomæ,* and *Pseudolecanium tokionis.* The first 3 species are described as new.

The redwood mealy bug, G. A. Coleman (pp. 409–420).—The author gives a detailed description of *Dactylopius sequoiæ* in all of its stages. The first specimens of the insect were found on small cultivated redwood trees near Stanford University, and were later found in the university arboretum, as well as through the Sierra Morena Mountains. The species was preyed upon by the larva of a ladybird, and an undetermined parasitic fly was bred from female scales.

The San José scale in Japan, S. I. Kuwana (pp. 14).—The author spent several months in Japan during the season of 1900 for the purpose of studying the distribution, relative abundance, and parasites of the San José scale in that country. The insect was found in all of the islands which were visited. The amount of damage varied from slight attacks in some orchards to complete destruction in others. With few exceptions, however, the insect was nowhere sufficiently abundant to endanger orchards. In some locations pear trees suffered more than apple trees. In one locality the oldest orchard, imported from America about 25 years ago, was not infested. The insect was not found on high elevations, but has been known to be present in Japan for the past 30 years. No native species of trees were infested. The insect is attacked by numerous parasites which almost entirely destroy the female scales in some localities. The food plants, as observed in Japan, include pear, apple, plum, peach, Japanese quince, currant, and willow. Several parasites and ladybirds were observed preying upon the San José scale. The species were not identified. In Japan the best spraying machines and insecticides have not been used for the destruction of the scale and it is, therefore, practically unchecked by artificial methods. Soapsuds, kerosene, and kerosene mixture have been applied with a paint brush in a manner which often causes the death of the trees.

The currant-bud mite or currant-gall mite (Phytoptus ribis), R. NEWSTEAD (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1901*), *No. 3, pp. 286–302, figs. 8*).—The author describes the appearance of the mite in its different stages and of affected buds. The life history of the mite was worked out again in detail. The mites first appeared in newly formed buds during the second and third weeks of July. Previous to that time they were found on the leafstalks. From this date they increased in numbers, until a maximum was reached in March and April. When the infested buds died the mites died with them in great numbers, and a migration to fresh buds was seldom noted. As many as 3,000 mites may be found in a single infested bud. All varieties of black currants are attacked. The author failed to find a mite on the varieties of red currant.

The author gives a review of the literature and means of combating this mite, with notes from original observations. The removal of infested buds proved generally unsuccessful, applied on a large scale. On a single row or small patches of currants the method is sometimes more successful. Cutting all bushes down to the ground is reported as an effective method of combating the mite. Liquid insecticides are not recommended. Experiments in immersing infested branches in hot water for various lengths of time gave fairly satisfactory results. The mites were destroyed by immersion for 1 minute in water at a temperature of 140° F. and for 15 minutes at a temperature of 115° F. While this method is perfectly successful in a laboratory, it can not be managed conveniently on a large scale in the field. Rather contradictory results have been obtained by different experimenters with the fumigation method by means of hydrocyanic-acid gas. The author recommends planting clean healthy stock in single rows between other crops or in isolated areas. Plants should be pruned so as to admit plenty of light and careful watch should be maintained for the first appearance of infestation, when infested patches should be immediately burned.

The fall army worm and variegated cutworm, F. H. Chittenden (*U. S. Dept. Agr., Division of Entomology Bul. 29, n. ser., pp. 64, figs. 11*).—The fall army worm (*Laphygma frugiperda*) feeds normally on grasses, cultivated grains, and a few weeds, and produces 2 or 3 generations per year, according to the location. In 1899 the infested territory comprised large portions of the United States east of the Rocky Mountains. The author gives a description of the insect in its various stages, accompanied with technical descriptions of the egg and larva, by H. G. Dyar. The insect is distributed from Canada to Florida, and west to Colorado and Montana. It also occurs in Jamaica, Brazil, and Cuba. It is considered indigenous to North and South America. Notes are given by the author on the common and scientific names under which the insect has been known and on the various reports which were received concerning its outbreaks in 1899, 1900, and 1901. During 1900 it was reported as injurious on corn, which it attacked in a manner similar to that of the bollworm, and also to the chick-pea, ruta-baga, hollyhock, and lamb's quarter. The insect was described somewhat more than a hundred years ago, but it was not until 1855 that it began to attract attention by its depredations. The food plants include grasses, cereals, cotton, peas, grapes, various fruit trees, and other plants. The egg masses which are deposited in the fall produce larvæ and, as a rule, pupæ before winter. The full-grown larvæ enter the soil to a depth of about an inch and become inclosed in earthen cells. The larvæ of the first generation appear in May and June. The egg period is determined as about 10 days. In the District of Columbia hibernation takes place exclusively in the pupal condition. The natural enemies of this insect include English sparrows, which feed upon the larvæ, blue jays, and a number of parasitic and predaceous insects of which the most important are *Winthemia quadripustulata*, *Frontina frenchii*, and ants.

When the fall army worm assumes the habits of the common army worm it may be combated by the same means which are usually adopted against the latter. Wherever the arsenical poisons can be conveniently and effectively used, this remedy should be adopted. Lawns may be successfully treated by application of kerosene emulsion. In some situations mechanical methods, such as rolling and the use of barriers, may be adopted with success. Clean cultural methods and rotation of crops are always indicated in cases of bad infestation, and fall plowing has the effect of breaking up the earthen cells in which the pupæ are found, and thus exposing them to climatic changes. Infested rice fields may be flooded, and where bad outbreaks of the species are expected wheat and rye should be sown late. In vegetable gardens the use of poisoned baits is recommended. A list is given of the literature relating to this subject.

The variegated cutworm (*Peridroma saucia*) is a common insect in gardens, pasture lands, fields, orchards, and greenhouses, and feeds upon a great variety of cultivated plants. The insect is considered as originally from Asia Minor or southern Europe, and its distribution is cosmopolitan. It occurs practically throughout the United States. A description is given of the insect in its various stages, and notes are presented on outbreaks which have occurred in various parts of the United States and in Canada. These outbreaks include attacks on crops in gardens and fields, and also on greenhouse plants. Extended notes are given on the food plants of the insect, which include a great variety of cultivated plants and weeds. As a rule, this cutworm hibernates in the larval stage, although hibernation takes place to some extent in the pupal and adult conditions. Considerable injury is done in the spring by larvæ which have hibernated. There are at least 2, and perhaps 3, generations in the latitude of the District of Columbia. Hibernated larvæ begin their attacks in May, and a second generation is produced which causes injury in July and August. The duration of the egg stage is about 3 weeks at moderate temperatures, while the pupal stage lasted for from 10 to 21 days. The natural enemies of this species include a number of parasitic insects, among which mention may be made of *Phorocera saun-*

dersii, *Archytas analis*, *Ichneumon capitus*, and *I. maurus*. The cutworm is preyed upon to some extent by the common ground beetle (*Scarites subterraneus*). The insect is also subject to a bacterial disease and to the attacks of a parasitic fungus (*Empusa aulicæ*). Robins, crows, blue jays, chickens, turkeys, and pigs are reported as feeding upon the cutworm.

The artificial remedies which are recommended in combating this insect include the use of poisoned bran mash, poisoned vegetable bait, placing tarred paper or cotton batting around the trees, spraying with Bordeaux mixture, and hand picking.

The army worm (Leucania unipuncta), E. A HOLMBERG (*Bol. Agr. y Ganadería, 1* (*1901*), *No. 2, pp. 3–8, pl. 1*).—An account is given of the geographical distribution, appearance, habits, and means of combating this insect. The remedies which are in common use in this and other countries for army worms are recommended.

Combating army worms, A. L. ARRIBALZAGA (*Bol. Agr. y Ganadería, 1* (*1901*), *No. 5, pp. 52–55*).—The author gives brief notes on the habits, life history, and means of combating *Eurycreon similis*, bollworm, and army worm. Attention is called to the agency of birds in destroying these insects.

Tent caterpillars (*Jour. Bd. Agr.* [*London*], *8* (*1901*), *No. 2, pp. 191–197, pls. 2*).—Brief descriptive biological and economic notes on *Clisiocampa neustria* and *Porthesia chrysorrhœa*.

Killing cankerworms in California, H. G. KEESLING (*Rural New Yorker, 60* (*1901*), *No. 2678, p. 371*).—The use of traps for catching the female moths of cankerworms or for preventing them from climbing the trees proved unsuccessful. The experiment with moth traps was conducted on 200 acres of fruit trees and the traps were given a careful test. Experiments with Paris green, on the other hand, gave good results. Paris green used at the rate of 1 lb. to 200 gal. of water was not sufficient to kill the worms, but when used at the rate of 3 lbs. to 200 gal. the worms were nearly all killed, and the author believes this to be the most successful method for fighting cankerworms. No injury was caused to the foliage by using the Paris green in this strength. Apparently it made no difference in this regard whether a small quantity of lime was mixed with the Paris green or not. During the experiments 3 different brands of Paris green were used without noting any difference in results. It is stated that the same strength of Paris green was used with success on apple trees in destroying the codling moth.

Insect enemies of the spruce in the Northeast, A. D. HOPKINS (*U. S. Dept. Agr., Division of Entomology Bul. 28, n. ser., pp. 48, pls. 16, figs. 2*).—The species of spruce upon which observations were made were *Picea rubens*, *P. canadensis*, and *P. montana*. A study of insect attacks upon these trees was made in Maine, New Hampshire, and Vermont. It was found that dead trees occurred in well defined areas and were not confined to particular conditions of soil, exposure, or altitude. A species of bark-mining beetle, described under the name *Dendroctonus piceaperda*, was found to be the primary cause of the death or unhealthy condition of the spruce. The insect passes the winter in all stages of larva and in adult condition. The beetles which develop from hibernating larvæ begin to emerge about the middle of June. Galleries were excavated and eggs deposited by June 19. Larvæ were found in these galleries during the last few days of July, and adult beetles were observed on October 4. In northwestern Maine there seems to be only 1 brood annually.

The beetle attacks only the spruce and only the larger trees. Entrance is made to the bark of healthy trees from 6 to 10 ft. from the ground, and trees which are weakened from disease may be attacked nearer the ground. A detailed description is given of the primary gallery and the secondary or larval mines. Evidence of infestation is to be recognized in the presence of balls of pitch pushed out by the beetles when excavating, in the pale or grayish green color of the leaves, and by the reddish appearance of the twigs after the leaves have fallen. Only 1 brood of beetles develops on the same tree unless, as sometimes happens, but one side of the tree is attacked one year and the other side the next year. The presence of beetles is suspected also where woodpeckers are noticed working upon the trunks of spruce in unusual numbers. A globular fungus (*Polyporus volvatus*) is usually associated with attacks of the beetle and is observed protruding from the holes made by excavation.

A parasitic insect (*Bracon simplex*) and a predaceous beetle (*Thanasimus nubilus*) were observed preying upon the bark beetle. The most important bird enemies of this forest pest are various species of woodpeckers. A few of the larvæ were found suffering from what appeared to be a fungus disease. Severe freezing or sudden climatic changes may kill the pupæ and young beetles to a slight extent. Among the injurious insects which were found associated with the bark beetle, the two most important were *Polygraphus rufipennis* and *Tetropium cinnamopterum*. Extensive experiments were conducted by Mr. A. Cary on the effect of girdling certain trees which were about to be cut for lumber, for the purpose of attracting the beetles to them. The results are reported in detail, and it appears from these experiments that the best period for girdling spruce trees to attract the bark beetle away from other trees is at the time when the first pupæ of the beetle begin to appear in the bark, and extending from that time until the beetles begin to fly. It was found that the beetles do not remain in dying or dead trees for more than one year. It is estimated that 3 pairs of beetles to the square foot of bark, throughout an extent of from 10 to 15 ft. of the trunk, are sufficient to kill a tree.

The remedial measures which are recommended in controlling this insect include the regulation of winter cutting so that as many of the infested, dying, and dead trees as possible may be cut and placed in the water before June 1; cutting trees which have recently been attacked in summer and removing the bark from their trunks and stumps; and girdling during the first part of June the trees where logging operations will be carried on during the following summer. The best method of girdling is considered to be that of hacking through the bark with an ax around the trunk about 2 or 3 ft. from the base.

Locust extermination (*Agr. Jour. Cape Good Hope, 18* (*1901*), *No. 12, pp. 820–833; 19* (*1901*), *Nos. 2, pp. 99–106; 3, pp. 165–171; 4, pp. 248–262*).—This report contains a summary of the investigations in locust extermination which have been carried out in South America, Africa, and other countries. The so-called North American fungus (*Empusa grylli*) operates most successfully during the warmer, damper part of summer and attacks well-developed insects rather than young ones. Experiments with the Argentina fungus, or Carcarañá, gave good results and indicated that much may be hoped for from this fungus. Less satisfactory results were obtained from the use of the South African fungus. Detailed notes are given on the peculiarities of culture which are favorable to the propagation of fungus epidemics among the locusts, on migrations of locusts, and the various influences which determine the course taken by the armies of locusts. W. Roe reports success in destroying locusts by spraying with a soap solution, to which cyanid of potash was added. A copy is given of the locust law passed by Argentina for the purpose of preventing, so far as possible, the excessive damage from locusts.

The Indian starling (*Acridotheres tristis*) was imported into South Africa for the purpose of testing its value in the destruction of locusts. The birds were found to destroy locusts in considerable numbers, but in some localities form the habit of destroying fruit, which constituted a more or less serious objection to their further importation.

A general report is given by C. Frers on the invasions of locusts in Argentina from 1898 to 1900. This report contains an account of the origin, development, and extent of the different locust plagues which occurred during that time, and the routes followed by the adult and young locusts. The hibernating zone or localities where winter refuge is sought most extensively by the locusts are indicated, as well as the most frequented localities for the deposition of eggs. A classified list is given of natural and artificial agencies which tend to the destruction of locusts.

These include parasites and predaceous insects, as well as other animals, and all of the mechanical and chemical remedies which have been suggested for the destruction of the insects.

Winter washing of fruit trees (*Jour. Bd. Agr. [London], 8 (1901), No. 2, pp. 145, 146; Bd. Agr. [London], Leaflet No. 70, pp. 2*).—A caustic alkali wash, made by dissolving 1 pound of commercial caustic soda in water and 1 pound of crude potash in water; after these substances have become dissolved, they are mixed together, ¾ lb. of treacle added, and then sufficient water is added to make 10 gal. This wash is recommended as efficient in removing moss, lichens, and dead bark from the trunks of trees, and for destroying woolly aphis, codling moth, oyster-shell bark louse, and the eggs of the red spider and plant lice.

Catalogue of the Tabanidæ, C. Kertész (*Extr. from Természet. Füzetek, 23 (1900), pp. 79*).—The author has compiled in this article a complete catalogue of the genera and species of the Tabanidæ which have thus far become known. In cases where the original descriptions were not accessible to the author the species were entered according to the citations in *Zoological Record* and *Archiv für Naturgeschichte*.

Mosquitoes. How they live; how they carry disease; how they are classified; how they may be destroyed, L. O. Howard (*New York: McClure, Phillips & Co., 1901, pp. 241, figs. 50*).—In this volume an account is given of the life history and habits of mosquitoes, their connection with malaria, yellow fever, and filariasis. A classification of genera and species of the North American mosquitoes is given, and the natural and artificial enemies of mosquitoes are discussed. Short chapters are presented containing directions for collecting and preserving mosquitoes, and giving analytical tables for identification of different species. The volume constitutes an elaborated form of bulletins by the author, especially Division of Entomology Bulletin 25 (E. S. R. 12, pp. 768, 769).

The fight against mosquitoes, W. J. Matheson (*Rural New Yorker, 60 (1901), No. 2681, p. 417*).—A brief account is given of the habits and life history of mosquitoes in their various stages. It is believed that no body of water which exists during the summer for as long a period as 3 weeks is free from the liability or even certainty of becoming a breeding place for mosquitoes. The use of kerosene oil, as commonly recommended, is considered a successful remedy.

Dipterous larvæ as occasional parasites of man, E. Peiper (*Fliegenlarven als gelegenliche Parasiten des Menschen. Berlin: Louis Marcus, 1900, pp. 76, figs. 41*).—The author briefly discusses the life history and habits of diptera which have been reported as parasites of man. A considerable number of species are considered and notes are given on the conditions surrounding the various cases of parasitism. A list of the literature on the subject is appended to the pamphlet.

Egg-laying workers, C. Dadant (*Rev. Internat. Apicult., 23 (1901), No. 11, pp. 220–226*).—The author gives a general discussion, with historical references, on the subject of the conditions under which this phenomenon among working bees is observed.

Armature of the prolegs of the silkworm, E. Verson (*Sull' armatura delle zampe spurie nella larva del filugello. Padua: Tipografia Cooperativa, 1901, pp. 27, pl. 1*).—The author describes in detail the anatomical structures of the prolegs of silkworms, with special reference to the development of the claws or bristles connected with these structures. The results of this anatomical study are discussed in connection with a critical review of the literature on the subject.

FOODS—NUTRITION.

Experiments on the digestibility of butter and certain butter substitutes, H. Wibbens and H. E. Huizenga (*Arch. Physiol. [Pflüger], 83 (1901), No. 10–12, pp. 609–618*).—A comparison was made of the digestibility of butter, margarine, and sana, a butter substitute which, according to the manufacturers, contains no milk fat. A number of the experiments were made with dogs; in others the authors themselves were the subjects. In the latter experiment, the butter or butter substitute was consumed as part of a simple mixed diet for periods of 3 days each. The coefficients of digestibility found in the experiments with men follow:

Coefficients of digestibility of rations containing butter and butter substitutes.

	Dry matter.	Protein.	Fat.
	Per cent.	*Per cent.*	*Per cent.*
Subject H:			
Diet containing sana	92.80	80.93	93.79
Diet containing butter	94.31	84.09	96.05
Diet containing margarine	94.22	85.12	96.08
Subject W:			
Diet containing sana	93.08	82.24	95.30
Diet containing butter	96.17	89.71	97.33
Diet containing margarine	94.94	88.65	95.98

The authors point out that there was practically no difference in the digestibility of the rations containing the different sorts of fat. Similar results were obtained in the experiments with dogs.

The comparative digestibility of raw, pasteurized, and cooked milk, C. F. Doane and T. M. Price (*Maryland Sta. Bul. 77, pp. 38, figs. 3*).—The digestibility of milk treated in different ways is discussed in the light of an extended review of the literature of the subject and of opinions which were gathered by interviews and correspondence with physicians in charge of children's hospitals. Digestion experiments with calves are reported on the comparative value of whole milk (raw and pasteurized at different degrees) and skim milk. Special crates were devised to accommodate the calves during the experiments, as well as bags for collecting the feces. The average results follow:

Digestibility of raw, pasteurized, and cooked milk by calves.

	Protein.	Fat.
	Per cent.	*Per cent.*
Whole milk, raw	94.79	96.82
Whole milk, pasteurized at 167° for 10 minutes	92.99	94.27
Whole milk, cooked	87.26	95.40
Skim milk	94.57	....
Whole milk, raw	92.64	96.10
Whole milk, pasteurized at 140° for 30 minutes	92.01	96.61

"It is almost always stated by authorities on such subjects that milk is entirely digestible. Theoretically, perhaps, it is, as it contains none of the material which is recognized as the indigestible part of grains and fodders. In practical work, however, there is found to be a relatively large portion indigestible. In the work recorded in this bulletin the digestibility of the milk fed would average about 93 per cent with the protein and a little higher with the fat, some of the percentages being much lower than this in individual cases. It is likely that had a smaller portion of milk been fed a larger percentage would have been digested, and by reducing the amount to the minimum required to sustain life it is possible that practically all fed would have been utilized in the system. But where sufficient milk is fed to insure substantial growth, nearly one-tenth of the dry substance is undigested."

The following general conclusions were drawn from the tests as a whole:

"Raw milk is more easily digested when fed to calves than either pasteurized or cooked milk. Contrary to theory, cooked milk when fed to the calves used in these experiments caused violent scouring in the majority of trials.

"A majority of physicians in charge of children's hospitals corresponded with favored the use of raw milk for infants when the milk is known to be in perfect condition, but favored pasteurized milk under ordinary conditions. With one exception all the physicians corresponded with discourage the use of cooked or sterilized milk for infant feeding.

"Skim milk was found to be as digestible [by calves] as whole raw milk."

The principles of modern dietetics, and their importance in therapeutics, C. von Noorden (*Internat. Mo., 3 (1901), Nos. 5, pp. 570–589; 6, pp. 679–702*).—The general principles of nutrition are discussed, as well as the progress of this branch of science in recent years and its special application to the treatment of disease.

The value of aroma bacteria for the hygiene of meat, F. Glage (*Ztschr. Fleisch u. Milchhyg., 11 (1901), No. 5, pp. 131–138, fig. 1*).—The occurrence and manner of distribution of aroma bacteria on meat, and related topics, are discussed in the light of the author's investigations.

Meat ration in the Tropics, P. R. Egan (*Sanitarian, 47 (1901), No. 384, pp. 395–399*).—Quoted from the *Boston Medical and Surgical Journal.* The author discusses the amount of meat and fat consumed by the residents of Porto Rico.

Rations during the China relief expedition (*Com. Gen. Subsist. U. S. Army Rpt. 1901, pp. 7–15*).—Considerable information is given regarding the food of the American and foreign troops in the China campaign. Discussing the vegetables available for the troops, the statement is made that the country furnished "a bountiful supply of vegetables, eggplant, green corn, sweet potatoes, beans, lettuce, etc."

The effect of sulphur fumes on flour, F. B. Guthrie (*Agr. Gaz. New South Wales, 11 (1900), No. 7, pp. 588, 589; 12 (1901), No. 6, pp. 715, 716, pls. 2*).—As shown by baking tests, bleaching flour with sulphur fumes injures its quality. In the author's opinion, grain so bleached is unfit for milling.

"It would appear that the action of sulphur fumes on flour is to affect the composition of the gluten. Gluten (moist) exposed similarly to sulphur vapor becomes sticky, forming a soft, gummy mass, which dissolves in water and alcohol to a milky solution. Ordinary gluten is insoluble in water and partly soluble in alcohol, one constituent (glutenin) being insoluble in alcohol, and the second constituent (gliadin) being soluble in alcohol.

"Sulphur fumes apparently attack one of the constituents of gluten—namely, the glutenin—and alter its characteristics. In order to test this, a sample of pure glutenin was exposed in the moist state, under a bell jar, to the fumes of burning sulphur. It very soon lost its coherent nature, became very soft and sticky, and dissolved to a milky solution in water and alcohol, the original gultenin being quite insoluble in either of these liquids."

Composition of flour, R. Hoagland (*Farm Students' Rev., 6 (1901), No. 10, pp. 155, 156*).—The characteristics and composition of the different grades of flour obtained in modern milling are treated of.

Fifteenth Annual Report of the Ohio Dairy and Food Commissioner, J. E. Blackburn (*Ohio Dairy and Food Com. Rpt. 1900, pp. 196*).—This report contains court decisions, prosecutions, and analyses made in accordance with the State Pure Food Law, and related topics. In a number of the analyses the proximate constituents were determined. The materials examined included oleomargarine, milk, vinegar, etc.

Decisions of the department of agriculture on the pure food act of 1895 (*Pennsylvania Dept. Agr. Bul. 80, pp. 19*).—The decisions regarding the State pure-food law are quoted, as well as standards and definitions of food substances.

ANIMAL PRODUCTION.

Concentrated feeding stuffs, L. A. Voorhees and J. P. Street (*New Jersey Stas. Bul. 153, pp. 53*).—In accordance with the State feeding-stuff law, the authors report the results of analyses made during 1901. The feeding stuffs examined include cotton-seed meal, linseed meal, linseed-cake meal, flaxseed meal, Chicago gluten meal, gluten feeds, dried brewers' grains, malt sprouts, wheat bran, ship stuff, hominy meal or feeds, as well as a number of mixed feeds, cereal breakfast food by-products, and condimental feeds. The results are arranged so as to compare the different concentrated feeds, carbohydrate feeds, feeds made from whole grains, and condimental feeds, and are discussed in detail.

The law regulating the sale and analysis of concentrated feeding stuffs in Wisconsin, W. A. Henry (*Wisconsin Sta. Bul. 89, pp. 8*).—The text of the Wisconsin feeding-stuff inspection law is quoted and discussed.

A mechanical ration computer, W. J. Spillman (*Washington Sta. Bul. 48, pp. 7, figs. 2*).—A mechanical device for calculating the amount of nitrogenous and nitrogen-free nutrients in any given ration is described, together with the method of operating it.

Steer feeding, G. H. True (*Arizona Sta. Rpt. 1901, pp. 326, 327*).—Continuing previous work (E. S. R., 12, p. 1074) to determine the comparative merits of feeding alfalfa hay alone and in combination with such materials as sorghum hay and hay from cereal grains, 2 lots of 4 steers each were pastured on alfalfa and fed mixed barley and alfalfa hay in addition. They gained 1.49 and 1.21 lbs., respectively, per head daily in a period of 5 weeks' duration. Lot 1 was then fed alfalfa hay and lot 2 wheat hay in addition to alfalfa pasturage for 9 weeks, the average daily gains per head being 1.28 and 0.83 lbs., respectively. This test and the earlier work are briefly discussed.

"During the 33 weeks [of this and previous tests when] alfalfa only was fed against combinations of alfalfa and other forages, the animals having only alfalfa gained 1.55 lbs. per day, while those receiving the combination gained 1.46 lbs. per day."

Report of grazing and feeding tests. Beef cattle and lambs, R. S. Shaw (*Montana Sta. Bul. 31, pp. 20, pls. 6*).—*Experiments with steers* (pp. 3–10).—The value of alsike pasturage was tested with 12 high-grade Shorthorn and Hereford yearling steers and 7 grade Jersey heifers. The animals grazed on an alsike pasture covering 5.04 acres, which was divided into 2 lots irrigated alternately during the early part of the summer. The test closed the first of October, the steers having been pastured 108 days and the heifers 93 days. The average gain of the steers per head per day was 2.75 lbs., and of the heifers 1.69 lbs. Rating the gains at 4 cts. per pound, the author calculates that there was a cash return of $36.19 per acre. The possible danger from bloating is spoken of. As the author notes, it is claimed by many that alsike is less likely to cause bloating than alfalfa or red clover.

A test to study the possibility of profitably feeding cattle under local conditions is also reported. Thirty-one steers (including those in the previous test) were pastured at the station farm from the first of October until November 13, on 112 acres of stubble, 57 of which were clover. They were then divided into 1 lot of 11 steers and 2 lots of 10 steers each. The selections were made so that lot 1 (steers used in the pasture experiment) showed the largest infusion of beef blood; lot 2, very nearly the same amount; while lot 3 was inferior. The 3 lots were fed for 137 days clover and barley meal, the average daily gain per head being 2, 1.75, and 1.71 lbs., respectively, the corresponding cost of food per pound of gain being 4.85, 5.16, and 5.31 cts. The steers were sold for slaughtering. Considering the test as a whole, the author states that there was a net profit of $3.95.

Lamb-feeding experiments (pp. 11–19).—Continuing earlier work (E. S. R., 12, p. 72) 3 feeding tests with lambs are reported. The comparative advantages of feeding marketable grain of good quality and screenings in addition to clover was tested with 3 lots of 53 lambs each. Lot 1 was fed clover with a grain ration of oats and barley of good quality, lot 2, clover hay and screenings, while lot 3 was fed clover hay only. In the 89 days of the test, which closed February 13, the average gains made by the 3 lots were 24.96, 28.08, and 21.15 lbs., respectively. Lot 1 consumed per head daily 2.9 lbs. clover and 0.56 lb. grain. The corresponding amounts for lot 2 were 2.94 lb. clover and 0.55 lb. screenings, while lot 3 consumed 3.32 lbs. clover. The cost of food per pound of gain in the 3 lots was 4.34, 3.34, and 3.53 cts., respectively. The author's conclusion follows: "It is best to use some grain along with alfalfa or clover in preparing lambs for shipping; a large amount is not necessary because of the quality of our coarse foods. Not more than one-half pound of grain per day throughout a feeding period of 90 days, or the equivalent of this if fed only throughout the latter portion of the period. This will of course only apply in those cases where Montana-grown legumes are used as roughage. Where first-class marketable grains are used it makes the ration too expensive. Good results can be secured from screenings or from cheap or unsalable grains."

The comparative value of clover hay and hay from mixed grains (spring wheat, barley, oats, and peas sown in equal amounts) was tested with 2 lots of 53 lambs each. In the 60 days of the test the lambs fed clover hay gained on an average 14 lbs., those fed the mixed hay 10.68 lbs.; the cost of food per pound of gain in the 2 lots being 3.63 and 4.6 cts., respectively. Greater and more economical gains were made on clover than on hay from cereal grains and peas. The author notes that while the results "represent in a practical way the comparative feeding values of clover and grain hay for fattening lambs, still, they may not represent accurately their relative food values for other classes of stock or from a standpoint of composition. While horses and cattle consume these readily there was much waste from the lambs, consisting of grain stems and vines of peas. The results from the use of the grain hay fell far below our expectations."

The effect of water supply during fattening was tested with 17 lambs fed clover hay, and screenings. They were given water once a day and were compared with lot 2 in the test noted above, receiving a similar ration but having access at all times to water. The average gain made by the lambs receiving a limited amount of water was 21.47 lbs., the cost of pound of gain being 4.51 cts. These lambs consumed per head daily on an average 3.08 lbs. clover and 0.55 lb. screenings. As pointed out by the author, smaller and less economical gains were made when the water supply was limited than was the case with the lot receiving an abundance of water. All the lambs used in the 3 tests were sold for slaughter, yielding a net profit of 30 cts. per head.

Sheep-feeding experiments in Nebraska (second experiment), E. A. BURNETT (*Nebraska Sta. Bul. 71, pp. 16*).—Continuing previous work (E. S. R., 12, p. 875) alfalfa hay and sorghum hay were compared with seven lots of 12 lambs each and three lots of 14. Lots 1 to 6 were fed corn alone or combined with oats or bran in different proportion in addition to alfalfa hay; lots 1 to 3 having shelter and lots 4 to 6 having no shelter. Lots 7 to 9 were fed corn alone, or with oats or bran with sorghum hay in addition. These lots and lot 10, which was fed corn and linseed meal in addition to sorghum hay, had no shelter. After some preliminary feeding with most of the lambs, the test proper covered 14 weeks. The average gain of the lambs in the lots fed alfalfa hay was 33.7 lbs. Of those fed sorghum hay and corn alone or with oats or bran, 20.7 lbs. The average gain of the lot fed sorghum hay, corn, and linseed meal was 26.7 lbs.

The profit per lamb on alfalfa hay was 72 cts. per head and on sorghum 32.8. Lot 1, fed on shelled corn and hay, made the largest total gain, 36.3 lbs. per lamb, and the cheapest gain (costing 3.25 cts. per pound), and ate the least food per pound of gain, namely, 3.53 lbs. of grain and 4.54 lbs. of hay. Lot 9, fed shelled corn, wheat bran, and sorghum hay, made the smallest gain, 18.4 lbs. per lamb, at the greatest cost per pound of gain, 5.7 cts. The largest amount of feed per pound of gain (6.99 lbs. of grain and 8.96 lbs. of hay) was eaten by lot 8, fed shelled corn, oats, and sorghum hay. The author notes that some of the lambs might have been profitably marketed before the close of the test, as they became too heavy for profitable feeding.

"In these experiments, as in the previous year, no marked advantage resulted from feeding bran. The total gains produced were slightly larger on corn and oats than on corn, and the gains on corn and bran were a little smaller than on corn.

"The lambs receiving alfalfa, which made the larger gains during the early part of the experiment, continued to make the greater gains during the last weeks of feeding, so that the difference grew more marked as the feeding continued.

"During the last 2 weeks the lots on sorghum ate very poorly, refusing to consume more than 1½ lbs. of corn per head daily, except in the case of the lot receiving 16 per cent linseed meal with its corn. This lot ate well and made good gains. All lots were thrifty and healthy during the entire experiment.

Comparative tests of the effect of beet molasses and molasses preparations in animal feeding, K. Gerland (*Ber. Physiol. Lab. Landw. Inst. Halle, 3 (1901), No. 15, pp. 1–55*).—The digestibility of beet-molasses feeds was tested with sheep. For purposes of comparison, digestion experiments were also made with alfalfa hay and with sugar, sufficient asparagin being added to the ration containing the latter to approximate the nonalbuminoid nitrogen content of the molasses. All the materials were fed with a basal ration of alfalfa hay, barley straw, palm nut meal, wheat bran, and brewers' grains, the ration being so made up that it contained per 1,000 kg. live weight, about 28 kg. dry matter, 2.4 kg. digestible protein, 0.8 kg. digestible fat, and 13 kg. nitrogen-free extract. The digestibility of the basal ration was also determined. The digestion experiments each covered a period of 10 days and were preceded by a preliminary period of like duration. The food, urine, and feces were analyzed. On the basis of the values obtained for the basil ration and the assumption that molasses being liquid is entirely digested, the author calculated the digestibility of the basal portion of the ration when fed with molasses and sugar to determine whether the digestibility of other feeding stuffs was increased or diminished by adding molasses to the ration. The coefficients of digestibility and these calculated results follow:

Digestibility of molasses and molasses feeds by sheep.

[a] Figures for one animal only.

The data for the study of the metabolism of nitrogen are reported. As shown by the average results, there was a gain of nitrogen in every experiment, ranging from 0.034 gm. on the basal ration to 0.206 gm. on the molasses-maize germ ration. The gains in weight ranged from 0.3 kg. per day on the basal ration to 0.8 kg. per day on the sugar ration.

The principal conclusions reached follow: With the exception of the cocoa-shell mixture, the molasses and molasses feeds were readily eaten. Unfavorable results were not observed when 4 kg. molasses per 1,000 kg. live weight was fed, but were noticed if the amount was increased to 4.8 to 5 kg. Feeding molasses, as in the above experiments, is profitable when the molasses is worth 87½ cts. per 100 kg. When molasses was fed a depression in the digestibility of the other feeding stuffs was noticed, which was about the same in all the tests. As regards cost, the ration containing the unmixed molasses was the cheapest; that containing beet-chip molasses the most expensive. The results obtained when sugar was fed were practically the same as with the rations containing molasses. It may be said, therefore, that the molasses did not have a specific effect. As regards cost, the sugar ration was more expensive than the molasses rations.

Sheep-feeding experiments, J. WITHYCOMBE (*Oregon Sta. Rpt. 1901, p. 22*).—The comparative merits of feeding sheep under shelter and in the open were tested with 2 lots of 6 lambs each. The rations, which are not described, were the same for both lots, and, the author states, were practically equal in quantity, except that somewhat more was wasted by the lot having shelter. In 11 weeks the lot fed in the open gained 155 lbs. and the lot fed under shelter 149 lbs. The 2 lots were then shorn, producing 21 and 27.75 lbs. wool, respectively. Ten lbs. of wool from each lot was tub-washed and dried, yielding 7.75 and 8 lbs., respectively. Brief notes are also made regarding a feeding experiment with steers which was regarded as unsatisfactory.

Spelt vs. barley, E. C. CHILCOTT and W. T. THORNBER (*South Dakota Sta. Bul. 71, pp. 94*).—During a 2 weeks' preliminary period, 24 lambs fed brome-grass hay and spelt and barley (1:1) *ad libitum*, made a total gain of 53 lbs., consuming 2 lbs. of grain per pound of gain. The lambs were then divided into 2 lots of 12 each. For 15 weeks lot 1 was fed unground spelt, and lot 2 unground barley, in addition to brome-grass hay. The average daily gain per head per week was 1.67 and 2.53 lbs., respectively, the grain consumed per pound of gain being 7.47 and 5.09 lbs. There was a calculated profit per lamb in the 2 lots of 44 and 92 cts., respectively. According to the authors' calculation, spelt was worth for feeding 40.68 cts. per bu. and barley 54.72 cts.

"It should be constantly borne in mind that the results obtained in this experiment apply to these grains only when fed as a single grain ration and fed whole, and should not be used without modification in determining the value of these grains when used as a part of the ration together with other grains. Nor can we predict what the results would have been if both grains had been ground. We believe, however, that it is perfectly safe to assume that in no case will spelt be found superior to barley, even when fed with other grains."

At the close of the test proper the rations previously fed were continued for 5 weeks, with the object of determining whether, as is sometimes claimed, unshorn sheep fed to about the limit of profitable gain may be shorn and fed longer to advantage. Shortly after the beginning of the supplementary period the sheep were shorn, the total fleece of the 2 lots weighing 79 and 80½ lbs., respectively. The total gains made by the 2 lots in the supplementary period were 7.5 and 6 lbs., respectively, the total grain fed 487 and 526 lbs.

"These sheep had undoubtedly been fed up to the limit before they were shorn, and the effect of the shearing . . . was entirely insufficient to materially effect their ability to lay on more flesh at a profit, or in some instances to retain what they had already acquired. What the effect would have been had this shearing been done earlier, before they had reached the limit of profitable feeding, we can not of course determine from this experiment, nor can we say what the effect would have been had the grain ration been changed. Enough has been learned from this experiment to show that feeders should be very cautious about attempting to get profitable gains from sheep that have nearly quite reached the limit of profitable feeding, or are 'finished' by simply taking their fleeces off, believing, as some feeders claim, that this will give them a new lease of life."

Pig-feeding experiments, J. WITHYCOMBE (*Oregon Sta. Rpt. 1901, pp. 22, 23*).—Three feeding tests with pigs are briefly reported. In 3 months 12 pigs having access to 0.16 acre of clover and fed in addition 317 lbs. of shorts and 1,276 lbs. of skim milk, made a gain of 253 lbs. In 6 weeks, 10 pigs on an acre of June-sown rape and receiving no grain ration gained 154 lbs.

A comparison of boiled clover and clover silage was made with 2 lots of 3 pigs each, all from the same litter. In 122 days lot 1 consumed 619 lbs. boiled clover, equivalent to 551 lbs. dry matter, and lot 2 consumed 2,032 lbs. clover silage, equivalent to 488 lbs. dry matter. In addition, each lot was given 488 lbs. of wheat and barley chop, 1:1. The gains made by the 2 lots were 154.5 and 128 lbs., respectively. The pigs were then rearranged to form 2 uniform lots of 3 animals each. Lot 1 was fed cooked wheat and barley chop and lot 2 the same materials dry. In 3 months each lot ate 1,834 lbs. of chop and 1,800 lbs. skim milk. The total gains were 328 and 470 lbs., respectively.

Soft pork; an investigation into its character and causes, F. T. SHUTT (*Canada Cent. Expt. Farm Bul. 38, pp. 47, pls. 3*).—The nature of soft pork is discussed and analytical data, noted from another source (E. S. R., 12, p. 581) are quoted. Chemical studies were also made of immature or unripe pork from pigs recently weaned. This pork contained a higher percentage of olein than firm pork.

"It seems probable that the fat of all young pigs contains a large amount of olein, and is consequently more or less soft. From this and subsequent work we are inclined to think that age and maturity or ripeness are factors of importance toward a 'firm' fat. [When the same ration was fed to mature and immature pigs] the fat of [the latter] invariably possesses a larger percentage of olein than that of the remainder of the pigs on the same ration, which were not slaughtered until they had reached a live weight of 180 to 200 lbs."

The author believes that the olein content furnishes the most reliable indication of relative firmness. Pork containing 68 per cent of olein or less is rated as "very firm;" that containing between 68 and 71 per cent, "firm;" between 71 and 73 per cent, "moderately firm;" between 73 and 75 per cent, "soft," and over 75 per cent, "very soft." These ratings correspond to the following factory ratings: Very firm, from 85 to 100 points; firm, 75 to 85; moderately firm, 70 to 75; soft, 50 to 70; and very soft, less than 50 points.

Two series of feeding tests are reported. In the first series the feeding stuffs used were corn, oats, barley, shorts, beans, peas, clover, and mangels, alone or in combination. The grains were fed whole or ground and the feeds dry, soaked or cooked. In one test the pigs were pastured on clover. The pork rating highest was produced on a ration of soaked oats, peas, and barley (1:1:1), the olein content being 67.2 per cent and the melting point 35.6°. The pork rated lowest was produced on a soaked corn-meal ration. Its olein content was 92.4 per cent and the melting point 27.7°. The more important conclusions follow:

"Of all the grain rations employed, that consisting of equal parts of oats, peas, and barley gave the firmest pork. It may further be added that the fat was deposited evenly and not too thickly, and that this ration gave a very thrifty growth. . . . When half the grain ration . . . consists of corn meal, the resulting pork shows an increased percentage in olein; in other words, a tendency to softness.

"In this ration (half corn meal, half oats, peas, and barley in equal parts) the feeding of it boiled gave a slightly higher olein content, but this is only apparent when the average from the four pens is taken into consideration.

"Considering the effect of feeding the ration of oats, peas, and barley during the first period (to a live weight of 100 lbs.) and corn meal during the finishing period, compared with the reverse of this plan—that is, corn first, followed with oats, peas, and barley—we may conclude that the former gives a firmer pork.

"In both methods mentioned in the preceding paragraph, no marked difference was to be observed from the ration fed dry or previously soaked, though taking an average of the 2 groups on each ration the 'dry' feed gave a somewhat higher olein content.

"When . . . corn meal formed half the first period ration, and the whole of the second period ration, the resulting pork was somewhat softer than from that of any of the rations already discussed. We conclude that the longer the period during which the corn is fed as a large proportion of the ration, the softer will be the pork.

"Beans produce a soft and inferior pork. The growth of the pigs so fed was poor and miserable and the deposition of the fat meager.

"Corn meal fed exclusively as the grain ration, either dry or previously soaked, results in an extremely soft fat, the percentage of olein being considerably higher than from any other ration tested. The pork was of an inferior quality. Here also we noted the miserable growth of the animals, the ration in no sense being an economical one."

In the second series the rations were similar to those in the first, including in addition, skim milk, rape, artichokes, and pumpkins. The pork rating the highest was produced on a ration of corn meal, oats, peas and barley, skim milk, and sugar beets. Its olein content was 66.9, and its melting point 32.3°. The least satisfactory pork was produced on beans, the olein content being 84.9 per cent and the melting point 29.5°.

The author's conclusions follow:

"One great controlling factor in the quality of the pork of finished pigs lies in the character of the food employed. Indian corn and beans tend to softness, *i. e.*, to increase the percentage of olein in the fat. If these grains are used they must be fed judiciously if first-class firm pork is to be produced. If fed in conjunction with skim milk it has been shown that a considerable proportion of Indian corn may be used in the grain ration without injuring the quality of the pork.

"A grain ration consisting of a mixture of oats, peas, and barley, in equal parts, gives a firm pork of excellent quality. Skim milk not only tends to thriftiness and rapid growth, but counteracts in a very marked manner any tendency to softness.

"Rape, pumpkins, artichokes, sugar beets, turnips, and mangels can be fed in conjunction with a good ration without injuring the quality of the pork.

"The fat of very young pigs and animals of unthrifty growth is softer than that of finished pigs that have increased steadily to the finishing weight."

Comparative experiments on the chemical composition of animal fat, V. HENRIQUES and C. HANSEN (*Skand. Arch. Physiol., 11 (1901), No. 3-4, pp. 151-165, figs. 3*).—A chemical examination of the fats of different animals showed a difference between the layer of fat on the surface and that in the interior of the body. The interior of the body is warmer than the surface, and it seemed possible that the temperature at which the fat was stored in the body had an effect on its chemical composition. A test was made with pigs to obtain information on this point. One was kept in a warm room. A second animal was kept in a cold room, but the body was sewed up in a sheepskin to protect it. A third animal was also kept in a cold room, but the body was not protected. The animals were fed for three months a similar ration and the fat then examined. The surface fat of pig No. 3 differed as regards iodin number and solidifying point from that from the other animals. The low temperature, according to the author, caused the formation of surface fat which melted readily and had a comparatively high olein content. On the other hand, the solidifying point of the internal fat of the 3 pigs did not differ greatly. A chemical examination was also made of the fat from different parts of the body of pigs fed barley and maize.

Feeding farm horses, C. W. BURKETT (*New Hampshire Sta. Bul. 82, pp. 27-52*).—Investigations on the proper feeding of farm horses, on the amount of water consumed, and on the cost of feeding are reported, the work covering some 2 years.

In the first series the following five rations were tested: Hay, bran, corn, gluten feed, 5:1:3:3; hay, bran, corn, oats, 5:1:3:4; hay, corn, and bran, 10:8:7; hay, corn, linseed-oil meal, 5:4:2; and hay, cotton-seed meal, bran, and corn, 10:1:2:8. Each of the 5 horses included in the investigation received one of the rations for 1 month, the rations being rotated, so that during the 5 months of the test each horse was fed all the rations. Ration No. 1, which cost on an average 19.3 cts. per day, was regarded as quite satisfactory. It was eaten with relish. One horse lost weight on it, while 2 gained somewhat and 2 remained in equilibrium. Ration No. 2, costing 22.5 cts. per day, was the most expensive of those tested. Three of the horses lost in weight on it, 1 gained, and 1 remained in equilibrium. The oats in the ration proved no more satisfactory than the other concentrated feeding stuffs, either in respect to the animal or the efficiency of the work. Had more been fed to keep the weight constant, it would have materially affected the price of the ration. Ration No. 3, costing 20.4 cts. per day, was relished more than the others. Two of the horses gained, 1 lost, and 2 remained in equilibrium. In the author's opinion this ration was healthful, palatable, and at the same time moderate in cost. Ration No. 4 cost 20 cts. per day. Two of the horses lost somewhat in weight. The others made slight gains or remained in equilibrium. Although the amount of oil meal fed per day was quite large, no bad effects were noticed. Ration No. 5 was the least expensive, costing 17.4 cts. per day. It was also the least bulky of the rations tested. Four of the horses remained in equilibrium or made slight gains, while 1 lost a little in weight. The author regards this ration as the least satisfactory, since none of the animals relished it at first on account of the cotton-seed meal. In this series of tests the amount of work varied from 103 to 240 hours per month.

To further test these rations under similar conditions of climate and work, each was fed to 1 horse for 1 month. The amount of work ranged from 209 to 314 hours. In every case there was a gain in weight, showing, the author believes, that all the rations were satisfactory and suited to the amount of work performed. At the close of this period all the horses were fed the linseed-meal ration for some 6 weeks. For about 9 weeks 3 of the horses were then fed rations Nos. 2, 3, and 5. During about 2 weeks the remaining 2 horses were fed rations Nos. 1 and 4. Their rations were then reversed until the end of the period. In every case the conditions of work were uniform. No marked variations in weight were observed. This, in the author's opinion, shows that abrupt changes in the ration may be made without bad effects, and that "there is no so-called single ration for horses. Any food stuff or combination of food stuffs that furnishes desirable nutrients at least cost should be considered in the preparation of rations."

The comparative value of corn stover and timothy hay and of corn, oats, and bran as part of a ration was tested from January 26 to April 9. The rations fed consisted of 12 lbs. of hay or corn stover alone, or with 14 lbs. of corn, oats, and bran in different mixtures, the most usual one being made up of equal parts of 2 of the grains. Four of the horses gained in weight and 1 remained practically in equilibrium. Although corn stover costs one-third as much as timothy hay, the author believes that it "has a feeding value, when fed either with corn and oats or corn and bran in the proportions it has been here, equal to timothy hay, and also when corn stover or timothy hay furnish the roughage of a ration, oats and corn half and half, and bran and corn half and half, have, generally speaking, equivalent feeding values."

To learn whether it was possible to substitute other grains for oats during a long period in summer feeding, the horses were continued on the grain rations mentioned in the preceding paragraph until October 8, being fed in every case 12 lbs. of timothy hay per head daily. Three of the horses remained practically in equilibrium as regards weight, while 2 gained somewhat. The results show, according to the author, that bran, which is much the cheaper of the two, may be substituted for oats. To test the value of bran and oats for winter feeding, the horses were continued on the same ration until April 29. One horse lost a little; the other gained. "These long periods of both summer and winter feeding show the value of the corn and bran ration for horses. The results evident from these experiments are fully consistent with all that has preceded."

The amount of water consumed was recorded in all these tests. Both the ration consumed and the amount of work performed influence the quantity of water drunk by work horses, although the individuality of the horse has the most marked effect. In the present investigation the quantity of water varied from 25,895 to 32,997 lbs. per year. Following are principal conclusions drawn by the author:

"Any food stuff or combination of food stuffs furnishing the desirable nutriment at least cost should be considered in preparing rations for horses.

"A mixture of bran and corn, half and half, is a good substitute for corn and oats for feeding work horses.

"Corn stover is a good substitute for timothy hay for winter feeding of horses because of its feeding value, the yield per acre, and commercial value.

"A change from a grain mixture, consisting partially of linseed-oil meal, slowly or abruptly, does not cause a decrease in weight in horses if a proper substitute ration is fed.

"The average total cost per year for actual food supply per horse was $74.32.

"The average cost for feed per hour's work done during 2 years was 3.4 cents."

Saturated limewater for the preservation of eggs, F. T. Shutt (*Agr. Jour. Cape Good Hope, 19 (1901), No. 1, pp. 55, 56*).—Directions are given for the use of limewater for preserving eggs.

DAIRY FARMING—DAIRYING.

Investigation in milk production, T. L. Haecker and E. W. Major (*Minnesota Sta. Bul. 71, pp. 265–300*).—Two experiments with dairy cows, previously reported (E. S. R., 12, p. 479), are reviewed with reference to protein consumption. In one experiment of 84 days' duration wheat was compared with barley and corn. The 12 cows used weighed on an average 954 lbs. The amount of dry matter consumed daily per head averaged 24.30 lbs., the nutrients being 2.01 lbs. of protein, 12.03 lbs. of carbohydrates, and 0.53 lb. of fat. Of the protein provided, 0.66 lb. was calculated as the amount needed for maintenance of body, leaving 1.35 lbs. available for milk production. The average daily yield of milk was 26.96 lbs., containing 4.1 per cent of fat. On an average 0.05 lb. of protein (exclusive of that for maintenance) was consumed per pound of milk produced. In the other experiment, which lasted 70 days, prairie hay was compared with timothy hay. The average weight of the 12 cows was 958 lbs. The dry matter consumed daily was 24.51 lbs., the nutrients being 2 lbs. of protein (0.67 lb. for maintenance and 1.33 lbs. for milk production), 12.90 lbs. of carbohydrates, and 0.60 lb. of fat. The yield of milk was 25.23 lbs. and the fat content 4.07 per cent. The protein (exclusive of that for maintenance) consumed per 1 lb. of milk was 0.048 lb.

"Taking the average amount of available protein charged to the cows in the 2 experiments reviewed as a basis, it suggests that an allowance of 0.046 lb. of available protein to a pound of milk of average quality yielded is sufficient to maintain the flow, and by increasing or decreasing this allowance by 0.004 lb. of protein for every 0.5 per cent of increase or decrease in the test of the milk, the ration will be adjusted to the needs of cows giving the various grades of milk. Milk testing 3.85 per cent fat is fixed as the standard average, and a cow giving that grade needs 0.046 lb. of available protein to each pound of milk she yields."

[The author uses the term "available" protein to mean that which he calculates was left for milk production after deducting that necessary for maintenance.—Ed.]

In another series of experiments, here reported for the first time, 4 lots of 4 cows each were fed several different rations during an experiment covering 3 four-week periods. The feeding stuffs, of which analyses are given, were bran, corn meal, gluten meal, oats, barley, fodder corn, silage, and prairie hay. The following table summarizes some of the data:

Summary of results of a feeding experiment with dairy cows.

	Average weight of cows.	Dry matter consumed.	Digestible matter consumed.			Yield of milk.	Fat content of milk.	Protein available for milk production.	Protein for 1 lb. milk.
			Protein.	Carbohydrates.	Fat.

The results are considered as indicating that –

"Cows giving ordinary yields of milk and butter fat do not require the amount of protein called for in the standard rations.

"The amount of milk a cow gives daily and its fat content measures the amount of protein the animal requires over and above what is needed for maintenance.

"There is a limit to the milk and butter fat-producing capacity of a cow at any given time. Feeding more protein than she needs for this production and for her own support is of no advantage.

"The excess of protein, with the corresponding excess of the other nutrients, will tend to cause her to lay on flesh and thereby shrink in milk flow.

"Grains ordinarily grown on the farm fed in conjunction with such roughage as fodder corn, corn silage, timothy, and prairie hay provide ample protein for cows doing ordinary dairy work."

Feeding experiments with dairy cows, J. F. DUGGAR and R. W. CLARK (*Alabama College Sta. Bul. 114, pp. 53–80*).—In 2 experiments, including 5 cows and lasting 8 weeks each, the object was to compare purchased and farm-grown feeds. The purchased ration was composed chiefly of cotton-seed meal and hulls and the farm-grown ration of cotton seed and sorghum hay. The average results of the 2 experiments showed a daily production of milk and butter per cow of 24.3 and 1.19 lbs., respectively, on the purchased ration and 17.53 and 0.93 lbs. on the farm-grown ration. The average cost of food per pound of butter on the 2 rations was, respectively, 15.3 and 10.35 cts., and the daily profit per cow 6.45 and 8.75 cts. The purchased ration was better eaten and more milk and butter were produced, but the profit was much less.

"On account of the larger amounts of food consumed, the cows while receiving the cotton-seed meal ration gained nearly half a pound a day in weight, while the cows eating cotton seed in smaller amounts lost 0.8 lb. per day."

The manure produced during the 16 hours of each day which the cows passed in the barn averaged 48.3 lbs., containing 16.6 lbs. of nitrogen per ton, when the cotton-seed meal ration was fed, and 33.9 lbs., containing 10.7 lbs. of nitrogen per ton, when the cotton-seed ration was fed. The percentages of phosphoric acid and potash in the 2 manures were practically the same. When stabled for the entire 24 hours the amount of manure secured was about double that obtained when the cows were stabled 16 hours per day.

In a test lasting 3 weeks green rye was substituted for the cotton-seed hulls and sorghum used in the above rations, with the result of increasing the yield and decreasing the fat content of the milk, the yield of butter remaining practically the same. Soiling is therefore pointed out as an effective means of reducing the bill for purchased feeds.

A pasture consisting of cowpeas and of corn from which the ears had been harvested was compared with an ordinary pasture of Bermuda grass, carpet grass, Japan clover, etc. When grazed on cowpeas the yield of milk was 15.8 per cent and the yield of butter 9.5 per cent greater than when the cows ran on the mixed pasture. "The value of the product of butter and of the increase in live weight of the cows averaged $4.47 per acre of corn and pea field grazed, after deducting the cost of the cotton-seed meal fed at the same time."

A contribution to the question of the profitability of dairy farming, C. Steinbruck (*Ber. Physiol. Lab. Landw. Inst. Halle, 3 (1901), No. 15, pp. 104–168*).—The author made an extended study of several points bearing upon the feeding of dairy cattle. The principal point investigated was the effect of increased amounts of protein in the ration upon the yield and composition of the milk. The experiments were carried on with 4 cows and covered a number of periods of 10 days each. Besides the amount and the composition of the food, the live weights of the animals were noted and determinations made of the amount and composition of the milk and the resulting manure. A large amount of tabulated data is given, and these are discussed at length, many similar pieces of work being cited. From his experiments and his review of the literature the author draws the following conclusions:

The individual productiveness of cows is the controlling factor in milk production, in comparison with which changes in the feed, within certain limits, are sometimes very inferior. The inferiority of the latter factor naturally varies greatly and can only be determined quantitatively by means of studies on a large number of individuals.

The food when given in amounts in excess of that necessary for the bodily functions and to maintain live weight has but small influence over the milk yield. While such feeding is reflected in the increased richness of the manure, the value of this increase is disproportionate to the cost.

As cows differ in their ability to respond to heavy feeding, this ability must be determined for each individual animal. In this respect adherence to fixed standards may lead to gross error.

The dairy herd, G. H. True (*Arizona Sta. Rpt. 1901, pp. 327–332, figs. 2*).—A monthly record of 6 cows for one year is given, with notes on the management of the herd. Weather conditions interfered with a feeding experiment with sugar beets. Exposure to storm greatly lessened the yield of butter fat, the decrease, however, being much less in the case of cows fed sugar beets on pasture.

Hygiene of cows during gestation, C. Bruner (*Jour. Agricole [Paris], 12 (1901), No. 140, pp. 194, 195*).—The author discusses briefly the feeding and general management of cows during gestation.

Composition of the milk of cows at different stages of the milking, P. Hardy (*Bul. Assoc. Belge Chim., 15 (1901), No. 6, pp. 228, 229; abs. in Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 22, p. 992*).—The fat increases from the beginning to the end of the milking, but, as pointed out by other investigators, the composition of the serum remains constant.

Purification of milk by centrifugal separation, C. H. ECKLES and S. E. BARNES (*Iowa Sta. Bul. 59, pp. 55–59*).—The results of experiments made at different times during the year to determine to what extent the bacterial content of milk is reduced by centrifugal separation, the distribution of bacteria in the skim milk, cream, and separator slime, and the effect of centrifugal separation upon the keeping qualities of the milk are briefly summarized. In 7 experiments determinations were made of the number of bacteria present in milk before separation and in the mixed skim milk and cream after separation. There was an average reduction of about 36 per cent. At the end of 24 hours milk which had been separated contained on an average 0.03 per cent less acid than nonseparated milk. In 8 other experiments the skim milk contained on an average 29 per cent of the number of germs present in the whole milk, the cream 24 per cent, and the separator slime 47 per cent. It is considered that centrifugal separation removes practically all the solid impurities from milk, but improves the keeping qualities of the milk little if any.

Sterilization of milk with hydrogen peroxid, HARRIETTE CHICK (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 20, pp. 705–717*).—A series of experiments were made on this subject, using a 3 per cent solution of the hydrogen peroxid. It was found that 0.2 per cent of the peroxid was sufficient for the complete sterilization of milk, and that the addition of 0.1 per cent sufficed to keep milk sweet for a week or so. It appeared to make no difference with sterilization whether the milk was freshly drawn or whether it had been allowed to stand some time so that fermentation had commenced. The peroxid, however, imparted a disagreeable, stinging taste to the milk, this being noticeable even in as dilute solutions as 1 part of peroxid to 10,000 of milk. The results, therefore, are considered unfavorable to the use of this material in milk for drinking. Small quantities of the superoxid which were decomposed in a short time did not sterilize the milk or preserve it sufficiently for practical purposes. Furthermore, the peroxid seemed to be quite stable in milk, especially in weak solutions, the proportion being a little changed by heating. The material is recommended, however, for the preservation of samples of milk for analysis, since it sterilizes the milk completely and causes no change in any of its constituents. For this purpose about 20 cc. of a 10 per cent solution of the peroxid is recommended per liter of milk, which amount is said to preserve the sample indefinitely.

Further observations upon ropiness in milk and cream, A. R. WARD (*New York Cornell Sta. Bul. 195, pp. 25–39, figs. 2*).—The so-called ropy milk from cows affected with garget is pointed out as entirely different in appearance and causation from ropy milk due to *Bacillus lactis viscosus*. The latter trouble is caused by a species of water bacteria with which the milk becomes infected after it is drawn, and does not make its appearance for 12 hours or more after milking. Reference is made to an earlier investigation of this subject by the author (E. S. R., 11, p. 282), and additional observations on the conditions under which ropiness occurs and means of prevention are reported.

In an investigation of an outbreak occurring during the summer of 1899 it was found by experiments that the utensils, the water in the cooling tank, and the dust in the air of infected rooms were means of disseminating the ropy milk bacteria. While the bacteria were not detected in the ice, this is considered as a possible source of contamination, especially as the bacteria show marked toleration toward cold.

In 1900 another creamery in the locality where the first outbreak was observed in 1898 encountered severe trouble from ropy milk. The utensils were thoroughly sterilized, the floor of the milk room was disinfected with a 5 per cent solution of sulphuric acid, and the water tank was disinfected by the addition of 1 oz. of potassium bichromate to each cubic foot of water. This method was effectual in getting rid of the trouble. The conclusion is drawn that with proper cleanliness of utensils, disinfection of the floor, and extra care to prevent contamination by water, ropy milk may be prevented.

Ropiness in milk and cream, A. R. Ward (*Dairy and Produce Rev., 1 (1902), No. 30, pp. 8, 9*).—This is essentially the article noted above.

A bacteriological study of the college creamery milk supply, C. H. Eckles (*Iowa Sta. Bul. 59, pp. 37–49*).—Samples of the mixed milk supplied to the college creamery were taken once a week during one year and subjected to fermentation tests and bacteriological examinations. The results are tabulated and discussed, and summarized as follows:

"The fermentation test shows when milk is in suitable condition for making good butter and cheese.

"This test applied to the milk from the patrons of the college creamery shows a great variation in quality during a year.

"This difference in fermentations is probably due to the conditions under which milk is handled during the different seasons of the year.

"The average quality of butter made under natural conditions corresponds with the quality of milk as shown by these tests and is dependent upon the condition of the milk. The principal reason for the fine quality of butter made in the summer and the poorer quality in winter is this difference in the fermentations in the milk.

"The number of bacteria found in milk as brought to the creamery varies with the temperature, season of the year, etc. In the winter on an average each cubic centimeter contains from 1,000,000 to 5,000,000. In the summer from 15,000,000 to 30,000,000, although these limits may be passed either way. The few bacteria found in milk during the winter makes it possible to control the fermentation to a large extent by the use of starters.

"The acid-producing bacteria are always present in quite large numbers and make up from 25 to 85 per cent and average for the year about 58 per cent of the total number. This class is present in smallest numbers when the quality of the milk is the poorest and in greatest numbers when the milk is the best.

"The class of bacteria (enzym producing) which coagulate milk sweet or dissolve the curd contains most of those injurious to butter making. They are present at all times of the year, but in far greater proportion when the milk is of the poorest quality.

"Bacteria having no visible effect on milk are always present in large numbers and make up from 20 to 55 per cent of the entire number.

"Gelatin liquefiers are almost always present in milk, and in the largest numbers in milk of a poor quality, especially during the winter months.

"Gas-producing germs belong mostly to the *Bacterium ærogenes* type and are found in milk at all seasons, but in far greater number during the hottest weather of summer.

"Milk brought to a factory once in 2 days is not necessarily injured in quality for butter making, and this can not be considered as the chief cause of bad milk and poor butter in winter."

The source of milk supply for towns and cities, A. W. Bitting (*Indiana Sta. Bul. 89, pp, 39–69*).—In a study of the milk supply of the city of Lafayette, Ind., covering one year, the author tested some 700 samples of milk and inspected the various dairy farms in the vicinity. The results of the study are embodied in a general discussion of the production and delivery of milk in cities and descriptions of 29 of the dairies furnishing milk to Lafayette. Topics considered in the discussion include the food value of milk, bacteria in milk, dairy herds, stables, food, water supply, milking, and the cooling and delivery of milk. In comparing methods of delivery it was found that the fat content of the milk delivered by drawing from the bottom of the can varied from 1 to 4.4 per cent, while that delivered by dipping remained uniform at 3.6 per cent. The number of cows in the different herds described varied from 4 to 70 and averaged about 21. The fat content of the milk as determined by from 1 to 9 tests in each case ranged from about 3.1 to 4.3 per cent, and averaged about 3.7 per cent.

New York milk supply, H. D. CHAPIN (*Sanitarian, 47 (1901), No. 385, pp. 481–491*).—A report of the efforts of the commission appointed by the Medical Society of the County of New York in improving the milk supply of the city.

Pasteurized bottle milk, C. KNOCH (*Molk. Ztg., 15 (1901), Nos. 38, pp. 677, 678; 39, pp. 697–699, figs. 13*).—A description of methods of pasteurizing milk in bottles, together with illlustrations of apparatus and buildings.

The milk "thermophore," L. VERNEY (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 17–18, pp. 646–653*).—The milk thermophore is an apparatus for keeping milk warm which is intended for infant's use, either pasteurized, sterilized, or in its original condition. It consists of a double-walled metal vessel, with a rack for the bottles in the central chamber, and the space between the walls filled with crystallized sodium acetate or similar material. The apparatus is of German manufacture, and has been tested by a number of investigators with somewhat contradictory results. In theory the practice is contrary to the usual rules for pasteurizing milk, which call for the rapid cooling of the milk after pasteurization.

According to the results obtained by the author in the case of raw milk the number of bacteria in the milk decreased in the first 2 to 5 hours of keeping in the thermophore, but increased after 8 or 9 hours to practically the same content as in milk which was not warmed. The bacterial flora of milk was changed by treatment in the thermophore, certain species, among others the peptonizing bacteria, decreasing very noticeably in number. Pathogenic micro-organisms in milk were not killed with certainty after several hours' treatment in a thermophore. The author concludes that there is considerable difference in the efficiency of the apparatus put out by the same company, and that the use of the milk thermophore for children's milk can not be recommended.

The action of the milk thermophore, C. HAGEMANN (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 17–18, pp. 640–645*).—A series of experiments by the author with raw, pasteurized, and boiled milk, and with sterilized milk inoculated with a number of pathogenic germs in general corroborated the antibacterial action of the thermophore as reported by a number of others. He concludes that infant's milk should not be kept in the apparatus beyond about 5 hours, and finds that the apparatus on the market varies considerably in efficiency.

Calculation of creaming and watering in the analysis of milk, LOUÏSE and RIGUIER (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 16, pp. 992–995*).—A series of formulas for calculating the extent to which fat has been removed from milk and water has been added.

The ripening of cream, H. W. CONN and W. M. ESTEN (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 21, pp. 743–752; 22, pp. 769–775*).—The authors here record a series of investigations which have been in progress for 3 years, in which a bacteriological examination was made of the unripened and ripened cream from 2 creameries and 4 private dairies. The object of the work was to determine the types of bacteria which produce the ripening of cream under the normal conditions of a Connecticut dairy. The number of bacteria in the cream collected at different times was determined by count, and an attempt was made to determine the species of bacteria in the ripened cream. The conclusions of the authors in regard to the bacteriological development that occurs during the normal ripening of cream are as follows:

"(1) Milk as it is drawn from the cow contains great quantities of bacteria; most of these are miscellaneous forms of liquefying bacteria and other nonacid species. At the outset the number of acid bacteria is very small.

"(2) All species of bacteria increase during the setting of the milk for the separation of the cream.

"(3) For a few hours the alkaline bacteria, and the others which have here been included under the head of miscellaneous, increase quite rapidly, while the lactic bacteria are hardly evident.

"(4) After about 12 hours the lactic bacteria have increased so much as to be as numerous as the others, and from this time on they continue to increase with great rapidity until a maximum is reached at about 48 hours; after this the number gradually decrease and they finally practically disappear.

"(5) The ripened cream contains prodigious numbers of bacteria, larger numbers than are known in any other natural medium. They are, however, nearly all lactic bacteria.

"(6) After the first 12 hours all species of bacteria, except the two lactic species, decrease in relative numbers and finally absolutely disappear.

"(7) The 2 common species, Nos. 206 [*B. acidi lactici*] and 202 [an extremely minute colony intensely acid], increase regularly from the beginning of experiments until the maximum. No. 208 [*B. lactis ærogenes*] is always present in considerable quantity and during the ripening increases in numbers though not increasing in proportion.

"(8) The cream which is received by a creamery is already half ripened, as indicated by the immense numbers of bacteria it contains. All of the changes which occur in the cream under the influence of the miscellaneous bacteria have already occurred, and the ripening that takes place in the creamery is due wholly, or almost wholly, to the growth of the lactic bacteria.

"(9) A ripened cream is almost a pure culture of acid bacteria, but this does not mean that ripening has been produced by these acid bacteria alone.

"(10) That the lactic bacteria play an important part in the ripening is perfectly evident; that they are the sole cause of the changes occurring in the ripening is not so evident.

"(11) The peculiar flavor of June butter, which is so much desired by the butter maker, is not due to the development of the common lactic bacteria. Butter ripened during the winter months develops the 2 species of lactic bacteria as abundantly and as quickly as does that ripened in June, but the flavor does not make its appearance. In the last 3 experiments recorded the June flavor was very noticeable in the cream, but the development of the acid bacteria, or the 2 species referred to, was practically the same as in all of the previous experiments. The June flavor, therefore, can not be due to these common lactic bacteria.

"(12) To what this June flavor is due we are not as yet satisfied. Whether it will prove to be due to the large growth of miscellaneous bacteria during the first few hours of ripening, or whether it is due to a difference in the chemical nature of the cream, remains for further experiments to decide."

A case of putrid butter, C. H. ECKLES (*Iowa Sta. Bul. 59, pp. 50–54, figs. 2*).—Samples of butter having a strong disagreeable taste and a putrid odor were brought to the station by the manager of a creamery in which the butter was made. In an examination of the butter 3 kinds of bacteria were isolated which produced very bad effects upon milk and were thought to be the cause of the fault. "The principal difference between the spoiled butter and good creamery butter in regard to the bacteria contained was an abnormal number of gelatin liquefiers in the former, which included some forms found to have a very injurious effect on butter." The conclusion was reached that the milk was contaminated in some way before delivery at the factory. The trouble disappeared from the factory after suggestions made by the station as regards cleanliness and pasteurization were followed and after a dry period which was broken by heavy rains about the same time.

Analyses of buttermilk, B. BÖGGILD (*Mälkeritid., 14 (1901), No. 30, pp. 457–463*).—Twenty-seven samples of buttermilk from 12 Danish creameries were analyzed in studying the value of buttermilk for human consumption. A number of the samples had been mixed with water in the churn, some containing nearly 20 per cent extra water. The fat content of the samples ranged from 0.12 to 0.44 per cent, the total solids from 5.66 to 8.88 per cent, albuminoids from 2.03 to 3.16 per cent, and lactic acid from 0.51 to 0.88 per cent. Comparing skim milk and buttermilk, the author concludes that they have about the same food value when the latter has not been diluted with water. Pure buttermilk should contain about 8.5 per cent of solids, 0.2 to 0.3 per cent of fat, and not less than 3 per cent of albuminoids. In good buttermilk a low fat content is accompanied by a high content of total solids.—F. W. WOLL.

An experiment with Tyrogen (Bacillus nobilis), E. VON FREUDENREICH (*Milch Ztg., 30 (1901), Nos. 32, pp. 497–499; 34, pp. 531–533*).—The author made an extended study of the influence of the *Bacillus nobilis* of Adametz in the ripening of cheese. Small cheeses were made from 10 liters of milk, portions of which had been inoculated with pure cultures of various bacteria; some were made without inoculations, and some from pasteurized milk. From a large number of experiments the author regards the *Bacillus nobilis* an undesirable species of bacteria for the ripening of cheese. The cheeses made with this micro-organism were in a great many instances of bitter flavor and undesirable aroma.

Dairy industry in Wisconsin, H. L. RUSSELL (*Wisconsin Sta. Bul. 88, pp. 11*).—The adaptability of different sections of the State to dairying is discussed, and statistics are given showing the total production of butter and cheese, the number of cheese factories, creameries, and combined factories, in each county of the State in 1901, and for comparison the number of factories in various counties of the State in 1896. The total number of cheese factories in 1901 was 1,540, creameries 1,086, and combined factories 71. The data show that "the most rapid development in the dairy industry is now taking place in the north-central and northwestern counties, rather than in the older settled regions to the south. The distinctively dairy belt that was marked in the State 5 years ago is now spreading rapidly to the northward and the westward, and it seems quite probable that the industry will reach as marked development in these portions as it has in the east and south." A wall map showing the distribution of the creameries and cheese factories in the State accompanies the bulletin.

Swedish dairying, 1800–1900, G. LILJHAGEN (*Meddel. K. Landtbr. Styr., 1901, No. 77, pp. 57*).—The report gives an account of the development of the Swedish dairy industry during the past century. Included in the report are methods of cream separation and of butter and cheese making; state and other measures for the advancement of dairying in Sweden; dairy statistics of production, exports, and imports; and a list of Swedish creameries and cheese factories. In 1900 the total number of butter and cheese factories in Sweden was 1,688. Of these, 1,215 were creameries, 287 cheese factories, and 186 combined creameries and cheese factories. The total quantity of milk handled by the factories was 842,280,576 kg. The creameries manufactured 26,114,018 kg. butter, 3,265,734 kg. full-cream cheese, 1,463,370 kg. half-cream, 182,809 kg. quarter-cream, and 2,523,542 kg. skim cheese. The number of butter or cheese factory patrons was 68,947.—F. W. WOLL.

Dairying in France, H. E. ALVORD (*Amer. Agr. (mid. ed.), 68 (1901), No. 24, p. 615.*)

Trade in dairy produce in the British West Indies, W. K. MORRISON (*Chicago Dairy Produce, 8 (1901), No. 55, p. 14*).—A popular discussion of market demands and supplies in the region indicated.

Bibliography of milk, first supplement, 1900, H. DE ROTHSCHILD (*Bibliographia lactaria, premier supplément, 1900. Paris: Octave Doin, 1901, pp. 98*).—This is the first supplement to the very extensive bibliography of milk issued by the author last year (E. S. R., 12, p. 786). The supplement covers the year 1900, and contains a classified list of 1,324 titles.

VETERINARY SCIENCE AND PRACTICE.

Investigations on the theory of bacterial infection, A. RADZIEWSKY (*Ztschr. Hyg. u. Infectionskrank., 37 (1901), No. 1, pp. 1–51, pl. 1*).—The literature on the subject is critically reviewed and especial attention is given in experiments to cholera vibrio, typhus bacillus, *Streptococcus pyogenes*, and the anthrax bacillus. From the experiments recorded in this paper the conclusion is drawn that a fatal bacterial infection involves 2 antagonistic processes—the rapid multiplication of the bacteria and their destruction. The author had already come to a similar conclusion regarding *Bacillus coli*, and believes that the same processes are characteristic of infections by other bacterial organisms. It is believed that the number of bacteria which are produced during the fatal infection is greatly in excess of the estimates which are commonly made. The number of bacteria which are found at any stage of the disease or at the time of death, in the diseased tissues, represents only the few which have escaped destruction during the progress of the disease. The pathogenic bacteria are destroyed in the serum of the infected animal and the organism in nearly every instance is able to immunize itself to some extent against the bacteria. The difference between the fatal and nonfatal infection, in so far as the reaction of the animal organism is concerned, appears in a comparatively late period of the disease and is not to be observed at the beginning of the infection. This difference consists largely in the more pronounced toxic effects which appear in cases of fatal infection.

The physiology of the leucocytes, A. LOMBARD (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 15, pp. 438, 439*).—From previous experiments it was believed to have been demonstrated that the toxic substance in refractory animals was located in the leucocytes. Further experiments were made to determine the influence of atropin and strychnin upon the leucocytes. From these tests it is concluded that hyperleucocytosis is a constant phenomenon after injection with atropin or strychnin. Within certain limits the more refractory the animal and the larger the dose the more pronounced is the process. The experiments were conducted on guinea pigs.

The leucocyte formula in certain experimental infections, C. ACHARD and M. LOEPER (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 16, pp. 486, 487*).—The experiments reported in this article were made on dogs and rabbits which were experimentally inoculated with various pathogenic organisms including glanders, anthrax, and actinomycosis. In all cases a leucocytosis ranging from 15–30 to 1,000 was obtained, during which the polynuclear cells varied from 76 to 94 per 100. This condition was maintained for a time varying from 3 to 6 days, after which the mononuclear elements became more numerous. The leucocyte formula appears to be quite independent of the nature of the pathogenic organism but depends upon the reaction of the animal to the infection.

Immunizing bodies in the organism, J. KLIMOFF (*Ztschr. Hyg. u. Infectionskrank., 37 (1901), No. 1, pp. 120–130*).—A series of experiments was conducted with cultures of anthrax bacillus 6 hours old and of typhus bacillus 24 hours old. The purpose of the experiments was to determine whether the immunity of animals to disease is due to the presence of alexins or similar bodies in the organism, or to osmotic reactions between the animal serum and the pathogenic bacteria. Experiments showed that rabbit serum in a fresh condition exercised a strongly germicide effect upon the anthrax and typhus bacilli. It was also determined by these experiments that the peptone content of the serum was not influenced by heating, and that the presence of peptone could not be assumed to determine the destruction of the bacteria.

The significance of salts for the germicide action of serum, LINGELSHEIM (*Ztschr. Hyg. u. Infectionskrank., 37 (1901), No. 1, pp. 131–172*).—This paper contains a report on an extensive series of experiments with anthrax bacillus and other pathogenic organisms. The experiments indicate that the influence of salts in increasing the germicidal action of animal serum has been much overestimated. It is believed that the germicidal action of serum does not rest upon an osmotic basis and can not be explained in a quantitative manner. The osmotic pressure of the serum is too small to account for the destruction of bacteria by its action, and when the osmotic pressure of such serum is artificially increased the germicidal action is not influenced proportionately.

The action of the essence of turpentine on virus, V. GALTIER (*Jour. Méd. Vét. et Zootech., 5. ser., 5 (1901), pp. 193–202*).—The author conducted a series of experiments with this substance upon the virus of glanders, tuberculosis, and anthrax. Glanders virus taken from lesions of this disease was sterilized by contact with pure essence of turpentine for a period of 30 hours. The glanders bacillus in culture tubes was sterilized in 49 minutes when turpentine was used in the proportion of 1 cc. to 3 cc. of the culture. The author concludes that essence of turpentine can advantageously be used in treating objects which have become infected with the glanders bacillus.

The tubercle bacillus emulsified in water, was sterilized in 18 hours by the addition of $1\frac{1}{2}$ cc. to 2 cc. of the emulsion. Fresh tubercle bacillus taken from tuberculous lesions in guinea pigs and emulsified in turpentine, was quite rapidly attenuated.

Spore-bearing anthrax cultures, to which turpentine was added at the rate of 6 cc. to 30 cc. of the culture, were considerably attenuated, but not completely sterilized at the end of 6 hours and 30 minutes. Emulsions of fresh anthrax virus treated with turpentine retained their virulence for a considerable time. Experiments showed that when fresh virus or spore-bearing culture was mixed with turpentine before inoculation into experimental animals, the turpentine seemed to have the effect of increasing the resistance of the animal to infection.

A report on the more important Italian publications in general pathology and pathological anatomy during the year 1900, O. BARBACCI (*Centbl. Allg. Path. u. Path. Anat., 12 (1901), No. 8–9, pp. 321–393*).—Italian literature on pathology of man and animals for the year 1900 is classified and briefly abstracted.

Serum diagnosis in tuberculosis, E. ROMBERG (*Deut. Med. Wchnschr., 27 (1901), No. 18, pp. 273–277*).—Experiments were made according to the method proposed by Arloing and Courmant for diagnosing tuberculosis, from the presence of a high agglutinizing power in the serum of suspected animals. The literature of the subject is discussed by the author in a critical manner, and the conclusion is reached that while the method is fairly reliable, there are many serious obstacles in the way of its general application in the manner which was first proposed. The difficulty of obtaining a sufficient amount of cultures is considered very great. In experiments for the purpose of obviating these difficulties the author found that suitable material could be obtained in large quantities and preserved for considerable time by killing tubercle bacilli, pulverizing them and emulsifying them in alkaline water. The best results were obtained when an emulsion was made by maintaining dried pulverized tubercle bacilli at a temperature of 37° C. in a $\frac{1}{2}$ per cent solution of soda lye in the proportion of 1 liter to 10 gm. of the bacilli. In experiments with this material it was found that the serum of tuberculous animals had the same curative action upon the emulsified tubercle bacilli as upon the living bacilli. It was also found that human blood serum would agglutinate the emulsion.

The elimination of tuberculosis from the dairy herd at St. Helena, C. J. POUND (*Queensland Agr. Jour., 8 (1901), No. 4, pp. 303–305, pls. 2*).—When first tested it was found that in the dairy herd at St. Helena 9 out of the 68 animals reacted. Four of the tuberculous cows were later used for breeding purposes and their calves were fed on tuberculous milk after it had been sterilized. When 4 weeks old the calves were tested with tuberculin without a reaction in any case. During 16 months after the first test the cows were subjected to the tuberculin test on four different occasions without responding. A careful post-mortem examination was made on each of these animals with the result that they were found to be tuberculous.

Tuberculosis in horses, Rabe (*Ztschr. Fleisch. u. Milchyg., 11 (1901), No. 8, pp. 242, 243*).—Detailed notes are given on the symptoms and the post-mortem findings in cases of tuberculosis in the horse.

Anthrax infection, L. Heim (*Arch. Hyg., 40 (1901), No. 1, pp. 55–62*).—The author observed that in preparations of anthrax bacilli stained with Löffler's methalyne blue, a capsule or membrane was differentiated in color from the remainder of the bacilli. The color of the capsule when stained by this method was a clear rose. This behavior of the anthrax bacilli was made use of in differential diagnosis between anthrax and other diseases and in making a diagnosis in suspected cases of anthrax. When this method is applied, rose-colored patches are seen in blood and in exudations which do not contain pus. In diseased tissue which contain the organisms of hog cholera, fowl cholera, and bubonic plague the rose color was not observed after the stain had been applied, and the author believes that this staining procedure offers a reliable method for diagnosing anthrax in diseased tissues.

Experiments on the curative action of anthrax serum, A. Sclavo (*Berlin. Klin. Wchnschr., 38 (1901), No. 18, pp. 481–484*.—The author first obtained satisfactory results with a curative anthrax serum from experiments on rabbits and sheep. From the sheep a serum was obtained which completely protected the rabbits against anthrax, although they had been inoculated 12 hours previously with an anthrax culture containing spores. It was found that different sheep reacted very differently to the preliminary treatment designed for the protection of the curative serum. In many cases, even when the doses of attenuated cultures were gradually increased to large size and were continued for a long time, these sheep possessed very weak protective power. The difference in the strength of the serum obtained by this method did not depend on the age, breed, or sex of the sheep, but appeared to be a peculiarity of the individual sheep. In some of the sheep which had been immunized against anthrax the author administered pilocarpin in order to determine whether the protective properties of the serum could be strengthened in that manner.

A study of actinomycosis, V. E. Mertens (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 16, pp. 649–654*).—Since several authors had classified actinomyces into 2 species, of which one was supposed to be virulent and the other not, and one aerobic and the other anaerobic, a special study of the matter was taken up by the author for the purpose of gaining new evidence on this point. Material containing the actinomyces organism was subjected to different conditions until from the original material which came from one source the 2 suggested species were obtained. The organism at the beginning of the experiments was growing at a temperature of 37° C., and was disposed to be anaerobic, but it was found possible to obtain aerobic actinomyces from this source which developed readily at much lower temperatures. The author made experiments on animals, by which it was determined that both forms of the actinomyces were pathogenic, although the anaerobic form seemed to possess the greater virulence. It is believed from these experiments that there is but one species of actinomyces.

Some results in the treatment of milk fever by the method of Schmidt-Kolding, I. A. Eiler (*Berlin. Tierärztl. Wchnschr., 1901, No. 17, pp. 261, 262*).—In this article statistics are brought together in 803 cases of milk fever which were treated with potassium iodid. Of the 803 cases, 615, or 76.6 per cent, recovered completely, while the others were slaughtered or died. The crisis of the disease in 350 cases came after 24 hours and in 68 cases after the second or third day. The body temperature at the outbreak of the disease was usually between 37 and 38.5° C., but varied from 36.4 to 41.5° C. As a rule but one dose was given, and this varied from 5 to 12 gm.

The treatment of milk fever by intravenous injection of potassium iodid,

W. WESSEL (*Berlin. Thierärztl. Wchnschr., 1901, No. 19, p. 287*).—A solution of potassium iodid was made containing 10 grams in 2 liters of water. This amount was injected into the milk vein or jugular vein, according to the position of the cow, the milk vein being chosen when the cow was unable to stand. Good results are reported from this treatment by the author, and it is believed that it possesses certain advantages over the usual method of making an infusion directly into the udder.

Lungworms in a large herd, N. O. LARSEN (*Maanedsskr. Dyrlæger, 12 (1901), No. 11, pp. 427–430*).—The author reports the outbreak of this disease among a herd of cattle, of which 43 were affected. The disease was due to the presence of *Strongylus micrurus* in the lungs. After post-mortem examinations of calves which had died of the disease, the remaining animals were treated 3 times daily with the fumes from a mixture of turpentine oil and creolin in equal parts. Of the 43 animals which were affected 9 died and the others recovered slowly.

Treatment of lungworm disease of cattle by intratracheal injection of a carbolic-acid solution, W. WESSEL (*Berlin. Thierärztl. Wchnschr., 1901, No. 16, pp. 249–252*).—An outbreak of this disease occurred among a number of young cattle which had been grazing on a low, wet pasture and had begun to show a considerable loss of flesh in August. The symptoms indicated the presence of lungworms and 20 gm. of a 1 per cent solution of carbolic acid was injected into the trachea of each animal. Considerable improvement was noticed in the breathing of the animals after 2 days, and coughing was much less pronounced. Of the 8 animals which were affected, 7 ultimately recovered. Similar results were obtained from an application of the same treatment in other cases of this disease.

Lungworms in sheep and the successful treatment, PETERS (*Ztschr. Fleisch u. Milchyg., 11 (1901), No. 8, pp. 239–241*).—Brief notes are given on a serious outbreak of lung and stomach worms which have been observed in recent years. An outbreak of *Strongylus contortus* occurred in a herd of 400 lambs, and the worms were found in abundance in the first stomach and also in the digestive stomach. As a treatment the author used picro-nitrate of potash. The salt is not easily soluble, and after dissolving 0.2 gm. in 100 gm. of water, ½ of this quantity was given to each lamb as a total dose. On the same estate an outbreak of lungworms occurred later and the author treated the disease by the same method. Five gm. of the solution made by dissolving 0.2 gm. of picro-nitrate of potash in 100 gm. of water was injected into the trachea of each sheep. Very satisfactory results were obtained from the use of this chemical. The owner of the sheep administered the same remedy by way of the mouth for lungworms, with favorable results. The lungworm disease of cattle has also been successfully treated in the same way.

Diagnosis of sheep scab, F. W. GARNETT (*Vet. Jour., 52 (1901), No. 311, pp. 262–265, pl. 1*).—In making inspection for sheep scab it was found necessary to adopt a convenient and reliable method which could be readily applied in all cases. The author believes that external symptoms which may be recognized by the naked eye are not entirely trustworthy, and relies upon microscopic examination in all cases. For this purpose no attention should be given to the tissue in the center of a scabby area, but a small tuft of wool should be cut from the healthy skin on the edge of the scabby area. If living mites are present at all, they will be found in considerable numbers on such wool.

Contributions to the study of Piroplasma equi, LAVARAN (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 14, pp. 385–388, figs. 15*).—This blood parasite is closely related to the organism of Texas fever, and is frequently found in the blood of horses in the Transvaal and other parts of South Africa. Its relationship to malaria of horses is not determined. It is believed, however, by the author, to be one, if not the chief, organism concerned in this disease.

Contagious pneumonia, BUTEL (*Rec. Méd. Vet., Paris, 8. ser., 8 (1901), No. 8, pp. 175–177*).—A general discussion of the symptoms and treatment adopted by Guillemain and Cadix in the treatment of 25 cases of this disease in horses.

Intravenous protective inoculation against pneumonia, KRÜGER (*Berlin. Thierärztl. Wchnschr., 1901, No. 16, p. 250*).—An outbreak of this disease occurred among horses, and the animals were inoculated with 100 gm. of serum on March 18 and 21, and again with the same quantity on April 10. The temperature was taken each morning for a number of days, and it was found that the symptoms of the disease began to disappear after 1 or 2 days. In other outbreaks of the disease animals were inoculated intravenously from 3 to 5 days with from 100 to 200 gm. There were no fatal cases during this treatment. Intravenous inoculation is claimed to possess certain advantages over the subcutaneous method, the chief of which is the more rapid and intensive action of the serum.

Mallein injections in Bavaria, KITT (*Wchnschr. Tierheilk. u. Viehzucht, 45 (1901), No. 18, pp. 205–210*).—Since 1892 mallein has been distributed gratis to veterinarians by the Royal Bavarian Veterinary High School. Reports have been forwarded concerning various tests which have been made with mallein in different parts of the country, and the results make a very satisfactory showing for the reliability of mallein as a test for glanders. It appears from these reports that no case of glanders failed to react to the mallein test and that no horse which was free from glanders gave a typical reaction to the test when twice repeated.

Omphalitis of colts, GOTT (*Berlin. Tierärztl. Wchnschr., 1901, No. 21, p 312*).—The author tried various methods in the treatment of this disease, but had best success with a solution of colloidal silver preparation. In one case 80 gm. of a ½ per cent solution was injected into the jugular vein of a colt for 3 days in succession. The beneficial effect of this treatment was shown after the first day, and the animal recovered.

Omphalitis in colts, H. SOHNLE (*Monatsh. Prakt. Thierh., 12 (1901), No. 8, pp. 337–367*).—The author isolated the organism which is concerned in producing this disease and describes its behavior on various culture media. It is described as a coccus with a capsule and is considered a variety of *Staphylococcus pyogenes aureus*. The organism is pathogenic for mice, rabbits, and guinea-pigs. Inoculation experiments were made on 2 horses, with the result that both died of characteristic symptoms of the disease. The author believes that the infection may be carried for a long period by the mother. It is suggested that since the pathogenic organism is now known, considerable improvement may be hoped for in practical methods of treating this disease.

Influence of atmospheric conditions on colic in horses, CHAUVAIN (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), No. 9, pp. 280–282*).—Observations on large numbers of horses used for military purposes showed quite conclusively that cases of colic are much more frequent during periods of rainy or cloudy weather, with a high temperature.

Filariasis of the suspensory ligaments of the pastern joints in horses, J. PADER (*Arch. Parasit., 4 (1901), No. 1, pp. 58–95, figs. 20*).—The author made a study of affections of the suspensory ligaments in the region of the cannon bone and found that a considerable percentage of these troubles are due to parasitism by *Filaria reticulata*. A detailed account is given of the anatomy of this worm and on the lesions caused by its presence in the tendons. Infested tendons frequently show nodules of various sizes upon their exterior. A change in the color of the tendons is often observed. It is generally believed that infestation by Filaria in these tendons occurs more generally than has previously been suspected. No method of treatment has been devised.

A peculiar skin disease accompanied by internal lesions resembling those of tuberculosis, J. A. W. DOLLAR (*Veterinarian, 74 (1901), No. 881, pp. 219–222, pl. 1*).—A 5-year-old mare, after passing through an attack of pneumonia, was observed to be suffering from a skin disease which was characterized by the development of an extensive swelling on the chest and numerous other tubercles of varying sizes under the skin. The treatment for this affection was ineffectual, and the animal was killed. The post-mortem examination showed numerous white or purple nodules of the size of a pea on the diaphragm and similar nodules in the lungs. A microscopic examination of these nodules revealed the presence of a form of coccus.

The teeth of the horse as affected by age—I, C. McCulloch (*Virginia Sta. Bul. 115, pp. 97–108, figs. 6*).—Brief notes are given on the structure and development of teeth, and on the character of the incisors, canine teeth, and molars.

The teeth of the horse as affected by age—II, C. McCulloch (*Virginia Sta. Bul. 116, pp. 109–126, figs. 17*).—Notes on the appearance of the teeth in horses from time of birth until the age of 5 years.

Animal parasites, J. Withycombe (*Oregon Sta. Rpt. 1901, pp. 23, 24*).—An investigation is made of the extent to which the liver fluke is prevalent in Oregon. From a large flock, nearly all of which was reported as having died from the attacks of this parasite, 7 sheep were secured for examination. Only a few fluke worms were found and it is believed that the loss of sheep was not due to the presence of these parasites. Stomach worms were found in one upon post-mortem examination, and 4 of the animals were given 4 drams of gasoline with 10 drops of carbolic acid in 4 oz. of milk daily for 3 days. As a result they gained rapidly in weight.

The treatment of sarcoptic mange with cresol liniment, Albrecht (*Wchnschr. Thierheilk. u. Viehzucht, 45 (1901), No. 17, pp. 194–198*).—Good success was reported from the use of this liniment in the treatment of mange of dogs and pigs.

AGRICULTURAL ENGINEERING.

Irrigation in India and America, E. H. Pargiter (*Irrig. Age, 15 (1901), Nos. 11, pp. 355–362; 12, pp. 393–400; 16 (1901), Nos. 1, pp. 6–12; 2, pp. 43–48; 3, pp. 79–82*).—The system of irrigation control in India is very clearly explained and compared with that in force in the United States. The management of land and water and the control of colonization are entirely in the hands of the government. The canals are practically all public. The application of irrigation water is regulated by the level of the ground water. The conditions of water supply are peculiarly fortunate in India. Even in dry seasons on the plains the rainfall in the mountains is sufficient to maintain a flow in the streams. This, with the melting of snows at the higher altitudes, gives a continuous and reliable supply. Rotation in the use of water is practiced in times of scarcity. In conclusion, it is claimed that while agricultural development in India under absolute government control has been slow it has been safe, while under private ownership in the United States it has been rapid, but accompanied by conflicts of interest, expensive litigation, and uncertainty of rights.

Irrigation in the West, W. E. Smythe (*Amer. Mo. Rev. of Reviews, 25 (1902), No. 1, pp. 75–80*).—This article discusses a plan of action for the National Government with regard to irrigation.

Current meter and weir discharge comparisons, E. C. Murphy (*Proc. Amer. Soc. Civ. Eng., 27 (1901), No. 7, pp. 798–806, pl. 1, figs. 2*).—This paper gives the results of a series of experiments made at the hydraulic laboratory of Cornell University to test the accuracy of velocity measurements obtained with the current meter used by different methods. The results bring out quite clearly the fact "that the accuracy of the current-meter discharge measurements plays only a comparatively small part in the accuracy of the measurements of stream flow. . . .

"In river gaging it is the accurate measurement of the volume flowing per day and per month that is desired. Single discharge measurement is only one of the factors on which this depends. Daily flow is found from a discharge curve giving the relation between discharge and river stage, and on the daily fluctuations in the stage.

The accuracy of the discharge curve depends on the accuracy of the individual discharge measurements, the permanence of the river bed, the position of the gage, and the accuracy of the gage readings. The accuracy of river-stage fluctuation measurements depends on the kind of instrument used for this purpose, its position, and the frequency and accuracy of the observations."

Hydraulic diagrams for the discharge of conduits and canals, based upon the formula of Ganguillet and Kutter, C. H. SWAN and T. HORTON (*New York: Engineering News Publishing Co., 1899, pp. 43*).

Profiles of rivers in the United States, H. GANNETT (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 44, pp. 100, pls. 11*).

Tests of agricultural machines, M. RINGELMANN (*Mem. Soc. Nat. Agr. France, 139 (1900), pp. 339–365, figs. 10*).—This article discusses the general subject of machine testing and gives descriptions of the machine-testing station at Paris and at the Universal Exposition.

Economics of road construction, H. P. GILLETTE (*New York: Engineering News Publishing Co., 1901, pp. 41, figs. 9*).

Machinery for refrigeration, N. SELFE (*Chicago: H. S. Rich & Co., 1900, pp. 416, figs. 213*).

Refrigerating machinery—its principles and management, A. R. LEASK (*London, 1901, rev. ed., pp. 296, ill.*).

MISCELLANEOUS.

Twelfth Annual Report of Arizona Station, 1901 (*Arizona Sta. Rpt. 1901, pp. 305–342*).—This includes a report of the director containing a general review of the work and publications of the station during the year, notes on the educational value of station work, an account of the date-palm orchard, and a financial statement for the fiscal year ended June 30, 1901; a report of the agriculturist and horticulturist giving brief notes on date-palm culture, tests of field crops, and irrigation and evaporation experiments; an account of experiments in animal industry noted elsewhere; a report of the botanist containing an account of work in range improvement and brief notes on the Australian saltbush, parasitic fungi, economic cacti, etc., and a report of the chemists containing notes on the examination of irrigation waters and analyses of sugar beets.

Annual Report of Oregon Station, 1901 (*Oregon Sta. Rpt. 1901, pp. 19–47*).—This contains a brief report of the director, a financial statement for the fiscal year ended June 30, 1901, and departmental reports reviewing at some length the different lines of station work and giving some of the results obtained during the year.

Annual Report of South Dakota Station, 1901 (*South Dakota Sta. Rpt. 1901, pp. 27–36*).—A brief review of station work during the year by the heads of departments and a financial statement for the fiscal year ended June 30, 1901.

Agriculture in China, C. DENBY (*Forum, 32 (1901), No. 3, pp. 328–340*).—This article is a general discussion on Chinese agriculture. The different crops are briefly treated.

Agriculture in New Zealand, M. MURPHY (*New Zealand Offic. Yearbook 1899, pp. 439–470*).—A statement of the agricultural and pastoral conditions of New Zealand. The production of cereals, root crops, flax, sugar beets, grasses, and leguminous forage crops is noted.

Agricultural education in the higher institutions of France and Algeria (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 21, pp. 517–520*).—The article gives a plan of agricultural instruction recently adopted at the School of Sciences, Algiers.

The national school of agriculture at Grignon, P. DECHAMBRE (*Monde Mod., 1901, No. 74, pp. 196–204, figs. 7*).—The history of this institution is given and the course of instruction and the management of the school are described.

NOTES.

Alabama Canebrake Station.—The work of the station during the present year under the new director will be along the same lines as heretofore, including investigations for the improvement of the impoverished soils of the prairie region; field experiments with cotton, corn, forage crops, fruits, and vegetables; experiments in floriculture, and studies of diseases of plants and animals.

Connecticut State Station.—C. J. Rice, for 18 years in charge of buildings and grounds, has resigned, and William Vietch has been appointed to fill his place.

Connecticut College.—E. H. Lehnert, B. S., D. V. S., has been appointed to the chair of physiology and veterinary science, *vice* N. S. Mayo.

Iowa Station.—The station has inaugurated an interesting and extremely important investigation in the breeding and feeding of cattle, through the financial aid and cooperation of the Union Stock Yards and Transit Company of Chicago. Fifty head of pure-bred and high-grade Galloway heifers have been purchased and are being bred to the Shorthorn bulls Scotland's Crown and Doctor White. Scotland's Crown is a roan Shorthorn bull imported by the college three years ago, and now conceded to be one of the best Shorthorn sires in America. Doctor White is a pure white Shorthorn bull purchased by the station at the recent International Live-stock Exposition at Chicago. This bull has been a prize winner at a number of leading live-stock shows during the past year. The pure-bred Galloway heifers are from such breeders as E. H. White, of Estherville, Iowa; David McCrae, of Guelph, Ontario, and O. H. Swigart, of Champaign, Ill.; and the grades from prominent breeders in Illinois. Some of these cattle were exhibited at the last International Live-stock Exposition at Chicago. In addition to the breeding features of the experiment, a careful record of the cost of production will be kept from birth until the cattle are finished for market, and various methods of feeding will be tested. Some of the cattle produced by this experiment will be retained for further investigation in breeding and feeding. A few pure white Shorthorn heifers are being purchased to be bred to Galloway bulls. This method of breeding is designed to produce steers of the famous blue-gray type and quality, which have been so popular in the leading markets and fat stock shows of Great Britain. It is conceded that this cross produces cattle that have no superiors for the block and for profitable feeding. The cattle produced in this way mature early and are of good form and make a high percentage of edible beef of an exceptionally fine grain and flavor, with an even distribution of fat.

Maine Station.—C. D. Holley, assistant chemist, has resigned to become chemist of the condensed milk company.

Michigan College and Station.—A. C. Bird, secretary of the State board of agriculture and of the college and station, has resigned to take effect May 31. T. A. Farrand has been appointed superintendent of the South Haven substation for fruit. The board has accepted bids and authorized the closing of contracts for the construction of a bacteriological laboratory and a bacteriological stable, to cost about $23,600. The new buildings will be used by both college and station. F. W. Robison has been elected assistant chemist of the station, *vice* L. H. Van Wormer, who resigned to accept the position of assistant analyst in the laboratory of the State Dairy and Food Department, at Lansing.

MINNESOTA COLLEGE AND STATION.—F. L. Washburn, formerly of the Oregon College and Station, and more recently connected with the University of Oregon, has been elected entomologist in the college and station. He will enter upon his new duties in June.

MISSISSIPPI COLLEGE AND STATION.—The recent appropriation of the State legislature is by far the most liberal ever made for the institution. Besides making provision for chairs of geology and mining and of civil and rural engineering, both of which are new, the appropriation carries the following provision for improvements and work: A new building for agriculture and horticulture, scientific departments, library, and museum, $40,000; infirmary building, $10,000; additional equipment for textile school, $13,030; additional equipment for mechanic arts department, $8,300; enlarging capacity of mechanic arts building, $5,000; residence for director of textile school, $1,500; equipment for English, veterinary, preparatory, agricultural, horticultural, and biological departments, $1,900; farmers' institutes for 1902–1903, $6,000; and a branch experiment station at McNeill, $13,000 for the biennial period. This is in the pine woods region where fertilizers are not used and do not pay under present conditions. In addition to fertilizer tests the aim will be to make a thorough test of a great variety of crops, giving much attention to orchard and garden crops. Work with live stock will probably be made a feature. The action of the legislature in appropriating for this branch station is the first substantial recognition on the part of the State of the importance of the work of the experiment station and the value of investigation as a basis for improving agricultural practice.

MISSOURI STATE FRUIT STATION.—T. M. Culver, of Koshkonong, Mo., has been appointed a member of the board of trustees, in place of L. O. Hailey, whose term has expired.

CORNELL UNIVERSITY.—The college of agriculture has announced the following cooperative experiments for the season 1902: Fertilizers—a soil test with nitrogen, phosphoric acid, and potash, singly and in combinations; wheat—tests of fly-resisting varieties, started last fall; beans—tests of standard field sorts; sugar beets—test of varieties and the adaptation of soils; potatoes—tests of varieties and methods of culture; buckwheat—varieties and methods of treating the crop, and alfalfa—a study of the adaptation of the different soils and methods of securing best results. A bill is now before the State legislature appropriating $200,000 for new buildings for the college of agriculture.

NORTH CAROLINA COLLEGE AND STATION.—Alexander Rhodes, assistant horticulturist, has resigned to accept the position of horticulturist at the State Normal School of Georgia, at Athens. B. F. Walton, a former graduate of the college, has been appointed superintendent of the agricultural experimental work of the station.

OHIO UNIVERSITY AND STATION.—Merritt F. Miller, a graduate of the agricultural college of the university, and recently connected with the Bureau of Soils of this Department, has been elected to succeed W. D. Gibbs. Under the bill which recently passed the State legislature providing for the reorganization of the board of control of the station, the governor has appointed an entirely new board, constituted as follows: F. Whittlesey, of Atwater; Alva Agee, of Cheshire; D. D. White, of Castalia; O. E. Bradfute, of Cedarville, and D. L. Sampson, of Cincinnati. The board has organized by the election of Alva Agee as president, O. E. Bradfute as secretary, and D. L. Sampson as treasurer. At a meeting held March 4, C. E. Thorne was reelected director, and the resignation of F. M. Webster was received, to take effect March 31.

RHODE ISLAND STATION.—J. W. Kellogg, assistant chemist in the department of feeds and feeding at the Massachusetts Station, has been appointed assistant chemist of the station, and entered upon his new duties March 15. L. P. Sprague, of the University of Vermont, has been appointed assistant horticulturist of the station, to take effect April 1. J. V. B. Watson, of Wakefield, R. I., has been reappointed a member of the board of managers for the term of five years. The former officers of the board have been reelected. A small glass house has been erected in connection with the remodeled incubator and brooder house, to supply green food to the young chicks which are reared during the winter season.

South Carolina College and Station.—C. E. Chambliss, entomologist, has been temporarily appointed botanist and bacteriologist in addition to his other duties. The new dormitory, with 80 lodging rooms and three recitation rooms, has been completed.

Texas College and Station.—A station council has been organized, consisting of Jefferson Johnson, of the board of trustees, the president of the college, and the director, chemist, and veterinarian of the station. W. C. Martin, assistant station chemist, has been granted a year's leave of absence to study at the Massachusetts Institute of Technology, and his place has been supplied for the year by N. Fraenckel, of New York City. Wilmon Newell, M. S., assistant entomologist at the Ohio Station, has been appointed to a similar position at this station. Plans have been accepted for the chemical and veterinary laboratory building provided for by the last legislature. It will be a two-story brick structure, and provided with the modern conveniences for instruction and laboratory work. A greenhouse, 16 by 42 feet, for the horticultural department of the college and station has been completed.

Utah Station.—The new cattle and sheep barns have been completed at a cost of about $12,000. Experiments with sheep are now under way, and a herd of pure-bred cattle is being purchased at a cost of $4,000.

West Virginia Station.—Gilbert M. John has been appointed assistant horticulturist of the station.

Wyoming Station.—A. C. Jones, of Laramie, has been elected a member of the board of trustees in place of Daniel C. Bacon, deceased. Cooperative work has been planned between the chemical and agricultural divisions of the station, in which digestion experiments will be undertaken with (1) the range grasses as they are found, gathered three or four times a year; (2) grasses growing on fenced area, to determine the yield and digestibility of the growth on the Laramie plains, and (3) grasses and other forage plants grown on the experiment farm with and without irrigation. The effects of small and large amounts of water used in irrigation on the character and value of the grasses will also be studied. Feeding experiments are in progress to compare alfalfa with native hay for sheep, to determine how much alfalfa and straw are needed to maintain horses through the winter, and in substituting alfalfa for wheat bran and native hay for a milch cow. Efforts are being made to provide suitable accommodations for sheep and cattle.

Statistics of Experiment Stations in the United States.—The latest statistics, contained in the annual report to Congress of the Office of Experiment Stations, show that there are now 60 experiment stations in the United States, exclusive of the substations. Of these, 54 receive Federal aid. The total income of the stations during 1901 was $1,231,881.55, of which $720,000 was received from the National Government. The remaining $511,881.55 represents the largest amount ever supplemented by State appropriations, analysis fees, sales of products, etc. To the Federal appropriation should be added $12,000 for the Alaska stations, $10,000 for Hawaii, and $5,000 for Porto Rico, besides the other appropriations to the Office of Experiment Stations for its work in general and the nutrition and irrigation investigations conducted under its supervision. The value of the additions to equipment of the stations during the year was unusually large, over $230,000, in comparison with $167,475 the previous year. These additions were distributed as follows: Buildings, $133,420.77; libraries, $26,303.49; apparatus, $15,309.48; farm implements, $13,085.45; live stock, $18,220.29, and miscellaneous, $25,025.10.

The stations now employ 688 persons in the work of administration and inquiry, as compared with 693 the previous year. There are 52 directors, 146 chemists, 62 agriculturists, 14 animal husbandmen, 78 horticulturists, 21 farm foremen, 31 dairymen, 49 botanists, 48 entomologists, 6 zoologists, 29 veterinarians, 14 meteorologists, 7 biologists, 5 physicists, 5 geologists, 21 mycologists and bacteriologists, 8 irrigation engineers, 12 officers in charge of substations, 29 secretaries and treasurers, 11 librarians, and 40 clerks. Besides these there are 77 persons unclassified, including superintendents of gardens, grounds, and buildings, apiarists, herdsmen, poultrymen, etc. During the year the stations published 445 annual reports and bulletins, as compared with 386 the previous year, which were supplied to over half a million addresses on the regular mailing lists. A larger number of stations than formerly supplemented their regular publications with press bulletins or circulars, issued at irregular intervals.

State appropriations for substations have been made as follows: In Kansas, $3,000 a year for the establishment and maintenance of a substation at the Fort Hays Reservation; in Michigan, $2,000 for the South Haven Fruit Substation and $3,000 for the Chatham Substation; in Minnesota, $11,200 for improvements at the substations, which are maintained by State appropriation; in Texas, an increase of the appropriation for the Beeville Substation from $5,000 to $7,500 for two years and $5,000 per annum for a new substation, which has been located at Troup; in Oregon, $5,000 a year for two years for a substation in eastern Oregon; in Utah, $6,000 for two years to establish a fruit experiment station in southern Utah; in Washington, $11,200 for the substation at Puyallup, including $2,000 for improvements. Alabama has continued State aid to the Canebrake Station, $2,500, and to the Tuskegee Station, $1,500; and Missouri has appropriated $26,525 for buildings and maintenance for the new State Fruit Experiment Station.

With the aid of funds given by the States, buildings have been erected during the past year at a number of the agricultural colleges, which will be used in whole or in part by the experiment stations. Wyoming has just completed a new science hall at a cost of $35,000. The New York State Station has erected a residence for the director and is now expending about $8,500 in remodeling the old residence into an administration building. North Dakota has erected two barns at a cost of $18,000 to replace the barn burned last year. Pennsylvania has finally completed and equipped its calorimeter building. Oregon has a new $3,000 station building; Storrs Agricultural College, a new dairy building; Alabama, a veterinary dissecting building and a new chemical laboratory; Colorado, an insectary; Washington, a greenhouse and insectary; Virginia, a new main barn and a piggery and abattoir; the Missouri State Fruit Experiment Station, a new station building; Kentucky, a barn for curing tobacco; New Jersey, a new barn, and Idaho, a piggery.

Referees of Association of Official Agricultural Chemists.—The executive committee has announced the following list of referees and associates for the year 1902: *Phosphoric acid:* Referee, C. H. Jones, Burlington, Vt.; associate, B. H. Hite, Morgantown, W. Va.—*Potash:* Referee, H. B. McDonnell, College Park, Md.; associate, Charles B. Beistle, State College, Pa.—*Nitrogen, determination of nitrogen:* Referee, Fred W. Morse, Durham, N. H.; associate, Edward B. Holland, Amherst, Mass.—*Separation of nitrogenous bodies:* Referee, L. L. Van Slyke, Geneva, N. Y.; associate, R. Harcourt, Guelph, Ontario.—*Soils:* Referee, F. P. Veitch, Washington, D. C.; associate, C. C. Moore, Washington, D. C.—*Dairy products:* Referee, George W. Cavanaugh, Ithaca, N. Y.; associate, C. A. Browne, jr., State College, Pa.—*Foods and feeding stuffs:* Referee, C. A. Browne, jr., State College, Pa.; associate, F. D. Fuller, Geneva, N. Y.—*Food adulteration:* Referee, W. D. Bigelow, Washington, D. C. (meat and fish, fermented and distilled liquors); associates, L. M. Tolman, Washington, D. C. (fats and oils, dyes); A. McGill, Ottawa, Canada (cereal products); H. W. Wiley, Washington, D. C. (infant and invalid foods); A. E. Leach, Boston, Mass. (saccharine products); L. S. Munson, Washington, D. C. (vegetables—

canned, dried, or otherwise preserved); W. H. Ellis, Toronto, Ontario (tea and coffee); F. T. Harrison, London, Ontario (cocoa); A. L. Winton, New Haven, Conn. (spices and condiments, baking powders and baking-powder chemicals); William Frear, State College, Pa. (vinegar); A. S. Mitchell, Milwaukee, Wis. (flavoring extracts); L. M. Tolman and L. S. Munson, Washington, D. C. (fruit products); W. M. Allen, Raleigh, N. C. (preservatives).—*Tannin:* Referee, William H. Teas, Ridgway, Pa.; associate, George A. Kerr, Damascus, Va.—*Insecticides:* Referee, J. K. Haywood, Washington, D. C.; associate, James Emory, Washington, D. C.—*Sugar:* Referee, G. L. Spencer, Washington, D. C.; associates, L. M. Tolman, Washington, D. C. (optical methods); L. S. Munson, Washington, D. C. (chemical methods); D. S. Davol, Caro, Mich. (special analytical methods used in sugar industry).—*Ash:* Referee, G. S. Fraps, Raleigh, N. C.; associate, F. T. Shutt, Ottawa, Canada.

Rice Experiment Station for Louisiana.—According to a note in *The Tradesman*, the rice convention recently held at Crowley, La., took preliminary steps looking to the establishment of a rice experiment station for southwestern Louisiana. Resolutions were adopted calling attention to the fact that when the experiment stations in Louisiana were established the rice industry was confined to planting along the banks of the Mississippi River, and that the three stations in the State each have their special fields of work and are "none of them favorably located for experiments on rice, especially for prairie rice growing, the development of which has taken gigantic proportions since the establishment of these stations." The present importance of the rice industry is held to make it imperative that scientific research be brought to bear on the many unsolved problems that confront the rice planter—such as irrigation, fertilizing, cultivation, and marketing of the crop, the merits of varieties, acclimation of varieties and improvement by breeding and selection, the diseases and insects affecting the crop, rice weeds and means of exterminating them, rotation of crops, etc. A committee of five persons was appointed to appeal to the next legislature for funds with which to establish and maintain a rice experiment station at some point in the rice belt in southwestern Louisiana.

Personal Mention.—Elwood Mead, irrigation expert in this Office, has gone to California, where he will deliver a course of lectures on irrigation laws and practice. On his return he will visit a number of places along the route to make final arrangements for the field work of the coming season.

C. T. Johnston, assistant in irrigation, has returned from a trip to Egypt, where he has made a study of the irrigation works and management in that country. His trip was a most profitable one, and in addition to securing extensive information on irrigation management and practice he obtained many excellent photographs of irrigation works and typical scenes. Incidentally he visited the Twfikieh School of Agriculture at Gizeh, near Cairo. The school has about 60 pupils, who are natives of the higher classes, and is conducted on a very practical basis. Each pupil has allotted to him a plat of about one-quarter of an acre of land which he carries on himself under supervision, receiving his share of the profit. The instruction is entirely in English. There is a great demand for the graduates of this school as managers of large sugar and cotton plantations, and difficulty is experienced in holding the pupils long enough to complete their course on account of this inducement. The school is maintained by the Egyptian Government, which is now erecting a fine large building and several smaller ones. It is now using an annex to one of Ishmael Pasha's palaces. The school has a farm of about 160 acres which is rented land. A rental of £12 an acre annually, or about $60, is paid for this land, but as it is supplied with water the year round and 3 crops are raised a profit is realized even at this high rental. The water used is all pumped from the Nile by steam and distributed in canals. In addition to the experimental work which the school is carrying on in various phases of cotton and sugar-cane culture, a large number of new fruits, mostly tropical and semitropical, are being tried and considerable work done with forage plants.

Prof. F. Lamson-Scribner, chief of the new bureau of agriculture in the Philippine Islands, sailed for Manila on the transport *McClellan* February 22. He was accompanied by E. D. Merrill, a former assistant in the Division of Agrostology, who has accepted the position of botanist in the new bureau.

Dr. F. A. F. C. Went, professor of botany in the university and director of the Botanic Garden at Utrecht, Holland, recently spent several days at the Agricultural Department at Washington on his return from a six months' trip to the Dutch colonies in the West Indies in the interest of his Government, which is making an effort to improve the agricultural and horticultural conditions of these colonies.

The Royal Bavarian Academy of Science has awarded the Liebig gold medal to Dr. O. Kellner, director of the Möckern Experiment Station, in recognition of his scientific investigations in the nutrition of farm animals and especially the requirements and metabolism of nutrients and energy.

Dr. L. Liebermann, director of the chemical experiment station at Budapest, has been appointed professor of hygiene and director of the hygienic institute in the University of Budapest, *vice* Dr. Josef Fodor, deceased.

Dr. E. Wein, adjunct in the central agricultural experiment station at Munich, has been appointed professor of agricultural chemistry at the Royal Bavarian Academy for Agriculture and Brewing in Weihenstephan, *vice* Professor Stellwaag, deceased. Presumably he will also succeed the latter in charge of the agricultural division of the station at that place. Dr. Henkel succeeds Professor Stellwaag as director of the dairy school.

Prof. C. Kraus, director of the Academy for Agriculture and Brewing at Weihenstephan, has been elected to succeed Prof. E. Wollny at the Technical High School at Munich.

Dr. W. Schneidewind, assistant in the Halle Station, has been selected to succeed the late Dr. Maercker as director of the agricultural chemical station, and Dr. L. Bühring as director of the control station.

Miscellaneous.—The prospectus has been issued of the first session of the Graduate School of Agriculture, to be held at the Ohio State University the coming summer. As previously announced, instruction will be given in three main lines—agronomy, zootechny, and dairying, and a special course will be given in plant and animal breeding. "The course in agronomy will include climatology and soil physics, vegetable physiology, fertilizers, and the culture and management of field crops. The course in zootechny will include the principles of animal form, the breeding and nutrition of domestic animals, and the application of these principles to the choice and management of beef and dairy cattle, sheep, swine, and horses. The course in dairying will include the science of dairying, especially its chemistry and bacteriology, the application of the science in practice, and demonstrations of improved methods of butter and cheese making. The course in plant and animal breeding will deal chiefly with methods of investigation and instruction in this subject and will be so arranged that it can be taken by students in any of the other courses." Instructions will be given by lectures, seminars, and laboratory demonstrations.

The faculty is comprised as follows: President, W. O. Thompson, Ohio State University; dean, A. C. True, Office of Experiment Stations; registrar, T. F. Hunt, Ohio State University, and a corps of thirty experts, selected from the various agricultural colleges and experiment stations, who will act as instructors.

The school is limited to persons who have completed a college course and taken a bachelor's degree, except that admission may be granted to nongraduates who are recommended by the faculties of their colleges as properly qualified. The school will open with inaugural exercises July 7, addresses being delivered by Hon. James Wilson, Secretary of Agriculture; W. M. Liggett, of Minnesota; H. C. White, of Georgia; W. O. Thompson, of Ohio, and A. C. True, dean of the Graduate School of Agriculture. The school will be in session four weeks, closing August 1.

A summer term has been added to the instruction given at the Wisconsin Dairy School. Students are admitted to this course at any time during the spring and summer after March 1, 1902. They are expected to remain at least ten weeks, although they may continue the work longer if desired. No previous experience in dairy work is required for admission to this course, which is intended for beginners or for persons with little practical knowledge of creamery or dairy work. While some lectures will be given, nearly all of the students' time will be occupied in the work of the various departments under the supervision of the instructors. Students will assist in the different factory operations, and learn to operate the various machines used in the manufacturing processes. Quizzes and examinations will be held to determine the progress being made.

A summer school of chemistry and biology, to be held at Wesleyan University, Middletown, Conn., during the month of July, has been announced. The program includes a course of lectures by Prof. W. O. Atwater on methods and results of investigations regarding food and nutrition, a short course in food analysis, a practical course in methods of dietary studies; lectures by Prof. H. W. Conn on bacteria with special reference to hygiene of the house, the dairy, and the farm, and a laboratory course in bacteriology by W. M. Esten. Other laboratory courses in chemistry will be given, if desired.

We note from *Nature* that a memorial tablet is about to be placed in Harpenden Parish Church, bearing the following inscription: "In affectionate memory of Sir John Bennet Lawes, Bart., F. R. S.; born at Rothamsted, December 28, 1814; died at Rothamsted, August 31, 1900. He used his long life and his great knowledge and experience as an agricultural chemist and as a practical and scientific farmer in the pursuit of truth and for the benefit of his fellow-men in his own country and in all parts of the world. This tablet is erected by the parishioners of Harpenden and others who deeply feel his loss as an example and friend."

Nature states that the late Sir J. Henry Gilbert bequeathed the portrait of himself, by his brother, Joseph Gilbert, to the University of Oxford, to be placed in the library of the Sibthorpian professor of rural economy.

Steps have been taken looking to the establishment of a laboratory for the examination of food materials at Vienna, Austria.

At the annual meeting of the Association of Directors and Organizing Secretaries for Technical Education in England, held the latter part of January, Mr. A. Keen, the president, delivered an address dealing with the question of rural education. Among the institutions needed he mentioned that there should be in every large county and in every group of smaller ones a farm school or an agricultural school or college for boys of 15 to 16 years of age and upward, providing a course of instruction for two or three years of a thoroughly practical character. These schools are intended primarily for boys who are to become farm bailiffs, agents, stewards, farmers, or market gardeners, and especially those who have had no suitable means of acquiring at home an intimate knowledge of farm and garden work and general practical experience.

The following in regard to drying beet leaves for feed in Germany is taken from the Consular Reports for February: "A plant for drying the leaves of the sugar beet has been erected near Göttingen. The factory began to be worked at the opening of the beet season and is proving very satisfactory. The fodder obtained is excellent, contains much nutritive property, is very dry, and is eaten readily by cattle. It has also a pleasant smell, similar to that of fresh sweetbread. The Government and agricultural authorities are taking much interest in this invention, which will notably increase the profits of the beet industry."

Vol. XIII. No. 8.

An attempt to bring experimental work more closely home to the German farmer and to teach him to help himself is described in a recent article by Dr. T. Pfeiffer, late of the University and Experiment Station of Jena. Dr. Pfeiffer believes that the individual farmer must, to a far greater extent than has been customary in the past, inform himself regarding the fertilizer requirements of his soil and similar questions by means of properly planned and conducted field experiments; and that individual experimenting furnishes the basis for very important advancement in the practice of rational agriculture. The reason that it is comparatively rare among German farmers is stated to be that the difficulties attending the making of field experiments have been much overestimated, and little has been done to counteract this impression. The farmers, lacking confidence in their ability to conduct experiments properly and draw reliable deductions, need encouragement and guidance, and to have their interest in the subject stimulated. To this end Dr. Pfeiffer suggested offering a system of prizes or premiums for the best conducted field experiments with fertilizers, the idea being that these object lessons carried on by the farmers themselves would broaden their understanding of the methods and lead to a greater amount of individual experimentation.

Dr. Pfeiffer first presented his plan before the Association of German Experiment Stations, at the meeting in 1898, in the form of a resolution expressing the approval of the scheme by the association. At that meeting, and the meeting the following year, the advisability of encouraging farmers to conduct fertilizer experiments, and of offering premiums for careful work, was discussed at much length. Dr. Pfeiffer urged that every carefully made experiment represented considerable labor and expense, and that a pecuniary incentive to do superior work should prove as helpful as the offering of prizes for excellence in animal production. He explained that he had not met with much success in securing the cooperation of farmers with the Jena Station, although attempts had been made to elicit their aid in various lines of experiment. His proposition, however, found very little favor in the association. The difficulties and dangers of such experiments and of the premium feature were emphasized by most of the speakers, and very little faith was expressed in the ability of the farmer to conduct experiments of any value, even to himself. Dr. Pfeiffer's proposition was finally rejected by the association, but a commission was appointed to consider the general subject of cooperative field experiments.

A system of premium experiments was, however, organized in Saxe-Weimar by Dr. Pfeiffer and carried out during the year 1900, the results of which are just published. The plan for the experiments was drawn up by a commission, and an agreement was entered into with the experimenters. The experiments were quite simple in plan and were under the supervision of the Jena Station. Nitrate of soda, Thomas slag meal, and potash salts were used in varying amounts. The premiums consisted of 2 first prizes of 300 marks each (about $75), 5 second prizes of 200 marks (about $50), and 8 third prizes of 100 marks (about $25). Each person awarded a prize was also to receive a handsome diploma. The funds for the prizes were secured from the representatives of the nitrate of soda interests in Berlin, the Union of German and Austrian Thomas Phosphate Manufacturers, and the Kali Syndicate. Dr. Pfeiffer refers to the probable objection to the source of the prizes, but explains that means could not be provided from the State, agricultural organizations, or other source to set the scheme on foot. The conduct of the experiments, the results, and the awarding of the prizes were all in the hands of a commission, upon which the donors of the prizes had no representative.

The original plan contemplated experiments with oats and fodder beets, but the proposition met with such favor that 112 farmers signified their intention of joining in the competition, which was beyond the capacity of the station to properly supervise. It was decided, therefore, to limit the experiments in 1900 to those who had selected fodder beets and to postpone those with oats until the following year, the prizes for which were secured from the same sources. This showing of interest among the farmers was especially gratifying to Dr. Pfeiffer, in view of previous attempts to secure the cooperation of farmers with the Jena Station.

The experiments in 1900 were carried out by 39 farmers, all of whom made returns of their observations during the year and the yields. As it was found impracticable, on account of possible delays from bad weather, etc., for a representative of the commission to be present at the harvest of the crop in each case, the agricultural societies in the localities where experiments were conducted were asked to appoint trustworthy persons who should represent and make returns to the commission. This plan proved entirely satisfactory, drew the societies into the scheme, and intensified the local interest in it.

The season was unfortunately dry and did not bring out the full effects of the different kinds and amounts of fertilizers. The experiments were useful, however, as a matter of instruction to the experimenters in the methods of such work and in arousing wider interest in individual experimentation. They also furnished some lessons in regard to the best plan for the conduct of such competitive trials. The results of the first year are held to be entirely satisfactory in demonstrating the practicability and usefulness of Dr. Pfeiffer's plan. Although he has since severed his connection with the Jena institution and gone to Breslau, it was planned to continue the experiments under the supervision of the agronomist, Professor Edler.

It may be questioned whether the premium feature of this plan is essential to the success of cooperative experiments under American conditions. The value of systematic and carefully supervised experiments by farmers, cooperating with some central agency, is quite widely appreciated in this country, both in their benefit to practical agriculture and from the pecuniary and educational standpoints. The results obtained by the Ontario Agricultural and Experimental Union, the New York Cornell Station, and in several other organized attempts at cooperative experimenting have demonstrated their utility. Such experiments are looked upon mainly as an educational agency—an effective means of inculcating sound principles, teaching correct methods, and encouraging and directing that spirit of inquiry and experiment which is essential to the modern farmer's success. They can be made effective, however, only by close and competent supervision.

A recent contribution to the subject of fertilizer experiments, which is interesting more as an example of reversion to generally discarded notions than as promising any material aid in the solution of the scientific and practical problems involved, is the so-called science of "euphorimetry," as expounded in *La Nature* by L. Cornet, a French writer. He defines the term as the art of measuring the fertility of the soil, and states its object to be to place agriculture in the list of exact sciences, to reduce its data to a scientific system, and to fix definite and positive rules for its practice. Sufficient data are thought to be at hand to make at least a beginning in the direction of laying down a mathematical basis for determining the relation between soil fertility and crop production. The first and principal difficulty is the choice of a type of comparison or scale of measurement. To meet this the author suggests experiments with different fertilizing materials and crops, similar to those made by Varembey with manures about 1843. In these experiments a field is divided into 4 equal parts. One part receives no fertilization, the other parts 10, 20, and 30 loads of manure, respectively. From the product of wheat, oats, rye, barley, etc., on the different plats so treated, the productive capacity of a given amount of manure for each crop is said to be readily calculated. Calling the effect produced by 1,000 kilograms of manure per hectare

1 degree of fertility, a "euphorimetric scale" is constructed, each degree of which corresponds to a definite product of crop. It may be objected, says the author, that the inconstancy of the seasons and the variations of the temperature may overthrow all predictions and destroy all calculations. This, he admits, may modify the importance of a given crop, but he holds that it can not weaken in any way the exactness of the theoretical results that are to be compared; and he explains that whatever may happen, the farmer who puts into his ground fertilizing material of any kind can say with assurance: "Since I have added certain degrees of fertility to the soil over and above what it was capable of producing by its unaided resources, I ought to produce so much wheat, oats, etc. Nature will make these for me; the temperature may sometimes interfere with the running of the machine and some irregularities in the annual crop may result; but it is only a question of time, and it is certain that the calculated degree of fertility will be realized entire."

No one doubts the desirability of reducing agricultural practice to a more scientific basis. But as the study of the subject has progressed it has been clearly shown that agricultural investigation can not be expected to furnish definite and positive "rules for farming," and it is especially surprising that in this day, when so much has been learned about soil fertility and the changes in location and condition which fertilizing materials undergo in the soil, such a theory as that of euphorimetry, which might possibly have passed current at the time when Varembey made his experiments, should be brought forward with any degree of seriousness.

The Russian Meteorological Bureau and the system of agricultural-meteorological stations connected with it are described in an official publication of the Department of Agriculture and Imperial Domains, recently received. This system of institutions for the study of agricultural meteorology was established in 1897. Its object is to bring observations on meteorology and on agricultural phenomena into closer relation, with a view to determining more definitely the effect of various meteorological conditions on crop production. Each meteorological station has connected with it a series of plats, not exceeding 1 deciatine (2.7 acres) each in area, on which various crops are grown. Adjacent to the plats are arranged the meteorological apparatus for measuring the temperature and humidity of the air, intensity of the sunlight, direction and velocity of the wind, etc. On the plats are installed a rain gauge, thermometers for determining the temperature of the soil at the surface and at different depths, and likewise apparatus for determining the humidity of the soil and measuring the snow fall. Phenological observations are made systematically on the crops under cultivation, and a record is kept of the different stages in the development of the plant, of all the work done on the plats, any injuries caused by meteorological or other factors, and the final yields of grain and straw. In addition to these observations some stations study the underground waters, the intensity of the sun's energy, the relation of the atmospheric conditions to cultivation of the soil, and similar matters.

The stations differ in their equipment, and on this basis are divided into two classes. Those of the second class have only the more common apparatus, and their studies are therefore of a more limited character.

The agricultural-meteorological stations are for the most part connected with the experiment stations, experimental fields, and agricultural schools, although some are located on private estates. In addition to the stations there are a large number of "observation plats," which are provided with simpler meteorological apparatus, some having, also, apparatus for the determination of soil moisture.

Early in 1901, when the article was prepared, there were 65 of these agricultural-meteorological stations, 21 of which were of the first class and 44 of the second class, and 113 observation plats, 90 of which were provided with apparatus for studying soil moisture in addition to the atmospheric conditions. The Meteorological Bureau, in addition to its work in agricultural meteorology, is elaborating plans for weather forecasting, although little has been done in that direction as yet.

The list of publications of the Meteorological Bureau includes papers on the practical importance of agricultural meteorology, instructions for making the simplest agricultural-meteorological observations, an article on the relation of the cereal crops to sun spots and meteorological factors, and a review of the observations of the agricultural-meteorological stations of Central Russia, together with a number of more popular publications on the relation of meteorological conditions to crop production.

This is evidently the most extensive and systematic series of institutions for the study of agricultural meteorology which has been inaugurated by any country, and its work will be followed with much interest. If nothing more is done than to work out satisfactory methods and a basis for correlating the meteorological and soil conditions with the production of staple crops, the results will be of widespread importance, and will pave the way for similar studies by the experiment stations in various countries.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Acidimetry of phosphoric acid with the alkaline earths, J. Cavalier (*Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 20–21, pp. 903–905*).—The author reports the results of experiments from which he concludes that phosphoric acid may be determined with sufficient accuracy by titrating with solutions of baryta, strontia, or lime, using as indicator either methyl-orange or paranitrophenol, preferably the former. With baryta water the concentration should not exceed 0.1 gram-molecule per liter. If very great accuracy is required baryta water should be used and phenolphthalein should be employed as indicator, the operation being conducted in such a manner as to give a crystalline precipitate. This may be obtained with solutions of various strengths, either hot or cold. With a concentrated solution the operation is more rapid when the liquid is heated. The change of color in this case is produced by the addition of 1 molecule of barium (BaO) to 1 molecule of phosphoric acid (H_3PO_4). For practical purposes baryta may be replaced by strontia, but only in concentrated solution. It can not be replaced by dilute strontia nor by limewater. When the precipitate is not perfectly crystalline the change of color of phenolphthalein is always progressive and uncertain. Under such conditions this indicator can not be used with baryta and strontia, since the results obtained with it are very variable, depending upon the stirring, dilution, and duration of the experiment, the amount of base required to cause change of color varying from 1 to 1.5 molecules. With lime the amount is higher and more constant. In dilute solutions (0.01 gram-molecule per liter) the change of color is produced quite regularly by the addition of about 1.5 molecules of base.

The determination of phosphoric acid in phosphates, J. A. Muller (*Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 23, pp. 1000–1002*).—For the standardization of the uranium solution used for the volumetric determination of phosphoric acid the author recommends acid sodium ammonium phosphate ($HNaNH_4PO_4.4H_2O$) as much more stable, and thus giving more accurate results than the ordinary crystallized sodium phosphate, which loses water readily. Crystallized dicalcium phosphate is also recommended for the same purpose, and a method for preparing this substance in pure form is described as follows: To a dilute solution of pure calcium chlorid add little by little a dilute cold solution of disodium phosphate until precipitation is complete, collect on a filter, wash, and dry in thin layers at 70° C. Analyses of the product so obtained by the molybdic and citric acid methods are reported. The first method gave 41.45 and 41.38 per cent, the second 41.55 and 41.29 per cent of phosphoric acid. It is claimed that the ammonium magnesium precipitate obtained by the first method contains a little lime that yielded by the second a little molybdic acid. The removal of these by dissolving and reprecipitating is described.

The artificial preparation of monetite (dicalcium phosphate), A. de Schulten (*Bul. Soc. Min., 24 (1901), p. 323; abs. in Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 23, p. 1008*).—This salt in pure and crystalline form is obtained by the slow action of hot nitric acid on a hydrochloric-acid solution of calcium phosphate.

Occlusion of magnesium oxalate by calcium oxalate. Solubility of calcium oxalate, T. W. RICHARDS, C. F. McCAFFREY, and H. BISBEE (*Ztschr. Anorgan. Chem., 28 (1901), pp, 71–89; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 468, II, p. 624; Jour. Amer. Chem. Soc., 23 (1901), No. 12, Rev. Chem., p. 201*).—Investigations are reported which showed that the occlusion of magnesium oxalate was dependent upon the distribution of undissociated magnesium oxalate between the solution and the solid substance, and that as the proportion of undissociated magnesium oxalate in solution was diminished the amount found in the precipitated calcium oxalate was reduced.

"The authors recommend the following process for the separation of calcium from magnesium, in solutions which should not be more than 150 normal with respect to magnesium: To the solution, an amount of ammonium chlorid equivalent to 10 times the amount of magnesium present is added, and sufficient oxalic acid, to which some hydrochloric acid has previously been added, to completely precipitate the calcium. The solution is then boiled, and very dilute ammonia is added in small quantities at a time until the whole is exactly neutral to methyl-orange. A large excess of ammonium oxalate is now added, and the mixture, after standing for 4 hours, is filtered and washed with very dilute ammonium oxalate.

"The solubility of calcium oxalate in pure water (0.0068 gm. per liter at 25°, 0.00955 gm. at 50°, and 0.014 gm. at 95°) is so large as to cause an appreciable error in exact analysis; in ammonium oxalate solution it is very considerably less soluble."

On the determination of perchlorate in nitrate of soda, GRIMM (*Chem. Ind., 24 (1901), p. 476; abs. in Chem. Ztg., 25 (1901), No. 76, p. 275*).—In the method proposed 20 gm. of the nitrate is strongly heated in a platinum, nickel, or iron dish on an asbestos plate, and covered with a large platinum dish, for 1 hour, with 3 gm. of manganese dioxid, the temperature being gradually raised. The difference between the amount of chlorin in the material before and after treatment is taken to represent perchlorate.

Detection of potassium by means of sodium picrate, C. REICHARD (*Ztschr. Analyt. Chem., 40 (1901), pp. 377–384*).—If an excess of a saturated (10 per cent) solution of sodium picrate be added to a solution of potassium chlorid (not weaker than 1 per cent) a precipitate of acicular crystals is formed. Other potassium salts (except carbonate and cyanid) must be of at least a 2 per cent strength. The reaction is not interfered with by sodium salts (except the carbonate), but the solution must be free from ammonium salts and free acids.

Agronometry, A. LONAY (*Bul. Assoc. Belge Chim., 15 (1901), No. 4–5, pp. 186–196; abs. in Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 22, p. 991*).—This is an account mainly of methods followed by the author in the analysis of soils.

The determination of biological arsenic, B. GALLI-VALERIO and C. STRZYZOWSKI (*Pharm. Post, 33 (1900), pp. 637–639, 649–651; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 12, pp. 545, 546*).—Methods of determining minute portions of arsenic contained in organic matter.

A modification of the sulphuric acid test for formaldehyde in milk, A. G. LUEBERT (*Jour. Amer. Chem. Soc., 23 (1901), No. 9, pp. 682, 683*).—In estimating nitrogen in milk by the Kjeldahl method the author noted that in the presence of a small quantity of formaldehyde there was a peculiar violet coloration of the potassium sulphate crystals and the sulphuric acid surrounding them. This led to trials from which the following method was devised for detecting formaldehyde in milk: 5 gm. of coarsely powdered potassium sulphate is placed in a 100 cc. flask, 5 cc. of the suspected milk distributed over it with a pipette, and 10 cc. of sulphuric acid (specific gravity 1.84) carefully poured down the side of the flask, and the whole allowed to stand. If formaldehyde is present, the violet coloration of the potassium sulphate takes place in a few minutes, the color gradually diffusing through the liquid. If no formaldehyde is present, the liquid at once becomes brown, rapidly changing to black. The test is sensitive to 1 part formaldehyde in 250,000 parts of milk.

The preservation and analysis of milk samples, M. A. DUBOIS (*Rev. Internat. Falsif., 14 (1901), No. 2, pp. 42, 43*).—A discussion of preservatives and methods of analysis.

Quantitative estimation of the fat in milk by means of water-free sodium sulphate, O. LE COMTE (*Jour. Pharm. et Chim., 6. ser., 13 (1901), No. 2, pp. 58–60; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 19, p. 897*).

The estimation of volatile fatty acids in butter by the Leffmann-Beam method, H. LÜHRIG (*Molk. Ztg., 15 (1901), No. 30, pp. 525–527*).—From a study of the method the author found that the variations in the amount of sulphuric acid added had but little influence upon the Reichert-Meissl number obtained.

The detection of cocoanut oil in oleomargarin and in butter, W. G. INDEMANS (*Rev. Internat. Falsif., 14 (1901), No. 2, pp. 39–41*).

The adulteration of fatty oils with mineral oils and its detection, E. GOLDBERG (*Farmaz. Gourn., 40 (1901), p. 375; abs. in Chem. Ztg., 25 (1901), No. 50, pp. 191, 192*).—The author quotes a series of analyses of 101 olive oils of which only 19 were unadulterated. To 10 there had been added foreign vegetable oils and to 72 mineral oils. Of 130 samples examined by the author in 1900, 22 were adulterated with vegetable oils and 54 with mineral oils. With the latter, some contained as much as 30 to 50 per cent of mineral oil. The adulterant was generally a Russian Baku naphtha of 300°. The determination of the adulteration in this case depends upon the fact that this mineral oil is not saponified with alkali.

Modification of Milliau's reaction for sesame oil, G. ARMANI (*Ann. Lab. Chim. Gabelle, 4 (1900), pp. 237–248; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 10, p. 461*).—The following modification is given for showing the presence of cotton-seed oil in mixtures without giving a coloration with certain kinds of olive and crucifer oils: Ten gm. of the oil is saponified with alcoholic potash, the alcohol evaporated, the soap dissolved in water and shaken in a separating funnel with 100 cc. ether and 30 cc. of 10 per cent hydrochloric acid. The ethereal solution is washed, the ether evaporated, and the residue dissolved in alcohol which has been purified by treating with potassium hydroxid and redistilling. The alcoholic solution is treated with 1 cc. of 5 per cent silver nitrate solution and immersed in a water bath at 80°.

The Hübl iodin solution, M. KITT (*Chem. Ztg., 25 (1901), No. 50, p. 540*).—A study of the Hübl iodin number by the Wijs method.

Results of the heating of vegetable oils and methods of determining the admixture of other oils, M. TORTELLI and R. RUGGERI (*Monit. Sci., 4. ser., 15 (1901), pp. 365–375; abs. in Chem. Centbl., 1901, II, No. 1, pp. 59, 60*).—Results of trials of various methods.

The use of the refractometer in the analysis of waxes, P. PROSIO (*Staz. Sper. Agr. Ital., 34 (1901), p. 122; abs. in Chem. Ztg., 25 (1901), No. 60, p. 221*).—The author employed the Zeiss refractometer in the examination of pure and adulterated waxes, both white and yellow. The temperature of 64° C. was used in all cases. The refractometer number of the pure waxes fell between 30 and 32, mostly between 30.5 and 31.5, while waxes adulterated with stearin or paraffin fell below 30. The addition of 5 per cent of stearin may be detected, but ceresin only when above 15 per cent is present. With the addition of rosin or carnauba the refractometer number ranged above 32.

Comparative analysis of beets by hot-water digestion and instantaneous diffusion methods, L. S. MARSH (*Beet Sugar Gaz., 3 (1901), No. 7, p. 158*).—The comparison of results with 20 samples showed an average 0.43 per cent higher for hot-water digestion.

Analysis of commercial glucose, determination of cane sugar in the presence of levulose, dextrose, and dextrin, H. PELLET (*Bul. Assoc. Chim. Sucr. et Distill., 18 (1901), No. 10, pp. 769-773*).

The determination of salicylic acid in wine, H. MASTBAUM (*Chem. Ztg., 25 (1901), No. 43, pp. 465-467*).—A description and discussion of methods and results.

Chemical division, New Zealand Department of Agriculture, B. C. ASTON (*New Zealand Dept. Agr. Rpt. 1901, pp. 269-288*).—This is a brief report on the work of the year ended March 31, 1901, including tests of Babcock apparatus; analyses of waters, fertilizers, soils, cream, butter, normal and condensed milk, cocoanut cake, arrowroot, fruit of the New Zealand passion flower (*Passiflora tetrandra*), Paris green and other poisons, sorrel seed, limestones, and miscellaneous materials; and a study of the dry distillation of native woods, the resin acid of the red pine or Rimu (*Dacrydium cupressinum*), alkaloids of Pukatea bark and of Tutu (by T. H. Easterfield).

Chemical division, H. J. WHEELER (*Rhode Island Sta. Rpt. 1901, pp. 257-267*).—This reports briefly on the fertilizer and feeding stuff inspection and other work in progress during the year, enumerates the field experiments, and gives analyses of dried blood, nitrate of soda, sulphate of ammonia, air-slaked lime, potassium carbonate, muriate and sulphate of potash, sodium carbonate and chlorid, acid phosphate, floats, and Damaraland guano.

Progress in the field of agricultural chemistry during 1900, H. G. SÖDERBAUM (*K. Landt. Akad. Handl. Tidskr., 40 (1901), No. 2, pp. 92-108*).

Select methods in food analysis, H. LEFFMANN and W. BEAM (*Philadelphia: P. Blakiston's Son & Co., 1901, VIII+383, pls. 4, figs. 53*).—A summary of analytical methods, adapted to the work of advanced students and practical chemists. The first 70 pages are occupied with general matter relative to specific gravity, boiling, melting, and solidifying points, polarimetry, microscopy, extraction, distillation, sublimation, indicators, etc. The detection of poisonous metals, coloring matters, and preservatives is treated in a short chapter, followed by the special methods, which cover all the principal classes of food materials, such as starch, flours, leavening materials, sugar and confections, fats and oils, milk and dairy products, beverages—alcoholic and nonalcoholic, condiments and spices, and flesh foods. An appendix contains useful tables. In addition to the methods of analysis, the origin and general characteristics of the various products are briefly described, and the usual forms of adulteration given. The volume is a comprehensive and convenient compendium on the subject, in the light of present knowledge.

An apparatus for ash estimations, H. WISLICENUS (*Ztschr. Analyt. Chem., 40 (1901), No. 7, pp. 441-449, figs. 3*).—The described apparatus for incinerating consists of the usual platinum crucible with a specially constructed cover. The air drawn through by an inspirator enters at the outer edge of the cover and passes out through a tube fastened at the center. The tube carrying the escaping gases is cooled by a water jacket, and bulbs are connected for collecting volatile portions of the substance given off. The apparatus is similar to that of Tucker. (E. S. R., 11, p. 506.)

An apparatus for determining fat, H. J. WHEELER and B. L. HARTWELL (*Rhode Island Sta. Rpt. 1901, pp. 268-273, pls. 2; Jour. Amer. Chem. Soc., 23 (1901), No. 5, pp. 338-343, figs. 2*).—An apparatus designed to overcome certain difficulties connected with the Knorr apparatus is figured and fully described. Among the improvements attempted, as summarized, are the following: A simple flask which can readily be cleaned and replaced in the apparatus; a rubber cup carrying the mercury for sealing and at the same time binding the flask to the apparatus; the bending of the tube from which the liquid ether drops so that the ether will fall upon the center of the substance undergoing extraction, and the prolongation of the same tube so that it may support the upper end of the extraction thimble; the collection of the ether in one receptacle at the end of the extraction without disconnecting the apparatus; the maintenance of the ether in a dry condition; and the loss of the least possible amount of ether.

A continuous hydrogen sulphid apparatus, H. Koch (*Chem. Ztg.*, *25* (*1901*), *No. 81*, *pp. 873, 874*, *fig. 1*).

An automatic filter washer, J. M. Pickel (*Jour. Amer. Chem. Soc.*, *23* (*1901*), *No. 8*, *pp. 589–593*, *fig. 1*).—A specially devised apparatus for use in washing water-soluble nitrogen out of mixed commercial fertilizers. The writer also believes it adapted for removing the water-soluble phosphoric acid.

On the measurements of high temperatures, H. Wanner (*Chem. Ztg.*, *25* (*1901*), *No. 93*, *pp. 1029–1031*).

BOTANY.

Report on a botanical survey of the Dismal Swamp region, T. H. Kearney (*U. S. Dept. Agr.*, *Division of Botany, Contributions from the U. S. National Herbarium*, *vol. 5*, *No. 6*, *pp. X+321–585*, *pls. 13*, *figs. 40*, *maps 2*).—A report is given of the botanical survey made during the summer of 1898 of the Dismal Swamp region in southeastern Virginia and adjacent parts of Virginia and North Carolina. The objects of the investigation were twofold: In the first place, it was sought to ascertain in what degree the character of the native vegetation of the region may serve as an indication of the quality and value of soil; and secondly, to make a study of the ecological distribution of the vegetation. The report discusses at considerable length the climate, geography and physiography, geology, soils, plant covering of the region, the affinities of the plants of this region to others, and the relation of the native plant growth to the character of the soil. Anatomical notes are also given of a number of species, showing their particular adaptations to their surroundings. The agricultural crops of the region are mentioned and their production described at some length. The influence of drainage, types of soil, native vegetation, etc., on plant growth is shown, and an attempt is made to outline the regions adapted to different forms of cultivation.

The origin and distribution of the cocoa palm, O. F. Cook (*U. S. Dept. Agr.*, *Division of Botany, Contributions from the U. S. National Herbarium*, *vol. 7*, *No. 2*, *pp. 257–293*).—The author traces the distribution of the cocoa palm throughout the world, quoting the current opinions relating to the origin and distribution of that economic plant. Contrary to the general opinion, the author states that the cocoa palm is not confined to the seashore or sea level, but is known to thrive in elevated inland regions where the soil and temperature conditions are favorable. He believes the original habitat of the cocoa palm is in all probability to be found in the alkaline regions of the Andes of Colombia.

The Cupresseæ, P. Mouillefert (*Rev. Hort.*, *73* (*1901*), *No. 10*, *pp. 231–234*, *figs. 14*).—Under this name the author has grouped a number of the genera which are commonly referred to the order Cupressineæ. The genera which he proposes to be included in this new grouping are Cupressus, Biota, Chamæcyparis, Thuya, Thuyopsis, and Libocedrus. The different genera are characterized, their differences and affinities being shown.

Brazilian stink grass, F. M. Bailey (*Queensland Agr. Jour.*, *9* (*1901*), *No. 2*, *p. 215*, *pl. 1*).—A brief report is given of specimens of grass obtained under this name which is highly recommended as a drought-resisting species. A small quantity of the seed was sown and proved of a vigorous habit of growth, very leafy, and likely to prove a good fodder grass. The grass was identified as *Melinis minutiflora*. It possesses a somewhat peculiar odor, but not of the disagreeable character suggested by its vernacular name. Its drought-resisting qualities are still to be proved.

The mushroom book; a popular guide to the identification and study of our commoner fungi, with special emphasis on the edible varieties, NINA L. MARSHALL (*New York: Doubleday, Page & Co., 1901, pp. 167*).

Studies on the means of dispersal of seeds, M. KRONFELD (*Studien über die Verbreitungsmittel der Pflanzen. Leipsic, 1900, pp. 42, figs. 5; abs. in Bot. Centbl., 87 (1901), No. 2, pp. 58–61*).—Studies are given of seed distribution by wind, especial attention being given Compositæ and Typha.

Plants as water carriers, B. D. HALSTED (*Pop. Sci. Mo., 59 (1901), No. 5, pp. 492–496*).—The author popularly describes the transfer of water through plant tissues.

The transmission of stimuli in plants, B. NEMEC (*Die Reizleitung und die reizleitenden Strukturen bei den Pflanzen. Jena: G. Fischer, 1901, pp. 153, pls. 3, figs. 10; rev. in Nature, 64 (1901), No. 1659, pp. 371, 372*).—The author reviews the previous ideas relative to the transmission of stimuli in plants, and gives an extended account of observations made by himself on this subject. The effects on protoplasm of wounding the sensitive regions of roots and other organs in the main confirm the conclusions of Tangl. The author distinguishes 2 traumatic phases as consequent on such an operation. The first, or primary, response consists in an aggregation of the protoplasm, and it may be of the nucleus also, toward the wounded end of the cell. This effect is propagated with diminishing rapidity in a direction away from the wound, and at a different rate in the different tissues composing the wounded organ. Shortly after this primary manifestation has passed over a cell, recovery follows, to give place to a secondary phenomenon. The protoplasm of the cells in the vicinity of the wounds assumes a more or less gelatinous character, and the vacuoles begin to undergo fusion. This secondary effect is apparently local and does not travel as far or as fast as the primary one.

The author claims to have demonstrated by means of appropriate stains, a continuous fibrillar structure in the cytoplasm. These fibrillæ traverse the cell chiefly in the longitudinal direction, and appear to connect with similar ones in the contiguous cells of the longitudinal series. They are almost always met with in sensitive and motile organs, to which they also appear almost exclusively confined, and the author believes they represent the means whereby stimuli are rendered transmissible.

The respiration of olives and the relation between the respiratory quotient and the formation of oil, C. GERBER (*Jour. Bot. [Paris], 15 (1901), Nos. 1, pp. 9–22; 3, pp. 88–94; 4, pp. 121–136*).—A study was made of the respiratory quotient of olives in the various stages of growth, as affected by variable influences such as temperature, wounding, etc., a preliminary account of which is given in E. S. R., 13, p. 527. According to the author, the growth of the olive may be divided into 3 periods. The first is from the time of fecundation until the pits become hard. During this time the fruits receive mannite from the leaves, storing it as a reserve material, only a small portion being used for the growth of the fruit. During this period the respiratory quotient was represented by 0.92, the volume of oxygen absorbed being in excess of the carbon dioxid given off. Little or no oil is present in the fruits at this time. The second period begins with the hardening of the pits and ends when the fruits are changed to a reddish-violet color. Mannite is still received from the leaves, but the reserve and newly elaborated material is rapidly transformed into oil. The gaseous exchange between the fruits and the atmosphere is influenced by this transformation and the respiratory quotient becomes as high as 1.40. The third period begins with the change of the fruit to a violet color, ending when it is fully ripe and falls from the tree. Mannite is still transported from the leaves to the fruits in small quantity, but is ultimately all transformed into oil. The respiratory quotient falls from the maximum attained in the previous period until an equilibrium is established between the gases. The author establishes the general proposition that fruits and seeds whose reserve of sugar or similar substance is transformed into oil present a respiratory quotient of unity or greater. This respiratory quotient shows the transformation of mannite or of glucose to oil in the fruit or organ which contains it. The studies further showed that temperature, wounding of the fruit, etc., influenced the formation of oil and consequently the respiratory quotient. It is said that in the south of France the reserve material which is transformed into oil is mannite, while probably in more northerly regions it is to be compared with glucose. In this respect there is some variation in the ripening of olives in different regions, but in the formation of acids, alcohol, ethers, etc., the phenomena observed are quite constant.

The influence of alkaloids on the respiration of plants, N. MORKOWINE (*Rev. Gén. Bot., 13 (1901), Nos. 147, pp. 109–126; 148, pp. 177–192; 149, pp. 212–226; 150, pp. 265–275*).—A report is given of an extended series of investigations on the effect of various alkaloids as shown in the respiration of plants. The subjects of the experiments were young shoots and etiolated leaves of *Vicia faba.* This plant was selected on account of its well-known intensity of respiration and the presence of a considerable amount of albuminoids. The leaves and young shoots were arranged in 2 series and placed in a sugar solution, and after remaining in this for 2 or 3 days one lot was removed and placed in a similar solution to which a definite amount of alkaloids had been added. The 2 lots of plants were then placed under identical conditions of light, temperature, etc., and the differences as shown by the respiration determined. The carbon dioxid exhaled by the plants was determined by means of a Pettenkofer apparatus. In the long series of experiments an increased respiration was noticed where the alkaloids were added to the solution, and in most cases an increase was shown in the ash of the plants at the end of the experiment.

The author's experiments further showed that the alkaloids presented toxic influences toward the plants similar to those shown by animal organisms. An important difference, however, is noted in the relative toxic properties. Arranged in order of the most poisonous toward plants the alkaloids were as follows: Quinin, cinchonin, caffein, morphin, cocain, strychnin, atropin, antipyrin, brucin, codein, and pilocarpin. These were not poisonous in dilute solutions except after a considerable exposure. Of all the substances experimented with the hydrochlorate of quinin was the most poisonous.

Poisonous action of mercury on green plants, J. W. DAFERT (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 1, pp. 1–10; abs. in Ann. Agron., 27 (1901), No. 7, pp. 350–352*).—The author has made a study of the action of the fumes of mercury on green plants, using in his experiments wheat, barley, rye, oats, clover, pine, aster, white mustard, and verbena. All the plants studied showed a great sensitiveness to the vapors of mercury, young plants being less resistant than older ones. The poisonous action is manifested by the destruction of the chlorophyll-bearing organs, especially in the young leaves, where it seems to check assimilation. The root system of the plants seems to be affected to a less degree, plants being able to grow in soils containing a considerable quantity of metallic mercury. Humidity favors the action of mercury, especially in herbaceous plants. On account of the frequent use of mercury in various physiological investigations, the author recommends that the surface of the mercury should always be covered by a film of glycerin, which checks the formation of vapor. Water and mineral oils do not seem to be as efficient in this respect as glycerin.

Fixation of metals by cell walls of plants, H. DEVAUX (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 1, pp. 58–60*).—By placing petioles of Aralia and young stems of Sambucus and of cucurbits in solutions containing various metals, after which the stems were examined spectroscopically, the author was able to note the presence in appreciable quantities of potassium, lithium, sodium, calcium, strontium, barium, iron, nickel, cobalt, cadmium, copper, lead, and silver in the cell walls of the plants;

and it is probable, although the reaction was less striking, that manganese, magnesium, and aluminium are similarly taken up. The proportion of the metal fixed by the cell walls is necessarily small, and increasing the strength of the solutions did not augment the amount of the metal observed. The solubility of the various salts did not seem to influence the fixation, nor was the nature of the acid which entered into the compound of any importance. It was also found that metals already fixed by the cell wall could be displaced by other metals when presented in solution.

On the occurrence of organic iron compounds in plants, U. Suzuki (*Bul. Col. Agr. Imp. Univ. Tokyo, 4* (*1901*), *No. 4*, *pp. 260–266*).—A series of experiments are reported in which the form of iron occurring in plants was investigated. The seeds and leaves of *Polygonum tinctorium* and *Indigofera tinctoria* are exceedingly rich in iron, which exists as inorganic salts. Ether, alcohol, and aqueous extracts of the plants showed no traces of iron, and sodium chlorid extracts gave but slight indications of its presence. A dilute alkali extracted a nuclein-like substance which contains the greater part of the iron of the original material. This may be precipitated and the proteids digested, leaving the products containing the iron, which amounts to 0.5 to 1 per cent of the nuclein-like substance. Tests made to isolate the so-called hæmatogen by the methods of Bunge and Stoklasa gave unsatisfactory results, and it is believed that the greater part of the iron in cases under investigation existed in a form different from hæmatogen. The iron compound which the author obtained was partially soluble by artificial pepsin digestion, while hæmatogen does not undergo any change nor is it affected by dilute hydrochloric acid acting for a short time. It is said that a similar iron compound exists in other plants and its distribution seems very wide.

On the distribution of zinc in plants, L. Laband (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, *4* (*1901*), *No. 11*, *pp. 489–492*).—A compilation of the results of analyses of a number of different plants, which show a wide distribution of zinc in different parts of plants and in different kinds of plants.

Contributions to the physiological knowledge of the tea plant, U. Suzuki (*Bul. Col. Agr. Imp. Univ. Tokyo, 4* (*1901*), *No. 4*, *pp. 289–296*).—Studies are reported on the occurrence of thein in different parts of the tea plant, the seeds, leaves, germinating seedlings, etc., being studied. When in a dormant condition the seeds of the tea plant contain no thein, nor do their proteids yield thein by the action of hydrochloric acid. The cotyledons of germinating seedlings contain it to a slight extent, while stems and roots contain a considerable amount, but the most is observed in the leaves, its quantity being nearly proportionate to the development of the leaves. Light seems to have no direct influence upon the formation of thein, since etiolated shoots, as well as those grown in daylight contain it. It is believed that thein is not a product of synthesis but of katabolism. Doubtful traces were observed in the bark of the shrubs, but the dormant buds contain it in considerable quantity.

On the localization of thein in tea leaves, U. Suzuki (*Bul. Col. Agr. Imp. Univ. Tokyo, 4* (*1901*), *No. 4*, *pp. 297, 298*).—Studies are reported in which the attempt is made to localize the thein of the leaves. If a section of the leaf be left for 2 days in a tannin solution a voluminous precipitate consisting of minute globules was produced in the epidermal cells, while the other tissues of the leaves showed only a slight turbidity. This precipitate consists of tannate of thein, as shown by its solubility in dilute ammonia. This also affords an easy way of distinguishing the precipitate from minute proteosomes, which solidify upon the absorption of ammonia, the tannate of thein being dissolved by it. These investigations show, it is claimed, that thein is localized in the epidermis of the tea leaves.

On the rôle of oxidase in the preparation of commercial tea, K. Aso (*Bul. Col. Agr. Imp. Univ. Tokyo, 4* (*1901*), *No. 4*, *pp. 255–259*).—It is said that the first operation in the preparation of green tea consists of steaming the fresh tea leaves immediately after their collection. This will preserve their color, while if exposed to partial drying in the sun they will gradually turn brown. The reason for these changes is sought, and it is believed that the development of the black color is due to the action of oxidizing enzyms upon the tannin of the tea leaves. The author has investigated the presence of various enzyms in the leaves and has come to the conclusion that the action of oxidase upon the tannin is quite evident, and the so-called fermentation of black tea is due to the action of oxidizing enzyms in the tea leaves. Oxidase, peroxidase, and catalase were tested for in green and black commercial tea, but none were found present. This is explained to be on account of the heating which takes place as a primary stage in the production of green tea, or as one of the final stages in black tea manufacture. Investigations as to the action of iron and manganese upon oxidizing enzyms were conducted, from which the author concludes that proteids containing iron and manganese are present in tea leaves.

On the economic importance of Nitragin, Maria Dawson (*Ann. Bot., 15 (1901), No. 59, pp. 511–519*).—An account is given of experiments conducted with peas in which the efficiency of Nitragin was tested. Two series of experiments were conducted, in one of which the plants were grown in media previously sterilized for 24 hours at approximately 200° C., while in the second series the plants were grown in the open air on unsterilized media. In the experiments with sterilized media the plants were grown in large pots containing ordinary garden soil, a gravelly subsoil, and pure silver-sand, with and without potassium nitrate. Before sowing the seed they were sterilized by being immersed in a 1 per cent solution of mercuric chlorid for 15 minutes. The Nitragin was applied directly to the pots. These experiments were carried on foı 3 consecutive years with practically the same results. The results obtained show that on ordinary garden soil, on sand, and on sand which had received the nitrate, inoculation with Nitragin was accompanied by a loss in the weight of the crop, while a small increase was secured in those plants grown on gravelly subsoil. The plants grown in the sand showed a considerable increase in the crop produced by a supply of nitrate alone, but inoculation with Nitragin in the presence of a sufficient supply of nitrogenous food, whether in the form of humus or of potassium nitrate, was not beneficial. In the open-air experiments the same general conclusion was reached. The tubercle organisms were present in all types of soil, though they seemed less abundant in clay and peat, and in these particular soils alone a large number of infections resulted from the inoculation. As regards the relative weights of the crop an increase was observed only in the plants grown in the gravelly subsoil, and even there it was very small. On peat, clay, loam, or ordinary garden soil the inoculation with Nitragin proved to be both useless and superfluous.

The nature of the bacteroids of the leguminous nodule and the culture of Rhizobium leguminosarum, R. G. Smith (*Proc. Linn. Soc. New South Wales, 26 (1901), pt. 1, pp. 152–155*).—The author briefly discusses the views of Hiltner and Stutzer regarding the nature of the bacteroids of the nodules observed on the roots of leguminous plants. These authors appear to show that bacteroids are degenerate or involution forms of *Rhizobium leguminosarum*. This opinion is not concurred in by the author of the present paper. He claims that the branching forms are in reality simple cells contained in a branching capsule, and that this is readily observed with organisms grown in artificial cultures, as well as those taken from root tubercles. Hiltner's claims that *Bacillus radicicola* requires infusion of leguminous plants for growth and development is not correct, as the author has successfully grown them in extracts of various plants, grass doing as well as extracts of lupines or other leguminous plants, and fairly luxuriant cultures have been obtained upon a gelatin medium containing glucose and inorganic salts.

A description of certain bacteria obtained from nodules of various leguminous plants, S. Burrage (*Proc. Indiana Acad. Sci., 1900, pp. 157–161*).—Studies have been inaugurated to ascertain whether the same species of bacteria always occurs in a given species of leguminous plants, whether the same species occurs throughout all the tubercles on the roots, and whether a given species of plant is always inoculated by the same species of bacteria. The morphology and biological characters are given of 5 species which have been separated from tubercles occurring on the roots of red clover, *Vicia sativa*, *Phaseolus nanus*, alsike clover, and buffalo clover. Cultures have been separated and are being studied from crimson clover, black locust, white clover, cowpeas, and alfalfa.

Spermatogenesis and fecundation of Zamia, H. J. Webber (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 2, pp. 100, pls. 7*).—A technical bulletin treating of the fertilization and fecundation of Zamia, based upon the author's studies while in charge of the tropical laboratory of this Department located in Florida.

ZOOLOGY.

Insectivorous birds (*West Indian Bul., 2 (1901), No. 3, pp. 243–250*).—Notes are given on the unusual injury to cultivated plants in the West Indies from grasshoppers. It is suggested that the introduction of the mongoose has led to the destruction of many native birds which naturally fed to some extent on grasshoppers, and that the unusual prevalence of grasshoppers is partly due to this cause. It was suggested that the Indian starling be introduced into the Island of St. Kitts for the purpose of testing its efficiency in destroying grasshoppers. The matter was investigated, and various opinions were obtained from different authors as to the advisability of this move. These opinions differed to a considerable extent, but the agricultural department recommended the introduction of the Barbados blackbird (*Quiscalus crassirostrus*), and birds were shipped from Barbados to St. Kitts. Preliminary reports indicate that these birds will prove effective in keeping the grasshoppers in check.

The food of the myrtle warbler, C. M. Weed and N. Dearborn (*New Hampshire Sta. Tech. Bul. 3, pp. 117–128, fig. 1*).—Brief popular notes are given on the habits of *Dendroica coronata*. An examination was made of the stomach contents of myrtle warblers killed in New Hampshire. It was found that a large proportion of the food of this bird consisted of the fruit of *Myrica cerifera*. This was especially the case in the autumn, when the fruits of this plant are most abundant. At that time insects constituted only about 30 per cent of the food. An analysis of the fruit of the bayberry was made by F. W. Morse. It is concluded that since the vegetable food of the myrtle warbler has no value, the insects eaten by this bird render it of some economic importance, and it is urged that the presence of the bird be encouraged about the farm.

The rat-destroying bacilli discovered by Danysz, J. Kiester and P. Kötgen (*Deut. Med. Wchnschr., 27 (1901), No. 18, pp. 275, 276*).—Special interest in the problem of destroying rats in large cities has been awakened by the increased danger from bubonic plague. The authors' experiments with the bacterial organisms discovered by Danysz show that rats which were fed on pure cultures died within 5 to 7 days without exception, and that white mice were killed in about the same length of time. The authors believe that in these organisms an effective method is found for the destruction of rats.

Corynethrix pseudotuberculosis murium—a new pathogenic bacillus for mice, Bongert (*Ztschr. Hyg. u. Infectionskrank., 37 (1901), No. 3, pp. 449–475, pls. 2*).—An outbreak of a disease of unknown character occurred among mice which were being kept in the laboratory for experimental purposes. The author made an investigation of this disease and isolated the pathogenic organism, which is described as new. The behavior of this organism on various nutrient media is described and its morphological characters are given in detail. White and gray mice were very susceptible to infection, while the author found it impossible to transmit the disease experimentally to field mice. Rats fed on cultures of the organism failed to develop the disease. Guinea pigs, rabbits, pigeons, and chickens were found to be completely immune to hypodermic, intraperitoneal, or intravenous inoculations of large doses of pure culture. A bibliography of this subject is appended to the article.

Zoological Record, D. SHARP (*Zool. Rec., 37 (1900), pp. 1177*).—This volume, as usual, contains bibliographical references to literature on general zoology, mammals, birds, reptiles, batrachians, fishes, tunicates, mollusks, brachiopods, bryozoans, crustaceans, arachnids, myriopods, insects, echinoderms, worms, cœlenterates, sponges, and protozoans. A list is given of the titles of journals, transactions, etc., which contain zoological papers which are noted in the volume, and an index of new genera and subgenera mentioned in the volume is given by the editor. In each subdivision of the volume the literature is arranged alphabetically according to authors and systematically according to subjects.

Laws for the protection of birds and game in the District of Columbia, T. S. PALMER (*U. S. Dept. Agr., Division of Biological Survey Circ. 34, pp. 8*).—Three laws are in force in the District of Columbia for the protection of game—the District game law of March 3, 1899; an act amending that law, approved March 3, 1901; and the Lacey Act. The objects of these laws are to preserve birds which naturally occur in the District, and to prevent the development of a market in the District of Columbia for birds and game illegally killed in the various States.

METEOROLOGY—CLIMATOLOGY.

Meteorological observations, J. E. OSTRANDER and H. L. BODFISH (*Massachusetts Sta. Met. Buls. 154, 155, 156, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during October, November, and December, 1901. The general character of the weather of each month is briefly discussed, and the December bulletin gives a summary for the year. The principal data in this summary are as follows:

Pressure[1] (inches).—Maximum, 30.69, January 3, January 20; minimum, 29.01, January 28; mean, 29.955. *Air temperature*[2] (degrees F.).—Maximum, 100.5, July 2; minimum, −10.5, December 7; mean, 46.9; mean sensible (wet bulb), 43.4; maximum daily range, 50, April 29; minimum daily range, 3.5, March 12; mean daily range, 20.5. *Humidity.*—Mean dewpoint, 37.6; mean relative humidity, 71. *Precipitation.*—Total rainfall or melted snow, 49.72 in.; number of days on which 0.01 in. or more rain or melted snow fell, 135; total snow fall, 52.3 in. *Weather.*—Total cloudiness recorded by sun thermometer, 2,590 hours, or 58 per cent; number of clear days, 81; number of fair days, 105; number of cloudy days, 179. *Bright sunshine.*—Number of hours recorded, 1,866, or 42 per cent. *Wind.*—Prevailing direction, W.; total movement, 50,353 miles; maximum daily movement, 520 miles, December 15; minimum daily movement, 3 miles, December 19; mean daily movement, 138 miles; maximum pressure per square foot, 24 lbs., September 11, S. *Dates of frost.*—Last, May 6; first, September 26. *Dates of snow.*—Last, April 3; first, November 11.

Meteorology, W. FREAR and C. W. NORRIS (*Pennsylvania Sta. Rpt. 1900, pp. 388–427*).—"The work of the past year has been chiefly a continuation of the work of the preceding years [E. S. R., 12, p. 618], including observations of the kind usually made by the United States Weather Bureau upon atmospheric phenomena and upon the amount of sunshine." Monthly summaries of observations are given

---

[1] Reduced to freezing and sea level.

[2] In ground shelter, 51 ft. below level of other instruments.

in the body of the report and the detailed record in an appendix. The summary for 1899 is as follows:

Summary of meteorological observations, 1899.

	1899.	Growing season (Apr.-Sept.).
Barometer (inches):		
Mean	30.051	
Highest	30.816 (Jan. 2)	
Lowest	29.336 (Dec. 24)	
Temperature (° F.):		
Mean	49.1	64.
Highest	96 (Aug. 20)	96 (Aug. 20).
Lowest	-20 (Feb. 10)	21 (Apr. 3).
Mean daily range	18.8	21.5.
Greatest daily range	38 (Aug. 17)	38 (Aug. 17).
Least daily range	3 (Feb. 13)	
Mean daily relative humidity (per cent)	78.4	74.7
Rainfall (inches):		
Total	34.87	17.63.
Greatest monthly	4.77 (May)	
Greatest daily	1.60 (Aug. 26)	1.60 (Aug. 26).
Number of days on which 0.01 in. or more of rain fell	1.27	60.
Mean percentage of cloudiness	43.2	35.8.
Number of days on which cloudiness averaged 80 per cent or more.	75	21.
Average hours of sunshine per day		7h. 6m.
Maximum velocity of wind per hour (miles)	32 (Mar. 7)	
Last frost in spring		Apr. 17.
First frost in fall		Sept. 30.

Report of the meteorologist, N. HELME (*Rhode Island Sta. Rpt. 1901, pp. 355–371*).—This includes general notes on the weather during the year ended June 30, 1901, and a tabulated record of observations at Kingston on temperature, precipitation, cloudiness, and prevailing winds during each month from July, 1900, to June, 1901, inclusive, with a summary for the year ended June 30, 1901. The latter summary is as follows:

Temperature (degrees F.).—Maximum, 97, August 11, 1900; minimum, −9, January 20, 1901; mean, 48.4; highest monthly mean, 71.6, July, 1900; lowest monthly mean, 21.8, February, 1901; highest daily mean, 83, August 11, 1900; lowest daily mean, 3.5, January 19, 1901. *Precipitation* (inches).—Total (rain and melted snow), 48.47; greatest monthly, 8.78, April, 1901; least monthly, 1.13, February, 1901; greatest in 24 consecutive hours, 3.67, March 26–27, 1901; snowfall—total, 15¾; greatest monthly, 8, February; least monthly, ¾, December. *Weather*.—number of clear days, 134; number of fair days, 97; number of cloudy days, 134; number of days on which there was precipitation of 0.01 in. or more, 114. *Prevailing wind*, west.

The ammonia in meteoric water and in red rain, A. CASALI (*Staz. Sper. Agr. Ital., 34* (*1901*), *No. 9, pp. 833–848*).—Observations during January, February, and March, 1901, on the amount of ammonia in fog, frost, snow, and rain are reported and discussed, as well as an examination into the nature and source of the mineral matter obtained from red rain which fell over Italy, West Austria, and Germany on March 10 and 11. A summary of the results of the first inquiry is given in the following table:

Ammonia in meteoric waters.

[Parts per thousand.]

	Maximum.	Minimum.	Average.
Fog	0.06970	0.01700	0.05140
Frost	.05140	.02730	.02754
Snow	.00935	.00289	.00629
Rain	.01428	.00068	.00561

The red rain examined contained solid matter to the amount of 19.64 gm. per liter. This material was subjected to microscopic and chemical examination. The chemical composition was as follows: Silica, 57.75 per cent; oxid of iron and alumina, 34.94 per cent; magnesia, 2.22 per cent, and lime, 4.87 per cent. The author concludes from his study of this material that it is of meteoric origin.

The dust fall of March 10 and 11, 1901, H. Svoboda (*Ztschr. Landw. Versuchw. Oesterr., 4 (1901), p. 360; abs. in Centbl. Agr. Chem., 31 (1902), No. 3, p. 201*).—Studies similar to those noted above are reported. The source of the dust is considered to be the deserts of North Africa.

The chemical and meteorological history of the atmosphere, J. Stevenson (*Meteor. Ztschr. [Vienna], 18 (1901), pp. 417–420*).

Climate and the effects of climate, H. R. Mill (*Quart. Jour. Meteor. Soc. London, 27 (1901), pp. 169–184*).

Climate, vegetation, and drainage of Cascade Mountains of northern Washington, I. C. Russell (*Jour. School Geogr., 5 (1901), pp. 281–289*).

A study of the agricultural meteorology of the district of Leon, Mexico, in its relation to ordinary and improved culture, J. M. Garcia Muñoz (*Mem. y Rev. Soc. Cient. "Antonio Alzate," 16 (1901), No. 1, pp. 5–29*).—This question was studied with reference to corn during 1893 to 1896. It was found that with the same meteorological conditions the yields were greatly increased by improved methods of culture.

Meteorological atlas of the Argentine Republic, E. A. S. Delachaux (*Atlas meteorológico de la República Argentina. Buenos Ayres: Campania sud-americana de billetes de banco, 1901, pt. 1, pp. 24, maps 24*).—Part 1 is devoted to the Province of Buenos Ayres.

The hail protection congress of Novare, Italy, V. Vermorel (*Grêle, 2 (1901), No. 12, pp. 3–9*).—A brief account of this congress, held October 22, 23, and 24, 1901. It is stated that the attendance was smaller and the interest less marked than at previous Italian congresses. The author thinks that before going further in this matter it is necessary to know what has been accomplished and what it is possible to accomplish by means of cannonading. No real advance is now being made in settling the question.

The influence of cannonading on rain and storms, J. M. Pernter (*Meteor. Ztschr. [Vienna], 18 (1901), pp. 371, 372*).

Shooting away hailstorms, E. P. Lyle, jr. (*Pearson's Mag., 12 (1901), No. 72, pp. 651–660, figs. 6*).

Weather shooting in ancient times, J. M. Pernter (*Meteor. Ztschr. [Vienna], 18 (1901), p. 372*).

Driving frost from fruit, M. Tindal (*Pearson's Mag., 12 (1901), No. 71, pp. 552–554, figs. 4*).

How is temperature measured? K. Arndt (*Prometheus, 12 (1901), No. 622, pp. 792–795, figs. 2*).—A brief explanation and discussion of the construction of different kinds of thermometers.

Instructions for the care and management of sunshine recorders, C. F. Marvin (*U. S. Dept. Agr., Weather Bureau Doc. 252, pp. 19, figs. 5*).—The second edition of these special instructions for the information and guidance of Weather Bureau observers.

The forecaster and the newspaper, H. M. Watts (*Washington: Government Printing Office, 1901, pp. 22, figs. 6*).—This is a paper read before the recent convention of Weather Bureau officials at Milwaukee, Wis., giving in full views briefly presented elsewhere (E. S. R.. 12, p. 1018).

WATER—SOILS.

Analyses of the waters of the state of São Paulo, Brazil, G. d'Utra (*Bol. Agr. São Paulo, 2. ser., 1901, No. 8, pp. 481–488*).—Analyses with reference to potability of a number of samples from different parts of the state are reported.

Investigations on drainage water, Creydt, von Seelhorst, and Wilms (*Jour. Landw., 49* (*1901*), *No. 3, pp. 251–275*).—A daily record of the flow of drains from July 28, 1899, to August 10, 1900, and weekly analyses of the drainage water are reported, with a description of the methods of analysis used and a discussion of the results. The analyses indicate that the loss of nitrogen from soils in the drainage even in case of heavy soils may be appreciable, while the loss of potash and of phosphoric acid is insignificant.

Pollution of streams by agriculture and manufactures, G. V. Khlopin (*Zazryaznenie protochnuikh vod khoz yaistvennuimi i fabrichnuimi ot brosami i myarui k ego ustraneniyu. St. Petersburg: K. L. Ricker, 1901, pp. 60*).

Study of the climate and soil of the clay and sandy clay region of Belgium (*Monographie agricole de la région limoneuse et sablo-limoneuse. Brussels: Ministry of Agriculture, 1901, pp. 1–71*).—This article gives and discusses data for monthly, seasonal, and annual temperatures at a number of places in the region; the temperature of bare and covered soils during different months of the year; sunshine, hail, rainfall, fogs, and storms; the geological characteristics of the region; physical and chemical analyses and characteristics of the soils, including analyses of matter soluble in cold hydrochloric acid of 1.18 sp. gr., in hydrofluoric acid, and in alkaline ammonium citrate in soils and subsoils from 38 localities; estimates of the amounts of fertilizing constituents per hectare; experiments with fertilizers on different classes of soil, and notes on the water supply. The results of the examinations of the soils show that as a rule these are somewhat deficient in phosphoric acid. The amount of potash soluble in cold concentrated hydrochloric acid is generally low, although the total potash as determined by treatment with hydrofluoric acid is high. The results of the fertilizer experiments indicate that the latter is to a considerable extent assimilable by plants and that potash fertilizers are not needed as a rule. The soils, especially those that have been under intensive culture, are poor in nitrogen, containing as a rule less than 0.1 per cent of this constituent. The amounts of lime and sulphates are low, but magnesia is believed to be present in sufficient quantity.

The climate and soil of the Jurassic region of Belgium (*Monographie agricole de la région Jurassique. Brussels: Ministry of Agriculture, 1901, pp. 1–23*).—Data are given for temperature, rainfall, rainy and dry periods, snow, rainy days, and storms, the geological constitution and the chemical and physical composition of the soils of the region, and its hydrological conditions. The soils of this region are very variable in physical character. While, as the analyses show, a few of the soils are quite rich in phosphoric acid, the larger part of them are only moderately supplied with this constituent, and are benefited by the application of phosphates. There is considerable potash present, but a large part is insoluble in hydrochloric acid. As a rule the application of barnyard manure suffices to supply the potash and nitrogen required for medium crops. Liming is beneficial in unlocking the potash, improving the physical condition of the clayey soils, and promoting nitrification by correcting the acidity, which is often sufficient to seriously retard the action of the nitrifying organisms. On account of the slow nitrification in many cases nitrate of soda has been found beneficial.

The tea soils of Assam, H. H. Mann (*The tea soils of Assam, and tea manuring. Calcutta: Indian Tea Association, 1901, pp. 1–59, 104–137, pl. 1*).—This is an account of investigations conducted under the auspices of the Indian Tea Association, including a report on two tours through the Assam Valley to study the causes of the decline in productiveness of the tea soils of this region and the means of improving them.

The general soil and cultural conditions are described, with suggestions as to improvements, and the physical and chemical properties of the soils, based on analyses of samples from typical virgin and cultivated areas, are discussed, the attempt being made "to describe, classify, and indicate the best method of manuring the tea soils of each district in the Brahmaputra Valley." It is shown that the soils used for tea culture in this valley vary from micaceous sand and gravel to stiff red clays.

The field observations as well as the analyses reported show a deterioration of the soils under continuous culture in tea as regards both yield and quality of product. This deterioration is considered to be largely due to decline in fertilizing constituents, especially organic matter and nitrogen, and may, to a large extent, be remedied by the judicious use of local supplies of fertilizing materials. "Tea requires for its successful cultivation a considerable quantity of organic matter and nitrogen in the soil—the best results being obtained only when more than 35 per cent of the nonsandy portions of the soil consists of organic matter and 0.8 per cent of nitrogen. Provided this is present, tea can be cultivated with success in presence of a minimum quantity of other constituents, notably phosphoric acid and potash; but to obtain high-quality tea these latter materials must exist in the soil in larger amount, and, other things being equal, the larger the quantity of phosphoric acid (in presence of sufficient nitrogen) the better will be the tea. . . . One might say that in general terms if on analysis a soil presents (1) less than 35 per cent of organic matter, or (2) less than 0.8 per cent of nitrogen, on the nonsandy portion of the soil it needs these constituents as manure; (3) less than 0.25 per cent of phosphoric acid, calculated in the same way, it needs phosphates, and if high-quality tea is to be produced 0.4 per cent should be present; (4) potash in amount less than 3 per cent of the oxid of iron and alumina, taken together, it needs potash manures. . . . Potash runs parallel with phosphoric acid, but is probably present in ample quantity in Assam soils. In short, much nitrogen with little phosphoric acid will produce rank growth with medium tea only—much nitrogen with much phosphoric acid will give luxuriant growth and high-quality tea—little nitrogen with much phosphoric acid will give high-quality tea, but comparatively little of it—and if there is a deficiency in both, tea can never be profitable. Other constituents besides the three named may possibly have an intimate connection with the quality of the tea. Lime probably has little or none—and is in any case present in ample quantity everywhere." Iron and manganese appear to be present in sufficient quanity in the Assam soils. Whether they exert any important influence on the growth of tea has not yet been definitely determined.

"The methods of manuring recommended are based on the necessity for the addition of organic matter and nitrogen in almost every case, of phosphates often, and occasionally of potash. In a heavy soil generally speaking green manuring crops previously manured with phosphates give the best method; in a light one usually cattle manure or oil cake, also with green manuring, form the best addition, taking into consideration the ultimate object of all manuring—the maximum improvement of the crop at the minimum of cost." (See also p. 749.)

A chemical study of the phosphoric acid and potash contents of the wheat soils of Broadbalk field, Rothamsted, B. DYER (*Phil. Trans. Roy. Soc.* [*London*], *ser. B, 194* (*1901*), *pp. 235–290*).—This gives in full the paper which was noted in abstract (E. S. R., 13, p. 30).

The Eocene deposits of Maryland, W. B. CLARK, G. C. MARTIN, ET AL. (*Maryland Geological Survey: Eocene. Baltimore: Johns Hopkins Press, 1901, pp. 331, pls. 64*).—This includes a historical review of the literature of the subject with a list of 113 references to articles on the subject; discussions of the general stratigraphic relations of the deposits, distribution of strata, general classification of the deposits, origin of the materials, stratigraphical and paleontological characteristics, geological and geographical distribution of species, correlation of deposits, and systematic paleontology of the Eocene deposits, with an index. These deposits are of special interest agriculturally, because they are largely glauconitic and contain the most extensive deposits of greensand marls.

"The Eocene deposits of the Middle Atlantic slope are typically glauconitic, and are found in their unweathered state either as dark gray or green sands or clays. The glauconite varies in amount from very nearly pure beds of that substance to deposits in which the arenaceous and argillaceous elements predominate, although the strata are generally very homogeneous through considerable thicknesses. At certain horizons the shells of organisms are found commingled with the glauconitic materials in such numbers as largely to make up the beds, producing what is known as a greensand marl. These beds are at times so indurated as to form true limestone ledges."

The report states that "two conditions are requisite for the formation of glauconite: First, the deposition of mineral particles of land-derived origin; and second, the presence of foraminifera. In the absence of either. glauconite will not be produced. On the other hand, it is retarded and finally ceases altogether as the amount of deposition of land-derived materials increases adjacent to the coasts. Only, then, within circumscribed limits, which are constantly subject to modification, is the formation of glauconite possible.

"Glauconite seldom, if ever, occurs pure in nature, but is mixed with greater or less amounts of arenaceous materials, producing what is known as greensand, a term which is commonly made to embrace the argillaceous deposits as well, particularly when the glauconite grains are visible, although they are more correctly green clays. When the deposits are distinctly calcareous they are generally known as greensand marls. No definite percentage of any of the constituents is required, and as they are so commonly intermingled the terms just described are used somewhat indiscriminately."

FERTILIZERS.

Pot experiments to test field observations concerning soil deficiencies, B. L. Hartwell (*Rhode Island Sta. Rpt. 1901, pp. 274–293, pls. 4*).—This article discusses briefly the difficulty of accurately determining the available or assimilable plant food in soils, maintaining that "analytical results have frequently failed to account satisfactorily in the case of given soils for differences caused by known fertilization and cropping." This failure is stated to be "probably due in many cases to the fact that the small amount of soil analyzed did not properly represent the large areas from which it was taken." A well-conducted soil test is considered the most satisfactory method of arriving at a knowledge of soil deficiencies, and it is recommended that "soils designed for use as standards in testing methods for determining assimilable plant food should in many cases be first subjected to pot experimentation." Pot experiments on oats during 2 years are reported with 1 soil each from Massachusetts and Indiana, said to be deficient in assimilable phosphoric acid, and 2 from Connecticut, supposed to be lacking in assimilable potash. The pots used were of the Wagner type, 8 in. in diameter and 8 in. deep, holding from 13 to 16 lbs. of the different soils. The systems of manuring followed and the yields of grain, straw, and entire crop are reported, as well as details of the method of conducting the experiments. In the case of only one of the soils did the results of the 2 years' experiments with oats agree fully with the field observations. It is suggested that this may have been due to other factors aside from deficiencies of plant food. For this reason it is recommended that "land upon which field experiments are to be conducted for showing its need of plant food should first receive such treatment, other than the application of the particular ingredient to be studied, as is economical and necessary for the proper growth of most agricultural plants."

The offering of premiums for fertilizer experiments as a means of promoting rational fertilizing, T. PFEIFFER (*Mitt. Landw. Inst. Univ. Breslau, 1 (1901), No. 5, pp. 1-45*).—The author refers to the unreliability of chemical analysis as a means of determining the fertilizer requirements of soils and discusses the relative merits of pot and field experiments. The former he considers a cheap and convenient means of studying fundamental scientific problems, but doubts whether the results so obtained can be directly applied in practice. Carefully conducted field experiments are considered the most reliable means at the command of the farmer for determining the fertilizer requirements of his soils. For this reason the author in 1898 recommended to the Association of German Agricultural Experiment Stations the adoption of a system of premiums to encourage farmers to undertake carefully planned and supervised field experiments with fertilizers (E. S. R., 11, p. 506) with a view to cheapening the cost and improving the methods of plant production in a similar manner to that long prevailing in the field of animal production. The advantages of such a system are explained, and the author describes the plan and reports the results in detail of 39 cooperative experiments begun in 1899 under a system of prizes ranging from 100 to 300 marks offered by the agents of the nitrate, Thomas slag, and potash salts interests. The results obtained were of a very encouraging nature and are taken to indicate the practicability of the plan.

Crop growing and crop feeding, W. F. MASSEY (*Pract. Farmer's Libr., 3 (1901), No. 3, pp. 383*).—"This book is the result of an effort to put into the plain language of the farm the facts which scientists have worked out in the laboratory, and which practical experience has proved to be applicable to the everyday work of the farm." It discusses the relation of air and soil to plant growth; plant breeding; the restoration and maintenance of soil fertility by means of fertilizers, leguminous plants, and proper rotations; plant food and the sources and functions of phosphorus and potash in fertilizers; tests of the needs of soils; fraud in fertilizers; mixing fertilizers on the farm; lime and liming; and gives special formulas and general instructions for fertilizing the principal farm, garden, and orchard crops. There is a special chapter on gardening under glass, and an appendix giving tables of composition of farm crops, fertilizers, etc. "The original design was simply to make the work a reference book on the use of fertilizers for the general farmer. But it is difficult to write of the use of fertilizers without going somewhat into details of cultural methods; and then, too, the market gardener, the orchardist, the florist, and the winter forcer of products under glass are all interested in the use of commercial fertilizers. Hence the idea of the work has grown so as to include some of the work of each. . . . So far as the garden crops and the work under glass are concerned, special attention is paid to the needs of the market gardeners of the South Atlantic and Southern States."

Green manuring with lupines and the use of nitrogenous fertilizers, C. SCHREIBER (*Rev. Gén. Agron. [Louvain], 10 (1901), No. 11, pp. 481-488, fig. 1*).—Pot experiments with oats and field experiments with rye in 1900 and 1901 to test the economy of using commercial fertilizers in connection with lupines as a green manure are briefly reported. The best results as regards yield and profit were obtained when the green manure was supplemented by commercial fertilizers, especially nitrate of soda, the latter being preferable to sulphate of ammonia as a supplemental nitrogenous fertilizer.

Use of town drainage as manure, W. H. MORELAND (*Dept. Land Records and Agr. Northwest. Provinces and Oudh, Bul. 18, agr. ser., 1901, pp. 3*).—This is a brief account of the successful use for irrigating different crops of the drainage water of the Meerut municipality. This drainage water "consists mainly of street rubbish, sullage water, and the like, diluted by the water with which the drains are flushed."

On sewage disposal and purification, J. GLAISTER (*Proc. Phil. Soc. Glasgow, 32 (1900-01), pp. 151-191*).—The methods of sewage disposal and purification, the relative merits of which are discussed in this paper, are divided into two main classes:

(1) Natural, including surface or broad irrigation, and (2) artificial, including (a) precipitation or chemical method, (b) intermittent downward filtration, and (c) bacteriolysis or the bacterial treatment. The first is considered "entirely impracticable for large populous centers" on account of its large cost, failure in time of frost and heavy rainfall, and liability to become malodorous in warm weather.

"With reference to sewage farms, it may be said with absolute correctness that, with everything else equal, they fail without the closest supervision. With that, however, added to the other conditions, such as suitable land, etc., they may be worked up to a high pitch of efficiency."

Analyses are reported which show that wet, compressed, and compressed and steam-dried sludge obtained by precipitation by lime have a comparatively low fertilizing value, the compressed sludge containing only 0.788 per cent nitrogen, which increases to 1.73–1.9 per cent when the sludge is steam-dried. The material contains very small amounts of phosphoric acid. "By the addition of chemical constituents it could be made a valuable manure."

The reduction of nitrates in the presence of barnyard manure, J. P. STREET (*New Jersey Stas. Rpt. 1900, pp. 79–88*).—The experiments here reported were a continuation of those of the previous year (E. S. R., 12, p. 321) and were conducted in the same manner except that loosely covered 400 cc. beakers were used instead of flasks, and a mixture of solid and liquid excrement was employed instead of solid manure alone. In one series 30 gm. of the mixture was placed in each beaker alone and with the addition of sodium nitrate alone at the rate of 83 lbs. per ton of manure, or with acid phosphate, kainit, gypsum, iron sulphate, and potassium sulphate, each at the rate of 26 lbs. per ton, and glucose, wheat straw, and pine shavings each at the rate of 133 lbs. per ton. In a second series ammonium sulphate alone or combined with acid phosphate, kainit, gypsum, and iron sulphate was substituted for the sodium nitrate. The experiments began January 22 and continued 33 days, the changes in ammonia, nitrates, and insoluble nitrogen being determined at 4 different periods. At the end of the experiment the nitrates had entirely disappeared in the tests in which glucose, straw, and shavings had been used. The loss where iron sulphate was used was 7.9 per cent less than where nitrate was used alone (without preservatives). "Acid phosphate and kainit seemed to have a slightly favorable effect, while plaster and sulphate of potash caused no additional loss." There was an increase of insoluble organic nitrogen in all of the tests, but this increase was apparently "smaller where nitrate of soda was used alone, or in connection with superphosphate, kainit, plaster, sulphate of iron, sulphate of potash, or shavings." With the straw there was about the same gain as with manure alone, and with glucose about twice as much. The results of the experiments with ammonium sulphate agreed closely with those obtained the previous year except in case of gypsum, "which, in 1899, was with sulphur the most effective preventive of loss used, but in 1900 was the least efficacious." The loss of ammonia varied from 13.1 per cent with iron sulphate to 33.8 per cent with gypsum. There was a large gain of insoluble organic nitrogen in these experiments, varying from 34 per cent where manure was used alone to 102.7 per cent where manure was used in connection with ammonium sulphate and gypsum.

Investigations relative to the use of nitrogenous materials, E. B. VOORHEES (*New Jersey Stas. Rpt. 1900, pp. 88–110*).—A continuation of experiments of the previous year (E. S. R., 12, p. 322) is here reported. The composition of the solid and mixed solid and liquid excrement of a cow in the fresh condition and after exposure to natural leaching from February 3 to April 13 (70 days) was found to be as follows:

Composition of fresh and leached cow manure.

	Fresh manure.		Leached manure.	
	Solid.	Solid and liquid.	Solid.	Solid and liquid.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Ash	1.831	2.645	3.176	3.005
Organic matter	12.375	12.281	19.781	18.381
Nitrogen (total)	.293	.463	.431	.498
Nitrogen soluble in water	.060	.211	.056	.169
Nitrogen as nitrates	.015	.031	....	....
Nitrogen as ammonia	.031	.090	....	.080
Nitrogen, soluble organic	.014	.090	.056	.089
Nitrogen, insoluble organic	.233	.252	.375	.329
Phosphoric acid	.372	.410	.504	.508
Potash	.141	.199	.350	.414

These figures show that there was in case of the solid manure a loss of 34 per cent of the nitrogen, 27 per cent of the phosphoric acid, and 10 per cent of the potash; but in case of the mixed solid and liquid excrement a loss of 44 per cent of the nitrogen, 16 per cent of the phosphoric acid, and 28 per cent of potash.

Pot experiments with oats and millet were conducted with the above manures in the manner described in the last report. Regarding the amount of nitrogen recovered by the crops as 100 in case of nitrate of soda, the relative availability of the different nitrogenous fertilizers in these experiments was as follows:

Relative availability of nitrogen in different forms.

	Oats.	Oats and millet.
Nitrate of soda	100.0	100.0
Sulphate of ammonia	72.9	77.9
Dried blood	58.5	61.3
Solid manure, fresh	12.0	43.1
Solid manure, leached	12.1	46.4
Solid and liquid manure, fresh	58.2	88.4
Solid and liquid manure, leached	20.0	33.0

Superphosphate applied broadcast, MAIZIÈRES (*L'Engrais, 16* (*1901*), *No. 44, pp. 1047, 1048*).—The dissemination of the phosphoric acid in the soil when superphosphates are applied broadcast is discussed.

Fertilizer experiments with apatite, feldspar, etc., J. SEBELIEN (*Tidsskr. Norske Landbr., 8* (*1901*), *No. 2, pp. 69–78*).

The use of ammoniacal fertilizers on calcareous soils, E. GIUSTINIANI (*Ann. Agron., 27* (*1901*), *No. 10, pp. 462–486, fig. 1*).—This is a continuation of previous experiments on the reactions which occur between calcium carbonate and ammonium sulphate in the medium of sterile sand (E. S. R., 12, p. 330). The experiments here reported consisted of (1) mixing ammonium sulphate and varying amounts of calcium carbonate with a good garden soil in glass bottles so arranged that the amount of ammonia given off could be determined; (2) determining the amount of nitrates present at different dates in similar mixtures of the soil in funnels; and (3) pot experiments with barley to determine the proportion of nitrogen recovered by the crop from soils fertilized with varying amounts of calcium carbonate, ammonium sulphate, and sodium nitrate. In order to lay down a rule for the use of ammoniacal fertilizers in calcareous soils the author undertook first to determine the loss of nitrogen due to the reaction between ammonium sulphate and calcium carbonate in quartz sand (see previous experiments referred to above) and a good garden soil. In the first case it was shown that in the absence of all bacterial action the reaction between the two salts was complete, and if a current of air was introduced the total ammonia was recovered more or less rapidly, depending upon the conditions of temperature and humidity of the medium, but independently of the proportion of lime. In sterilized garden soil, however, the losses were much smaller, the constituents of the soil possessing an absorbent power for the ammonia, retaining under the conditions of the experiment from 40 to 60 per cent of the original nitrogen added. The amount of ammonia driven off from the soil was in direct relation to its richness in lime, the temperature, and the humidity. If the soil was dry the elimination of ammonia was more rapid, but the reaction was soon arrested and the quantity of nitrogen lost was consequently less. In sandy media phosphatic slag caused a very rapid decomposition of the ammonium sulphate, due, evidently, to the free lime which this substance contains. In the experiments on nitrification it was observed that the oxidation of ammonia was quite slow in the rich garden soil, but the losses of ammonia were insignificant. A part of the nitrogen escaped oxidation only when a large excess of lime was added to the soil and the temperature raised.

In the experiments with barley grown on quartz sand and fertilized with ammonium sulphate it was observed that with a medium application of lime nitrification was slow, the losses of nitrogen were quite appreciable, the crop utilized only a part of the nitrogen, and the roots of the plants were injured by the ammonia salt. When, however, the conditions of the medium were more favorable to oxidation of ammoniacal nitrogen, the plants utilized a large part of the nitrogen and the yield was but slightly lower than that obtained with nitrate of soda, although in a sandy medium quite rich in lime ammonium sulphate is generally quite inferior to nitrate of soda as a nitrogenous fertilizer. The fractional application of the nitrogenous fertilizer to some extent favored fructification and increased the proportion of nitrogen in the grain.

It thus appears that ammoniacal fertilizers can be used to best advantage on calcareous soils under conditions favorable to nitrification and to the retention of ammonia, such as occur in moist rich soils. In such soils, however, nitrification of the ammonia is quite slow and the action of ammonium sulphate is for this reason much less rapid than that of sodium nitrate, although much more durable in its effects. Ammonium sulphate is not suited to use either on sandy soils without lime or on such soils containing a large proportion of calcium carbonate. A light soil, in which the proportion of lime does not exceed 5 to 20 per cent, may be benefited by ammoniacal fertilizers provided it is not subjected to drought. In this case also it is desirable to apply the fertilizer fractionally during the earlier months of growth. If the ammonium sulphate is to be used in connection with phosphatic slag, the latter should be applied several days in advance of the former in order that the free lime may become carbonated.

A contribution to the question of liming, SCHLEYER (*Deut. Landw. Presse, 29* (*1902*), *No. 2, p. 12*).—The beneficial effect of liming on fruit trees is reported, and an account is given of the different effects of iron sulphate solution on charlock (*Raphanus raphanistrum*) growing on soil deficient in lime and on that abundantly supplied with lime. In the first case spraying with 10 and 15 per cent iron sulphate solution produced no result, while in the second case a spray of 10 per cent solution quickly killed the weed. It is suggested that on the soil deficient in lime the plants contained an excess of oxalic acid and this prevented the reaction between the iron sulphate and the tannic acid of the plant, resulting in blackening and death.

Fertilizer experiments with lime and marl, P. HILLMANN (*Mitt. Deut. Landw. Gesell., 16* (*1901*), *Nos. 44, pp. 256–258; 46, pp. 265, 266; 47, pp. 272, 273; 48, pp. 275–278; 49, p. 281; 50, pp. 284–287*).—Cooperative experiments in different parts of Germany are reported. These showed in the majority of cases the need and value of liming and marling. On heavy soils containing as much as 0.5 per cent of lime the application of the latter was beneficial.

On the development and present status of the perchlorate question, H. G. Söderbaum (*K. Landt. Akad. Handl. Tidskr., 39 (1900), No. 5–6, pp. 338–345*).

Commercial fertilizers, E. H. Jenkins et al. (*Connecticut State Sta. Rpt. 1901, pt. 1, pp. 94*).—This includes a statement of fertilizer sales in Connecticut in 1901, the text and an abstract of the State laws relating to fertilizers, a list of manufacturers securing licenses under these laws, notes on the sampling and collecting of fertilizers, explanations regarding the analysis and the valuation of fertilizers, a review of the fertilizer market for the year ended October 31, 1901, and tabulated analyses and valuations of 432 samples of fertilizing materials, including nitrate of soda, dried blood, cotton-seed meal, castor pomace, superphosphates, sulphate of potash, muriate of potash, double sulphate of potash and magnesia, kainit, tobacco ashes, bone, tankage, dry ground fish, bone and wood ashes, cotton-hull ashes, wood ashes, limekiln ashes, tobacco stems, lime refuse, soot, wool waste, carbonizing dust, garbage tankage, and muck.

Commercial fertilizers (*Kentucky Sta. Bul. 95, pp. 133–190*).—The results of analysis of 438 samples of fertilizers are reported and briefly discussed. "Of the 438 samples analyzed, 83, representing 71 brands and 30 firms, fell so far below the guaranteed analyses in phosphoric acid, nitrogen, or potash, or any two, or all three of these ingredients, that the deficiencies could not be accounted for by variations in sampling or analysis. . . . The great majority of the manufacturers, however, have furnished in most instances fertilizers fully up to the guarantee."

Analyses of fertilizers, C. A. Goessmann (*Massachusetts Sta. Bul. 77, pp. 30*).—Analyses of fertilizers collected during 1901 under the provisions of the State law and of miscellaneous materials sent to the station for examination are reported. The miscellaneous materials include wood ashes, cotton-hull ashes, walnut ashes, pine-wood ashes, ashes from soft coal and sawdust, muriate of potash, nitrate of soda, cotton-seed meal, tobacco stems, bone, tankage, ground fish, dissolved boneblack, calcium carbonate, gas lime, muck, marl, river sediment, and samples of marsh and ordinary soils.

Analyses of commercial fertilizers, W. F. Hand et al. (*Mississippi Sta. Bul. 68, pp. 32*).—"This bulletin contains the analyses of the principal brands of commercial fertilizers that have been found on the Mississippi markets during the season of 1900–1901."

Fertilizers (*New Jersey Stas. Rpt. 1900, pp. 15–78*).—This is mainly a reprint of Bulletin 145 (E. S. R., 12, p. 840) with the addition of statistics of the fertilizer trade in New Jersey during 1899 and preceding years, the market prices of fertilizers, text of the fertilizer law, and lists of inspectors, and of manufacturers whose goods were inspected in 1900. From data furnished by 92 out of 112 firms selling fertilizers in New Jersey in 1899 it is estimated that the total consumption of fertilizers in the State was 61,727 tons, valued at $1,573,093. "Complete manures represent 70 per cent of the total number of tons sold in 1899 and 76 per cent of the total value of all sales." The statistics reported show that there has been a decline in the price of the actual plant food furnished in fertilizers since 1886.

Analyses and valuations of fertilizers, L. A. Voorhees and J. P. Street (*New Jersey Stas. Bul. 154, pp. 55*).—This bulletin discusses the trade values of fertilizing ingredients in 1901; the cost, valuation, purchase and guaranteed and actual composition of fertilizers, home mixtures, and special fertilizers; and reports the results of examination of 59 samples of standard unmixed fertilizing materials, 308 brands of complete fertilizers representing 79 manufacturers, 25 samples of ground bone, and 37 of miscellaneous products. In addition there are reported the analyses of 8 samples of home mixtures and 18 samples of mixtures especially compounded by manufacturers to order. The materials examined included, in addition to the mixed fertilizers, nitrate of soda, sulphate of ammonia, dried blood and ammonite, dried and ground fish, tankage, hair manure, superphosphates, muriate of potash, sulphate of potash, kainit, wood ashes, marl, lime, and garbage refuse. About 81 per cent of the brands of fertilizers examined contained as much total plant food as was claimed, but in only 65 per cent was the plant food distributed in the proportions stated. The averages for all brands of complete fertilizers examined during 1901 are as follows: Total nitrogen 2.31 per cent, total phosphoric acid 10.48 per cent, available phosphoric acid 8.08 per cent, insoluble phosphoric acid 2.40 per cent, potash 5.77 per cent, station valuation $21.19, selling price $27.31. "It appears that the manufacturers are delivering on the average somewhat less total plant food than in 1900, but at about the same price per ton."

Commercial fertilizers, H. J. Wheeler et al. (*Rhode Island Sta. Bul. 81, pp. 111-122*).—This bulletin contains analyses of a portion of the fertilizers collected during 1901. The fertilizers examined during this year were much inferior to those of recent years as regards agreement with guarantee. A large proportion of these deficiencies were in the phosphoric acid.

FIELD CROPS.

Range improvement in Arizona, D. Griffiths (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 4, pp. 31, pls. 6, figs. 5*).—This bulletin contains a report on experiments with grasses and forage plants in cooperation with the Arizona Station. An outline is presented of experiments undertaken on a range reserve tract, a piece of public land set aside by the President for the use of the Secretary of Agriculture. A number of letters are reproduced in which the present and past conditions of the grazing lands of southern Arizona are briefly noted. The various species of forage plants, comprising plantains, saltbushes and allied plants, native legumes, cacti, and grasses, are discussed with regard to their value and their distribution.

An estimate based on figures obtained from 18 different plats of the quantity of feed furnished by the plantains on the range reserve tract in the spring of 1901 shows an average yield of 992 lbs. of dry material per acre. On areas where the creosote bush predominates the yields were smallest, varying from 16 to 2,466 pounds per acre. The maximum yield on a single plat amounted to 3,087 lbs. The adaptability of the plantains to grow on the sandy desert mesa is discussed, and an account is given of the distribution of their seed and its germination. Of the different species, Indian wheat (*Plantago fastigiata*) is considered the most important.

The saltbushes and other plants of a like character treated in this connection are the shad scale (*Atriplex canescens*), the most important of the group; the grease wood (*Sarcobatus vermiculatus*), which grows in the moister alkaline regions, and winter fat (*Eurotia lanata*), an almost exterminated species on the open range. Among the native legumes the mesquite (*Prosopis velutina*) has the greatest value. The screw bean (*P. pubescens*) is reported as being also common. *Astragalus nuttallii*, a species common to the moister mesa region, is mentioned as furnishing much palatable feed under favorable conditions.

Opuntia fulgida, *O. spinosior*, *O. versicolor*, and *O. arbuscula*, are given as the species of cacti most frequently used for forage in the vicinity of Tucson. A test of singeing the spines from a specimen of *O. spinosior* proved that the plant without the spines was palatable to stock.

The different species of grasses occurring in the region are briefly noted. The species found on the river bottoms are saccaton (*Sporobolus wrightii*), salt grass (*Distichlis spicata*), drop seed (*Sporobolus cryptandrus*), *S. strictus*, and Arizona millet (*Chætochloa composita*).

Black grama (*Hilaria mutica*), *H. jamesi*, curly mesquite (*H. cenchroides*), blue grama (*Bouteloua oligostachya*), low grama (*B. polystachya*), woolly foot (*B. eriopoda*), side oats grama (*B. curtipendula*), and black heads (*Pappophorum wrightii*) are mentioned as among the most important nutritious species commonly found on the open mesa range. *Chloris elegans*, everlasting grass (*Eriochloa punctata*), vine mesquite (*Panicum obtusum*), *P. colonum*, *Eragrostis neomexicana*, and feather grass (*Andropogon torreyanus*) are reported as occurring in moist locations. On the general mesa six weeks grama (*Bouteloua aristidoides*) is found in large quantities after the summer rains. During the second week in October the author found gentle slopes near the foot hills nearly covered with short growths of *Bouteloua aristidoides*, *B. polystachya*, *Pappophorum wrightii*, and *Nazia aliena*. The grasses reported as occurring in the mountains are *Andropogon contortus*, *A. leucopogon*, *Trachypogon secundus*, *Elionurus barbiculmis*, *Hilaria* sp., *Bouteloua bromoides*, *B. oligostachya*, *B. curtipendula*, *Trioda mutica*, *Eragrostis lugens*, *Muhlenbergia gracillima*, *M. porteri*, *Epicampes rigens*, and *Aristida* sp.

The range reserve tract and the different experiments recently begun are described in detail and various methods for range improvement are suggested.

Miscellaneous forage crops, G. C. Watson and E. H. Hess (*Pennsylvania Sta. Rpt. 1900, pp. 284–306, pls. 3*).—The results of experiments with crimson clover, Canada field peas, flat pea, vetches, spurry, millet, and sunflower, conducted at the station some years past and reported in part in a former publication (E. S. R., 11, p. 436), are reviewed.

Crimson clover sown early in May matured seed in one season. Larger yields were obtained from this crop when sown in July than from August or September sowings. It is recommended that the Canada field pea should be sown with oats in the proportion of 1½ to 2 bu. of peas to 1½ bu. of oats. The experience with the flat pea showed that the seed should be scalded and soaked before planting. The authors advise planting this crop in rows far enough apart to admit of horse cultivation. Russian and spring vetch were grown with good results. Vetch grown with oats was much more satisfactory than when sown alone. The yields of spurry did not indicate that this crop was as profitable as the more common forage crops. Russian gray and Russian white sunflowers grown for 3 years in succession yielded from 41.01 to 53.26 bu. of seed per acre. For poultry the seed is not considered as economical as the cereals.

Plant culture experiments at Norway Agricultural College, 1899–1900, B. R. Larsen (*Christiania, 1901, pp. 48*).—The report gives an account of variety tests of grains, potatoes, and forage plants conducted in different parts of Norway under the direction of the plant culture experiment station of Aas Agricultural College.—F. W. WOLL.

Notes on agriculture in Tunis, A. Kebaïli (*Bul. Dir. Agr. et Com., 6 (1901), No. 20, pp. 257–286*).—This article describes the culture of cereals as practiced by the natives and by Europeans, the use of grazing lands, and the income of the farmer; presents statistics on the agricultural production of the country, and suggests measures by which the native might be induced to adopt improved methods of farming.

Report on tests of sport varieties of cereals in 1899, K. Kittlauss (*Deut. Landw. Presse, 28 (1901), Nos. 1, pp. 79, 80; 15, pp. 115, 116; 16, pp. 127, 128*).—Similar work has been previously reported (E. S. R., 11, p. 538).

Variety tests in 1900 and future work in this direction, Edler (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 25, pp. 145–147*).—A brief résumé of the work, presented as a paper before the German Agricultural Society.

Frost injuries to winter cereals in 1901, P. Sorauer (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 33, pp. 195–197*).—This article treats of the distribution of frost, its intensity and duration necessary to injure winter cereals, the resistance of varieties, and the conditions favoring frost injuries.

Planting Vicia faba on fields of injured winter cereals, R. Schmoldt (*Deut. Landw. Presse, 28 (1901), Nos. 29, pp. 249, 250; 30, pp. 260, 261; 31, pp. 268, 269; 32, pp. 279*).

Mustard and turnips as catch crops, P. Genay (*Semaine Agr., 21 (1901), No. 1053, pp. 228–230*).—In connection with a general discussion of the subject analyses of both plants are reported.

Alfalfa on muck, W. E. Imes (*Amer. Gard., 22 (1901), No. 351, p. 635*).—The author reports growing 8 tons of dry alfalfa hay per acre on muck land in Michigan.

Soil inoculation for alfalfa, G. C. Watson and E. H. Hess (*Pennsylvania Sta. Rpt. 1900, pp. 307, 308*).—Inoculation tests for alfalfa with Nitragin and with soil from an alfalfa field are reported. The best results were obtained on the plat treated with soil from alfalfa ground. The use of Nitragin also showed some effect. The yields in general indicated that alfalfa is not well adapted to shallow limestone soils.

The influence of potash salts on the development of barley, J. Stoklasa and J. Pitra (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 5, pp. 567–582, fig. 1*).—The work here reported consisted of pot experiments made to determine the influence of potassium chlorid as a fertilizer on the qualities of brewing barley. The pots were divided into 5 groups of 10 pots each, according to the quantities of potassium chlorid applied. Each pot received 0.5 gm. of nitrate of soda and 1 gm. superphosphate furnishing 0.161 gm. of phosphoric acid, while the quantity of potassium chlorid per pot varied from 0.5 gm. to 3 gm. The results of the experiments are summed up in the following table:

Effect of potassium chlorid as a fertilizer on the quality of barley.

Potassium chlorid applied per pot.	Vitality.	Viability.	Husks.	Starch in dry matter.	Protein in dry matter.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
None	99	97	11.9	57.38	12.86
0.5 gram	99	98	9.8	63.52	9.14
1.0 gram	100	96	8.6	64.00	10.02
1.5 gram	100	95	9.3	61.20	10.31
3.0 gram	98	96	10.2	57.68	10.82

These results show that a rational application of muriate of potash in conjunction with superphosphate and nitrate of soda was beneficial to the development of the barley plant and the improvement in quality of the grain.

Thick vs. thin seeding of corn (*New Jersey Stas. Rpt. 1900, pp. 265, 266*).—Southern White corn was planted June 8, the kernels being placed 10, 12, 14, and 16 in. apart in the drill on 4 different plats. The seed required per acre at these different rates of planting was 6, 5, 4, and 3 qt., respectively. The largest yield was obtained where the kernels were planted 10 in. apart and 6 qt. of corn were used per acre. This plat yielded 9.03 tons of silage corn, or 20.7 per cent more than the plat with the thinnest planting. The plat with the thickest planting suffered most from dry weather and produced the smallest ears, but still results indicate that the thickest planting was the most profitable for silage corn.

Cotton, E. Grimley (*Queensland Agr. Jour., 9 (1901), No. 1, pp. 113–121, figs. 2*).—A paper on cotton culture in Queensland, treating the subject largely from a financial standpoint and discussing the conditions under which it may be profitably grown.

Cotton in Egypt, Y. Henry (*Agr. Prat. Pays Chauds, 1 (1901), No. 1, pp. 55–88, figs. 2*).—This article describes a number of cultivated varieties of cotton, discusses the climate and soil of Egypt, and gives concise descriptions of the methods of growing, ginning, and baling cotton in that country. Chemical and physical analyses of the soil and an analyses of Nile water are reported.

Comparative tests of red clover from different countries, O. Burchard (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 31, pp. 450–454*).—From the results obtained it is concluded that red clover from North American sources is better able to stand severe winters than red clover obtained from Southern and Western Europe.

Emmer: A grain for the semiarid regions, M. A. CARLETON (*U. S. Dept. Agr., Farmers' Bul. 139, pp. 16, figs. 3*).—This bulletin is a popular discussion on the value and use of emmer and its adaptation for cultivation in the semiarid regions of this country. The botanical characteristics of emmer are pointed out and compared with those of spelt. The names often incorrectly used for this grain are given, and its history and distribution are outlined. Experiments with emmer at some of the experiment stations and tests made by individual farmers are briefly reviewed, and a number of analyses of the grain are shown in tables. Descriptions are given of 2 varieties of spring emmer, Ufa and Yaroslav, and attention is called to the fact that at present no varieties particularly adapted for fall seeding are grown in the United States. The valuable qualities secured from crossing emmer with common varieties of wheat are enumerated as follows: (1) Resistance to fungus attacks, (2) drought resistance, (3) increased fertility of the head, (4) nonshattering, (5) stiffness of straw, and (6) increase of gluten content of the grain. The cultivation of this crop is briefly noted.

Note on the culture of Manila hemp in the Philippines, DE BÉRARD (*Agr. Prat. Pays Chauds, 1 (1901), No. 1, pp. 89–104*).—The varieties of *Musa textilis* principally cultivated in the island of Luzon are briefly described and notes on the climate, soil, culture, and cost of production are given.

Experiments in acclimatizing winter oats, SCHLACHT (*Deut. Landw. Presse, 28 (1901), No 60, pp. 519, 520, fig. 1*).—This article discusses the methods of acclimatizing winter oats and the conditions required to insure success.

Experiments with oats and peas (*New Jersey Stas. Rpt. 1900, pp. 264, 265, pls. 2*).—Experiments in growing oats and peas for grain and for hay are reported. Two bu. each of oats and peas per acre were sown broadcast. The yield amounted to 50 bu. of seed, weighing 24 lbs. per bushel, and 2,205 lbs. of straw. The mixture of grain consisted of 75 per cent of oats and 25 per cent of peas. The analysis of the crop during storage, and of the grain and straw at the time of thrashing, is given in a table. The same mixture grown for hay and harvested the last week in June produced a satisfactory yield. The composition of the green and cured fodder is tabulated.

The ground-nut crop, J. W. LEATHER and C. BENSON (*Dept. Land Records and Agr., Madras, 1900, Vol. 2, Bul. 41, pp. 167–174*).—Notes are given of the peanuts raised in India and the amount of oil and moisture, etc., in a number of varieties.

Fourth report on potato culture, L. A. CLINTON (*New York Cornell Sta. Bul. 196, pp. 43–59, fig. 1*).—This work is in continuation of tillage experiments with potatoes now in progress for a number of years (E. S. R., 10, p. 950). This bulletin gives the results for 1899, 1900, and 1901.

In 1899 a plat sprayed 6 times with Bordeaux mixture and Paris green yielded at the rate of 48 bu. of potatoes more per acre than a plat not sprayed. The results obtained in 1900 indicated that thorough preparation of the soil and intensive tillage are insufficient for the absorption and retention of moisture when the supply of humus is not maintained. In 1901 the average yield of the plats planted May 16 was 250 bu. per acre, the yield of a plat planted on June 12, 162 bu. per acre, and the yield of another plat planted June 17, 197 bu. per acre. Spraying with Bordeaux mixture increased the yield in nearly every case during the entire period. A test of pruning potato vines to one main stalk showed that this process did not increase the yield. The author recommends harrowing potato land after potatoes are planted and before the plants are above ground. Notes are given on potato planters and diggers, spraying apparatus, and methods of keeping seed potatoes.

The influence of selecting seed tubers from productive plants on the yield of potatoes, VON SEELHORST and G. FRÖLICH (*Jour. Landw., 48 (1900), No. 4, pp. 317–324*).—The experiments here described are in continuation of work previously reported (E. S. R., 13, p. 41). The results obtained agreed with the results of previous work, and the authors consider their conclusions of the previous year substantiated, namely, that by the selection of seed the yield of potatoes may be materially increased and the rapid deterioration of varieties prevented.

Correlation and transmission in the rye plant with special reference to the color of the grain, A. GEERKENS (*Jour. Landw., 49 (1901), No. 2, pp. 173–192*).—For the purpose of this work 3 kinds of rye—Goettinger, Pirna, and Russian—were grown in pot and field experiments. The Goettinger and Pirna rye had been selected on the basis of typically formed heads with a desirable number of well-formed grains, while in the case of the Russian rye, strongly yellow and green-colored grains were selected from a quantity of seed. In the pot experiments the tillering capacity, the weight of the plant, and other data concerning the different parts of the plant were determined. Owing to the quantity of the material, the plants grown in the field were not studied so minutely. In the pot experiments all poorly developed plants and in the field test all single-stemmed plants were not considered.

The only difference noticed before the heads appeared was in the development of the plants due to the difference in weight of the grains used for seed. Immediately before the blossoming period it became quite noticeable that the progeny from broad heads with many spikelets produced strong, stiff, upright standing spikes, as compared with long, loose, and bending spikes from square, loose heads with a smaller number of spikelets. This observation leads to the conclusion that the form of the head of parent plants is to a considerable degree transmitted to the progeny. A comparison of the other data showed that as a rule a decrease in the length of the rachis is associated with a decrease in the length of the stem and an increase in the number of spikelets per 10 cm. of the rachis. The number of grains decreased regularly and quite perceptibly as the rachis shortened. There was no great difference noticeable in the number of grains per 10 cm. of the rachis, but the different varieties did not give similar results. In the case of Goettinger and Russian rye this factor remained constant through the different groups, while with the Pirna variety it was greatest where the rachis was of medium length. A short rachis was associated with a smaller number of grains per spikelet than a long rachis. It was further found that the weight per 100 grains decreased slightly with the decrease in length of the rachis. The thickness and the weight of the stems, heads, and grains decreased considerably and regularly with the length of the rachis. The weight of the heads and grains showed a decrease in proportion to the decrease in weight of the stem. Concerning the color of the grains the author concludes that there seems to be a relation between green grains and heads crowded with spikelets, and between yellow grains and loose heads, but that this relation is too weak to manifest itself in all cases. In the progeny of short and crowded heads the weight of the grain and the heads were the lowest of the variety. The number of grains per head was also lowest in the progeny of short, crowded heads, and the weight per 100 grains was in general a little lower than the weight per 100 grains of the progeny from loose heads. The form of the head had no influence on the tillering capacity. The weight of the plant and of the grain per plant was lowest in the progeny of short, crowded heads. From these data it is seen that the best results in the progeny were obtained from the square, loose heads. The field experiments showed that in all instances the color of the grain had been transmitted in a high degree to the progeny. There was no discernable difference in the tendency of transmission between the two colors. In most cases with Goettinger and Pirna rye the progeny of green-colored grains had the heavier heads, the heavier weight of grains, and the largest number of grains per head. In the case of the Russian rye, however, the progeny of the yellow grains produced heavier heads and grains. The weight per 100 grains of the Pirna rye was largest in the plants grown from the yellow seed, while the Goettinger and Russian rye gave the heavier weight per 100 grains from the green-colored seed. The tillering capacity was greatest in the plants grown from yellow grains. In the pot experiments the weight of the plants and the weight of the grain per plant were in favor of the progeny of green-colored seed, while in the field experiments these weights were in favor of the yellow seed. The author states that although there is a series of similar results, the experiments do not show an absolute advantage in favor of either color when, as in this case, the grains were all taken from the same form of head. It was found that the protein content of the grain was apparently transmitted in exceptional cases only to a very small extent. The data collected in making these experiments are reported in tables.

The influence of environment upon the composition of the sugar beet, H. W. Wiley (*U. S. Dept. Agr., Bureau of Chemistry Bul. 64, pp. 32*).—This bulletin is devoted mainly to the study of climatic influences on the composition of the sugar beet. The meteorological, analytical, and geodetic data obtained in experiments conducted by the Bureau of Chemistry in collaboration with the Weather Bureau, and a number of experiment stations located in regions of different climatic conditions, are reported. The average results are summarized in the following table:

The average results with Austrian Special Kleinwanzlebener sugar beets grown under different climatic conditions in 1900.

Locality.	Analytical data.			
	Weight.	Yield per acre.	Sugar in the beet.	Coefficient of purity.

Geneva, N. Y	14 44	42 53 00	453

In several instances the meteorological data in the above table are taken from the records of the station nearest to the locality reported. At the Utah Station, where the beets were grown under irrigation, the sugar content varied from 15 to 18 per cent. The advisability of applying water to a beet field as late as September 1 is considered doubtful. The influence of fertilizer was studied in connection with this work at the Wisconsin Station, where a fertilized portion of a plat yielded almost 4 tons more per acre and produced a richer beet than an unfertilized portion. The general results show that a high sugar content and a high latitude ran very evenly together. The highest percentage of sunshine, nearly 75 per cent of the possible hours of sunlight, was recorded at Lexington, Ky., and the lowest, 59.2 per cent, at Agricultural College, Mich. The observations on the influence of sunlight seemed to show that the diffused light coming through the clouds is apparently as effective as the direct sunlight. The results further show that a low sugar content was closely associated with a high temperature, and that the purity of the juice, although subject to many variations, had a general tendency to follow the percentage of sugar. The figures also show a direct relation of the average length of day from sunrise to sunset to the sugar content of the beet. The short day was associated with a low sugar content, and the long day with a high sugar content. The rainfall, especially in its distribution, was found to bear a very important relation to the sugar content. "The ideal conditions for the growth of the beet are an even distribution of the rainfall of from 3 to 4 in. during the months of May, June, July, and August, and a reduction of the rainfall for September and October."

The influence of intensely drying the soil on the development of the sugar beet, J. J. Vaňha (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 5, pp. 562–566*).—A quantity of clay soil of uniform texture was divided into 3 parts, the first being given an ordinary moisture content; the second, thinly spread out and completely dried by the action of the sun, and the third portion placed in an open kettle and subjected to a temperature of from 80 to 100° C. until dry as dust. These differently treated soils were then put in pots for the growth of sugar beets. All pots were given the same quantities of water and fertilizers with the exception of the check pots, which received no fertilizer. The total yield of the fertilized as well as the unfertilized pots was increased by drying the soils. Drying at from 80 to 100° C. gave the best results, more than doubling the yield. The quality of the beets was also favorably influenced by drying the soil. The total yield of sugar was increased as the drying of the soil was intensified. The purity coefficient was diminished slightly on account of an increase in the solids not sugar.

A note on teosinte, C. Chalot (*Agr. Prat. Pays Chauds, 1 (1901), No. 1, pp. 129–136*).—A general discussion on the culture of teosinte and a report on a cultural test with this plant made at the experiment station at Libreville, in the French Kongo country. The chemical composition of the plant is given.

Wheat (*Kentucky Sta. Bul. 94, pp. 121–130, pls. 2*).—Variety tests with wheat are reported and botanical descriptions of the different varieties, with field notes on the same, are given. Similar work has been previously reported (E. S. R., 12, p. 1035). The season of 1901 was unfavorable, and the yield was about one-third less than the year previous. Dawson Golden Chaff, Lancaster Red, Indiana Swamp, Beech-wood Hybrid, Rudy, Fultz, and Harvest King were the most productive varieties during this season, yielding 30.6, 31.5, 31.7, 33, 33.4, 36.3, and 36.3 bu. per acre, respectively. The weight per measured bushel for the different varieties was much less this season than in 1900.

Macaroni wheats, M. A. Carleton (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 3, pp. 62, pls. 11, figs. 2*).—This bulletin treats of the characteristics, distribution, adaptability, cultivation, and marketing of macaroni wheats; discusses the effects of local variations in soil and climate on the quality of these wheats, and briefly reports the results of experimental comparisons of varieties. Statistics are given on the Russo-Mediterranean traffic in macaroni wheat. The following varieties, which have well-marked characteristics and have attained a high reputation, are briefly described: Gharnovka, Arnautka, Kubanka, Pererodka, Beloturka, Velvet Don, Black Don, Sarui-bugda, Medeah, Pellissier, Candeal, Nicaragua, Wild Goose, Missogen, and Polish. Meteorological data for the regions of Russia where these varieties are largely grown and for sections in this country adapted to their culture are tabulated. In discussing the climatic conditions of these regions the author calls attention to the fact that "the normal yearly rainfall of the Great Plains at the one hundredth meridian, where wheat growing is at present practically nonexistent on account of the lack of drought-resistant varieties, is nearly 3 in. greater than that for the entire semiarid Volga region, which is one of the principal wheat regions of Russia, and which produces the finest macaroni wheat in the world." Comparative notes on foreign and domestic macaroni are given and analyses of macaroni produced from different wheats are tabulated. The bulletin further treats of the use of macaroni wheats for bread and of the preparation of semolina or flour used in the manufacture of macaroni.

Fertilizer experiments with wheat, J. OSTERSPEY (*Fühling's Landw. Ztg., 50 (1901), Nos. 12, pp. 417–423; 13, pp. 449–455*).—This experiment was made with highly bred and selected Squarehead wheat on a soil poor in lime. The purpose of the work was to determine the effect of an application of phosphoric acid in the forms of superphosphate and Thomas slag, and of a top-dressing of nitrogen as nitrate of soda and sulphate of ammonia, in addition to a medium application of barnyard manure. The influence of either the phosphoric acid or the nitrogen used with barnyard manure was also studied. Superphosphate increased the yield when applied in addition to barnyard manure, but this increase was not sufficient to make its use profitable, either when used alone or in connection with a nitrogen application. The use of Thomas slag, however, at the rate of 1,500 kg. per hectare was found economical in all cases. The average results of the application of sulphate of ammonia at the rate of 100 kg. per hectare showed neither an increase nor a loss, while 125 kg. of nitrate of soda per hectare given in 2 applications proved highly profitable. The simultaneous use of fertilizers furnishing phosphoric acid and nitrogen produced a profit under those conditions only when the use of the one or the other alone was profitable.

HORTICULTURE.

Report of the assistant in horticulture, A. T. JORDAN (*New Jersey Stas. Rpt. 1900, pp. 213–255, pls. 4*).—Experimental studies are reported on the effect of irrigation, the relative effects of fertilizers with and without irrigation upon early and total yield, and the effect of the addition of nitrate of soda. The results secured with asparagus and a number of bush and orchard fruits in 1900 are recorded in detail and compared with results secured the 2 previous years. The daily and monthly precipitation for the season is also included.

Asparagus (pp. 218–222).—Contrary to the results obtained in 1898 and 1899, unirrigated asparagus plats gave the larger early and total cut. Palmetto was the most productive variety grown in 1900. The increase in early asparagus with this variety was worth commercially $24.60, and the early and total cut $111.77, more than any other variety grown. Plats fertilized with complete fertilizers have given the largest early cut, while the lowest yields have regularly appeared on the nitrate of soda plats. The difference in favor of selected crowns as compared with commercial roots, which was very marked at first, has been growing less and less each year, and in 1900 the yields were practically identical.

Blackberries (pp. 222–225).—Erie has been the most productive blackberry grown, and Agawam the least. Irrigation increased the early yield in 3 out of 4 cases, but the total yield was larger on the unirrigated plats. In previous years the results have been considerably in favor of irrigation. The addition of an extra amount of nitrate of soda was without benefit.

Raspberries (pp. 225–227).—Turner gave the largest yield, 4,327 qt. per acre, but "it crumbles badly and is very undesirable." Cuthbert, which stood first in 1899, yielded but 3,316 qt. in 1900. The combined yields in 1900 of all the unirrigated plats were slightly greater than from the irrigated as regards early and total yield. The effect of different fertilizers has been irregular. Plats receiving extra amounts of nitrate of soda have, on the whole, given decreased yields.

Currants and gooseberries (pp. 227–230).—A quart of currants has been found to weigh about 20 oz. Victoria was the most productive sort in 1900, yielding 7,507.2 qt. per acre, followed by Red Dutch, 6,764.4 qt. The increased yield due to irrigation was 15.6 per cent. Plats fertilized with barnyard manure have given the best yields, followed by complete commercial fertilizers, while the poorest results have been obtained when additional amounts of nitrate of soda have been added.

With gooseberries, Houghton, with a yield of 14,391.8 qt. per acre, was the most productive sort, with Downing second, 13,860.8 qt. Irrigation increased the yields in 1900 about 10 per cent. In previous years the heaviest yields have been obtained on the unirrigated plats. Barnyard manure has given better yields than any other fertilizer, followed by complete commercial fertilizers containing an extra amount of nitrate of soda.

Strawberries (pp. 230–240).—Nitrate of soda added to complete fertilizers resulted in increased yields. In early yield better results were secured with subirrigation than with surface irrigation, but in total yield the surface irrigated plats exceeded the subirrigated by 13 per cent and the unirrigated by 28 per cent. The surface irrigated plats also gave the largest late yield. Subirrigated plats gave 12 per cent greater yields than no irrigation.

In the study of the relative merits of matted row and hill culture, the hills were set in main rows 4 ft. apart with 3 rows a foot apart, and the plants 1 ft. distant in the rows. Thus set, it required 32,670 plants to set an acre. The matted rows were 4 ft. apart with plants 18 in. distant in the row. Only one-third as many plants were required to set an acre by this method, and the cost of labor was approximately only one-third as much as by the hill system. The following 11 out of 35 varieties grown have given larger yields by the hill system than by the matted row, showing that some varieties are much better adapted to hill culture than others: Gandy, Gladstone, Hunn, Johnson Early, Lady Thompson, Margaret, Parker Earle, Ridgeway, Starr, Warfield, and Wm. Belt.

"On the other hand, there are those in which the yields from the matted rows far exceed that from the hills, and thus the matted rows of Bismark and Buback have given more than double, while that of Glen Mary, Manwell, Ocean City, and Sample have given nearly double the yield obtained from the hills."

The most productive variety grown by the hill system was Warfield, with Wm. Belt and Big Berry (Corsican) close seconds. In the matted row Sample led, yielding 30,154 qt. per acre, followed by Bederwood (19,010 qt.), Cobden Queen (18,070 qt.), and Manwell and Bismark, each yielding over 17,000 qt. per acre.

The varieties most prolific in the formation of runners were Cobden Queen, Johnson Early, Sample, Tennessee, and Warfield. Brief notes are given on the 35 varieties grown, as well as tabulated data regarding early and total yields, freedom from producing runners, etc.

Tree fruits (pp. 240–255).—Experiments largely with fertilizers and irrigation are reported with apples, standard pears, peaches, dwarf pears, plums, and cherries. The crop secured with plums, cherries, and peaches in 1900 was the first one, and much of the data recorded are given as matter of record. On the whole, the irrigated plum plats gave increased yields of about 30 per cent as compared with the unirrigated.

No increase resulted with cherries. Dwarf plums on irrigated plats gave 17 per cent better yields than on unirrigated. The fruit was somewhat larger. Much difference occurred in the time of ripening of different trees of Newman plum and Crawford and Susquehanna peaches. Sneed was the earliest peach to ripen, followed 3½ weeks later by Triumph, the second earliest, and 3 weeks after Triumph by Champion, the third earliest. Sneed has not yet proved very productive, Triumph somewhat more so, and Champion very productive. Crosby has been a sure bearer, with medium sized fruits.

Three peach trees set according to the Stringfellow method and 3 according to the usual method came into bearing in 1900. On the whole, trees set according to the usual method yielded 28 per cent more fruit than those set by the Stringfellow method. Along with this experiment another in thinning was undertaken. Where over two-thirds of the fruit set was removed in thinning, 2.83 baskets of fruit, worth $2.83 per basket, were produced. Where only one-third of the set was removed, approximately 1 basket more fruit per tree was obtained, but its value was only $1.76, as against $2.83 in the preceding case. In the case of the third tree where the total set was not quite as large as the others and with 28.84 per cent removed in thinning, 3.53 baskets, worth $1.59, were obtained.

Some data with illustrations are given showing the value of renewing old peach orchards by cutting back.

Horticultural division, F. W. Card and G. E. Adams (*Rhode Island Sta. Rpt. 1901, pp. 227–244, pls. 9*).—Notes and some data are here given on the fruiting habits of blackberries, pollination and manuring of blackberries and raspberries, plant selection, mixing of field and sweet corn when planted in close proximity to each other, crossing and pollinating melons, and methods of planting fruit trees. Some data on the San José scale, apple maggot, and carnation stem rot included in the report are noted elsewhere in this issue.

With Agawam, Ancient Briton, and Early Cluster blackberries, the flower clusters were near the main stem, usually within 2 to 4 buds, while with the Taylor variety there were found to be nearly always 4 to 8 sterile buds next to the main stem, and unbranched canes often did not develop flowers within 2 or more feet of the ground. It is suggested, therefore, that it is not advisable to practice as close pruning with Taylor as with the other varieties noted. Agawam and Early Cluster blackberries when planted together were observed to give considerably better yields than when planted separately, due, it is thought, to better pollination being secured. Some data on the yield of blackberries and raspberries fertilized with different combinations of commercial fertilizers are given but no conclusions drawn.

In experiments in plant selection, work with especially early fruiting canes of Taylor blackberries and of Cuthbert raspberries is noted. It is hoped to propagate the early fruiting tendencies of these selected specimens. In this connection, 5 plants of Kansas raspberries which to the eye promised to be among the best and most productive plants were marked, and the fruit at picking time counted and weighed. With these 5 plants the number of berries varied from 576 to 851 per bush, and the weight of fruit from 648 gm. to 1,130 gm. The average weight of the berries from different plants varied from 1.13 to 1.43 gm. It is pointed out that these variations might have been very much greater had the comparison been made between the poorest and best plants in the field rather than between the 5 best ones.

The experiment here reported on planting sweet corn in close proximity to Longfellow flint corn is in continuation of that reported in 1898 (E. S. R., 11, p. 928). At that time no kernels of the sweet corn type were observable on the flint corn ears, while there was an abundauce of yellow kernels on the sweet corn ears. The year following 3 plantings of corn were made from the crossed corns as follows: (1) With yellow kernels found on the sweet corn ears; (2) with apparently normal sweet corn kernels from sweet corn ears that also contained yellow kernels; and (3) with kernels taken from field corn ears which appeared normal, but which had been grown near sweet corn. The yellow kernels from the sweet corn were planted in an unfavorable place and failed to grow. The white kernels produced ears showing very little mixing, only now and then a kernel appearing which was not true. The kernels from the field corn produced ears which showed numerous sweet corn kernels.

"It seems safe to conclude, therefore, that the presence of sweet corn in proximity to field corn does not influence the character of kernels of the latter during the season of growth, while the field corn does affect the sweet corn, entirely changing the character of the kernels pollinated by it. Kernels of field corn may, however, be fecundated by sweet corn pollen, and the result will show the following year when those kernels are planted, though the effect has not been visible upon the kernels themselves. It seems, however, that when sweet corn has been crossed by field corn the effect generally if not always shows, and that kernels which do not show the effect will give a pure product the following year."

Further experiments with crossed and self-pollinated muskmelons and watermelons (E. S. R., 11, p. 928) are reported. Seed from a green-fleshed watermelon crossed with a pink-fleshed variety when planted produced melons intermediate in character beween the 2 fruits, the flesh having a yellowish cast tinged with pink. The seeds also varied in character. Sixty-four crosses and pollinations were made in 1899, and 45 in 1900. Nothing could be detected in the resulting fruit or seed which tended to show any immediate influence of the pollen on either color of the fruit or character.

Further notes and illustrations are given on the growth of fruit trees differently topped and root pruned at the time of transplanting to the permanent orchard (E. S. R., 11, p. 928). The result of 3 years' observations are thus summarized by the authors: "For practical purposes the most rational method seems to be to leave all sound roots and shorten back the tops, which not only helps to bring about a proper balance between root and leaf, but also improves the subsequent character of growth of the tree."

The garden book for practical farmers, T. Greiner (*Pract. Farmer's Libr., 3 (1901), No. 2, pp. 190, figs. 129*).—In this number methods of laying out the garden are discussed, garden tools illustrated and described, directions given for making hotbeds, cold frames, and cheap greenhouses, and popular information given regarding gardening operations and the control of insect and fungus pests affecting garden crops.

Experiments with nitrate of soda on early beets, T. Brown (*New Jersey Stas. Rpt. 1900, pp. 110–114*).—This experiment with table beets is in continuation of that previously reported (E. S. R., 11, p. 444). It differs from it only in the larger plats used. Its purpose was to study the value of increasing amounts of nitrate of soda for table beets grown in rich garden soil. The amount applied varied from 400 to 700 lbs. per acre. The effect on the increased earliness of the crop, total yield, and value of the crop on the different plats are recorded. As in the previous year, the extra earliness of the crop was considerably increased by the use of the nitrate, varying in amount from 6.5 per cent in the case of the application of 400 lbs., to 13.4 per cent when 600 lbs. per acre was applied. The total increased value of the crop due to the use of nitrate varied from $30.20 when 400 lbs. per acre was applied, to $68 when 700 lbs. was applied. On the whole, an average return of $5 was obtained for every dollar invested in nitrate of soda. The average increased net value of the crop per acre was $54.15, showing, as in the previous year, the practical importance of a sufficiency of available nitrogen for quick-growing garden crops where earliness is a prominent factor in the profits.

An experiment with different forms and amounts of nitrogen on muskmelons in 1899 and 1900, C. C. Hulsart (*New Jersey Stas. Rpt. 1900, pp. 114–123*).—The first year's work in the use of different amounts and forms of nitrogen for muskmelons has already been noted (E. S. R., 11, p. 445). The average increased yield from the use of nitrate of soda in 1899 was 110 per cent, sulphate of ammonia 84 per cent, and dried blood 108 per cent—results in accord with those of the preceding year. The amount of nitrate of soda used in the first group of plats was 150 lbs. per acre, sulphate of ammonia 120 lbs., and dried blood 200 lbs. The actual amount of nitrogen applied was the same in each case. These amounts seemed to conduce to a normal growth of melons. When the amounts were multiplied by $1\frac{2}{3}$ and $2\frac{1}{3}$ the yield of melons was considerably depressed and the value of the crop decreased. The effect of the fertilizers on earliness is somewhat conflicting in the different groups; the average percentage of early melons for all groups is as follows: Nitrate of soda 34.6 per cent, sulphate of ammonia 44.6 per cent, and dried blood 54.5 per cent. The proportion of culls from the nitrate of soda plats for the 2 years, 1898 and 1899, averaged 24.7 per cent, from the sulphate of ammonia plats 31.6 per cent, and from the dried blood plats 31 per cent.

In 1900 the experiment was modified to study, in addition to the features already noted, the relative advantages of 2 and 3 applications of the different nitrogenous fertilizers. Unfavorable weather interfered with the experiment. In the main the results correspond with those of the 2 preceding years. Two applications proved more effective with nitrate of soda than 3, but the unfavorable weather experienced does not give weight to this result.

Experiment with different forms and amounts of nitrogen upon sweet corn, C. C. Hulsart (*New Jersey Stas. Rpt. 1900, pp. 124–130*).—This experiment was begun in 1898 (E. S. R., 11, p. 446) and has now been conducted 3 years. Nitrate of soda, sulphate of ammonia, and dried blood have been compared as sources of nitrogen for sweet corn. In the first group of plats 150 lbs. of nitrate of soda, 120 lbs. of sulphate of ammonia, and 200 lbs. of dried blood, furnishing the same amount of nitrogen in each case, were used per acre. In the second and third groups these amounts were multiplied by $1\frac{2}{3}$ and $2\frac{1}{3}$. The results of the experiment at the end of 3 years show an increase in yield for the different forms of nitrogen of from 23.3 to 40.2 per cent. The largest yield of both corn and stalks in every instance, save nitrate of soda, has been obtained with the heavier applications of nitrogen. The total results are in favor of sulphate of ammonia as a source of nitrogen for corn, though there is but little difference between the ammonia and the dried blood. The gross returns for the 3 years for the use of sulphate of ammonia were $12.66 per acre, dried blood $9.95, and nitrate of soda $9.69. The cost of the fertilizers in each case averaged about $4 per acre, thus showing a very satisfactory net profit from the use of these fertilizers on soils already in good cultural condition.

An experiment with cabbage in 1899, C. C. Hulsart (*New Jersey Stas. Rpt. 1900, pp. 131–133*).—Nitrate of soda, sulphate of ammonia, and dried blood were used alone in increasing amounts with cabbage. All 3 forms of nitrogen gave greatly increased yields over the control plat, but the dried blood, applied at the rate of 270 lbs. per acre, was most effective. Nitrate of soda, applied at the rate of 200 lbs. per acre, stood a close second. The average increased value, due to the use of all the fertilizers, was over $50 per acre. All forms were about equally effective in hastening the earliness of the crop.

Irrigation experiments, E. B. Voorhees (*New Jersey Stas. Rpt. 1900, pp. 182–212*).—The author discusses the subject of irrigation in the humid climate of the Eastern States, basing his statements largely on the results secured in New Jersey with blackberries, raspberries, gooseberries, currants, and miscellaneous crops. Nearly all the data given have appeared previously (E. S. R., 11, pp. 735, 1039). Topics discussed are the shortage of water in humid regions, in which it is shown that in 53 out of the last 60 years in New Jersey there has been at least 1 month in the growing season when there was such a deficiency of rainfall as to cause a serious shortage of crops, 33 years in which the deficiency extended through 2 months, and

18 years for 3 months; the amount of water required for irrigation; storage of water; small irrigation plants and the cost of the same; irrigation in humid *vs.* arid districts; furrow irrigation; and flooding small beds of plants. Experiments at the station show a gain from irrigation with a number of crops as follows: Early cabbage, 31.3 per cent; onions, 16.9 per cent; sweet corn, 51.5 per cent; sweet potatoes, 72.6 per cent; Lima beans, pole, 23.8 per cent; watermelons, 44 per cent; white potatoes, 36.4 per cent; and bush Limas, 8.8 per cent.

In some experiments carried out by G. A. Mitchell under the station auspices irrigation regularly promoted earliness of maturity with Early Jersey Wakefield cabbage and increased the profits $18.24 per acre. With tomatoes the profits were increased about $18, with watermelons $25, and with sweet potatoes $43.68 per acre by irrigation.

Experiments in the crossing of plants, B. D. HALSTED (*New Jersey Stas. Rpt. 1900, pp. 428-447, pls. 7*).—A report is given of attempts made in crossing plants, the experiments having been made within the past 2 years. Cucumbers, Lima beans, tomatoes, sweet corn, and salsify have been successfully crossed. Two crosses of White Spine and White Pearl cucumbers were successfully made and plants grown from each. The fruits of the crosses showed the influence of both parents, but they appeared much more nearly like the White Spine. The crosses with Lima beans were made between the varieties Burpee and Henderson. The resultant crosses, of which 20 were obtained, showed in the size of plants that they were midway between the parent plants. The vigor of many of the plants was remarkable. In the combinations secured it was desired to obtain a better bearing variety than Burpee, and the points desired have been obtained, but the quality remains to be fixed. Experiments are reported in which an upright growing variety of tomato and one with large reclining vines were crossed. The first variety produced red fruit of medium size, the second a large yellow fruit. A large number of seedlings were produced, and great differences were noted among the plants in size, color, form of foliage, etc. The product obtained from a yellow fruit resulting from a cross of the Dwarf Champion on a Golden Sunrise was a red fruit indicating a cross, although the color was not of the same tint as that of the staminate parent. The product of the reverse cross was quite uniform in all respects, all the fruits being red. Two plants were obtained which seemed to be exceptional in their characters; one was from the first lot of those from red fruits. The fruitfulness was far less than surrounding plants, and the fruit was smaller and almost seedless. The flowers were larger than usual and the foliage somewhat mottled. The second plant was almost gigantic in size of stems and foliage. It combined the leaf characters of the 2 parent plants, and the flowers were of an unusually large size. One of the most remarkable facts was the smallness of the fruit, averaging only about an inch in diameter. The yellow variety of tomato used sometimes shows fruit more or less blotched with red, but it is suggested that the redness of the yellow fruits is not a result of crossing with the red variety.

Experiments in crossing sweet corn are continued from the previous year (E. S. R., 12, p. 353). The primary object of the experiments was to test the susceptibility of the varieties Black Mexican, Stowell Evergreen, Egyptian, Stabler Nonpareil, and First of All, to bacterial diseases and corn smut. A number of crosses were incidentally obtained, which are reported upon at some length. The crosses indicate an increased vigor of the plant, although a striking exception was noted in the case of black grains upon an ear of Egyptian. Pink grains from Egyptian gave a very prolific crop of corn of remarkably uniform appearance, with light, dark, and pink grains thoroughly mixed. Subsequent plantings of these varieties have been made but the varieties are not yet established. The results of this season's work seem to indicate that there is a much greater influence of the male plant than the female on the style of the ear and color of grains.

A species hybrid between the cultivated salsify and the wild species is reported upon at some length. The hybrid seems to be intermediate between the 2 parent forms.

Experiments in plant hybridization, G. MENDEL (*Jour. Roy. Hort. Soc.* [*London*], *26* (*1901*), *No. 1, pp. 1–32*).—Herewith is given a translation of this paper which was first published in 1865 in the *Abhandlungen des naturforschenden Vereines in Brünn* (volume 4). The importance of the article attracted little attention at the time, owing to the greater attention being given to the Darwinian doctrines regarding the problems of species. Recently work along this line has been resumed by a number of hybridists and the article rediscovered and found to have an unusual value in this connection. In the article the results are given in detail of 8 years' experiments with peas (*Pisum sativum*), and the law is definitely established for the plants under observation that "in respect of certain pairs of differentiating characters the germ cells of a hybrid, or crossbred, are pure being carriers and transmitters of either the one character or the other, not both." The original parental characters remain intact and do not coalesce but reappear in the progeny in a certain definite ratio, in accordance with their "dominant" or "recessive" characteristics. When peas were crossed which differentiated from each other in one characteristic only, the hybrid character of the progeny so closely resembled that of one of the parental forms that the other either escaped observation completely or could not be detected with certainty. The character which is transmitted intact or almost so in the hybridization is termed by the author the "dominant" character, and those which become latent in the process the "recessive" characters; and it is further shown that it is immaterial whether the dominant character belongs to the seed-bearing or to the pollen-bearing plant, the form of the hybrid remains the same in both cases. As a result of several series of experiments in which peas were used which differed from one another in one characteristic only, it was definitely established that the relation of the dominant to the recessive characters, in the case of the pea at least, is as 3:1. The hybrid forms which maintain the recessive characters in the first generation remain constant in their offspring for all subsequent generations and do not vary as regards this character. When the seed showing the dominant character is grown, however, and self-fertilized, two-thirds yield offspring which show the dominant and recessive characters in the proportion of 3:1, while only one-third remain with the dominant characters constant. The ratio of 3:1 which appears in the first generation therefore resolves itself in the second generation to 2:1:1, and this relation, it is thought, will probably hold true for all subsequent progeny, since in trials as regards form and color of the peas it held good for 6 generations through which the experiment was carried.

Peas differing from one another in several characteristics were also experimented with and the results secured are given in great detail. As the number of differentiating characters increases, the complexity of the results also increases, but "for the whole of the characters involved in the trials the principle applies that the offspring of the hybrids in which several essentially different characters are combined represent the components of a series of combinations, in which the developmental series for each two different characters are associated. It is demonstrated at the same time that the relation of each two different characters in hybrid connection is independent of the other differences in the two original parental stocks."

In investigating the composition of the egg and pollen cells of hybrids, the theory that "pea hybrids form egg and pollen cells which, in their constitution, represent in equal numbers all constant forms which result from the combination of the characters when conjoined by fertilization," was justified experimentally. Experiments with beans (*Phaseolus* spp.) led to a like conclusion.

The article contains an introductory note by W. Bateson, in which a brief biographical sketch is given of the author and some comments made upon the paper. In these remarks Mr. Bateson states that it is hardly too much to say that Mendel's laws of hybridization deduced in these experiments "are worthy to rank with those that laid the foundation of the atomic laws of chemistry."

Further contribution regarding the differential value of characters in crossing beans and peas, E. Tschermak (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 6, pp. 641–731, figs. 12*).—An extended study of the characteristics of the seed of peas and beans obtained by crossing different varieties and species. The work was carried out along lines laid down by Mendel. In all the tests it is stated that Mendel's scheme lost something of its generality, but nothing of the importance for theoretical and practical plant breeding purposes of its classical doctrine of the differential value of characters in transmission.

Onion culture, T. C. Nye (*Truck Farmer, 5 (1901), No. 2, pp. 56–59*).—The method of the author in growing Bermuda onions on a large scale in Texas is given. Heavy fertilizing, transplanting, and irrigation are given as essential factors in successful culture. Early planting of sets in August and September resulted in total failure. Sets, in the author's experience, should not be put out before November. From 7 acres 147,000 lbs. of onions were secured, which sold for 2¼ cts. per pound.

The Bermuda onion, H. W. Brown (*South. Farm Mag., 9 (1901), No. 7, pp. 26, 27*).—Cultural directions are given for growing Bermuda onions in the South. The use of imported seed is insisted upon.

The chayote: A tropical vegetable, O. F. Cook (*U. S. Dept. Agr., Division of Botany Bul. 28, pp. 31, pls. 8*).—An extended account is given of the nature, culture, and economic value of the chayote. This is a tropical vegetable belonging to the squash family. It is now grown quite extensively in Porto Rico, Mexico, tropical America, Algeria, East Indies, and Australia, and is believed to be worthy of cultivation in the Gulf States, California, Hawaii, and the Philippines. The plant is a perennial climbing vine, sensitive to frost, and requires a long season to come to maturity. It will endure where the ground does not freeze in the winter. The vine dies back, but the reserve material in the root enables it to grow again when favorable conditions appear. One vine will cover about 20 sq. ft. of surface and bear from 300 to 500 fruits in a season. The fruit is pear-shaped and weighs from 8 oz. to 3 lbs. It contains but one seed. This germinates readily and the fruit normally continues alive for some time after separation from the plant. The fruit is cooked and eaten like summer squash, and is otherwise prepared. The flavor is considered by some more delicate than squash and by others as insipid. Mixed with rosella it has the flavor of apple sauce. The vines, fruit, and roots are also valuable as fodder. An analysis is given of the tuberous roots, which show a starch content of 20 per cent. It is believed that the chayote will prove valuable as a winter vegetable for shipment to northern city markets.

Lessons in pomology from 1899–1900, J. H. Hale (*Connecticut Bd. Agr. Rpt. 1900, pp. 214–237*).—Popular review of the development of the fruit industry along various lines, with many suggestions regarding culture, packing, shipping, etc.

Fruit harvesting, storing, marketing, F. A. Waugh (*New York: Orange Judd Co., 1901, pp. VIII+224, figs. 61*).—This book purports to be a practical guide to the picking, grading, packing, storing, shipping, and marketing of fruit. Methods of fruit storage are given most attention and a number of plans detailed for constructing storage houses in which ice refrigeration or cooling by ventilation are the important factors. Under the subject of harvesting, the utilization of waste fruits is discussed and suggestions given regarding methods of drying, evaporating, canning, etc. The appendix is an important practical part of the work. It contains data on the imports and exports of fruits of the United States, fruit-package laws in different States, apple-shippers' rules regarding quality and grades of fruit, regulations of the National League of Commission Merchants of the United States, including a roster of the members in the principal cities, commission charges on different fruit and vegetables, refrigerator cars and shipments, etc.

Experiment in root pruning, R. GOETHE (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1900–01, pp. 18, 19, fig. 1*).—Thirty apple trees were used in this experiment; 15 were root pruned according to the usual method, and 15 close root pruned according to the Stringfellow method. The 2 lots were planted in similar soils under like conditions and treated exactly alike in all other respects. Of the 15 trees root-pruned according to the usual method, 14 grew well and made a good root system; while of the 15 pruned according to the Stringfellow method, 12 died outright.

Root-pruned trees in Mexico, H. L. TROTT (*Rural New Yorker, 60 (1901), No. 2698, p. 690*).—The author holds that success in root pruning by the Stringfellow method is a question of latitude rather than climate. It is stated that in setting out a plantation of 500,000 coffee trees, 2 to 5 years old, the trees were cut back to a trunk of 6 in. and a root of 6 in., and shipped. When these were set out 2 in. more were cut off both trunk and root. The stubs were then planted in holes driven by a pointed stick. These stubs grew well and made trees superior to those grown from unpruned nursery stock because they branched low. Rubber trees were successfully grown in the same way.

Self and cross pollination: The influence of pollination on the form of the seed, R. GOETHE (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1900–01, pp. 19–24, figs. 14*).—This is an account of some experiments to determine the degree of fertility or sterility of apple and pear blossoms to their own pollen, and of the effect on the form of the seed of crossing different varieties of pears. Illustrations are given of the parent seed in each instance and of the seed of the crossed fruit.

Fertilizing orchard fruits, A. WAGNER (*Wiener Illus. Gart. Ztg., 26 (1901), No. 10, pp. 345–352*).—A comprehensive popular article on orchard fertilizing.

Subtropical fruits in Florida, A. A. BOGGS (*Fruitman's Guide, 12 (1901), No. 298, pp. 12, 13, 17*).—A paper read at the Buffalo meeting of the American Pomological Society, 1901. The status in Florida of the pineapple, citrus fruits, mango, avocado, pear, papaw, etc., is noted.

Nursery culture of apples, J. P. ANDREWS (*Nat. Nurseryman, 9 (1901), No. 10, pp. 254, 255*).—Some of the problems confronting nurserymen in the Northwest are presented and discussed.

Study of the ripening of apples, R. OTTO (*Proskauer Obstbau-Ztg., 1901, July; abs. in Chem. Centbl., 1901, II, No. 8, p. 553*).—The changes in the composition of apples brought about by ripening and storing were studied by the author. The water content of apples decreased as the green apples approached maturity, while the dry matter increased. The 4 per cent of starch present in the green apples examined decreased at first slowly, later rapidly, and finally disappeared entirely as the apples ripened. The ash content of the dry matter decreased with the ripening period and with storage. The cellulose content remained constant during the early stages of ripening. The nitrogenous matter and cane-sugar content increased with ripening, but decreased with storage. The total acid, calculated as malic, decreased constantly as did also the small amount of pectin present.

Culture of the date palm, G. SCHWEINFURTH (*Gartenflora, 50 (1901), Nos. 19, pp. 506–517; 20, pp. 541–546*).—This is a popular article dealing with the cultural and climatic condition required in date growing, fertilizers, irrigation, pollination, varieties, renovation of old palm trees, grafting, statistics of the industry, and the problem of changing the sex of palms.

The fig in Asiatic Turkey (*California Fruit Grower, 26 (1901), No. 697, p. 1*).—The methods followed in curing and packing figs in the vicinity of Smyrna are noted and contrasted with California methods.

The olive in Tunis, M. MINANGOIN (*Tunis: Dir. Agr. et Com., L'Olivier en Tunisie, 1901, pp. 70, pls. 10, figs. 4*).—This deals with the propagation, culture, and varieties of olives grown in the different fruit regions of Tunis. Other phases, such as manuring, irrigating, and insects and diseases of olives, are also considered, and a chapter given to the discussion of the relative advantages of the proprietor assuming entire directions and responsibility in the growing of olives, and of his furnishing the land to small farmers who plant and care for the orchard and pay the rent by giving the proprietor a certain portion of the crop.

Observations on olives in Asia Minor, G. C. Roeding (*Pacific Rural Press, 62 (1901), No. 16, p. 245*).—Methods of oil production are principally discussed. The vast acreage of olives in Asia Minor makes it impossible for the olive mills to utilize the crop as fast as it is gathered. The fruit is therefore stored in stone vats in the open air. These vats are about 8 ft. wide, 8 to 10 ft. long, and 8 ft. deep. After a vat is filled it is covered over with a heavy cloth resembling burlap. Boards are then placed above this and weighted with heavy stones. No precautions are taken to keep out rain. It seems to make no difference whether rain goes in or not. Olives thus stored lose their shape and become a mass of flesh and pits. They do not spoil or become rancid, however, and the oil produced from them is rather heavy and greasy, though not disagreeably so, and possesses a good bouquet.

Pickling ripe and green olives, F. T. Bioletti (*California Sta. Bul. 137, pp. 21*).—This bulletin presents the results of experiments by the station in pickling ripe and green olives by the lye and salt methods, and is the outcome of many complaints received by the station reporting failure in pickling when the methods recommended by the station were followed. (E. S. R., 11, p. 46.)

Experiments with pickling ripe olives (pp. 3–13).—The olives used in this experiment were nearly all dead ripe. They had been picked and shipped without any special precautions and were considerably bruised. The problems investigated were whether large, overripe, bruised olives, which were otherwise in good condition, could be used to produce wholesome marketable pickles, and whether such pickles could be preserved in good order for a reasonable length of time. The olives were sorted and graded, and experiments made with 8 varieties. They were covered with a 1.4 per cent lye solution, and in most cases with a 2 per cent salt solution at the same time, and left from 7 to 20 hours, after which they were rinsed and covered with a 2 per cent salt brine. The brine was changed from time to time and gradually increased in strength for 25 to 38 days, at the end of which time they were placed in a 12 per cent salt solution and either immediately or about 8 months later transferred to (1) a fruit preserving jar and left untreated, (2) an earthen jar and kept submerged by a floating cover, or (3) a fruit preserving jar and heated to 80° C. once and sometimes 3 times. In some instances the jars were sealed and heated, and again they were covered with a layer of paraffin before sealing and heating. The details and results of all these different methods are given at length.

The results of the experiments show "that even soft, overripe olives may be successfully pickled by proper modifications of the lye and salt method, even when the fruit has been somewhat carelessly handled before pickling and when the water used is not of the purest. The main precautions in such cases are to use a certain amount of salt from the beginning of the process, and to watch carefully for the first appearance of scum or slime on top of any of the liquids in which the olives are immersed. On the appearance of the slightest of these signs of fermentation, the solution must be changed and the receptacle thoroughly disinfected with boiling water. The salt hardens the flesh and makes it more resistant to fermentative organisms which exist in the water, and at the same time the antiseptic properties of the salt, even when used in such small proportions as 2 per cent, are probably of use in delaying the increase of these organisms, molds, and bacteria. All the samples, with the exception of the Sevillano, kept without perceptible deterioration for 8 months in open jars after pickling, although they were unprotected from the air except for a floating wooden cover. A ring of mold formed around the edge of the cover, but there was no perceptible injury to the flavor of the pickles, except for a slight moldiness in taste of the Sevillano."

Eleven unheated samples kept in a fair to good condition for 11 months, but they were all more or less spoiled within 32 months. Twenty samples heated to 80° C. kept perfectly for 32 months, at the end of which time they were as good as when made, with the exception of one sample which deteriorated slightly.

"It may be concluded from this that heating to 80° C. (176° F.) is a sufficient means of preserving ripe olives, even in weak brine, for an indefinite period in hermetically sealed glass jars, provided that they are exposed to no greater changes of temperature than occur in an ordinary room in Berkeley. . . . There is every reason to believe that a slightly higher heating, say to 90 or 95° C., would have made them perfectly secure in any climate. . . . The only objection to heating noted was that it causes a diffusion of the coloring matter of the olives into the brine, so that after heating the olives were lighter-colored and the brine darker than before. This diffusion, however, takes place in time even with unheated olives, and at the end of 32 months the unheated olives were in most cases actually lighter-colored than those which had been heated."

The results of the test indicate that Gordal, Manzanillo, Columbella, and Regalis are the best varieties for home use; and that Sevillano, Mission, Picholine, Manzanillo, and Gordal are most satisfactory for market purposes.

Experiments in pickling green olives (pp. 13-21).—Experiments have been made to determine the best methods of pickling green olives so as to preserve the green color. None of the usual methods of treating ripe olives, either with comparatively strong lye for short periods or with weaker lye for a longer period, was successful and in pure running water the olives turned brown the quickest. This fact suggested that possibly the oxygen in the air dissolved in the water might be a factor in the discoloration. Further experiments were therefore made with weak lye solutions which had been boiled to expel the air. The olives were kept in the lye solution until their bitterness was neutralized. With the weaker solutions it was found necessary to renew the lye several times. After neutralization they were pickled with salt solutions of gradually increasing strength as with ripe olives. By this treatment it was found possible to produce green olives which retained their color for 12 months. It is necessary first to find the proper strength of the lye solution to use for the variety or grade of olives to be pickled. This may be done by using a series of pint fruit-preserving jars containing the olives. In these should be poured different strength lye solutions beginning with ½ per cent and increasing by ½ per cent to 3 per cent solutions. When a solution is found just a little stronger than is necessary to neutralize the bitter principle in the olives in 48 hours, this strength should be chosen for curing the bulk of the crop. The proper strength having been determined, it is recommended that the olives be placed in a 50 gal. barrel having a 4 or 5 in. bung-hole and covered with lye. After soaking 48 hours the lye should be drawn off, the olives washed quickly with 2 changes of fresh water, and covered immediately with a 2 per cent brine solution. This should be replaced successively by 4 and 8 per cent solutions, allowing each solution to remain from 48 to 72 hours, depending on the size of the olives, and finally by a 12 per cent solution.

"The essential part of the process is to avoid exposing the olives to the air during the pickling, until all the bitterness and acid are completely neutralized by the lye. After this the green color seems to be fixed, and exposure to the air does not change it much, though it is well, all through the process, to avoid leaving the olives uncovered by liquid any longer than necessary.

"As different varieties of olives and even the same variety in different seasons and from different localities differ very much in bitterness, the importance of treating each variety separately is evident, as each will require lye solutions of different strength to neutralize them. Very bitter olives, such as Mission, Sevillano, Manzanillo, and True Picholine, require solutions containing from 1½ to 2½ per cent of pure potash lye, while olives containing little bitterness, such as Ascolano and Columbella, require only from ½ to 1 per cent solutions. As many of the commercial lyes are far from pure, some containing not more than 50 per cent of potash, the number of preliminary tests must usually be at least six, as indicated above. Preliminary tests conducted as described do not require an analysis of the lye, though it is probable that lyes containing a large amount of common salt would act more slowly; and with such lyes a treatment exceeding 48 hours might be necessary."

Nitrate of soda for oranges (*Pacific Coast Fruit World, 12 (1901), No. 4, p. 6*).—The writer states that from 3 to 5 lbs. of nitrate of soda per tree, according to size, scattered over the ground in the early spring, while it is moist, and immediately cultivated in, seems to give the best results with oranges. "Too large a dose tends to coarsen the fruit or thicken the rind, while the wood growth and general vigor of the tree is greatly stimulated."

Pineapple growing, P. H. Rolfs (*U. S. Dept. Agr., Farmers' Bul. 140, pp. 47, figs. 4*).—This is a popular article dealing with the outdoor culture of pineapples in Florida, and the diseases and insects affecting the same. Figures are given on the cost of growing pineapples and the possible profits in the business. Such matters as harvesting, packing, shipping, and canning the fruit, fertilizing and irrigating the plants, etc., are discussed in considerable detail.

Culture of the Queen pineapple, T. Coomber (*Gard. Chron., 3. ser., 30 (1901), No. 772, pp. 269, 270, fig. 1*).—Methods observed by the author in growing the Queen pineapples under glass are given.

Manures for tea in Assam, H. H. Mann (*The tea soils of Assam, and tea manuring. Calcutta: Indian Tea Association, 1901, pp. 60–103; figs. 2*).—The chapters of this work included within these pages treat of the general principles of tea manuring and of the materials suitable for this purpose in Assam, and the method of their application. Peat bheel is considered one of the best top-dressings for tea, to increase its luxuriance, in Assam. In one experiment the use of this material increased the yield of tea about 25 per cent. The tea from the dressed plat gave a slightly brighter liquor than that from the undressed plat, but otherwise did not differ in value from it, thus showing that contrary to the general impression in the province no decrease in quality is likely to result from the use of this material as a top-dressing. It is stated that not more than 100 to 120 tons should be used per acre. Peat bheel soil is formed by the decay of many generations of rank growing plants, the principal part of the decay taking place under water. This material contained from 21 to 30 per cent organic matter and 0.6 to 0.68 per cent nitrogen in the samples reported. The greater use of cattle manure on all Assam tea soils is urged. Mustard and the legume "mati kalai" (*Phaseolus aconitifolius*) have been most successfully used as green manures. The "mati kalai" has proved the better of the two. This plant should be sown in April or May. It is urged that some green-manure crop should occupy the ground during the greater period of the rains, and form a normal part of tea culture.

The use of the leguminous "sau" tree (*Albizzia stipulata*) in tea gardens is stated to produce undoubted beneficial effects, probably due to the fixation of the nitrogen in the soil by its roots; though some analyses made by the author of soils under these trees gave only irregular results, and whether or not nitrogen is increased in the soil through the agency of this tree could not be determined by these analyses. Some objections to these trees are that they induce long, stalky growth and hence a lower quality of tea, and in addition encourage various insect pests and blights. A rotation of these trees, not to exceed a period of 3 years, is suggested to overcome these objections.

The use of either mustard or castor cake as a manure gave immediate and profitable results without decreasing the quality of the tea. The cake is best applied before the first hoeing in spring. It may be applied in a trench around each bush about a foot away from the stem, but broadcasting and hoeing in is considered almost as good.

The mustard is considered about four-fifths as valuable as the castor cake, and linseed cake a little more valuable than the mustard cake. The use of the nitrates of soda and potash and of sulphate of ammonia as fertilizers for tea is not as satisfactory as some of the more permanent forms of nitrogen, and should not exceed, in the author's opinion, 5 per cent in any fertilizer mixture. Basic slag is considered one of the most satisfactory sources of phosphoric acid for tea manuring. This is the element most closely related to quality of tea (see article on Tea soils, p. 723).

Burning tea prunings and returning the ashes to the soil is believed to be safer than burying them. If the garden is entirely free from blight, however, the prunings may be buried. In this case they should be buried as soon as cut and covered at least 6 in. deep with soil. If basic slag is used it may be dusted over the prunings in the trenches at the rate of 400 to 500 lbs. per acre. When basic slag is used without the prunings it may be broadcasted on the surface either at the autumn deep hoeing or with the first spring hoeing, and then followed with a crop of "mati kalai" in May, to be hoed in in June. Wood ashes is also recommended as a phosphatic fertilizer to be used in the same manner as basic slag. Lime is not required to any great extent in Assam soils, but may be used to help rot buried prunings in the place of basic slag, and for its fungicidal effects. Potash manures are not deficient in Assam soils, and while potash may form a component part of the fertilizer mixtures for tea it should never be applied alone. Relative to time and methods of manuring, the author is of the opinion that this should be carried on the year before heavy pruning of the plant takes place.

Rotation of manures is suggested as follows: First year, light dressing of bheel soil, not more than 4 in. thick when put on; second year, crop of mustard in May and June to be hoed in as a green manure; third year, 8 cwt. per acre of basic slag in November; fourth year, crop of "mati kalai" in May and June, to be hoed in as a green manure; fifth year, nothing; sixth year, 7 tons per acre of cattle manure in March; seventh year, nothing. Modifications of the above rotation are also suggested.

Culture and preparation of tea, A. DOLABARATZ (*Rev. Agr. Réunion, 7 (1901), Nos. 7, pp. 272–281; 8, pp. 321–325*).—Notes on the culture, preparation, and on the quality of Réunion tea.

Instructions for growing tea from seed (*Bol. Agr. y Ganadería, 1 (1901), No. 13, pp. 20, 21*).—Methods of growing tea from seed, transplanting, etc., are given.

Small fruits in 1900, J. P. PILLSBURY (*Pennsylvania Sta. Rpt. 1900, pp. 352–371*).—The results obtained in tests with 65 varieties of strawberries, 32 of raspberries, 4 of blackberries, 8 of currants, and 12 of gooseberries are recorded in tables and notes. Similar earlier work with these fruits has been reported (E. S. R., 12, p. 645). In the experiment with strawberries the fruiting period extended from June 4 to July 9. Meek Early and Ella were the earliest varieties tested and Hunn the latest. Warfield has been the best yielding variety grown at the station for the past 4 years. In 1900 the best 5 varieties in point of yield in hill culture were Crawford, See No. 5, Brandywine, Crescent, and Dayton, in the order named; and the best 5 varieties in matted rows were Brandywine, Warfield, Crawford, Ohio Centennial, and See No. 5. In the comparison which is being made between the hill system and matted row culture of strawberries—with regard to the production of berries of large size—the results of the season seem to show a decided increase in favor of the matted row. With 19 varieties grown by both systems there was a difference varying from 0.05 to 2.7 gm. in favor of the hill system, and with 35 other varieties the difference varied from 0.01 to 3.65 gm. The average results, as regards yields per acre, with a large number of varieties grown from 2 to 4 years at the station by both systems of culture are quite largely in favor of the matted row.

The phosphates in strawberry culture (*Sci. Amer. Sup., 52 (1901), No. 1349, pp. 21625, 21626*).—The method of fertilizing strawberries observed by M. Condon in France is stated. By this method the following fertilizers are applied by mulching in the month of March: Seven kg. sodium nitrate, 3 kg. superphosphate, and 4 kg. potassium chlorid per acre. This mixture costs scarcely 8 francs per year, and is said to occasion an increased production of 65 to 70 kg.

Grapes in Germany, J. C. WHITTIER (*Pacific Coast Fruit World, 12 (1901), No. 4, p. 4*).—An account of the grape industry on the Rhine, between Cologne and Bingen.

The influence of cross fertilization on the form of the seed, R. GOETHE (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1900–01, pp. 64–66, figs. 3*).—Some illustrations are given on the results obtained in the form of the seed in cross fertilizing different varieties of grapes.

Manufacture and commerce of dried raisins in Central Tunis, L. GERARDIN (*Bul. Dir. Agr. et Com., 6 (1901), No. 20, pp. 247–251*).—Methods of preparing dried raisins in Turkey, Spain, and the islands of the Eastern Mediterranean are also noted.

Preservation of posts by different methods, C. SEUFFERHELD (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1900–01, pp. 45, 46*).—Posts used in vineyards were dipped in different solutions to preserve them against rot. The period of the experiment covers 24 years. The best results have been secured with tar. Only 9 per cent of fir posts impregnated with tar had rotted at the end of 24 years. At the end of 20 years 33 per cent of those impregnated with copper sulphate had rotted; nevertheless, the ease and cheapness with which posts, particularly green posts, can be saturated with copper sulphate solutions seems to make its use more desirable than that of the tar.

Wall and water gardens, GERTRUDE JEKYLL (*New York: Charles Scribners' Sons, 1901, pp. 177, pls. 133*).—The beautifying of the garden and home by the use of rocks, walls, and water is made the special feature of this book. There are named and described some of the rock and wall plants easiest to grow and directions given for their use and culture. The making and planting of terrace and garden walls in sun and shade, the construction of rock gardens, planting of lakes, ponds, small streams, bogs, tubs, stream margins, etc., are discussed in as many chapters and richly illustrated. Water lilies, their uses, and the varieties best adapted for different purposes, is the subject of the last chapter. The book, while written from the English standpoint and illustrated largely from English examples, contains many helps and suggestions for American gardeners.

Lilies and their culture, G. B. MALLETT (*Gard. Chron., 3. ser., 30 (1901), Nos. 759, pp. 22–24; 760, pp. 41, 42, fig. 1; 761, pp. 66, 67, fig. 1; 764, pp. 129, 130; 765, pp. 146, 147, figs. 2; 766, p. 164; 767, pp. 181, 182*).—The various groups and more important species of lilies are described and their culture characteristics noted.

On the history of the orchid-flowered or Italian cannas, C. SPRENGER (*Rev. Hort., 73 (1901), No. 19, pp. 446–448*).—Some orchid-flowered cannas originated by the author are noted.

The proper use of shrubs, G. C. BUTZ (*Pennsylvania Sta. Rpt. 1900, pp. 372–382, pls. 6*).—The use of shrubs in ornamental plantings about the home is considered and descriptions given of a large number of ornamental shrubs of recent introduction.

Experiments with lawn grasses, B. D. HALSTED (*New Jersey Stas. Rpt. 1900, pp. 460, 461*).—Nine plats of grasses seeded in the spring of 1896 have been kept closely cut with the lawn mower in each succeeding season and the present condition of each plat is shown. The Rhode Island bent grass continues in good condition and the Kentucky blue grass has proved very satisfactory. Redtop and perennial rye grass seem to be depreciating rapidly.

Distribution of seeds and plants, E. J. WICKSON and J. B. DAVY (*California Sta. Seed Bul., 1901–02, pp. 7*).—This gives a list of the seeds and plants available for distribution throughout the State and the rules governing their distribution.

FORESTRY.

The influence of forests in preventing floods, P. VESSIOT (*Rev. Eaux et Forêts, 40 (1901), No. 19, pp. 590–593*).—The influence of forests on the humidity of soil and drainage, upon infiltration, upon subterranean waters and the outflow of springs, and upon floods is treated in separate chapters, together with a review of a recent publication by Ebermayer. It is claimed that the leafy cover of the forest prevents to a great extent the violent downfall of water and retains an important amount of the precipitation. It also protects the soil from the drying action of the sun, as well as from nocturnal radiation, and prevents wide variation in the maxima and minima of temperature such as result in late frosts. The humus, moss, and other ground covering absorb a great amount of water, which slowly percolates through it and in this way checks to a great degree the erosion which takes place in unprotected regions. The network of roots acts materially in holding the soil in place. The forest cover is said to retain from 20 to 40 per cent of the atmospheric precipitation. Much of this is given off by the transpiration of the plants. This reduces the temperature and increases the humidity of the surrounding region. As to the influence on precipitation, the author claims that observations made at Nancy, France, from 1867 to 1872 showed that 24 per cent more water fell upon timbered regions than in the open in the months from May to October, and about 12 per cent in the remaining 6 months of the year. This difference is believed to be due to the forest cover as reacting upon the atmosphere.

The upper limits of forest vegetation on mountains, C. FLAHAUT (*Rev. Eaux et Forêts, 40 (1901), Nos. 13, pp. 385–401; 14, pp. 417–439*).—The forest vegetation of the mountains of France is described at some length, particular attention being paid to the alpine and subalpine zones. The principal species which characterize these regions are described. The forest vegetation does not appear to extend beyond the subalpine limits, which are determined by a number of climatic and other conditions. The alpine and subalpine meadows are described and notes given upon their distribution. The subalpine zone is characterized in France by coniferous trees, and is determined by climatic conditions which coincide with the upper normal limits of woody plant growth. The alpine vegetation is herbaceous, or small shrubs. The reforestation of portions of the subalpine zone upon which the timber has been destroyed is possible, and suggestions are given whereby it may be carried out, but the attempt to introduce forest growth in the alpine regions is considered futile.

Important Philippine woods, G. P. AHERN (*Manila, 1901, pp. 112, pls. 43*).—This work consists mainly of a compilation of notes on the most important timber-tree species of the Philippine Islands, giving information concerning the Philippine forests, characteristics of the leading timber-tree species, value of the same (present and future), and methods of procedure to secure licenses to cut timber. Extracts are given from the forestry regulations, stating the conditions under which timber may be cut. The timber trees of the country are divided into 6 groups, the stumpage price per cubic foot of the State timber varying from 1 to 14 cts. per cubic foot. Of the more valuable groups it is not permitted to cut any for fuel. The different species of trees are arranged according to groups in which the popular and scientific names, so far as known, are given. The State forests are estimated to comprise from 20,000,000 to 40,000,000 acres. In some places the cuttings have been very small, while in other provinces most of the readily accessible timber has been cut. The present forestry regulations enumerate 396 species, in addition to which a number of others are known, so that at present there are 665 native tree species listed. On account of the lack of means of communication and the character of laborers to be obtained, forest exploitation will be exceedingly difficult. There are no pure forests of any one species, and in order to obtain a cargo of any particular timber it would be necessary to secure the same from different sections. The local and oriental markets are discussed at some length, and the prices of different kinds of timber are quoted. Fifty species of the more important timber trees of the islands are described at considerable length, their characteristics and uses being given.

Chapters are also given on the depredations caused by the white ant, and an experiment with a number of American and native woods is briefly described. Oregon pine, bull pine, and spruce were completely destroyed within 30 days, while hemlock, California redwood, and California white cedar were practically uninjured. Notes are given on the strength and weight of the more common timbers, and their uses are mentioned. A brief chapter is given on the gutta-percha industry of the islands, and a list is given of more than 50 species or trees belonging to the orders Sapotaceæ and Urticaceæ, which may be expected to yield gutta-percha. The report concludes with a brief list of authorities cited.

The yield of oak high forests, WIMMENAUER (*Allg. Forst u. Jagd Ztg., 67 (1901), May, pp. 157–163; June, pp. 193–198*).—A brief statement is given of the oak forests along the Rhine, and the value of the stand at various ages is shown. The questions of rents and soil productive values are discussed at some length. The forest values and interest upon investments are given. The maximum value as an investment seems to be attained when the trees are from 80 to 100 years old. The open stand with coppice system is also considered. The increment for the system is shown and the money value of different density and age is indicated.

The cork oak, E. A. MÜLLER (*Abhandl. K. K. Geogr. Gesell. Wien, 2 (1900), No. 7, pp. 75, pls. 2, chart 1; abs. in Bot. Centbl., 86 (1901), No. 9, pp. 314–316*).—Treats of the natural history of the cork oak (*Quercus suber*) and gives its distribution, uses, methods of handling, etc.

Notes on the red cedar, C. MOHR (*U. S. Dept. Agr., Division of Forestry Bul. 31, pp. 37, pls. 2, figs. 13, map 1*).—A report is given on the red cedar, in which is included *Juniperus virginiana* and *J. barbadensis,* the trees not being distinguished in their forest and timber characteristics. The red cedar is one of the most widely distributed of our forest trees, occurring from Canada to the Gulf, and westward to the limit of tree growth in the Mississippi Valley. It usually occurs in rather small areas over this large region, and commercial areas are found only in the southeastern part of the United States. The distribution of the tree through its region of greatest production is described at some length, together with notes on its uses, rate of growth, timber characteristics, insect and fungus enemies, etc.

Plantations of timber trees as a commercial speculation, J. S. CHEESBROUGH (*Agr. Gaz. New South Wales, 12 (1901), No. 6, pp. 717–720*).—A statement is given of the probable profit accruing from a plantation of 100 acres planted to red cedar (*Cedrela toona*). This tree is said to mature its crop in about 40 years, at which time the value of the crop at present market prices would be about $14,000 per acre above all expenses.

A new means for protecting coniferous seedlings against white grubs, A. MILANI (*Allg. Forst u. Jagd Ztg., 67 (1901), Aug., pp. 268–273, figs. 3*).—A description is given of a sort of vessel in which the seedlings are grown for 6 to 8 years, when by disintegration the roots are set free. The material from which it is made is porous enough to admit water, does not act injuriously upon the roots, and protects them until old enough to withstand the grubs.

Turpentine and rosin, W. M. STEUART (*Twelfth Census United States, Census Bul. 126, pp. 12*).—A report is given of the turpentine and rosin industry of the United States, comparisons being made between the present status of those industries and their condition during the period of the 5 previous census years. The number of establishments at present engaged in this industry, as reported in the bulletin, is 1,503, with a capital of $11,847,495, which produced products valued at $20,344,888, an increase of 124 per cent in the number of establishments and 151 per cent in the value of the products over the previous census year. This industry, which is confined to the long-leaf pine region, is of commercial importance in but 7 States, viz, Alabama, Florida, Georgia, Louisiana, Mississippi, North Carolina, and South Carolina. The development of the industry and methods of gathering the rosin, and the preparation of the various products, are described at some length.

The increase of the forest domain of Belgium (*Rev. Eaux et Forêts, 40* (*1901*), *No. 20, pp. 630, 631*).—Since 1897 the forest domain of Belgium has been increased by 2,847 hectares at a cost of 2,761,727 francs. In 1900 and 1901 the extension amounted to 1,768 hectares, of which 826 were high forest and coppice, 82 coppicè, 613 coniferous forest, and 242 uncultivated or abandoned lands.

Forest fires in Gascony, MILLIES-LACROIX (*Les incendies dans les forêts de pins des landes de Gascogne. Paris: Mouillot, 1901, pp. 70*).—A discussion of proposed legislation regarding forest fires in the pine forests of Gascony.

The forest, its influence and management, F. W. CARD (*Rhode Island Sta. Rpt. 1901, pp. 245–253*).—A popular paper on forest influences and forest management.

The treatment and management of forests, particularly of deciduous trees, L. BOPPE (*Rev. Eaux et Forêts, 40* (*1901*), *No. 15, pp. 449–455*).—The author calls attention to various methods whereby the management of forests may be improved so as to provide increased returns.

Forest improvement. An outline of lectures with numerous references, R. HESS (*Die Forstbenutzung. Ein Grundriss zu Vorlesungen mit zahlreichen Litteraturnachweisen. Berlin: Paul Parey, 1901, pp. XV + 318*).

Experiments in thinning, SCHWAPPACH (*Allg. Forst u. Jagd Ztg., 67* (*1901*), *June, pp. 198–202*).—The principles of forest thinnings are discussed and various applications in practice pointed out.

Annual review of the publications and more important events in forestry, forest zoology, agricultural chemistry, meteorology, and forest botany for the year 1900 (*Allg. Forst u. Jagd Ztg., 67* (*1901*), *Sup., pp. 93*).—Lists of publications, reviews of articles and works, and accounts of important events in the departments indicated are given.

SEEDS—WEEDS.

The seed coats of certain species of the genus Brassica, A. J. PIETERS and VERA K. CHARLES (*U. S. Dept. Agr., Division of Botany Bul. 29, pp. 19, pl. 1, figs. 6*).—A study was made of the seeds of different species of Brassica to ascertain if possible how to distinguish certain valuable high-priced seeds from those which are less valuable or worthless weed seed. The external appearance and gross anatomy of the seeds of 7 species of Brassica are discussed and the histological characters are illustrated and described at considerable length. A brief key is given for determining the seeds of the species studied. This key is based upon the characters mentioned above.

The action of concentrated sulphuric acid upon seed, particularly upon the hard seeds of certain Leguminosæ, F. TODARO (*Staz. Sper. Agr. Ital., 34* (*1901*), *No. 7, pp. 613–689*).—On account of the desirability of increasing the germination of hard seed, which often occur in great numbers among leguminous seed, and for the treatment of beet and other seed to hasten their germination and to destroy fungus spores that may have found lodgment upon the seed bolls, the author conducted an extended series of experiments on the effect of sulphuric acid when applied to a great variety of seeds of leguminous and other plants. He found that concentrated sulphuric acid of a density of 1.84 acted upon hard seeds of all leguminous plants, rendering them capable of prompt germination. Hard seeds of various leguminous species were found to withstand immersion in concentrated sulphuric acid, without any injury to their viability, for about 1 hour at a temperature of 25 to

28° C., or a somewhat longer period at a lower temperature. Among other leguminous plants, the seeds of which are not characterized as hard, immersion in concentrated sulphuric acid was injurious except when applied for a comparatively few minutes. Ordinarily leguminous seeds which belong to species that are characterized by the occurrence of hard seeds are resistant to the action of sulphuric acid. In all the experiments with leguminous seeds treated with concentrated sulphuric acid the germination of the hard seeds was effected and a more rapid and uniform sprouting was secured. In order to secure the best results from treatment with sulphuric acid the seed should be repeatedly washed to secure the elimination of the acid and planted immediately. If the seeds are left to dry the advantage secured by the treatment is lost. In experiments with seeds of lotus, sulla, etc., it was found that 30 parts sulphuric acid to 70 of water gave results which were equal to those secured by the use of concentrated acid. Upon such seed as sulla, bird's foot clover, melilotus, black medick, etc., it was shown that concentrated sulphuric acid not only secured the greater total germination but appreciably hastened it.

Experiments in which hemp was treated with sulphuric acid showed the germinative power was always diminished by the immersion. Seed bolls of beets showed no injury, even when the immersion was prolonged considerably beyond the time necessary for the destruction of the fungi which are contained in the seed boll. This fact can be made use of in disinfecting beet seed before planting. Sulphuric acid showed itself injurious upon the seed of all cereals experimented with. It was found that the seed of various grasses, if submerged for 2 or 3 minutes in concentrated sulphuric acid, had their glumes attacked to such an extent that the effect produced upon germination was decidedly favorable. Cuscuta seed showed that they were not only resistant to the action of sulphuric acid, but their germination was in many cases favored by the treatment. The seeds of *Plantago lanceolata*, verbena, Rumex, spurry, foxtail, and some others which frequently occur in red-clover seed were all destroyed by a brief immersion in the sulphuric acid, without any detriment whatever to the red-clover seed.

Seeds of commercial saltbushes, G. N. Collins (*U. S. Dept. Agr., Division of Botany Bul. 27, pp. 28, pls. 8*).—Illustrated descriptive notes are given of the fruit and seed characters of 23 species of Atriplex. On account of the increased interest in the saltbushes this study was made to determine, if possible, some means for the definite recognition of the different species by seed characters.

The duration of vitality in the seeds of Castilloa elastica, W. R. Tromp de Haas (*Teysmannia, 12 (1901), No. 7–8, pp. 442–444*).—A note is given of the results of keeping seeds of Castilloa in charcoal powder, in earth, and in a vacuum. The seeds in charcoal germinated 80 per cent after 4 weeks, while all but 5 per cent of those kept in earth for the same time had lost their vitality. The seeds kept in a vacuum for 4 weeks were all dead.—H. M. PIETERS.

Some factors in the germination of seed, C. Sajo (*Prometheus, 12 (1901), No. 587, pp. 236–238*).—An account is given of experiments with a number of kinds of seeds of perennial plants, and it is believed that in addition to heat, light, and moisture, other factors are to be considered, prominent among them the action of bacteria.

Germination in distilled water and the poisonous effect of copper solutions, P. P. Dehérain and E. Demoussy (*Ann. Agron., 27 (1901), No. 11, pp. 553–559, figs. 3*).—An account is given of experiments made by the authors to determine the effect of distilled water on the germination of seed, and also the poisonous influence of traces of copper. This paper has been previously noted from a summary published elsewhere (E. S. R., 13, p. 143).

Seed testing, T. W. Kirk (*New Zealand Dept. Agr. Rpt. 1901, pp. 329–339*).—During the period covered by the report about 400 samples of farm seeds were examined by the author. The purity and germination of the different varieties of seed are shown in tabular form, from which it appears that a decided improvement is noted in the quality of seed over that formerly reported. The samples obtained were secured by private individuals, so that the seed merchants could not have information as to the use to which they were to be put. The results, as shown by the test, seem to warrant the belief that the publication of seed tests has demonstrated its value as a means for securing a better quality of seeds in the open market.

Report of seed testing at Modena in 1900, F. Todaro (*Staz. Sper. Agr. Ital., 34* (*1901*), *No. 11, pp. 881–889*).—The report shows that 1,226 tests of seeds of all kinds were made during the year, the principal varieties being alfalfa 421, red clover 360, and white clover 304. The maximum, minimum, and average percentages of purity, germinability, and intrinsic value of the different kinds of seed are shown in tabular form. In most cases an increase is shown in the percentages over the averages for 10 years with the same kinds of seed.

Tables of standards for agricultural seeds, and average data for seed examinations at Swedish seed control stations, 1895–1899, A. Lyttkens (*Meddel. K. Landtbr. Styr., 1901, No. 75, pp. 52*).

The origin, present condition, and future of the Swedish seed control, B. Jönsson (*K. Landt. Akad. Handl. Tidskr., 40* (*1901*), *No. 3, pp. 204–215*).

Report of Danish seed control, 1898–99, O. Rostrup (*Copenhagen, 1900, pp. 57*).

Experiments with weeds, B. D. Halsted (*New Jersey Stas. Rpt. 1900, pp. 458–460*).—In continuation of the weed experiments hitherto reported (E. S. R., 12, p. 350) a list is given of the weeds occurring for the fourth season upon the weed plat. A number of species which were reported as quite aggressive in the earlier years have disappeared, and the list for 1900 shows the most aggressive weeds to be ragweed, smartweed, sorrel, wild carrot, dandelion, velvet leaf, night flowering catch fly, sheep sorrel, oxeye daisy, narrow-leaved plantain, etc., their aggressiveness being in the order of enumeration.

On the eradication of charlock by means of iron sulphate solutions, A. B. Vestergaard (*Ugeskr. Landm., 47* (*1901*), *No. 47, pp. 451–454*).

DISEASES OF PLANTS.

Report of the botanist, B. D. Halsted (*New Jersey Stas. Rpt. 1900, pp. 407–476, pls. 5*).—The principal lines of investigation conducted by the botanical department for the year covered by this report were experiments with various truck crops and salad plants, studies of pear blight, asparagus rust, chrysanthemum rust, crossing of tomatoes, beans, salsify, and corn, and a continuation of weed studies.

Experiments with turnips have been continued, and the former opinion that air-slaked lime is a remedy for club root was again confirmed. The fungus causing the club root of turnips was reported as having been observed on specimens of rape. The effect of mulching potatoes was investigated, a small gain being given for the mulched ground. The investigations of potato scab were continued and it was found that the variety Green Mountain was most susceptible to the disease, while State of Maine, White Star, and Queen were less so. Winter rye as a cover for the ground was without influence on the production of scab.

Experiments with beets showed that sulphur was efficient in reducing the scab on those roots. In the bean experiments only the bacterial blight was observed, and the foliage of both varieties which were experimented with was equally infested but neither severely injured. Spraying with Bordeaux mixture was apparently without marked results in the prevention of this disease. Negative results were obtained in the experiments where Lima beans were given 6 applications of Bordeaux mixture, the plants in no case showing any disease. The yield for the sprayed plants was somewhat less than for those not treated with the fungicide. The effect of mulching on peas was studied, but no marked difference was noted between plants upon mulched and unmulched land, and no disease appeared. The effect of mulching and spraying with Bordeaux mixture was tested on tomatoes. The presence of disease was quite limited and the experiments are of rather doubtful value.

Experiments with cucumbers sprayed 8 times with Bordeaux mixture were without practical results, since the vines were nearly destroyed by insects before the appearance of any disease. Experiments with lettuce are reported, in which the bacterial blight was present to a small extent but the Septoria was quite abundant, particularly upon the variety Wonderful. The plants were not equally infested upon all parts of the plat, and this uneven distribution is attributed to the removal of the soil from some spots for experiments elsewhere. This seems to indicate a marked retentive power of the soil in holding the germs of the lettuce leaf spot. Plats of eggplant were sprayed 8 times with Bordeaux mixture, but the leaf blight appeared on different plats, although the sprayed were less infested than those untreated. The superior appearance of the plants is reputed to be due, however, to the comparative freedom from beetles occasioned by the application of the Bordeaux mixture. In continuation of previous seasons' work, the author again tested a number of varieties of salad plants, among them Swiss chard, New Zealand spinach, and Malabar spinach. The Swiss chard was sprayed 9 times with Bordeaux mixture, which rendered the plants comparatively free from leaf spot. The effect of new and old land upon crop production showed that, as a whole, the rotation of crops is the best method of keeping plants in good health. A green winter cover seemed to be without appreciable effect upon the health of plants. Winter and spring mulching, except in the case of potatoes, did not give any appreciable advantage either in yield or in diminishing disease.

The author reviews experiments in spraying. During the past season but one fungicide, Bordeaux mixture, was employed. On account of the limited occurrence of many of the more troublesome diseases, striking results were not obtained, but where important differences were secured they were generally in favor of the plants which had been given applications of the fungicide.

Experiments were conducted with hemp to ascertain the influence of environment upon the sex of the plant. This plant, as is well known, is diœcious and the greatest difference was noted in plants grown upon very rich soil. Here there were more than twice as many pistillate as staminate plants. The effect of early, medium, and late production of seed was tested and there was found to be a decided increase in the number of pistillate plants of the later over the earlier gathered seed.

Experiments are also reported with buckwheat, in which the effect of the soil on the production of the long and short styled flowers was investigated. There seemed to be no relationship between the fertility of the soil and the dimorphic forms of the flowers.

Experiments with ornamental plants are briefly reported, but none of these were sprayed during the present season except to destroy insects.

Notes are given on the white mold of radish, in which the life history of the fungus is described. Associated with it is frequently another fungus, *Peronospora parasitica*. The two can be readily distinguished by the appearance of their summer spores. An account is given of an attack of grape mildew upon grapes in an arbor at the station. The disease first made its appearance on the fruit clusters early in June, but soon after was noticed upon the foliage and stems. Two species of grapes were grown upon the arbor and the disease is reported to have been most severe in its attack upon the species which possessed woolly leaves, the smooth-leaved variety being fully 2 weeks later in showing any trace of disease.

Experiments with pear blight were continued from the previous year (E. S. R., 12, p. 354). It is believed that there is little to indicate the best time of pruning for the prevention of this disease. The effect of fertilizers has been investigated for a number of years, and during the past year the trees which withstood the disease to the greatest extent were those which had received no manure or fertilizer. Great individuality was noticed among the different trees and no conclusions can be drawn concerning the effect of fertilizers upon fruitfulness.

In continuation of the report of the previous year (E. S. R., 12, p. 354), experiments were conducted with asparagus to test the value of different substances in preventing the spread of the rust of this plant. This experiment was undertaken on account of the general opinion that the less susceptible varieties of asparagus are those possessing a thick epidermis, and it was thought that artificial coatings might be of value without having any particular fungicidal action. For this purpose gelatin, creolin, glue, lime, milk, and soap were sprayed upon the plants, 6 applications being given them. The smallest amount of rust was noticed upon the plants which received the soap spray, followed by gelatin, milk, creolin, glue, and lime in the order enumerated. The trials, however, were on such a small scale that conclusions are not safely warranted from the results obtained. Inquiries were sent out to all the experiment stations in the country to ascertain the range of the asparagus rust. From the replies received it seems that the rust is widely scattered in the central portion of the United States and that it is quite injurious. In some instances the parasitic fungus *Darluca filum* is reported as aiding materially in keeping the disease in check.

Investigations of the chrysanthemum rust have been continued, and the inspection of various establishments of chrysanthemum growers showed the disease to be very prevalent. A circular was issued (E. S. R., 11, p. 946) describing the disease and suggesting remedies. Studies are being pursued from which it is hoped that more rational methods of treatment may be found. A brief discussion on fungi as related to weather completes the report.

The year has been comparatively free from complaints of those fungi that ravage truck crops. The temperature was cool in the spring and very hot in summer with considerably less precipitation than usual, and to these factors is attributed the freedom from fungus attacks.

An epidemic of currant anthracnose, F. C. Stewart and H. J. Eustace (*New York State Sta. Bul. 199, pp. 63–80, pl. 1*).—During the past season a serious outbreak of the leaf blight or anthracnose of currants, caused by the fungus *Glœosporium ribis*, was reported in parts of New York. The lower leaves were yellow and thickly covered with small brown spots, and nearly all currant plantations in the Hudson River Valley were more or less affected. The disease affects the lower leaves first, working upward, causing the foliage to drop. In addition to attacking the leaves, the fungus occurs on the leafstalks, causing conspicuous sunken spots; also upon the fruit, stems, berries, and new canes. This is believed to be the first report of the occurrence of the fungus on the wood of the cane. Contrasting characters are drawn between this and other diseases of the plant, and the fungus is described in considerable detail. As far as the authors' investigations are concerned, the disease was more destructive in old plantations than among young plants. Plants in the nursery row were last to be attacked, and consequently suffered least. The different host plants of the fungus are enumerated. While it may attack several species of Ribes, it seems to have a decided preference for *R. rubrum*, to which belong the red and white varieties of cultivated currants. It is also reported as occurring on black currant and cultivated gooseberry, but the authors have failed to find any serious injury to the black currant or the occurrence of the fungus upon the gooseberry. A considerable variation in the susceptibility of varieties was noted, but the investigations have not been sufficiently advanced to warrant publishing lists of resistant varieties. For the prevention of this disease, although the authors have not conducted extensive experiments in this line, it is recommended that the bushes should be thoroughly sprayed with Bordeaux mixture, the first application to be given before the leaves appear, the second as the leaves are unfolding, and thereafter throughout the season at intervals of 10 to 14 days until the fruit is two-thirds grown. Where attacks of currant worm are expected, Paris green or green arsenoid may be advantageously added to Bordeaux mixture.

Notes from the botanical department, F. C. STEWART and H. J. EUSTACE (*New York State Sta. Bul. 200, pp. 81–101, pls. 5*).—Notes are given on a number of investigations conducted by the botanical department during the past year.

Trouble with pear trees in a nursery cellar.—Early in March the station was requested to investigate a serious trouble among pear trees in the nursery cellar of a Rochester nurseryman. Twenty-five thousand 3-year-old standard pear trees had been tied in bundles and placed in the cellar in an upright position. The bundles of trees were set in rows and the roots covered with sand after the usual custom. The bark on the trunks and branches of the trees when examined was of normal color and apparently healthy to a height of about 3½ ft., but beyond this the bark was black and many of the branches were dead. This condition prevailed throughout the cellar in a strikingly uniform manner. Upon investigation it was found that during the winter the sand about the roots of the trees froze and remained frozen until February, when the trees were dug out of the frozen sand and packed for shipment. Much difficulty was experienced in removing the trees from the sand, and it was decided to build a fire in the cellar to thaw it. This was done on February 27, and a few days later the trees were observed in the unhealthy condition above described. It appears that the heated air rose to the ceiling, which was unusually tight, and the warm layer of air caused the rapid thawing of the branches resulting in their destruction. The trees were rendered almost useless for wholesale purposes, although many of them which were cut back and sold at retail subsequently developed into good stock.

Shot-hole fungus on cherry fruit pedicels.—The shot-hole fungus (*Cylindrosporium padi*) is more or less prevalent throughout New York, being especially common on the English morello. While examining trees severely attacked by the fungus, the authors observed the fruit pedicels considerably affected. The leaves had fallen so that the trees looked quite bare and the fruit pedicels were so generally attacked that it was difficult to find one which was entirely free from the brown spots. The presence of these spots on the pedicels caused the fruit to ripen unevenly; many of the fruits were dwarfed and some withered without coming to maturity.

In connection with the appearance of this fungus on the fruit pedicels, the authors observed a spotting of the green fruits in which numerous small, brown, slightly sunken spots appeared on the fruits at the time they were about the size of peas. The spots enlarged as the fruits grew, but there was no tendency to rot. As the cherries began to swell and color in ripening, the spots disappeared, so there was little or no loss from this cause. The cause of this spotting is unknown.

Anthracnose of yellow toadflax.—The authors report the occurrence of the anthracnose of snapdragon on the common wild yellow toadflax (*Linaria vulgaris*). While the disease does considerable damage to the weed, it is not thought probable to turn the fungus to any practical account as an aid to the eradication of the weed.

Imperfect fertilization and the little peach disease.—During the past season the authors were called to investigate a suspected outbreak of the "little peach" disease. Instead of this disease it was found to be simply a case of imperfect fertilization. It is common to find unfertilized peach fruits in the spring on trees, but they generally fall early in the season, in what is called the June drop. The unusual feature in the present case was the persistence of the unfertilized fruit until ripening time, some of them making considerable growth. In the little peach disease ordinarily the pit is of normal size and contains a well-developed kernel, whereas in the present case the pit was abnormally small and contained no kernel, or at most an abortive one. When the tree is affected by the little peach disease, all fruits on a branch are affected and are fairly uniform in size, whereas in the case under consideration normal and small fruits were found on the same branch. Several instances of imperfect fertilization of fruits are cited, and no apprehension is felt for succeeding crops.

Tile drain clogged by fungus.—A report is given of the clogging of the tile drain to a vinegar cellar by a fungus which proved to be *Leptomitus lacteus*. The fungus produces a growth resembling the "mother" of vinegar and had to be removed in various ways from time to time. The application of a small quantity of copper sulphate to the drain succeeded in eradicating it. The authors believe that the clogging of drains in this manner is more common than is generally known.

Occurrence of a fungus in refrigerators.—The attention of the authors was called during the summer to the improper working of a refrigerator. Upon investigation it was found that the drain pipe was plugged throughout its entire length with a fungus growth of a gray or dirty gray color, consisting of a mixture of fungus mycelium and dirt from the ice. It had a slimy, slippery feel and clung together in sheets or rope-like masses several inches in extent. An examination of the fungus showed spores resembling those of Fusarium, although species of this genus rarely live in water. The definite determination of the organism has not yet been made. The simplest and most effective way of getting rid of this fungus would be to occasionally wash out the drain pipe and ice chamber of the refrigerator with boiling water.

Botanical botherments, F. H. HALL, F. C. STEWART, and H. J. EUSTACE (*New York State Sta. Buls. 199 and 200, popular ed., pp. 12, pls. 2*).—A popular summary of the above bulletins.

Experiments with smut, M. B. THOMAS (*Proc. Indiana Acad. Sci., 1900, pp. 123, 124*).—A report is given of field trials for the combating of oat smut with solutions of formalin. Three fields were sown in April with seed which had been soaked 40, 60, and 90 minutes in a solution of 1 part formalin to 200 parts of water. The seed used were from a badly infested crop, and a similar area was sown with untreated seed. No difference in the fields was noted at the time of germination, and but little difference until the time of cutting. At this time fully 15 per cent of the heads of the untreated seeds were smutted, while not a single stalk was observed from the fields where the seed had been treated. Of the 3 separate lots of treated seeds, the one soaked for 60 minutes seemed to be the best, and that time is recommended as safe and efficient for the treatment.

Seed barley treated with bluestone, J. R. MARTIN (*Queensland Agr. Jour., 9 (1901), No. 2, p. 187*).—The author reports the successful prevention of smut by the soaking of seed barley in copper sulphate solution. The seed is soaked for from 2 to 3 hours in a solution which is made so that about ¼ lb. of the chemical is used for every bushel of grain.

Rust in wheat and other cereals, V. THIELE (*Agr. Jour. Cape Good Hope, 18 (1901), No. 12, p. 809*).—The author briefly describes the use of a fungicide known as "Ceres Beize," which is said to be efficient in preventing rust, smut, and other diseases of cereals.

The generic nomenclature of cedar apples, J. C. ARTHUR (*Proc. Indiana Acad. Sci., 1900, pp. 131-136*).—The author's conclusions are given relative to the nomenclature of the common cedar apples which have hitherto been described as species of Gymnosporangium. As a result of his investigations it was claimed that Tremella replaces the name Gymnosporangium as a genus of Uredineæ, and the necessary changes of synonymy are indicated.

A disease of mangolds and sugar beets, R. H. BIFFEN (*Dept. Agr. Cambridge Univ. Rpt. 1901, pp. 87-89*).—The author reports having observed in July, 1900, a disease of mangolds in which the first noticeable symptoms were a browning of the outer leaves, while the inner ones became yellowish-green and much wrinkled. The disease seems to first show itself along the edge of the leafstalk. Upon examination the root showed no external symptoms of disease beyond being drier and tougher than normal. When cut across, the vascular bundles were stained with a purplish-black color. Specimens removed from the field and grown in the greenhouse showed that while the disease did not actually kill the plants it greatly stunted their growth. Examination of the vascular bundles showed that they were filled with a mucilaginous mass containing large numbers of bacteria. The symptoms presented by this disease seemed to be identical with a disease reported on sugar beets, and it is believed to be due to the same cause.

Bacterial disease of the potato, G. BATTANCHON (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 37, pp. 318–321*).—An account is given of the occurrence in a number of localities in France of the bacterial disease of potatoes believed to be identical with that described by Erwin F. Smith as due to *Bacillus solanacearum* (E. S. R., 8, p. 895). The characteristics of the attack are described at some length and a number of instances cited to show the extent of injury caused by the attack.

A bacterial disease of tomatoes, W. STUART (*Proc. Indiana Acad. Sci., 1900, pp. 153–157, figs. 2*).—This is an abstract of an article published in the Thirteenth Annual Report of the Indiana Station (E. S. R., 13, p. 57).

A report on the condition of vineyards in portions of the Santa Clara Valley, F. T. BIOLETTI and E. H. TWIGHT (*California Sta. Bul. 134, pp. 11, figs. 4*).—An investigation was carried on to determine the cause of the failure and death of a large number of vines in certain parts of California during the past 3 years. The dying of the vines was most conspicuous in the Santa Clara Valley, but similar cases were reported from other regions. In the Santa Clara Valley nearly all the older vineyards were more or less affected, in some cases nearly every vine being destroyed; in others the injury was sporadic. The distribution of the injured and dead vines was such as to suggest that the disease was not of an infectious parasitic nature. Dead vines were found to have been severely injured, usually by the cutting off of large branches at pruning, and leaving large wounds. These did not heal over and a decay set in, resulting in some cases in the hollowing out of the interior of the vine. This decay furnished a suitable locality for boring insects and the growth of wood-rot fungi. It was noted that in nearly every case the dying vines were old, although there was a great difference in the behavior of different varieties. The death of the vines, as shown by the investigation, seems to be due to a number of causes which may be more or less supplementary. Among them are mentioned growing on excessively gravelly soil, susceptibility of certain varieties due probably to heavy bearing, large wounds made in pruning, age of the vine, and the injurious effect on the young growth by spring frosts. These causes acting independently or in combination, together with the combined effect of the heavy crops of 1896 and 1897, and the 4 years of drought which followed, are believed to be the reason for the destruction. It has been suggested that the death of the vines was due to what is known as the California vine disease, but the destruction in this case bears no resemblance to that disease.

Powdery mildew on grapes, J. M. GUILLON and G. GOUIRAND (*Rev. Vit., 16 (1901), No. 404, pp. 293–295*).—The authors report the abundant occurrence of the perithecial stage of *Uncinula spiralis* upon grapes in a number of localities in France. The powdery mildew in Europe does not ordinarily produce the perithecia, but the climatic conditions seem to have been favorable to an abundant production during the season.

Combating grape mildew by early pruning, L. PLAGNES (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 44, p. 510*).—It is claimed that pruning grapevines in October, following this treatment with 2 applications of sulphur in the early spring, is of decided advantage in combating the grape oidium. Experiments are cited in which comparisons were made between vines pruned in October and others in February or March, both of which received the same sulphur treatment. The result of this experiment was decidedly in favor of the early pruning.

Some fungus diseases resembling black rot, V. DUCOMET (*Prog. Agr. et Vit. (Ed. L'Est), 22 (1901), No. 34, pp. 225–233, pl. 1*).—In a previous publication (E. S. R., 11, p. 759) the author described a number of fungus diseases which were of importance on account of their great resemblance to the grape black rot. In the present paper a number of other leaf diseases are described which, although usually of infrequent occurrence, sometimes cause considerable injury to the plants attacked. The resemblance to black rot is shown in the effect produced upon the foliage of the plants. The diseases described are leaf spots of walnut, due to *Marsonia juglandis;* of oleander, caused by *Septoria oleandrina;* of linden, due to *S. tiliæ;* of poplar, caused by *S. populi;* of capers, due to *Cercospora capparidis;* of cork oak, due to *Phyllosticta ilicina;* of vetch, caused by *Ascochyta viciæ;* of quince, caused by *Sphæropsis cydoniæ;* and of hackberry, due to *Taphrina celtis.*

Grape rot and Coniothyrium, L. DEGRULLY (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 32, pp. 161, 162*).—Editorial comments are made on the gray rot of grapes which is reported as abundant in a number of regions of France. Attention is called to the claims made for a number of fungicides as means for the prevention of this and other diseases. Among those commented upon are copper-sulpho-steotite and a mixture of steotite and aluminum. The author states that neither of these substances seems to be very efficient in preventing gray rot. Against the white rot, frequent sprayings with copper fungicides are recommended and it is thought that the treatment will to some extent keep in check the gray rot.

Gray rot of grapes, J. GUÉNIER (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 36, pp. 295, 296*).—A gray rot of grapes, caused by attacks of *Botrytis cinerea*, is reported to have caused serious losses in many regions of France during the past year, in some places as much as 50 per cent of the crop being destroyed within 2 days. The fungus is said to have acquired a greater importance than that of the black rot, and thus far no adequate means for its prevention seems to have been found. Characteristics of the fungus and its attack upon the grape are described.

White rot of grapes, J. D. CATTA and A. MAIGE (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 16, pp. 398–400, figs. 3*).—The occurrence of white rot of grapes in the north of Africa is noted and descriptions given of the fungus (*Charrinia diplodiella*). For the prevention of the attacks of this disease the authors recommend spraying thoroughly with the better fungicides.

The use of soda against grape oidium, A. LEBEDEFF (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 41, pp. 424–426*).—A report is given of the use of a 2 per cent solution of sodium carbonate for the prevention of grape oidium. The vines were sprayed at frequent intervals during the season with this fungicide and very satisfactory results secured. The author suggests that from 200 to 400 gm. of common glue be added to each hectoliter of the fungicide in order to make it more adhesive. It is also thought possible that by replacing with sulphur the second treatment, which is ordinarily given during the flowering period of the vine, the efficiency of the fungicide will be still more improved.

A root rot of grapes in Portugal (*Agr. Jour. Cape Good Hope, 19 (1901), No. 7, pp. 463–466*).—An account is given of a disease of grapevines which is becoming very troublesome in parts of Portugal. This is caused by a fungus similar to and probably identical with *Rosellinia necatrix*. The use of carbon bisulphid about the roots of the vines is recommended as a means for preventing the distribution of the mycelium through the soil. Diseased vines and other plants subject to attacks of the fungus should be destroyed and good drainage, which is of primary importance, be provided.

The red rot of coniferous trees (*Rev. Eaux et Forêts, 40 (1901), No. 18, pp. 563, 564*).—A description is given of the red rot caused by *Trametes radiciperda*, which attacks spruce and Scotch pine.

Carnation stem rot, F. W. Card and G. E. Adams (*Rhode Island Sta. Rpt. 1901, pp. 233, 234*).—In continuation of the experiments hitherto reported (E. S. R., 12, p. 966), an attempt was made to determine the effect of stable manure and chemical fertilizers in potting soil on the carnation stem rot. Cuttings were started in clean sand, after which half were potted in soil which received no stable manure but which was supplied with chemical plant food, and the other half was started in ordinary potting soil. When planted out, the same precautions were taken with the soil. At the end of the season no stem rot developed in either lot. The indications seemed to show that as in the previous year the use of stable manure did not produce greater injury than chemical fertilizers.

Rose mildew, E. O. Orpet (*Amer. Gard., 22 (1901), No. 358, pp. 745, 746*).—Ivory soap is said by the author to be a specific for rose mildew. A bar of the soap is dissolved in a pail of boiling water and diluted to 6 pailfuls. The mixture may be used with one-third less water and be safe, but it is stated that it is a preventive at the above strength if sprayed on with a fine spray with force.

Mildews, C. W. Dodd (*Gard. Chron., 3. ser., 30 (1901), No. 771, p. 254*).—Brief popular descriptions are given of mildews which attack a number of ornamental plants. Among those described are the mildews of roses, Michaelmas daisies, irises, hybrid montbretias, and hybrid saxifrages.

An atlas of plant diseases, G. Delacroix (*Atlas de pathologie végétale. Paris: J. Lechevalier, 1901, pls. 59*).—Illustrations are given of a large number of diseases of plants caused by fungi, insects, and other parasites, as well as a number of common abnormal growths.

ENTOMOLOGY.

Report of the entomologist, J. B. Smith (*New Jersey Stas. Rpt. 1900, pp. 479–572, figs. 10*).—During the season of 1900 there were droughts accompanied with high temperature and resulting in an increase in the numbers of Hessian fly and Angoumois grain moth and a decrease in the numbers of plant lice. It is reported that the San José scale does not develop so rapidly or breed so long in the northern as in the southern counties of New Jersey. It appears, however, that there are no local conditions in the State which are adverse to the development of this species. Most nurserymen have constructed fumigating houses of boxes for the treatment of all their stock. The sinuate pear borer is reported from a number of localities. In nurseries trees showing infestation by this insect are ordered destroyed. Peach thrips prevailed to an injurious extent in the latter part of the season and destroyed the leaders of many trees. Kerosene emulsion was applied against this insect in 2 nurseries with practical results. Pear psylla occurred in a number of localities, but appears to have been effectively checked in orchards where crude petroleum had been applied during the previous winter. The chief insects of plums during the season were plum plant lice and the curculio. Quince curculio is reported as having been unusually injurious. An account of its life history is presented. There is no time during the life cycle of the insect when it may be successfully reached by insecticides, and the method of combating it which was recommended by the author consists in jarring the trees daily during the period when the beetles are found in the orchard. Eggs of the apple plant louse were noticed in great numbers in the spring, but the insects did not develop to the usual extent. In some localities the species had almost disappeared by the middle of May. Injuries to strawberries are reported from the attacks of ground beetles. In one locality this pest occurred in such numbers as to become annoying in houses. On currants, attacks of plant lice, currant worms, spanworms, and the San José scale are reported. Pea louse caused considerable damage in several parts of the State. Red clover appears to be the normal food of the insect, and later in the season it flies from the clover to pea vines. English sparrows are reported as feeding upon the pea louse to such an extent that the insects were exterminated in some localities. Cabbage worms and cabbage-root maggots caused considerable injury in certain localities. The cabbage plusia is reported as very numerous and destructive throughout the State. Corn, especially sweet corn, was badly infested with corn worms. The best means of controlling this insect is fall plowing. Hessian fly caused great damage during 1900. The southern part of the State was comparatively exempt, while the northern portion was badly infested. Late-sown wheat suffered as much or more than that which was sown earlier. Angoumois grain moth caused an unusual amount of damage during 1900. The life history and habits of this insect are described and the usual remedies are recommended. Potato beetle attracted considerable attention, being considered the most injurious insect in some parts of the State. Its attacks on tomatoes and eggplants were especially severe. Blister beetles were destructive throughout the State on a large variety of plants, including strawberry, tomato, potato, and beet; carrots and peppers were avoided. Horn fly had largely disappeared for a number of years, but occurred in large numbers in 1900. *Cetonia inda* is reported as eating into fruits, including apples, plums, and peaches. *Daremma catalpæ* occurred in large swarms in several localities and defoliated the catalpa badly. The life history of the insect is given. It is much attacked by parasites and various diseases and large numbers of the broods may be destroyed by destroying a few leaves on which the larvæ first appear. Later, spraying with Paris green will be found effective.

Experiments with crude oil soap showed that this substance is unsatisfactory as a winter treatment. Potash fish-oil soap with an admixture of tobacco, when used as a winter application, was very injurious to vegetation, especially peach buds, and it appeared that the tobacco added nothing to the killing power of the mixture. Many complaints are reported as to the ineffectiveness of Paris green, and it is suggested that possibly insects, such as potato beetles, are acquiring an increased resisting power to this poison. In the work of the author as State entomologist special attention is given to San José scale; but during the inspection of nurseries the sinuate pear borer was considered sufficiently dangerous to debar nurserymen from obtaining a certificate until the insect was destroyed. A brief summary is given of the reports of correspondents throughout the State regarding injurious insects. Insecticide work was continued in the experiment orchard. No trees were harmed by applications of undiluted oil where the oil was applied as a spray. It was found, however, that peach buds could be killed by drenching with oil. A few varieties of apples were injured by fruit growers whose general success in the use of crude oil had been previously very good. With regard to the dilution of oils, it is urged that it is the oil which kills insects, and that the water simply serves to spread the oil over a greater area. In the opinion of the author the application of undiluted oil is to be preferred in all cases. A discussion is given to the subject of the varieties of crude oil coming from different localities.

A brief report is made of a trip to various countries of Europe for the purpose of studying insect conditions and the state of economic entomology in those countries.

The insect book, L. O. Howard (*New York: Doubleday, Page & Co., 1901, pp. XXVII+429, pls. 48, figs. 264*).—In this volume the author presents a popular account of bees, wasps, ants, locusts, flies, and various other groups of North American insects, exclusive of moths, butterflies, and beetles. Special attention is given to the consideration of the life history of one or more numbers of each group in as great detail as the present knowledge will permit. Various unknown points in connection with the life history of each species are also noted for the purpose of directing investigation along those lines. Analytical tables are presented for the identification of some of the more common species of each order of insects, and bibliographical references are given to literature where further information may be obtained on these groups. An extended bibliography on entomology is given, reprinted from Bulletin 24 of the Division of Entomology of this Department, and short chapters are presented on methods of collecting and preserving insects for study. The plates are reproduced from photographs and are all original in this volume.

Injurious insects, E. FLEUTIAUX (*Agr. Prat. Pays Chauds, 1 (1901), No. 3, pp. 393–396*).—Brief notes are given on a species of Aræocerus which attacks menado coffee when stored, eating out the inside of the berries. A brief account is also given of Dryocœtes, injuring the custard apple; *Apate monacha*, an enemy of coffee and cacao, and *Prodenia littoralis*, which attacks the cotton plant.

The potato worm in California (Galechia operculella), W. T. CLARKE (*California Sta. Bul. 135, pp. 30, figs. 10*).—This is considered the most important insect pest of the potato in California, the damage to the potato crop being estimated in some years at 25 per cent. Following upon the attacks of this insect various fungi are observed to obtain a foothold in the injured portions of the potato and hasten the destruction of the tubers. Injuries to potatoes in the field are usually not so great as in storage, though sometimes the whole crop is destroyed. Bibliographical notes are given in connection with the various descriptions and published articles of this insect. The species is described in detail in all its stages. The eggs are laid either upon a stem of the potato vine or in the bodies of the tubers. Usually the eggs are deposited singly, but sometimes more are laid near the same potato bud. The color of the larva depends somewhat upon the material upon which it is feeding, whether the inside of the tuber or the green material of the stem or surface of the tuber. The larva when 6 weeks old comes to the surface of the tuber and pupates in the mouth of the burrow, or in some depression of the potato, or in the cracks of the bins or sacks in which the potatoes are stored. The life history of this species was carefully followed by the author, and the complete life cycle is stated as being ordinarily from 63 to 69 days, except for the winter generation, when 84 or 85 days may be required. The egg stage requires from 7 to 10 days, the larval from 42 to 45 days, and the pupal from 14 to 16 days. The injury from this insect may be to the growing plant and to the tubers. When the growing plants are attacked the eggs are deposited at the base of the leaf and the larvæ, on hatching, bore downward through the stem and finally enter the tuber. In the tuber they feed either through the substance or immediately underneath the epidermis. Potatoes may therefore become infested through the stalk, through tubers which are exposed in the hill, through tubers which are allowed to lie on the ground for some time after digging, and while in storage. Field experiments demonstrated that if affected stalks are removed and destroyed as soon as they are noticed, the infestation does not proceed any further. It was found, also, that lantern traps were very effective in catching the moths. More moths of this species than of all other species combined were captured by lantern traps, and 60 per cent of those captured were females. The larva feeds inside of the stem or tuber, and therefore no spraying experiments were tried. It was demonstrated by experiments that when the earth was well pulverized about the hills and all potatoes carefully covered, no infestation took place, although check hills which were covered with cloddy or lumpy soil became quite badly infested. It was therefore concluded that careful, compact hilling reduces the infestation to a minimum. Experiments showed that when potatoes were exposed after digging, especially in the evening or over night, a considerable proportion of the tubers almost invariably became infested. When potatoes which were known to be uninfested were piled up in the field and covered with infested stalks, it was found that about 70 per cent became infested, while potatoes which were not covered with stalks remained uninfested. A series of experiments were conducted for the purpose of determining the effectiveness of removing and destroying the stalks while the larvæ were still in them. It was found that by destroying all of the potato tops about one week before the time of digging and while the larvæ were still in the stalks that the potatoes remained uninfested; the removal and destruction of infested potato tops is therefore considered an effective and practical means of controlling this insect. It was shown by experiments that moths may winter over in infested potatoes which are left in the ground. Experiments with potatoes in storage showed that the insect may rapidly increase under such conditions, and that a slight infestation may cause the almost total destruction of large quantities of stored potatoes, if no means are taken to destroy the insect during a whole winter. Experiments with carbon bisulphid in the destruction of this species in stored potatoes were successful. It is recommended that 5 treatments be given to each lot of potatoes, one when the potatoes are stored, and a second, third, fourth, and fifth treatment at intervals of about 2 weeks. For treating 1,000 cu. ft. of space, which would hold from 200 to 250 sacks of potatoes, 5 times, from 5 to 7½ lbs. of carbon bisulphid will be required. It was recommended that native food plants of this species, such as *Solanum douglasii*, *S. nigrum*, *S. umbelliferum*, and *S. xanti*, be destroyed. In addition to the other remedies already mentioned, it is recommended that all potato tops in fields which had been infested should be destroyed.

Brief notes are also given on 2 species of flea-beetles (*Epitrix subcrinita* and *E. hirtipennis*), for which spraying with Paris green in the proportion of 1 lb. to 150 gal. of water is recommended. Yellow ground crickets belonging to the genus Stenopelmatus are sometimes reported as injuring potatoes by biting out portions of the surface of the tuber.

Successful sprayer for the pea louse, E. D. Sanderson (*Rural New Yorker, 60 (1901), No. 2685, pp. 41, 42, figs. 2*).—Notes are given on previous insecticide work in controlling this insect. A description is given of the spraying machine which has been devised for operation upon infested peas. The general appearance of the sprayer from a distance is that of a grain drill, and it is furnished with a tank containing a pump with an air chamber above the tank, which is attached by gearing to one of the wheels. Underneath the tank are pipes leading to nozzles from which the spray is delivered. As the spraying machine moves along, the vines are picked up by a V-shaped wooden fork and held in such position as to receive the spray with best effect. The machine sprays 3 rows, and the total cost per acre for labor and materials is about $2.50.

San José scale insect: Its appearance and spread in Connecticut, W. E. Britton (*Connecticut State Sta. Bul. 135, pp. 14, pls. 5*).—A brief account is given of the introduction of the San José scale into this country, its discovery and distribution in Connecticut, nursery inspection in the State, legislation with regard to the insect, its life history, description of various stages, food plants, means of distribution, effects on trees, and remedies to be used in combating it. Spraying experiments were made with kerosene, crude oil, and whale-oil soap. In these experiments it was found that crude oil or kerosene in 20 per cent mixture with water, if thoroughly applied, killed the scales without causing any serious injury to the trees. It is not regarded as safe to apply either crude oil or refined kerosene on damp cloudy days. In some localities a solution of whale-oil soap containing 2 lbs. of soap per gallon of water is preferred, but this treatment is more expensive and not quite so effective in destroying the insects as either kerosene or crude oil. Greater difficulty is also experienced in applying whale-oil soap in the form of a spray. For summer treatment it is recommended that kerosene be applied in a 15 per cent mixture in water, or whale-oil soap in the proportion of 1 lb. to 5 gal. of water. In fumigating nurseries, the formula for producing hydrocyanic-acid gas as used by the author was as follows: Cyanid potash (97 per cent) ⅝ oz.; sulphuric acid (specific gravity 1.83) 1¼ oz.; water 1⅞ oz. per 100 cu. ft. of space. This treatment is not certain to kill all scales, but is considered one of the surest methods of destroying them in nursery stock. The illustrations accompanying the bulletin include figures showing infested pears, discoloration of apples and pears due to infestation of San José scale, the scales on peach twigs and on plum leaves.

San José scale, F. W. CARD and G. E. ADAMS (*Rhode Island Sta. Rpt. 1901, pp. 241–244*).—Experiments in combating this insect were conducted on city lots which were more or less infested. Two lines of treatment were tried in 1900, one with whale-oil soap and the other with kerosene. In the spring of the present year these lines of treatment were supplemented by crude petroleum, which was applied to most of the trees treated with kerosene in the autumn of 1900. The first application was made November 7, after most of the leaves had fallen. A mixture of kerosene and water of uncertain proportions was used, on account of the imperfections of the pump. The percentage of oil was probably between 15 and 20. The mixture was applied to apple and pear trees. Apple, pear, and quince trees were also treated with whale-oil soap, 1 lb. to 2 gal. of water. On April 13, 1901, the trees were again treated, whale-oil soap being applied on those trees which had received this substance in the previous autumn, but at the rate of 2 lbs. to 1 gal. of water. Most of the trees which were treated with kerosene the previous fall received crude petroleum in the spring, in about a 25 per cent mixture. The other trees were treated with a 25 per cent mechanical mixture of kerosene and water. Kerosene proved to be more effective than whale-oil soap as an autumn treatment. No injury to the trees was apparent. More live scales were found after soap had been used than where kerosene had been applied. When the trees were examined on June 19 no live scales were found on those which had been treated with crude petroleum, but a number of apparently living scales were found on the trees which were treated with whale-oil soap and with kerosene. The authors conclude that petroleum treatment is the most effective and satisfactory remedy for San José scale, being also cheaper and more easily applied.

Scale insects of importance and list of the species in New York State, E. P. FELT (*Bul. New York State Mus., 9 (1901), No. 46, pp. 289–382, pls. 15, figs. 5*).—A general discussion is presented of the characteristics, number of species, injuries, means of dispersal, and means of recognizing the various scale insects of economic importance. An analytical key for the identification of the more important species is given. A special account, including description, life history, food plants, natural enemies, and remedies, is given of oyster-shell bark louse, scurfy bark louse, San José scale, European fruit scale, Putnam's scale, *Aspidiotus forbesi*, and *A. hederæ*. Bibliographical references are given in connection with the discussion of each species. A short chapter is devoted to a discussion of the remedies which have been found effective against scale insects. These remedies include whale-oil soap, alone and in combination with crude petroleum; crude petroleum, undiluted and in emulsions; kerosene, pure and in emulsions, and fumigation by hydrocyanic-acid gas.

A technical study of 4 species of Aspidiotus (*A. ancylus*, *A. ostreæformis*, *A. perniciosus*, and *A. forbesi*, by Margaret F. Boynton is included in the report. This study is concerned with detailed descriptions of anatomical characteristics by which the 4 species may be definitely identified. A list of the scale insects found in the State of New York is appended to the bulletin.

Scale insects of the Lesser Antilles—I, H. MAXWELL-LEFROY (*Imp. Dept. Agr. West Indies, Pamphlet No. 7, 1901, pp. 63, figs. 20*).—This pamphlet contains a general account of scale insects, including the following subjects: Life history and anatomy, distribution, injurious effects, means of dispersal, preventive measures, remedies, a description of the common species in the Lesser Antilles, and a list of their food plants. The number of species which are discussed in a special manner is 20, and includes, besides others, *Lecanium hemisphæricum*, *L. longulum*, *L. hesperidum*, *L. mangiferæ*, *L. nigrum*, *L. oleæ*, *Aspidiotus articulatus*, *A. ficus*, *A. destructor*, *A. personatus*, *A. dictyospermi*, *Diaspis amygdali*, and *Mytilaspis citricola*.

Report on the protection of olive culture from an enemy which threatens the destruction of olives, BORRIGLIONE (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 20, pp. 500–508*).—The olive fly (*Dacus oleæ*) is considered one of the greatest enemies of olive culture. The larvæ feed on the pulp of the olive, completely destroying it. The olives which are stung fall to the ground prematurely, and furnish an oil of an inferior quality. Of the many remedies which have been proposed for combating this insect the author considers none as permanently effective, except where all the residents of a given locality cooperate in fighting the insect. For destruction of the larvæ while hibernating in soil, carbon bisulphid is recommended as effective. Brief notes are also given on *Phlœotribus oleæ*.

Apple maggot, F. W. CARD and G. E. ADAMS (*Rhode Island Sta. Rpt. 1901, p. 227*).—Observations in 1899 indicated that deep plowing of orchards in spring might serve as a check on the apple maggot. The results obtained in 1900 were not encouraging; fully 75 per cent of the fruit was affected in an orchard which had been treated in this way. Further experiments are being conducted for the purpose of determining the conditions which influence this excessive infestation.

Notes on the life history of Alsophila pometaria, W. E. HINDS (*Canad. Ent., 33 (1901), No. 7, pp. 185–190, figs. 7*).—The insect is described in its various stages, and notes are given on its history and life habits. The egg mass, containing 220 eggs, was found on the golden willow on March 14. The mass was kept at the temperature of the laboratory until April 23, when the larvæ began to emerge. During the last larval stage the insect feeds voraciously, but becomes sluggish near the end of the stage. The larvæ enter the earth and form cases of soil particles, held together by silk threads. The pupæ were allowed to remain in the soil until October, when an examination disclosed the fact that all of them had been destroyed, probably by red ants.

Erinose of the vine, F. T. BIOLETTI and E. H. TWIGHT (*California Sta. Bul. 136, pp. 7, figs. 5*).—This disease is characterized by swellings of the upper surface of the leaves, with depressions on the lower surface. When numerous, the swellings may cause deformation of the leaves, but no change of color. The leaves retain their green color until late in the season. The lower surface of the infested leaves becomes covered with a felt of white hairs, which later in the season becomes brown.

The cause of the disease is the presence of a mite, *Phytoptus vitis*. A description of the mite is given. The 4-legged larvæ hibernate in the bark of the vine or among the bud scales. The mite rarely causes serious injury to the vine; occasionally, however, it may interfere with the growth of the vines and reduce the crop to some extent. The worst infestations observed in California were on Flame Tokay and Mission varieties. The mite was also found on Zinfandel and Muscat. The use of sulphur checks the progress of this disease, and where this treatment is regularly applied the mite does not occur to any great extent. Cuttings from affected vines may be disinfected by placing them in water at a temperature of 122° F. for 10 minutes.

Means of combating Tortrix ambiguella in spring and summer, J. LABORDE (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 23, pp. 693–707*).—The author makes a detailed report on the various methods which have been used for destroying this insect in its different stages. During the spring and summer *T. ambiguella* and *Endemis botrana* occur in vineyards in all stages, and artificial methods of destruction must be chosen with reference to the special conditions of each case. The methods which have been most successfully used for destruction of the moths are the use of lantern traps and catching by means of rackets moistened with liquid insecticides. The conditions which are most favorable to the use of lantern traps are dark nights without rain and with a moderate temperature. Notes are given on the numbers of moths captured by these methods in different months of the year. In the destruction of the eggs various insecticides have been used, including sulphuric acid in 1 or 2 per cent solutions, essence of terebinth and soap, and kerosene emulsion. The most successful remedy for destroying caterpillars was found in Bordeaux mixture to which arsenical soap had been added. Spraying with these insecticides caused a nearly complete destruction of the caterpillars and caused no injury to the grapes. The author believes that while artificial remedies may be adopted in the combating of the insect in all its stages, it is specially desirable that the chief efforts should be directed toward destroying the insect in its larval stage.

The ravages of Tortrix pilleriana in the Beaujolais, and the destruction of the moths by means of acetylene gas lamps, G. Gastine and V. Vermorel (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 13, pp. 488–491*).—The author made use of acetylene lamps with the jet of the height of from 12 to 15 cm., situated above the center of a shallow circular metallic vessel of from 40 to 50 cm. diameter. The vessel was partly filled with water covered with a film of kerosene. In using these lamps in vineyards it was noticed that comparatively few moths were captured in the early evening. The most abundant captures took place late at night. Detailed tables are given showing the number of moths of *T. pilleriana*, and a number of other insects caught by each lamp for each night. From these tables it appears that from July 13 to 31, 170,000 moths of *T. pilleriana* were captured, or an average of 940 moths for each lamp per night. The cost of maintaining an acetylene lamp was found to be about 8 centimes per night.

Smyrna figs growing in California, H. E. Van Deman (*Rural New Yorker, 60 (1901), No. 2680, p. 403*).—The author recounts the history of attempts to introduce the fig insect into California for the purpose of fertilizing Smyrna figs. A large quantity of good fruit was produced as a result of the successful introduction of this insect, and the fruit, according to the opinion of the author, is equal to that which is imported directly from Smyrna.

Orchards, insects, diseases, and spraying, F. Sherman (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 10, pp. 9–24, figs. 7*).—The benefits of spraying are briefly discussed in a general manner. A report is given upon an inspection of orchards of the State, in which especial attention is given to the quality and quantity of the fruit and the comparative prevalence or scarcity of the insect and fungus pests. Directions are given for the selection and management of different kinds of spraying apparatus, together with formulas for Bordeaux mixture, Paris green, and kerosene emulsion. A list of the nurserymen doing business in the State is presented, and suggestions are given to intending purchasers concerning inspection of nursery stock before it is accepted.

Beneficial insects, H. Fæs (*Chron. Agr. Canton Vaud, 14 (1901), No. 22, pp. 555–559, figs. 3*).—Descriptive, biological, and economic notes on species of ichneumon and tachina flies.

Scavenger beetles and the fertilization of the soil, C. Onelli (*Bol. Agr. y Ganadería, 1 (1901), No. 1, pp. 27–29*).—The author calls attention to the work of various species of scavenger beetles in altering the physical characters of the manure of cows and horses and in burying these substances beneath the soil. The well-known habit of these insects in burying small balls of manure in which their eggs are deposited makes it necessary to remove about 5 cc. of soil for each ball. Estimates are given by the author of the amount of earth thus removed from given areas by scavenger beetles. This quantity in localities where the beetles are numerous is so large that it may be compared with the work of earthworms. In making excavations underneath and around the droppings of cows and horses it was found that the soil was rendered more loose and friable by the work of the beetles, and that small particles of the manure were scattered through the soil at various depths. In pasture land the droppings of domestic animals contain many seeds of grasses which are still capable of germination if placed in favorable conditions; these seeds are buried by the insects along with the manure and at a suitable depth for the development of vigorous grass plants. It is believed that a considerable saving in the fertilizing value of the manure is made by being buried beneath the soil where it is not subject to desiccation. When thus placed beneath the surface of the soil it is distributed in small quantities in immediate contact with the roots of the grasses and is thus more immediately available for these plants. The species of insects which are most concerned in this work are *Copris campestris*, *C. cylindrica*, *Phænus imperata*, and *Ontophagus hirculus*.

Aquatic insects in the Adirondacks, J. G. Needham and C. Betten (*Bul. New York State Mus., 9 (1901), No. 47, pp. 383–612, pls. 36, figs. 42*).—This report is based on the results of a study of the life history of about 100 species of insects. During this work 10 new species and 2 new genera were discoverd and many additions were made to the knowledge of the life history of the other known species. The work was done along the Saranac River and included the study of the aquatic insects found in various small ponds and streams in this region. A description is given of the location, and the methods of biological research which were adopted. The life histories are given in detail of a number of species of Plecoptera, Ephemerida, Odonata, Neuroptera, Trichoptera, and Diptera, besides brief notes on other orders of insects. A list of sawflies, with descriptions of 2 new species, is given by A. D. Macgillivray. New species of Diptera are described by D. W. Coquillett, and new parasitic Hymenoptera are described by W. H. Ashmead.

A monograph of the Culicidæ or mosquitoes, F. V. Theobald (*London: British Museum of Natural History, 1901, vols. 1, pp. XVIII + 424, figs. 151; 2, pp. XIII + 391, figs. 148; 3, pp. 8, pls. 42*).—The present monograph constitutes the most complete account of mosquitoes which has ever been published. In the first volume a general discussion is given on the anatomy, life history, habits, and geographical distribution of mosquitoes. The natural enemies of mosquitoes are mentioned and a brief account is presented of the agency of mosquitoes in carrying malaria, yellow fever, filariasis, and other diseases. A synoptic table is given for the identification of the different genera of the family, 22 of which are recognized by the author. A table is given showing the species of each genus, and another table is presented giving the geographical distribution of the species of mosquitoes. In all, 122 species which had previously been described are recognized as good species and redescribed, while 136 new species are described. This brings the total number of species recognized in the monograph up to 258, with a possible addition of 42 species not yet identified, which would make the total number 300. It is stated that in the collections of the British Museum there are 100 or more new species which will be described in a subsequent volume. It will probably also become necessary to revise the genus Culex, on account of its unwieldy nature, and perhaps to exclude certain species from that genus. An extensive bibliography on mosquitoes is given in the second volume, which is also furnished with an index. The figures and plates are original, 37 of the latter being done in color, while 5 of the plates are from micro-photographs of the wing scales of different species of mosquitoes.

FOODS—NUTRITION.

Studies on bread and bread making at the University of Minnesota in 1899 and 1900, H. Snyder (*U. S. Dept. Agr., Office of Experiment Stations Bul. 101, pp. 65, pls. 3, fig. 1*).—The investigations reported cover studies of (1) the comparative nutritive value—including both composition and digestibility—of graham flour, entire-wheat flour, and standard patent roller-process flour milled from the same lot of hard Scotch Fife spring wheat; (2) the comparative digestibility of bread and of oatmeal in experiments with a ration consisting of a large, a medium, and a small amount of bread and milk, and of a large and a small amount of oatmeal and milk; (3) the digestibility of bread made from flour in which the proportion of starch is increased; and (4) the quality of the bread as affected by increasing or diminishing the proportion of starch, by raising or lowering the temperature of the flour, by prolonged heating of the flours, and by blending different types of flour.

The digestion experiments with standard patent white bread, entire-wheat bread, and graham bread, gave the following average coefficients of digestibility:

Digestibility of different sorts of bread.

	Protein.	Fat.	Carbohydrates.	Energy.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Standard patent white bread	85.3	56.4	97.5	90.1
Entire-wheat bread	80.4	55.8	94.1	85.5
Graham bread	77.6	58.0	88.4	80.7

The principal results of all of the experiments follow:

Chemical analysis showed that the patent flour contained a little less protein than the graham and entire-wheat flours, but its protein was more thoroughly digested than that of the coarser flours. The digestibility of first and second patent flours was not appreciably different from that of standard patent flour. In every case the digestibility was high, doubtless owing to the fact that the flours were finely ground. Generally speaking, small rations were somewhat more thoroughly digested than larger rations, and bread and milk a little more thoroughly than oatmeal and milk. This the author believes is due to the fact that the oatmeal was much coarser than the flour from which the bread was made.

An increase in the proportion of starch in flour caused a slight decrease in the digestibility of protein. When starch was added to flour with a high percentage of gluten containing 37.2 per cent glutenin and 62.8 per cent gliadin, the size of the loaf was not reduced. The physical qualities of the bread, however, were materially altered. It contained less moisture than bread made from normal flour. When the proportion of starch in flour was diminished by the addition of moist gluten, the size of the loaf was not increased. These experiments indicate that the character of gluten rather than the starch content of flour affects its bread-making qualities, the size of the loaf being determined by the ratio of gliadin to glutenin rather than by the percentage of gluten present.

The effect of the temperature of the flour used for bread making was most noticeable in the rate of expansion of the dough and the physical quality of the bread, the best bread being obtained when the temperature of the flour was about 70° F. Prolonged heating of flour impaired its bread-making qualities, affecting both color and lightness.

By blending hard and soft wheats the undesirable properties of each were counterbalanced. When flour containing a high percentage of glutenin was mixed in equal proportions with flour containing a high percentage of gliadin, the loaf produced was larger and of better quality than that from either flour alone, but was not equal in quality to that produced from wheat containing a normal, well-balanced gluten.

A further study of the losses in the process of making bread, L. A. Voorhees (*New Jersey Stas. Rpt. 1900, pp. 134–176*).—A number of experiments are reported on the losses of material involved in bread making and related topics. A part of this work has been abstracted from a previous publication (E. S. R., 11, p. 768). The experiments not previously noted, according to the author, "have shown that the variability in the loss of dry matter, as observed in the results of different investigators, may occur as readily in the experiments of a single investigator, and at a single bakery, since the range of the same in these experiments [which were made under such condition] was from 1.41 per cent to 3.76 per cent. The experiments have also shown the usual disappearance of the fat. If this loss of fat is considered absolute, in some of the experiments the loss of carbohydrates was not sufficient to account for their consumption by the yeast to a sufficient degree to raise the bread. . . .

"An examination of the crust and crumb of bread separately in search for the seat of this discrepancy revealed the unexpected result that in the composition of the dry matter of each there was but little difference; and the crumb, which had been subjected to a temperature probably no higher than that of the boiling point of water, showed as decided a lack of ether extract as the crust which received the full heat of the oven, whereas the fuel values of crust, crumb, and raw materials were practically the same. In fact the similarity of composition of the dry matter in crust and crumb was such as to warrant the assertion that the losses and destructive processes occurring in the crust, while of greater magnitude, perhaps, affected the nutrients in the same relative manner as in the crumb, so that the composition of their dry matter was practically the same. Their fuel value was also practically the same, and while there may have been complications in the case of the crust which renders it advisable to suspend judgment, it is probable that the composition of the dry matter of the crumb of the bread was practically the same as that of the dough, or raw materials, which is to say that not more than a trifle of the fat was actually lost."

Experiments on losses in cooking meat, 1898–1900, H. S. Grindley, H. McCormack, H. C. Porter (*U. S. Dept. Agr., Office of Experiment Stations Bul. 102, pp. 64*).—The author reports 29 experiments on the losses sustained when meat is cooked by pan broiling, *i. e.*, frying in a hot pan without the addition of fat, and by boiling and stewing. In the latter experiments the water used was of different emperatures at the start and the time of cooking was also varied. The principal conclusions which were drawn follow:

The chief loss in weight during the cooking of beef is due to the driving off of water. When beef is "pan-broiled" there appears to be no great loss of nutritive material. When beef is cooked in water from 3 to 20 per cent of the total solids is found in the broth. The material thus removed from the meat has been designated as a loss, but is not an actual loss if the broth is utilized for soup or in other ways. Beef which has been used for the preparation of beef tea or broth has lost comparatively little nutritive value, though much of the flavoring material has been removed. The amount of fat found in the broth varies directly with the amount present in the meat—*i. e.*, the fatter the meat the larger the quantity in the broth. The amount of water lost during cooking varies inversely as the fatness of the meat—*i. e.*, the fatter the meat the less the shrinkage in cooking. In cooking in water the loss of constituents is inversely proportional to the size of the piece of meat. In other words, the smaller the piece the greater the percentage of loss. The loss appears to depend upon the length of time of cooking. When meat in pieces weighing from 1½ to 5 lbs. is cooked in water at 80 to 85° C. (175 to 185° F.) there appears to be little difference in the amount of material found in the broth whether the meat is placed in cold water or hot water at the start. The nature of the nitrogenous ingredients of the broth is not yet fully understood. This subject is now being studied in connection with further inquiries regarding the changes in meat in cooking.

The examination of egg pastes, A. Schmid and E. Philippe (*Schweiz. Wchnschr. Pharm., 39 (1901), pp. 330–341; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 1, p. 32*).—Analytical data are reported.

Milk as food for man at different ages, F. E. Hellström (*Helsingfors, 1901; rev. in Tidn. Mjölkhushall., 10 (1901), No. 23, p. 90*).

A new source of food (*Dietet. and Hyg. Gaz., 17 (1901), No. 12, pp. 728, 729*).—It is stated that an edible meal may be prepared from horse chestnuts by extracting the pulverized nuts with alcohol.

A study of the diet of the laboring classes in Edinburgh, carried out under the auspices of the town council of the city of Edinburgh, D. N. Paton, J. C. Dunlop, and Elsie M. Inglis (*Edinburgh: O. Shulze & Co., 1901, pp. 104*).—Dietary studies are reported of 15 families living in the thickly congested districts of Edinburgh. As regards income, the families were divided into 3 groups: (1) those with the regular wages under \$5 per week, (2) those with \$5 to \$5.75 per week, and (3) those with incomes of from \$7 to \$10 per week. The different families and groups are discussed at some length. On an average, it is stated, the typical diet of an Edinburgh laborer's family contained 107 gm. protein, 88 gm. fat, and 479 gm. carbohydrates, together furnishing 3,228 calories. Both the protein and the energy were regarded as too small. More than one-half the protein was supplied by vegetable foods. Although more money was spent for animal foods than for vegetable foods, more nutritive material was supplied by the latter. The average cost of the diet was about \$1 per man per week. The principal foods used were bread, potatoes, milk, vegetables, sugar and beef. Relatively large amounts of more expensive foods, such as beef, milk, and eggs, were consumed, and a relatively small amount of cheaper food, such as oatmeal, peas, and barley. The authors note that there is a tendency to use bread and tea or bread and butter in place of the oatmeal porridge once so commonly eaten. The superior food value of porridge is pointed out. In order to improve the diet of families like a number of those cited, the authors believe that they should be taught "(1) that a diet of tea and bread, or of tea, bread and butter (the lazy diet), is faulty; (2) that the faults of the tea and bread diet can be corrected by the free use of meat, eggs, or other animal food, but that this mode of correction is expensive; (3) that the faults can also be corrected by the free use of oatmeal with milk, or of peas or beans, without extra cost; and (4) that to correct the faults of a tea and bread diet, either money spent on animal food or labor spent on the cooking of vegetable food is necessary; if they have not the former, the money, they must use the latter, the labor of properly cooking more nutritive foods."

Some results of recent dietary studies in the United States, O. F. Tower (*Western Reserve Univ. Bul., n. ser., 4 (1901), No. 3, pp. 47–63*).—Recent dietary studies made in the United States are discussed, and a dietary study, made by the author, of a professional man's family in Cleveland, Ohio, is reported. The average amounts consumed per man per day were: Protein 98 gm., fat 87 gm., carbohydrates 377 gm., together furnishing 2,735 calories.

Dietary studies at Western Reserve University, O. F. Tower (*Western Reserve Univ. Bul., n. ser., 4 (1901) No. 6, pp. 146–164*).—Two dietary studies are reported; one was made at a boarding club consisting of men students, and the other at a club consisting of women students. The former consumed on an average per man per day, 140 gm. protein, 157 gm. fat, and 444 gm. carbohydrates, the fuel value being 3,830 calories. The average amounts consumed per woman per day in the second study were 103 gm. protein, 131 gm. fat, and 348 gm. carbohydrates, the fuel value being 3,060 calories. This was calculated as equivalent to 129 gm. protein, 164 gm. fat, 435 gm. carbohydrates, and 3,825 calories per man per day. The results of these studies are compared with similar data obtained elsewhere.

Proteids and their value from the standpoint of the physiology of nutrition, A. Jolles (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 24, pp. 1163, 1164*).—In a paper presented at the Hamburg meeting of German Naturalists and Physicians, 1901, the author reports experiments on the nutritive value of different proteids. In his opinion, unless nitrogen is present in any given proteid in a form which yields urea it is not well utilized. Hexon bases were recovered in the feces and not in the urine.

Since the form in which nitrogen is present determines its nutritive value, the author believes that it is not possible to learn the nutritive value of proteids by the ordinary analytical methods.

Influence of formic aldehyde upon the metabolism of children, F. W. Tunnicliffe and O. Rosenheim (*Jour. Hyg. [Cambridge], 1 (1901), No. 3; abs. in British Med. Jour., 1902, No. 2143, Epit., p. 16*).—From their experiments the authors conclude that "in healthy children dilute formic aldehyde given with food (1 in 9,000) produces a retention of water in the body, but has no appreciable effect on nitrogen or phosphorus metabolism or fat assimilation, though a tendency in larger doses to diminish phosphorus and fat assimilation, referable to an influence upon pancreatic digestion, is inferred. In a delicate child no retention of water in the body results, and there is a diminution in nitrogen, phosphorus, and fat assimilation, with intestinal irritation, referable to interference with pancreatic digestion. In all the cases the excretion of lecithin was diminished, and no intestinal antiseptic action was noticed, while the general health remained constant."

Cleaning fruit before it is eaten, B. Ehrlich (*Arch. Hyg., 41 (1901), No. 2, pp. 152–176*).—A number of instances are cited in which diseases were conveyed by fruit gathered, marketed, or handled under unsanitary conditions. The author points out that micro-organisms adhere readily to the surface of fruits. Experiments were therefore undertaken to determine the number and kinds of such micro-organisms. The smallest number were found on blueberries and plums and the largest number on currants and cherries. It was found to be possible to remove the greater number of micro-organisms by washing.

ANIMAL PRODUCTION.

Fodders and feeds (*New Jersey Stas. Rpt. 1900, pp. 177–180*).—Analyses are reported of oat and pea forage, hay and straw (manured in different ways), ground oats and peas, alfalfa of different cuttings, alfalfa hay, cowpeas and Kafir corn forage, wheat fodder, crimson clover, ground beans, hominy meal, hominy feed, cotton-seed meal, middlings, wheat bran, pea meal, gluten meal, dried distillers' grains, dried brewers' grains, corn meal, oat feed, and several commercial feeds. The wheat fodder had the following percentage composition: Water, 77.26; protein, 2.35; fat. 0.68; nitrogen-free extract, 11.97; crude fiber, 5.92; and ash, 1.82.

Market prices of commercial feeds (pp. 180, 181).—The average market price in New Jersey of a number of feeding stuffs for several years is recorded.

Inspection of feeding stuffs, W. H. Jordan and C. G. Jenter (*New York State Sta. Bul. 198, pp. 33–61*).—Under the provision of the State feeding-stuffs law analyses were made of samples of cotton-seed meal, linseed meal, gluten meal, gluten feeds, germ oil meal, special gluten, malt sprouts, proprietary feeds (cereal breakfast food by-products), corn bran, barley, poultry foods, offals from milling wheat and rye, and ground grains, chiefly mixed corn and oats. The bulletin also contains a list of the brands of feeding stuffs licensed in the State for the year 1901, comments on the facts shown by the analysis made, as well as suggestions to manufacturers and consumers.

Pea-vine hay, W. F. Massey (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 9, pp. 19, 20*).—Directions are given for curing pea-vine hay.

Hay of Norwegian fodder plants, F. H. Werenskiold (*Tidsskr. Norske Landbr., 7 (1900), No. 11, pp. 498–509*).—Chemical and botanical analyses of 62 samples of hay from grasses and legumes, 28 samples of hay from mountain pastures (*säterhö*), and 27 samples of marsh and woodland hay (*skoghö*). The ordinary food constituents are given in all cases; also digestible and indigestible albuminoids and amids.—F. W. WOLL.

The utilization of potatoes (*Braunschweig Landw. Ztg., 69 (1901), No. 51, pp. 214, 215*).—The possibility of profitably feeding potatoes when they are low in price is discussed, and directions given for feeding them to different farm animals.

Milk-molasses feed (*Braunschweig Landw. Ztg., 69 (1901), No. 51, p. 216*).—A brief account of the nature and uses of a feed made from molasses and the albumin and casein of skim milk.

On the feeding value of seaweeds, P. R. Sollied (*Tidsskr. Norske Landbr., 8 (1901), No. 1, pp. 13–30*).—Chemical analyses are given of samples of Fucus, Laminaria, and Sarcophyllis species, with a discussion of their value as feeding stuffs, and a bibliography on the subject.—F. W. WOLL.

Rice ensilage (*Queensland Agr. Jour., 9 (1901), No. 4, p. 415*).—A brief note is given on the successful use of rice for silage. The crop was cut when the rice was in the ear but before the grains had begun to harden.

On the physiological valuation of nutrients—animal metabolism, H. Isaachsen (*Tidsskr. Norske Landbr., 7 (1901), No. 10, pp. 433–470*).

Concerning metabolism when water is withheld, A. Spiegler (*Ztschr. Biol., 41 (1901), No. 2, pp. 239–270*).—Experiments are reported and discussed.

The resorption of fat is due to the fact that it is rendered soluble in water, E. Pflüger (*Arch. Physiol. [Pflüger], 86 (1901), No. 1–2, pp. 1–46*).—Experiments are reported and discussed.

Further investigations on the resorption of fat in water soluble form, E. Pflüger (*Arch. Physiol. [Pflüger], 88 (1901), No. 6–8, pp. 299–338*).—A large number of experiments are reported.

Concerning the value of soaps in the resorption of fat, E. Pflüger (*Arch. Physiol. [Pflüger], 88 (1901), No. 9–10, pp. 431–452*).—Experiments which are reported in detail and an extended review of the subject led the author to the conclusion that fatty acids are absorbed in a form in which they are loosely bound together; that is, in a labile condition. This is regarded as midway between a dissociated condition and a condition of stability. The resorption of fat, however, necessitates a cleavage into fatty acids and glycerin.

Resorption in the intestine—III, R. Höber (*Arch. Physiol. [Pflüger], 86 (1901), No. 3–4, pp. 199–214*).—A study of resorption by the epithelial cells of the intestine.

Concerning quantitative resorption in the large and small intestine, F. Reach (*Arch. Physiol. [Pflüger], 86 (1901), No. 5–6, pp. 247–258*).—From experiments with gelatin and albuminose solutions, with and without salt, the conclusion is drawn that resorption is much greater in the small intestine than in the large intestine.

On the resorption of artificially colored fat, L. Hofbauer (*Arch. Physiol. [Pflüger], 84 (1901), No. 11–12, pp. 619–627*).—The additional experiments reported confirm the author in his opinion that minute particles of fat pass the intestinal wall without saponification. (E. S. R., 12, p. 981.)

Experiments on resorption, digestion, and metabolism in Echinoderma, O. Cohnheim (*Ztschr. Physiol. Chem., 33 (1901), No. 1–2, pp. 9–54*).—Report of large number of investigations.

The chemistry of peptic and tryptic digestion of proteids—I, D. Lawrow (*Ztschr. Physiol. Chem., 33 (1901), No. 3–4, pp. 312–328*).—From experiments which are reported in detail, the conclusion is drawn that when pig stomach is allowed to digest itself, decomposition being hindered, the long-continued action of pepsin induces as deep-seated cleavage of protein as trypsin.

Investigations on the occurrence of proteolytic enzyms in the animal body, S. G. Hedin and S. Rowland (*Ztschr. Physiol. Chem., 32 (1901), No. 6, pp. 531–540*).—Numerous experiments were made to show the presence of enzyms in the organs and tissues of cattle, calves, horses, and dogs and to study their nature when present. The principal deductions are summarized as follows: The spleen, lymphatic gland, kidneys, and liver of the different classes of animals examined contained a proteolytic enzym which was most active in an acid solution. The skeletal muscles also contained a proteolytic enzym, but it is relatively less active and its action was practically the same in alkaline, acid, and neutral solutions. An enzym found in the muscles of the heart was similar in action to that as present in the organs enumerated above.

Studies of muscle heat, M. BLIX (*Skand. Arch. Physiol.*, *12* (*1901*), *No. 1–2*, *pp. 52–128*, *pls. 3*).—Experimental methods are described and an extended series of investigations reported and discussed.

Concerning a hitherto unknown reducing body in blood, P. MAYER (*Ztschr. Physiol. Chem.*, *32* (*1901*), *No. 6*, *pp. 518–530*).—According to the author's investigations, glycuronic acid united with some other body is a normal constituent of beef blood.

Feeding experiments with molasses and ground peat, O. KELLNER, O. ZAHN, and H. VON GILLERN (*Landw. Vers. Stat.*, *55* (*1901*), *No. 4–5*, *pp. 379–388*).—Experiments were made with 2 sheep on the digestibility of molasses, fed with and without the addition of ground peat. In both cases the basal ration consisted of meadow hay, and the digestibility of this feeding stuff alone was studied. The special object was to determine the influence of ground peat on the digestibility of the molasses. The average results follow:

Digestibility of molasses and molasses feeds—Average of two sheep.

	Organic matter.	Protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Pentosans.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
1,000 gm. meadow hay	64.8	59.7	54.8	68.7	60.5	64.9
850 gm. meadow hay, 250 gm. peat meal, and 100 gm. molasses	49.5	42.9	44.8	53.9	43.8	51.4
800 gm. meadow hay and 100 gm. molasses	65.9	58.4	53.5	71.3	59.0	62.0
Calculated for molasses alone	77.5	49.0	....	87.9	....	....

The authors conclude that not only is the ground peat itself indigestible, but it diminishes the feeding value of the other materials, since it increases the amount of nutrients excreted in the feces.

The Angora goat, G. F. THOMPSON (*U. S. Dept. Agr., Farmers' Bul. 137*, *pp. 47*, *figs. 7*).—A popular edition of a publication previously noted (E. S. R., 12, p. 1077).

Poultry division, A. A. BRIGHAM (*Rhode Island Sta. Rpt. 1901*, *pp. 297–333*, *pls. 6*).—Brief statements are made concerning the work of the station poultry division. The work included brooding experiments with incubator chickens (see p. 793), a study of poultry diseases (see p. 793), determinations (by Martha Austin) of the amount of carbon dioxid in the air of incubators, breeding experiments with Belgian hares resulting in the production of a black strain, and other investigations, which are reported elsewhere in detail.

The determinations of carbon dioxid are not regarded as sufficient for drawing definite conclusions as to the influence of the amount on the hatching of eggs. The object of the investigation was to learn why so large proportion of chickens expire on the nineteenth or twentieth day of incubation when the embryonic growth is nearly or quite complete.

Preservation of eggs (pp. 304–323).—The value was tested as a preservative for eggs of water glass, dry table salt, limewater and salt brine, vaseline, ashes, gypsum, powdered sulphur, powdered sulphur and sulphur fumes, permanganate of potash, salicylic acid and salt brine. Some of the eggs used were fertile, others infertile. The general deductions drawn from the investigations follow:

"Of the different methods tested in this series of experiments the old way of using slaked lime and salt brine proved to be very effectual, and has also the advantage of being inexpensive. It is also not difficult to practice. For a period of a few weeks only, smearing the eggs with vaseline may prove an effective method of preservation. In the place of vaseline almost any clean, greasy substance may be used. For a period of a few months only, packing in dry table salt is worthy of recommendation. Of all the substances experimented with, the water glass solution proved most worthy of commendation. The . . . experiments showed that the water glass solution could be reduced to 3 per cent and still retain its preserving quality. Water glass can be obtained of druggists at from 40 to 60 cts. per gallon. It is easily manipulated and the solution may be repeatedly used. The eggs should be completely immersed in the solution, and if any eggs float, an inner cover which will sink them below the surface of the liquid should be used. In several tests where the eggs were placed in stone jars inverted saucers were used for this purpose. The expense for the water glass at 60 cts. per gallon would amount to about two-thirds of a cent per dozen eggs. This does not include the expense of the jar or other receptacle, which may be of stoneware, glass, or wood."

Notes on Rhode Island Reds (pp. 324-333).—The origin and characteristics of the strain of poultry known as Rhode Island Reds is discussed.

Trap nests, T. H. TAYLOR (*Rhode Island Sta. Rpt. 1901, pp. 334-346, pl. 1, dgm. 1*).—Comparative tests were made with a number of sorts of trap nests. The author noted the number of times the nests operated and failed to operate, as well as the number of eggs laid in the nest, outside the nest, etc.

"Although it is possible by the use of trap nests to determine the number of eggs laid by individual hens, the impracticability of their use on a large scale is evident, since the expense of attending them overbalances in a business sense the results obtained. In all the tests here reported it was found necessary to look at the nests during the busy laying season at least 5 times per day, and if a hen had laid each time it took considerably more than the 'one minute a day' claimed by more than one of the inventors to release the hen and credit the egg to her account. . . .

"We fail to see how any of the devices could prevent egg eating, as was claimed for some of them. In all the nests the hen had access to the egg after it was laid, and in one or two instances a hen was known to eat the egg."

Narrow, medium, and wide rations for chickens, T. H. TAYLOR (*Rhode Island Sta. Rpt. 1901, pp. 347-354*).—Tests extending over 3 years were made of the comparative value of narrow, medium, and wide rations. In every case 3 lots of 10 chickens each were used. The chickens fed the medium ration were given cracked corn in the morning and at night a mash of mixed ground grain and beef scrap, the nutritive ratio of the ration being 1:5. The lot receiving the narrow ration received oats in the morning and the same mash at night as lot 1. In addition they were given cut green bone 3 times a week. The nutritive ratio was 1:2.8. The lot fed the wide ration received the cracked corn in the morning and at night a mash of bran and corn meal. The nutritive ratio of this ration was 1:8.4. The tests covered a total of 92 days. In every case the greatest number of eggs was produced on the narrow ration and the smallest number on the wide ration. The average cost of the feed per hen per day on the 3 rations was 0.19, 0.18, and 0.16 ct., respectively. The cost per egg on the 3 rations, 0.97, 0.8, and 1.34 cts., respectively.

Chemical analyses showed that the manure from the narrow ration contained the largest percentage of nitrogen.

American breeds of fowls. II, The Wyandotte, T. F. McGREW (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 31, pp. 30, col. pls. 10, figs. 3*).—The origin of the Wyandotte breed and the characteristics of the different classes are treated of. The bulletin also contains information on breeding Wyandottes, their value as general-purpose fowls, and related topics.

Poultry division (*New Zealand Dept. Agr. Rpt. 1901, pp. 178–185, pls. 7*).—Statistics of the poultry exported are given, and poultry raising under local conditions and similar topics are discussed.

A Queensland duck farm (*Queensland Agr. Jour., 9 (1901), No. 4, pp. 398–400, pls. 2*).—A descriptive article.

Renewed studies in oyster culture, J. NELSON (*New Jersey Stas. Rpt. 1900, pp. 315–359, pls. 4*).—Experiments on the artificial propagation of oysters are reported, and the general principles of oyster culture discussed. The author believes that the methods of the artificial propagation of oysters are not sufficiently developed so that they can be successfully applied commercially.

"Meanwhile the method of shell planting with intermixed spawners has been shown to be eminently successful and to meet the wants of the oyster planters. The only thing that stands in the way of its immediate development in our State is the unsatisfactory legal status of the business."

DAIRY FARMING—DAIRYING.

Report of the assistant in dairy husbandry, C. B. LANE (*New Jersey Stas. Rpt. 1900, pp. 257–264, 266–311, pls. 8*).—The principal lines of dairy work during the year are reported upon in detail.

Soiling crops (pp. 260–264).—Fourteen forage crops were grown for soiling purposes, tabulated data for which are given showing the dates of seeding and cutting, amount of seed used, cost of labor, seed, and fertilizers, and the yield, together with notes on the different crops.

Experiment with wide vs. balanced rations (pp. 266–273).—A ration composed of silage, timothy and clover hay, wheat bran, and corn-and-cob meal, and having a nutritive rate of 1:8.9, was compared with a ration composed of silage, timothy and clover hay, wheat bran, dried brewers' grains, and cotton-seed meal, and having a nutritive ratio of 1:5.4. The two rations were fed to 2 lots of 2 cows each for 30 days and were then reversed, and after a transition period of 7 days were fed for 30 days longer. The yield of milk was 12.8 per cent greater and the yield of fat 14.6 per cent greater on the "balanced" than on the wide ration. The fat content of the milk averaged 4.24 per cent on the wide ration and 4.32 per cent on the balanced ration. When the wide ration was fed the cost of food for 100 lbs. of milk and 1 lb. of butter was, respectively, 69.1 and 13.9 cts., and when the balanced ration was fed 66.3 and 13.2 cts., respectively. The animals also made a greater gain in live weight on the balanced ration.

Feeding twice vs. three times daily (pp. 273–276).—Four cows were divided into 2 lots and fed the same ration, composed of silage, dried brewers' grains, wheat bran, and cotton-seed meal, morning and evening during 2 periods of 15 days each. In addition, lot 1 during the first period and lot 2 during the second period were fed cornstalks at noon. When fed 3 times a day the cows produced 2.4 per cent more milk and 2.7 per cent more butter and made a greater gain in live weight than when fed twice a day. The gain in milk is estimated as paying for the cornstalks actually eaten at the rate of $4.35 per ton.

Number of tests required in testing cows for quantity and quality of milk (pp. 277–289).—Tables are given showing the yield and fat content of the milk of 2 cows tested daily and at intervals of 7, 14, 21, and 30 days for 5 months. Tests made once a week gave 100.3 per cent of the actual yield of milk and fat as shown by the daily record; tests made once in 2 weeks, 99.7 per cent of the milk and 99.3 per cent of the fat; tests made once in 3 weeks, 99.5 per cent of the milk and 102.2 per cent of the fat; and monthly tests 99.6 per cent of the milk and 98.3 per cent of the fat. The conclusion is drawn that quite satisfactory records may be obtained by tests at intervals of 7, 14, 21, or 30 days. It is recommended, however, that composite samples for at least 2 days be taken where the intervals are longer than 2 weeks. Reference is made to results obtained at the Illinois and Vermont stations relative to the number of tests required during a period of lactation.

Dehorning cattle (pp. 289–294).—A record is given of 3 cows for 20 days preceding and 20 days following dehorning, and also for both periods for 3 other cows not dehorned. The yield of milk of the dehorned cows decreased 16.9 per cent and of the other 3 cows 13.6 per cent during the second period as compared with the first. Notes are given on preventing the growth of horns by means of caustic potash. In experiments with 6 calves the best time for making the application was found to be between the fifth and tenth days.

Cost of producing milk (pp. 295–298).—Data showing the cost of the milk production of the herd of 30 cows for the year ending April 1, 1900, are given and averaged with similar data obtained during the 3 preceding years. The average yield of milk per cow for the 4 years was 6,467 lbs., and the average cost per quart of milk, including food, labor, and interest on and decrease in the value of the herd, was 2.39 cts.

Soiling crop rotation (pp. 298–301).—Tabulated data are given showing the total yield and amount of nutrients obtained per acre from the various combinations of crops supplying forage to the dairy herd from May 1 to October 1.

Dairying in relation to soil exhaustion (pp. 301–303).—The amount of fertilizing elements contained in the feeding stuffs purchased was decidedly greater than that in the milk produced by the station herd during 4 years.

Record of the dairy herd (pp. 303–311).—A monthly record of 27 cows is given for the year ended April 1, 1900. The average yield of milk per cow was 6,380 lbs. and the average fat content of the milk 4.57 per cent. The best cow produced 9,511 lbs. of milk and 452 lbs. of butter and the poorest cow 3,135 lbs. of milk and 233 lbs. of butter. The author considers that a cow producing less than 5,000 lbs. of milk per year is unprofitable.

The waste in handling and delivering milk for 4 years averaged 8.3 per cent.

Methods of dairy feeding, H. Hayward (*Pennsylvania Sta. Bul. 56, pp. 6*).—An experiment covering 3 thirty-day periods was conducted with 15 cows divided into 3 uniform lots to compare feeding in pens and stalls and to test the effect of having water constantly before cows in stalls. During the first and third periods the 3 lots were tied in stalls and turned out once a day in the yard to be watered. During the second period lot 1 was turned loose in a pen 12 by 26 ft., and furnished with a constant supply of water; lot 2 received the same treatment as during the first and third periods; and lot 3 was confined in stalls and given a constant water supply. The same ration was fed throughout. The results are summarized as follows:

"(1) The results of this experiment failed to show any advantage in having water constantly before the cows in the stable. The cows that were turned into the yard for water once a day made as good returns as those having constant access to water in the stable.

"(2) Much more bedding was required to keep the cows clean and comfortable in the pens than in the stalls. Apparently it would not be economical to keep milch cows loose in pens on farms where the supply of bedding is limited.

"(3) Considerably less labor was required to care for the cows in the pen than for those in the stalls. The increase in the amount of bedding would also result in the production of a greater bulk of manure.

"(4) The fewest bacteria were found in the milk of those cows which stood in the stalls constantly, and which were consequently the cleanest."

Feeding experiments to determine the effect of increasing amounts of concentrated feeds upon the yield of milk, K. Hittcher (*Molk. Ztg., 15 (1901), Nos. 30, pp. 527, 528; 31, p. 547; 32, pp. 563, 564*).—Two feeding experiments, one made with 39 cows and the other with 42 cows, are reported. In each case the cows were divided into 3 lots as nearly alike as possible, and fed for 4 periods varying in length from 3 to 9 weeks in the first experiment and from 4 to 12 weeks in the second experiment. Varying amounts of concentrated feeds consisting of wheat bran, sunflower cake, palm-nut cake, and brewers' grains were fed the different lots in addition to coarser feeding stuffs. In the first experiment feeding 7 lbs. of concentrated feed was more profitable than feeding 10 or 13 lbs., and in the second experiment feeding 4 lbs. was more profitable than feeding 7 or 10 lbs.

A study of individuality of dairy cows in a modern dairy barn, W. A. Conant (*Rhode Island Sta. Bul. 80, pp. 41–107, pls. 14*).—A detailed account is given of the kind and amount of food eaten and the yield and fat content of the milk produced by each of 11 cows during the period from December 1, 1900, to March 14, 1901, together with illustrations and notes on the history and characteristics of each cow. The feeding stuffs used were Chicago gluten meal, cotton-seed meal, wheat bran, wheat middlings, oat hay, and corn silage. The data for each cow as regards the amounts of the several feeding stuffs and of the different nutrients which gave the best results, the average yield of milk for all the rations fed, and the yield for the most favorable ration, etc., are summarized in tables. Various suggestions are made throughout the article in regard to the feeding and care of cows and a full account is given of the management of one of the cows at calving time. Averaging the results for the whole herd and the different feeding stuffs separately, the best yield of milk was obtained with 1.29 lbs. of Chicago gluten meal, 1.81 lbs. of cotton-seed meal, 3.83 lbs. of wheat bran, 4.05 lbs. of wheat middlings, 5.73 lbs. of oat hay, and 38.85 lbs. of corn silage. The best results were obtained with 21.07 lbs. of digestible dry matter, 2.10 lbs. of digestible protein, and a nutritive ratio of 1:5.9.

Pan-American model dairy, V. E. Fuller (*Jersey Advocate and Dairyman, 1 (1901), No. 37, Sup., folio*).—Ten breeds were represented by 5 cows each. The record as given shows the kind, quantity, and cost of food consumed, and the milk, fat, and solids produced by each cow for the 6 months of the test. The following table summarizes the yield of milk, fat, and solids by breeds for the entire test as well as the cost of food and the net profit in estimated butter and in solids·

Record of 5 cows each of 10 breeds for 6 months, showing total production, cost of food, and net profit by breeds.

Breed.	Yield of milk.	Yield of fat.	Yield of solids.	Cost of food.	Profit in butter.	Profit in solids.
	Pounds.	*Pounds.*	*Pounds.*			
Jersey	26,986.3	1,223.88	3,770.08	$137.77	$225.41	$200.63
Guernsey	27,134.5	1,248.09	3,754.99	136.99	230.11	202.56
Ayrshire	32,998.2	1,219.44	4,185.32	140.74	217.91	235.87
Shorthorn	31,986.2	1,129.77	4,086.59	162.08	171.82	205.64
Holstein	39,059.9	1,275.85	4,760.57	164.57	210.62	262.15
Polled Jersey	20,326.6	948.31	2,831.73	109.62	169.24	145.18
French Canadian	24,615.2	984.11	3,277.36	113.11	176.45	181.83
Brown Swiss	30,890.3	1,123.15	3,943.03	147.30	182.99	207.51
Red Polled	28,713.0	1,141.81	3,773.73	138.15	198.15	201.15
Dutch Belted	24,893.3	847.50	3,066.50	132.48	116.79	132.60

The Red Polled and Dutch Belted cows were selected from a comparatively small number available for this purpose, and during the first 18 days of the test the Dutch Belted were represented by 3 cows only. "The first deduction that would naturally be drawn from the net profit in estimated butter is that the breeds which are specially bred for the dairy show a very strong lead in this particular." The Red Polled is noted as a possible exception to this statement. The Guernseys made the greatest profit in butter, with the Jerseys second, and the Ayrshires third. The Holsteins produced the most milk and solids, and stood first as regards profit in solids, but fourth as regards profit in estimated butter. The Ayrshires are considered as having made an excellent showing.

Lessons from the model dairy, E. Van Alstyne (*Abs. in Jersey Advocate and Dairyman, 1 (1902), No. 45, pp. 6, 7*).—The author draws a number of deductions from the records of the Pan-American model dairy, among which, in substance, are the following: The best cows are not all in any one breed. The Channel Islands cattle are certainly the ones to be selected for butter production. For milk production without regard to fat content the Holsteins are to be selected, especially if the food supply is plentiful and easily obtained. Size alone is no criterion of the value of a dairy cow. An excessive grain ration was not always the most economical. Bran, 6 lbs., and "gluten" (containing 28 per cent of protein), 4 lbs., as a basis for the grain ration gave the best results. Corn silage was shown to be an economical feed in summer as well as in winter. No change in the character of the feed produced any notable change in the fat content of the milk. Nutritive ratios varying from 1:4 to 1:6 gave as good results with particular cows or feeds as a nutritive ratio of 1:5.5.

The importance of exercise and principles of breeding are also briefly discussed in this connection.

On the productive capacity of Funen (Danish) cattle, N. Petersen (*Mälkeritid., 14 (1901), No. 32, pp. 491–502*).—An investigation of the progeny of prize bulls of the Funen breed with reference to their productive capacity. The report includes data for 1,116 cows in 26 different herds that competed for prizes in agricultural society herd contests during 1894–1900. The data have been used for discussions of many questions bearing on dairy practice, and on relations of yield of milk, age of animals, or time of lactation to quality of milk produced, etc.—F. W. WOLL.

Report of Milk Control Station, Christiania, Norway, 1900 (*Aarsbr. Offent. Foranst. Landbr. Fremme, 1900, pp. 319–325*).—The average fat content of 154,725 samples of milk tested at the Christiania Milk Control Station during 1896 to 1900 was 3.477 per cent. The monthly averages, including between 10,000 and 15,000 analyses each, were as follows: January, 3.439 per cent; February, 3.411 per cent; March, 3.362 per cent; April, 3.344 per cent; May, 3.305 per cent; June, 3.432 per cent; July, 3.545 per cent; August, 3.543 per cent; September, 3.629 per cent; October, 3.662 per cent; November, 3.577 per cent, and December, 3.509 per cent.—F. W. WOLL.

Reports of milk control stations in Trondhjem and Bergen, Norway, 1900, T. Soelberg and K. Seielstad (*Aarsbr. Offent. Foranst. Landbr. Fremme, 1900, pp. 326–334*).

Skimming and churning in Norwegian creameries, S. J. Benterud (*Aarsbr. Offent. Foranst. Landbr. Fremme, 1900, pp. 287–292*).—Investigations of the thoroughness of skimming and churning in Norwegian creameries gave the following results: Out of 110 samples of separator skim milk 12 contained less than 0.1 per cent of fat and 20 more than 0.2 per cent, the average fat content being 0.16 per cent. Of 87 samples of undiluted buttermilk from ripened cream, 14 contained less than 0.25 per cent and 14 more than 0.5 per cent, the average being 0.4 per cent.—F. W. WOLL.

Observations on separators, H. Hayward (*Pennsylvania Sta. Rpt. 1900, pp. 318–320*).—Tabulated data are given for 17, 16, and 31 tests, respectively, of the United States No. 1, the Sharpless Tubular, and the Alpha Acme DeLaval separators.

The food source of milk fat, with studies on the nutrition of milch cows, W. H. Jordan, C. G. Jenter, and F. D. Fuller (*New York State Sta. Bul. 197, pp. 32*).—An experiment with one cow reported in an earlier bulletin of the station (E. S. R., 9, p. 1083) led to the conclusion that milk fat, in part at least, can be formed from carbohydrates. In the present bulletin additional experiments concerning the source of milk fat and other questions relating to the metabolism of the milch cow are reported and briefly summarized as follows:

"Three cows were used: Cow 12 fed a fat-poor ration in which the protein supply was gradually decreased from 2.6 lbs. daily to 1.6 lbs. and then gradually restored to the maximum, with accompanying increase and decrease in carbohydrates, so that the digestible dry matter of the ration was kept fairly uniform; cow 10 fed a ration with normal supply of fat at first which was gradually increased to 1.4 lbs. daily, then gradually restored to the normal; and cow 2 fed the herd ration having a nutritive ratio about 1:5.6. These rations were quite varied in character and contained some fat-extracted foods, yet showed a quite uniform digestibility of about 70 per cent of the dry matter. It is believed that this figure represents fairly the digestibility of rations made up in part of silage and containing a fair proportion of high-class grains. A widening of the nutritive ratios appeared to render rations less digestible, especially the protein. The marked changes in protein content and in fat content of rations did not produce noticeable changes in the character or composition of the milk. In the former test, during 59 days, 18.4 lbs. of fat was formed in the milk which could not have had its source in food fat or food protein and could hardly have been drawn from the cow's body fat, as she increased in weight 33 lbs. in the same time. In this test cow 12 in 74 days produced 39 lbs. of fat similarly unaccounted for, with a body gain of 15 lbs.; and cow 2, in 4 days, $1\frac{1}{4}$ lbs. These amounts of fat must have come from the carbohydrates in the food.

"A lessening of protein supply in the food did not produce a corresponding decrease in protein in the milk solids, but caused a marked lessening of protein decomposition in the body. Calorimeter determinations show that the heat value of urine bears no constant relation to its nitrogen content, and also prove that the formula used in computing heat energy of urine, $N \times 5.343$ cal., is greatly in error, actual results being from 3 to 4 times as large as calculated by this formula. The energy values of nutrients as given by Rubner—protein and carbohydrates each 4.1 cal. and fats 9.3 cal.—appear to be fully high enough for herbivora, even when the loss due to escape of unoxidized gases, methane chiefly, is not considered.

"Over 40 per cent of the available energy value of the rations was used for maintenance, over 30 per cent reappeared in the milk solids, leaving a balance of from one-fifth to one-fourth of the ration. The logical conclusion is that this balance, in part at least, sustains the work of milk secretion."

Fat in milk from starch in food, F. H. HALL ET AL. (*New York State Sta. Bul. 197, popular ed., pp. 8*).—A popular summary of the above bulletin.

A feeding experiment with sheep, showing the influence of the fat in the ration upon the amount and composition of the milk, A. MORGAN ET AL. (*Chem. Ztg., 25 (1901), No. 87, pp. 951–953*).—This experiment was carried on during a portion of 2 years and was made with the object of ascertaining the influence of the fat in food upon the fat content of the resulting milk. In comparison with the usual ration, consisting of a number of common foods, rations were fed poor in fat and rich in fat. The ration poor in fat was made up of carbohydrates containing small amounts of fat, and the ration rich in fat was made up in part of sesame cake and peanut oil. The rations consisted of about 167 gm. of digestible protein and 600 gm. of nitrogen-free stuff including fat, to each 50 kg. of live weight. The fat content of the rations ranged about 10, 50, and 76 gm., respectively. The dry susbtance of the milk obtained in feeding the ration poor in fat contained the following per cents, more or less, than those obtained with the normal ration: Fat −7.1, sugar +2, ash +0.5, and nitrogen +0.6 per cent. The ration rich in fat gave, in comparison with the normal ration, the following per cents, plus or minus: Fat −1.2, sugar +0.6, ash +0.1, nitrogen +0.05 per cent. These experiments will be continued, but from the results so far obtained it would appear that fat in food in the form of sesame cake or peanut oil, in certain amounts, has an important influence on the fat content of the milk. In a ration with a nutritive ratio of 1:3.6 and a fat content equal to about 1 gm. to 1 kg. of live weight, the addition of more fat in lieu of carbohydrates tended to a diminution in the yield of milk fat; a decrease in the fat in the food, if below a certain limit, caused a decrease in the fat content of the milk and an increase in the sugar, ash, and nitrogen. Again, the fat in the food may cause an increase in the fat content of the milk, but not of the other components. The fat in the food in increased amounts produces an increased fat content of the milk, up to a certain limit. Beyond that it varies with the individuality of the animal, and in an unusual amount may even cause a lessening of the fat content.

Investigations concerning the germicidal action in cow's milk, O. F. HUNZIKER (*New York Cornell Sta. Bul. 197, pp. 61–91, dgms. 3*).—The source of bacteria in milk is briefly discussed and investigations to determine the presence and degree of germicidal qualities in milk and the conditions most favorable for their action are reported in detail. The cause of the germicidal action in milk, according to the author, is unexplained. The data for the experiments are tabulated, and 3 diagrams are given showing graphically the germicidal action in milk as affected by temperatures ranging from 40 to 70° F. by heating to 149–212° F., and by the acidity of the milk. From the results of the experiments, which are discussed at some length, the following conclusions are drawn:

"(1) Freshly drawn milk of most cows contains varying germicidal qualities.

"(2) The degree of the germicidal action varies greatly in milk of different animals and sometimes in milk of the same animal taken at different milkings.

"(3) The bactericidal influence behaves differently at different temperatures. It appears to be greatest, while it lasts, at 70° F.; at lower temperatures it is less pronounced but of longer duration. At 70° F. the maximum duration of the germicidal action was 12 hours, the average duration 3 to 6 hours.

"(4) Heat is detrimental to the germicidal agent. Milk subjected to a temperature of 149° F. for 40 minutes had lost its bactericidal qualities.

"(5) The acidity in milk did not increase appreciably while the germicidal action lasted. A decided and continuous increase of acidity occurred only about 15 to 20 hours before the milk curdled.

"(6) Owing to the lack of control over the germicidal power, the latter can at present be of little value in practical dairying.

"(7) So far as investigations up to the present time have shown, the best means of improving the keeping quality of milk, without the use of chemical preservatives, seems to be scrupulous cleanliness and low temperatures."

Studies in dairy bacteriology and dairy science, E. PETERSSON (*K. Landt. Akad. Handl. Tidskr., 39 (1900), No. 5–6, pp. 275–317*).—A report of the following German, Swiss, or Danish dairy institutes or schools: Göttingen, Hameln, Fulda, Kiel, Stargard, Kleinhof-Tapiau, Berne, and Copenhagen, and of the dairy experiment stations connected with the larger of these institutions. A detailed outline of a short bacteriological laboratory and lecture course given by Professor Salomonsen, Copenhagen, is presented, as are also the results of work on the occurrence of lactic-acid bacteria, their general morphological and biological characteristics, done by the author in the dairy bacteriological laboratory at Göttingen Agricultural Institute.—F. W. WOLL.

Milk bacteria investigation, V. A. MOORE (*New York Produce Rev. and Amer. Creamery, 1902, Jan. 22, p. 29*).—The following deductions are drawn from a study of bacteria in milk:

"(1) Milk as it is drawn from the udder contains a variable, but rarely an excessive, number of bacteria.

"(2) Ordinarily the dirt and finer particles of dust that fall into the pail during the process of milking carry a large number of bacteria with them into the milk.

"(3) If the stables are kept clean, the cows groomed, and the skin of the udder and surrounding parts are carefully moistened before milking, the number of bacteria that gain entrance to the milk from without can be greatly reduced.

"(4) The bacteria in the freshly drawn milk do not begin to multiply to any great extent for from 6 to 9 hours when kept at a temperature of 70° F., or below. After that time they multiply very rapidly if the temperature is favorable.

"(5) If the milk is carefully protected and promptly cooled down to and kept at a temperature of 40° F., the number of bacteria in it will not subsequently exceed the number present at the close of the milking process. This number should not exceed a maximum of 100,000 per cubic centimeter. If intelligent care is exercised a minimum of at least from 10,000 to 50,000 per cubic centimeter should be maintained. If cooled to 55° F., like results are obtained for at least 36 to 48 hours and often for a longer period.

"(6) An excessive number of bacteria in milk at any time within 72 hours after it is drawn indicates that it has not been carefully handled. When this is the case, the milk is liable to contain acids and by-products which may be injurious to the consumer. There is also the further danger, as exemplified in many epidemics of typhoid fever, diphtheria, and other infectious diseases, that the general carelessness in protecting milk against contaminations would permit the entrance into the milk of disease-producing bacteria, should these be present on the premises where the milk is produced.

"(7) There is a pronounced germicidal action in the milk of certain cows. It is absent in that from others. In the mixed milk from a dairy it has but a slight value in reducing the actual number of bacteria, but it seems to be the effective agent in preventing the increase of bacteria immediately after the milk is drawn unless it is kept at the body (98° F.) temperature."

Bacterial life of milk, H. L. RUSSELL (*Columbus: Ohio State University Dept. Agr., 1901, pp. 15, pl. 1, figs. 5*).—An address on this subject delivered before the Ohio State Dairymen's Association.

On sterilization of milk, A. JOHANNESEN (*Eira, 1901, No. 11; Tidn. Mjölkhushall., 10 (1901), Nos. 32, pp. 125, 126; 33, pp. 129, 130*).

Reports of periodical butter exhibits in Hangö, Finland, for 1898–99 and 1899–1900 (*Helsingfors, 1900, pp. 19; 1901, pp. 18*).—In the third series of butter exhibits, 1898–99, 210 creameries furnished in all 420 tubs of butter, the average weight being 54.1 kg. The butter contained on the average 12.9 per cent of water, 94.3 per cent of the samples containing between 10 and 15.9 per cent. Over 13 per cent of the tubs lost brine while kept in storage, the maximum amount lost being 770 gm. and the average amount 245 gm. The loss in weight of the tubs during storage amounted to 0.44 per cent.

In the fourth series, 1899–1900, 185 creameries took part, furnishing 446 tubs of butter. The average water content of the butter was 14 per cent, the limits being 10.5 and 19.1 per cent. Both reports give statistics as to the size and management of the creameries participating in the exhibits and summaries of butter scores, weights, etc.—F. W. WOLL.

Danish butter exports, 1899–1900, B. BÖGGILD (*Tidsskr. Landökon., 1900, No. 12, pp. 565–574*).—The gross exports during the year were 149,292,724 Danish pounds, the net exports 108,980,892 Danish pounds, the average price received being 95.5 öre (23.5 cts. per pound avoirdupois).—F. W. WOLL.

VETERINARY SCIENCE AND PRACTICE.

Trichinosis in Germany, C. W. Stiles and A. Hassall (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 30, pp. 211*).—The purposes of the investigation as reported in this bulletin were to ascertain the value of microscopic examination of pork products in Germany, to determine whether cases of trichinosis had been definitely traced to American pork bearing a stamp of inspection from this Department, and to investigate the basis for charges made in Germany against American meats. In the bulletin the following subjects are discussed: The history of the discovery of trichinosis, life history of the parasite, preventive measures, trichinosis as an international question between Germany and America, local regulations regarding trichinæ in Germany, number of trichina inspectors, the expense of such inspection, and statistics on the amount of American pork imported into Germany for the years 1892 to 1898.

In addition to this general discussion the report contains a detailed statistical review of trichinosis in Germany during the years 1881 to 1898, inclusive. In this review the conditions in Prussia, Saxony, Bavaria, Brunswick, Bremen, Alsace-Lorraine, Hamburg, and Lübeck are considered separately. Special attention is given to the subject of European cases of trichinosis of alleged American origin. Translations are presented of an article by Rudolph Virchow on American trichinæ, and by Bouley on importation of salted pork of American origin, and an extended bibliography on the subject of trichinosis in Germany is appended to the report. The bibliography is arranged alphabetically according to authors and chronologically under each author.

The information contained in the report is from German sources and largely from official reports. It appears from the official German reports that microscopic inspection of pork as carried out in Germany is not successful in detecting all the cases of trichinosis in hogs, and in fact a considerable portion of cases of trichinosis in man are traced directly to pork which had been inspected by German inspectors and passed as free from trichinæ. The evidence for trichinosis in man from eating pork of American origin is considered inconclusive.

The utilization of meat condemned on account of trichina, Edelmann (*Deut. Thierärztl. Wchnschr., 9 (1901), No. 18, pp. 181, 182*).—While the complete destruction of such meat or its use for technical purposes satisfies all sanitary requirements in the matter, the author believes that the meat may safely be given to inspectors or other persons who understand the danger of it when not sufficiently cooked.

Studies on Echinococcus alveolaris or multilocularis, N. Melnikow-Raswedenkow (*Beitr. Path. Anat. u. Allg. Path., 1901, sup. 4, pp. 295, pls. 6, figs. 94*).—The general results of this investigation may be briefly stated as follows: The alveolar echinococcus is found in animals and man primarily not in the liver but in other organs such as the brain, spleen, and suprarenal bodies. The changes which are induced in the tissues of the host through this parasitism depend upon the peculiarities of the parasite itself. The unilocular or multilocular hydytids are different species of parasite and do not represent the encysted stage of the same species. This parasite has a much wider distribution in Russia than has previously been suspected.

The sources and methods of infection are not well understood. The treatment in animals is not very satisfactory on account of the very great expense. In man, the only treatment is surgical. Infection experiments in which it was attempted to develop a mature form of this worm in the alimentary canal of other hosts were only slightly satisfactory.

Relation of bovine tuberculosis to the public health, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 33, pp. 36*).—This bulletin is a report which was read before the American Public Health Association in Buffalo on September 16, 1901. The topics discussed in the report include extent of bovine tuberculosis in Europe and the United States, effect of products of diseased animals on the public health, and the communicability of bovine tuberculosis to man. The report is of a controversial nature, and an attempt is made to show that the evidence upon which Koch based his statement that the disease is not transmissible from animals to man or from man to animals is not well founded. Numerous experiments of different investigators showing positive infection and extensive development of tuberculosis by feeding cattle upon tubercular material of human origin are cited. It is argued that since bovine tuberculosis is communicable to a large number of widely separated species of animals, it is probably communicable to man. Especial attention is given to a discussion of cases of accidental infection of man by bovine tubercle material, the infection of man by milk from tuberculous cows, and the extent and significance of intestinal tuberculosis in man. It is admitted that it is not absolutely proved that any case of tuberculosis in man was caused by tubercle material of bovine origin, but the evidence is considered as strong as could be expected in the absence of positive experiments.

Studies of tuberculosis and cow temperatures, J. NELSON (*New Jersey Stas. Rpt. 1900, pp. 361–404, pls. 5*).—Tables are presented showing the record of abortions in the college herd. The rate of abortion is reported to have continued uninfluenced by treatment, which has been accurately applied. Further study on the subject is required.

The records of tuberculin tests on the college herd are presented in a tabular form. One animal was slaughtered on account of the presence of physical signs of tuberculosis, and after the application of the tuberculin test it was found that at least 7 other animals in apparently good health were infected with tuberculosis. The results of post-mortem examinations of these animals are given in detail. The general college farm herd was retested for the fifth time and the results are tabulated. The herd is tested twice each year. It is considered necessary to apply the tuberculin test thus often in order to detect any new cases of tuberculosis which may have arisen in the interval since the last test. Of the 7 cases which reacted, 5 were known to be tuberculous and had reacted on previous tests.

The study of the normal temperature of cows was undertaken for the purpose of determining the fluctuations in temperature which may occur under ordinary circumstances. This matter is of importance, especially in its bearings on the interpretation of the results of tuberculin tests. The fluctuations of the temperature of the cows show wide limits. These variations in temperatures are rapid, so that even in a single day the highest and lowest temperatures may differ more than the temperatures of successive days at the same hour. The temperatures of the cattle in a herd do not vary in unison. One animal may show a high temperature while another shows a low. The variations in temperature may be much more frequent in one animal than in another. In order to determine accurately the normal temperature of an animal it is necessary to obtain a full record of the normal temperature at different times of the day and under different conditions, and the observations should be numerous and close together. The record of normal temperatures should be complete in another respect, viz, it should continue during the hours corresponding to those at which reaction temperatures are taken. In general there is a rise of temperature which begins during the feeding and milking time, reaches the climax a few hours afterwards, and then subsides. This produces two marked elevations of temperature during each day. The results of extended observations on the normal temperatures of cows are presented in a tabular form.

The author describes some apparatus devised for use in a bacteriological laboratory. One device consists of a wire-cloth cylindrical basket into which are fitted 2 tin disks perforated with holes of the right size for receiving test tubes. In disinfecting plugs for test tubes the author's method is as follows: Dry, clean tubes are plugged with absorbent cotton, the plugs being carefully trimmed so that the cap can be readily drawn over them. The plugged tubes are then subjected for 2 or 3 hours to a temperature of 300° F. During this process the cotton becomes somewhat charred. The fire is then shut off and when the test tubes are cool enough to handle each one is dipped, plug end downward, in a solution consisting of 100 parts water, 20 parts alcohol, and 3 parts copper sulphate.

The tuberculin test of imported cattle, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 32, pp. 22*).—This bulletin is of a controversial nature, and in it the author argues for the necessity of continuing the application of the tuberculin test to all imported cattle. The various subjects which are discussed include the necessity of guarding against tuberculosis, danger from the disease, losses caused to farmers by tuberculosis, the necessity of the tuberculin test in detecting the disease, and the desirability of continuing present regulations for controlling the disease.

Tuberculosis of the udder in goats, C. SCHROEDER (*Ztschr. Fleisch u. Milchhyg., 11 (1901), No. 9, pp. 261–266*).—A detailed report is made on the symptoms and post-mortem findings in the case of a goat which suffered from this disease. The clinical symptoms were those of bronchitis together with large tuberculous swelling of the right side of the udder. This swelling contained numerous small tubercles, some of which were caseous or calcified. The milk of the goat was used for human food for some time after the disease had appeared, and the author strongly urges the necessity of inspecting goats the milk of which is used for human consumption, in order to detect any cases of tuberculosis.

Generalized tuberculosis in the horse, O. MARTIN (*Ztschr. Fleisch u. Milchhyg., 11 (1901), No. 9, pp. 269, 270*).—The author describes the peculiarities and course of tuberculosis in the horse and gives detailed descriptive notes on the symptoms and pathological lesions of one case in which the larynx and bronchial glands were affected, as well as various other abdominal and thoracic organs.

Lupus in cattle, N. MACKEL (*Ztschr. Fleisch u. Milchhyg., 11 (1901), No. 9, pp. 268, 269*).—Notes are given on the appearance of tuberculosis of the skin in cattle. In one case where lupus was evident on the side of the animal a post-mortem examination exposed evidences of a few tubercules in the lungs. It was found by making a tuberculin test with the other animals of the herd that all had become infected with tuberculosis.

The value of tuberculin as a test for tuberculosis, C. J. VALENTINE (*Jour. Agr. and Ind., South Australia, 4 (1901), No. 10, pp. 809–811*).—The article is of a controversial nature and deals with the question of the reliability of the tuberculin test in cases of long and short standing. Brief notes are given on the extent to which the test is made in the various countries of Europe, and the application of the test is urged by the author.

The application and significance of tuberculin in combating tuberculosis, N. K. PETERSEN and B. BANG (*Maanedsskr. Dyrlæger, 13 (1901), No. 2, pp. 49–75*).—This discussion is in the form of 2 articles by the 2 authors, and is concerned with various controversial matters regarding the use of tuberculin in stamping out tuberculosis.

Experimental studies on acid-proof bacteria which resemble the tubercle bacillus, HÖLSCHER (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 10, pp. 425–428*).—These organisms were first discovered while examining milk and butter for the presence of tubercle bacilli. Inoculation experiments were made on 80 guinea pigs, rabbits, and white mice. None of the experimental animals developed tuberculosis or were affected to such an extent as to give evidence of any serious disease. Some of the animals were killed, and a post-mortem examination gave evidence of a peculiar pathological appearance in the liver of a few, while no evidence was obtained for the presence of tubercle bacilli.

Measures for preventing the transmission of tuberculosis in the milk of cattle, Marsac (*Jour. Agricole* [*Paris*], *12* (*1901*), *No. 137, pp. 143, 144*).—The author considers the danger from this source of sufficient importance to warrant the putting forth of every effort to prevent the spread of contagion in milk. He has recommended that a special scientific corps be appointed for this work, that public and private schools be interested in the movement, that milk dealers be compelled to register and submit their products for examination, and that the names of approved dealers with healthy animals and good milk be published from time to time.

Indemnities for tuberculous cattle, A. Laquerrière (*Jour. Agricole* [*Paris*], *12* (*1901*), *No. 138, pp. 151–154*).—The author discusses this problem from various points of view, and comes to the conclusion that in cases of animals which are totally condemned the loss should fall upon the seller. In the cases of partial condemnation the contract may be allowed to hold, but the buyer should be reimbursed for the amount of his loss, as determined by the inspector who condemned the meat.

Interesting diseased-meat case in Edinburgh (*Vet. Jour.*, *52* (*1901*), *No. 311, pp. 267–275*).—This article contains a detailed report of a case of prosecution for selling meat suspected of being tuberculous. The evidence obtained by experts from a microscopic examination of the meat was considered as proving that the meat was tuberculous, but the defendant succeeded in establishing the point that he had no reason for suspecting the meat and could not have known that it was tuberculous.

Bibliography of literature on tuberculosis (*Rev. Tuberculose, Paris, 8* (*1900*), *No. 2, pp. 268–299*).—A classified list of titles of literature relating to tuberculosis of man and animals published during the year 1900.

Public veterinary service, Metzger (*Deut. Tierärztl. Wchnschr.*, *9* (*1901*), *No. 21, pp. 215–217*).—During the year 1900 preventive inoculation for swine erysipelas according to the Lorenz method was made on 15,208 hogs. So far as reports were received, injurious effects were noted in only 3 cases as a result of the inoculation. The vaccine material is furnished at a very moderate price for private use, but only to veterinarians, who are under obligation not to use the material outside of the country.

A map is given showing the distribution of foot-and-mouth disease in Germany at the end of April, 1901, and brief notes are presented on the success which has been obtained in fighting sheep scab and on the prevalence of blackleg during the year 1899.

Concerning the existence of sensitizing substances in antibacterial sera, J. Bordet and O. Gengou (*Ann. Inst. Pasteur*, *15* (*1901*), *No. 5, pp. 289–302*).—The authors investigated the question concerning the existence and relationship of alexins and sensitizing substances as found in normal and immunized sera. Experiments were conducted on sera obtained from various sources, including guinea pigs vaccinated against anthrax, horses vaccinated against swine erysipelas, guinea pigs immunized against typhoid fever, and human typhoid fever patients in convalescence. From these experiments it is concluded that specific sensitizing substances are of constant occurrence in organisms which have been subjected to vaccination. These substances are not so readily influenced by heat as are the alexins and do not exert any direct injurious influence upon the bacterial organisms. Their effect upon bacteria is to cause the latter to absorb the alexins by which they may be ultimately destroyed. The action of alexins upon bacteria varies according to the species of micro-organism which is concerned.

The process for collecting and distributing large quantities of serum, G. Poujol (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 14, pp. 424-427, figs. 3*).—The author describes in detail an apparatus suitable for collecting blood in large quantities and separating the serum, together with notes on accessary apparatus necessary for dividing the serum into equal quantities.

Texas or acclimation fever, C. A. Cary (*Alabama College Sta. Bul. 116, pp. 227-289*).—The author gives a general account of the nature of Texas fever, including details concerning the blood parasite which causes the disease, the pathological changes in the blood, the quarantine line established by the Federal Government, and the appearance and habits of the cattle tick. It is argued that ticks could be exterminated in Alabama inside of 2 years if all cattle owners would put forth their best efforts in this direction. One advantage to be derived from the extermination of the ticks would be the unrestricted cattle trade with the North and with Europe at all seasons of the year. If ticks were destroyed in certain localities only, other Southern animals raised in localities where the tick no longer exists would not be immune and would be subject to fatal attacks of the disease, provided the beasts should become infested with ticks. Notes are given on the symptoms of Texas fever, the appearance of the organs of animals dead with the disease, and the various methods for producing immunity. The author undertook to immunize animals which might be sent to the station for that purpose. The results of these inoculations are presented in tabular form. Only one death occurred from a fatal relapse after immunity had apparently been produced. The author believes that one mistake was made in that 3 full-blooded bulls which were inoculated for the purpose of rendering them immune to Texas fever were not permitted to become infested with ticks early enough in the following spring. The danger of a too serious infestation of ticks later in the season should always be borne in mind in connection with inoculation experiments. The author believes that better results will be obtained if the second inoculation dose contains 2½ cc. of defibrinated blood, rather than 1½. According to M. Francis, whose opinion is quoted, the best age for inoculation is between a few months and 2 years, preferably about 1 year, and the best time of the year from November to March. In the Texas experiments about 90 per cent of all Northern cattle which were brought into the State and inoculated were successfully immunized against the disease.

Blackleg in Kansas, and protective inoculation, P. Fischer and A. T. Kinsley (*Kansas Sta. Bul. 105, pp. 27*).—A general account is given of the occurrence, geographical distribution, cause, symptoms, and period of incubation of blackleg. Brief notes are given on the influence of climatic conditions, breed, sex, and age of animals upon the development of the disease. The symptoms of anthrax, malignant œdema, and septic metritis are given for the purpose of distinguishing these diseases from blackleg. A historical account is presented of work of various authors in devising methods for vaccinating animals against this disease. At the station vaccination was first made in 1898, according to the method of Arloing. From a total of 54,393 cattle vaccinated by this method 323, or less than 0.6 per cent died after vaccination. The loss in an equal length of time before vaccination amounted to 4.23 per cent. A few accidents were experienced from improper care in vaccinating. In the manufacture of single vaccine of a virulence intermediate between that of the 2 vaccines which were used in the previous experiments the authors also secured good results. Of 11,268 animals which were vaccinated 34, or about 0.3 per cent died after vaccination. In a similar number of animals during the same length of time 308, or 2.75 per cent died before inoculation. The authors believe that the double vaccination is safer and more effective than the single vaccination.

Anthrax in Algeria: Natural immunity of pure native races of cattle, E. MARTIN (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 12, pp. 271-277*).—It was long believed that anthrax did not exist in Algeria. The disease, however, had been confused with blackleg, and careful microscopic tests disclosed the fact that it frequently occurs in a typical form. Notes are given on the various periods of the disease. During a study of anthrax by the author, it was found that pure races of native cattle were naturally immune to the disease. Inoculations with virulent blood in doses of from 1 to 3 cm. failed to produce the disease in Arabian cattle, while similar inoculations in imported cattle or crosses between imported cattle and native stock readily developed symptoms of anthrax. Infection could not be produced, either by inoculation in the jugular vein, by subcutaneous injection, or by feeding with virulent anthrax material. It appears, therefore, that the influence of race may be very decisive in determining the degree of susceptibility to anthrax. It is indicated that cattle raisers will take up the question of determining to what extent the knowledge of the immunity of native cattle may be taken advantage of in producing more improved breeds.

Anthrax infection of carnivorous animals, L. LANGE (*Hyg. Rundschau, 11 (1901), No. 11, pp. 529-532*).—A brief review is given of the literature on the subject of anthrax in carnivorous animals, and an account is presented of an outbreak of this disease among the animals in the Royal Zoological Garden in Posen. During the outbreak of anthrax 2 lions, 1 jaguar, and 1 jackall died of the disease, and several bears apparently had mild cases, from which they recovered. The disease was contracted in each case from eating the meat of a horse which had died of anthrax.

Foot-and-mouth disease, P. BRUNO (*Gior. R. Soc. Accad. Vet. Ital., 50 (1901), No. 16, pp. 379-382*).—A discussion is given of the sanitary measures at present adopted in Italy and elsewhere for the control and eradication of this disease. The author believes that by careful and thorough application of these methods the disease may be successfully controlled.

Treatments for foot-and-mouth disease, H. LERMAT (*Jour. Agricole [Paris], 12 (1901), No. 134, pp. 86, 87*).—No satisfactory direct treatment for this disease has been devised. In case of an outbreak of the disease, it is advisable to disinfect the premises as thoroughly as possible and apply antiseptic washes to affected parts of the animals. The substances which are recommended for this purpose include salicylic acid, corrosive sublimate, lysol, sulphate of iron, etc.

Diarrhea in young calves, LESAGE and DELMER (*Ann. Inst. Pasteur, 15 (1901), No. 6, pp. 417-439*).—This disease has long been known as prevalent among young calves and fatal in a large proportion of cases. The peculiarities of its occurrence and distribution indicate clearly that the disease is contagious. The authors made an examination of the blood and various organs of calves affected with the disease and identified a species of Pasteurella as the cause of the infection. A technical description is given of the organism and an account of its prevalence and occurrence in the bodies of diseased calves. The organism is found before and after death in the blood, the alimentary tract, and the nasal mucous secretion. *Bacterium coli* is also found in conjunction with the pathogenic organism, but is not found in the blood during life. It is not considered, therefore, as in any way directly concerned in the production of the disease. The disease is considered identical with "white scour" of Ireland. The authors prefer the use of the term diarrhea to enteritis or septicæmia, which latter terms refer only to one phase of the symptoms. In new-born calves the disease develops sometimes rapidly, within from 1 to 2 days, or more slowly, within from 8 to 20 days. In such cases the organism gains entrance to the animal through the umbilical cord. The first period of the disease is characterized by an inflammation of this structure. Later the organism passes into the blood and causes a septicæmia which persists until death. Occasionally the septicæmia disappears and the pathogenic organism continues to multiply in the alimentary tract and in the respiratory organs. Where the disease occurs in calves of greater age it is believed that the organism finds entrance through the nasal passages. Experiments conducted by the authors for the purpose of attenuating the organism were partly successful. Cultures of the organism maintained for 1 hour at a temperature of 60 or 70° C. failed to produce any immunity to the disease when inoculated for preventive purposes.

White scour and lung disease of calves in Ireland, E. Nocard (*Rec. Med. Vet. Paris. 8. ser., 8* (*1901*), *No. 10, pp. 231–244*).—Detailed notes are given on the symptoms and pathological lesions of this disease. A bacteriological study indicated clearly that white scour is due to an umbilical infection, which may be prevented by cleansing the cows with a solution of lysol before parturition. It is recommended that the umbilical cord be washed with a mixture containing 1 liter of water, 2 gm. of metallic iodin, and 4 gm. of potassium iodid; and later with a solution of 2 gm. of metallic iodin in 1 liter of methyl alcohol.

Contribution to the study of jaundice, or hæmoglobinuria of cattle in Tunis, E. Ducloux (*Bul. Dir. Agr. et Com., 6* (*1901*), *No. 20, pp. 244–247*).—The author investigated the disease which is known in Tunis under various names and which prevails to a considerable extent. A preliminary study of the subject showed a striking resemblance of the disease to Texas fever. A further study confirmed this idea, and the blood parasite of Texas fever was found in affected animals.

Enzootic abortion, J. Steele (*Vet. Jour., 52* (*1901*), *No. 311, pp. 275–278*).—The symptoms and nature of this disease are discussed in detail and the usual antiseptic precautions are recommended.

The injurious effects of certain grass seeds on live stock, J. D. Stewart (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 3, pp. 357–360, pl. 1*).—Attention is called to the injurious effects of certain grass seeds which bear sharp awns. The grasses mentioned as being most injurious are barley grass and "spear grass." The injurious effects of these awns on horses are more severe than on cattle, but even in the latter animals swellings are produced upon the jaw from the irritation set up by the presence of these awns in the flesh. Such swellings have in some instances been mistaken for tuberculosis or actinomycosis.

The action of acid salts of morphin on ruminants, Hess (*Arch. Wiss. u. Prakt. Thierh., 27* (*1901*), *No. 3–4, pp. 233–268*).—The author discusses the literature of the subject in connection with an extensive bibliography. The results obtained by different experimenters are very contradictory, but the desirability is recognized of finding a more convenient method of narcosis for ruminants than by ether or chloroform. It was found during the numerous experiments of the author that none of the ruminants or hogs were immune to the action of morphin and that the stimulating effect of normal doses was especially noticeable. When large doses were given serious paralytic effects were observed, as is the case in man, and a complete narcosis was not produced without administering doses which were likely to prove fatal.

Rumenotomy, Nüesch (*Schweiz. Arch. Thierh., 43* (*1901*), *No. 2, pp. 60–62, fig. 1*).—A description is given of an instrument designed for making an incision into the first stomach in case of tympanites. The instrument has a sharp point upon a short blade of moderate width and is circular in cross section behind the blade. The circular part of the instrument carries a groove on one side, which extends into the handle and permits the gas to escape.

The teeth of cattle and sheep as affected by age, C. McCulloch (*Virginia Sta. Bul. 118, pp. 145–155, figs. 8*).—Brief descriptive notes on the anatomical characteristics of the teeth of cattle and sheep, with a short account of the changes which they undergo.

The teeth of the horse as affected by age, C. McCulloch (*Virginia Sta. Bul. 117, pp. 129–144, figs. 25*).—Brief notes on the changes which take place in the teeth of the horse between the ages of 6 and 21 years.

21164—No. 8—02——7

A study of the larvæ of Gastrophilus in the stomach of the horse, J. GUYOT (*Arch. Parasit., 4 (1901), No. 2, pp. 169–221, figs. 11*).—A review is given of the literature of the subject in connection with a bibliography of the more important articles relating to Gastrophilus. A historical discussion is presented on *Gastrophilus intestinalis*, *G. hæmorrhoidalis*, and *G. nasalis*. Special attention is devoted to *G. intestinalis*, which is considered by the author to be a more correct name than *G. equi* for the common species which infests the stomach of the horse. The eggs in different stages of the larvæ are described in detail and considerable attention is devoted to the manner in which the larvæ are attached to the wall of the stomach, and to the pathological lesions which their presence causes. Experiments were conducted for the purpose of testing the action of certain chemicals on young larvæ. It was found that the larvæ could live for 4 days in ordinary water, for 1 day in olive oil, and for 14 hours in corrosive sublimate in the proportion of 1 : 1,000. When placed in certain volatile substances such as bisulphid of carbon, benzin, ammonia, sulphuric ether, and chloroform, the larvæ died instantaneously. Experiments with full-grown larvæ showed that they could live 5 days immersed in a 3 per cent solution of formalin, and for 1 hour in a saturated aqueous soluton of corrosive sublimate. It was found that young larvæ, which were hatched from eggs which had been removed from the hair of the horse, were alive 3 months after the removal of the eggs. The pathological lesions caused by the botflies in the stomach of the horse are restricted to the mucous layer of the stomach which is destroyed at the point where the botflies are attached. An accumulation of leucocytes at such points is also noted.

Rabies, M. P. RAVENEL (*Pennsylvania Dept. Agr. Bul. 79, pp. 28, figs. 3*).—A general discussion of this disease is presented, including its history and distribution; a list of animals subject to the disease; the cause of the disease; nature of the virus; method of invasion; resisting power of the virus; danger from bites of rabid animals; period of incubation; influence of seasons; the various types of the disease in man, dog, cat, horse, cow, and birds; pathological changes in the tissues of animals attacked by the disease, and the various features of the Pasteur method of preparation of vaccine; and treatment of affected animals.

The action of leucotoxic serum on lesions in the central nervous system in cases of rabies, C. FRANCA (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 17, pp. 502–504*).—Experiments previously conducted with rabies indicated that death was partly due to an excessive formation of leucocytes during the acute stages of the disease. It was decided, therefore, to try experiments for the purpose of testing this theory. Dogs were experimentally inoculated with rabies and after the appearance of the acute symptoms were treated with injections of the leucotoxic serum. Considerable improvement was noted, and another injection gave evidence of increased benefit from this treatment. Further work along this line is promised, and the author believes that toxins may ultimately be produced which may be used for the purpose of preventing too pronounced development of leucocytes.

Negative chemotaxis of the leucocytes of rabbits which have been inoculated with a pure culture of the bacilli of fowl cholera, A. ZILBERBERG and J. ZELIONY (*Ann. Inst. Pasteur, 15 (1901), No. 8, pp. 615–629, pl. 1*).—The author briefly reviews the literature on the subject and discusses in detail the methods and results of his investigations. Since rabbits are especially susceptible to fowl cholera these animals were considered most suitable for investigation on the subject of negative chemotaxis. The experimental animals were inoculated hypodermically and in the body cavity with pure cultures from artificial nutrient media and from natural fluids of the body. The animals were killed within from 1 to 5 hours after inoculation and various organs, including the liver, kidneys, spleen, spinal column, and lungs, were examined for the purpose of determining the relation between the pathogenic bacteria and the leucocytes. After a hypodermic or intraperitoneal injection of a virulent culture of fowl-cholera bacilli from gelatin, the complete absence of the phagocytosis on the part of the leucocytes was observed. Similar conditions were found after intravenous injections of virulent cultures from the serum of the body cavity. The author explains the phenomenon of phagocytosis, which was observed in rabbits which had been inoculated with virulent cultures of fowl-cholera bacilli developed on an artificial medium, by the presence of any such cultures of nonvirulent bacilli. It was shown that the white blood corpuscles of the rabbit do not surround the virulent bacilli of fowl cholera during any stage in the progress of the disease. It is not believed that this fact is due to a poisonous influence of the bacilli upon the leucocytes, but the phenomenon is explained as an example of negative chemotaxis.

Biological division, C. CURTICE (*Rhode Island Sta. Rpt. 1901, pp. 201–224*).— Numerous experiments were made for the purpose of determining the conditions which influence the rate of mortality among chickens during incubation or in artificial brooders. Of 58 chickens placed in an outdoor brooder, 53 died within 3 weeks. The cause of death was in most cases lung trouble of the nature of pneumonia, and was due to exposure to sudden changes of temperature. Some of the chicks died of congestion of the lungs and others of intestinal troubles. On account of this great mortality, experiments were conducted for the purpose of securing a uniform temperature and observing the influence of these conditions upon chickens. The best results were obtained when the temperature of the room was kept high enough so that no marked difference of temperature prevailed between the air in the room and that in the brooders. When the temperature in the brooder was kept too high, it was found that the exposure of the chickens to changes of temperature in moving in and out of the brooder were liable to cause disease and death. Box brooders were constructed and heated by setting a papier-maché or wooden pail of water at a temperature of 140 to 165° upon them. It was found possible to maintain the temperature of the brooder by this means between 75 and 90° F. Green food was obtained for the chickens, mostly in the form of lettuce, in addition to cracked grain and wheat, oatmeal, scraps, and animal food (consisting for the most part of boiled eggs, boiled liver, and animal meal). A number of chickens were taken from a warm incubator and placed in cotton-lined baskets, supposed to be warm enough to protect the chickens. They were carried for about three-quarters of a mile and placed in brooders. About 60 per cent of these chickens died later from lung diseases due to the temperature changes.

During these experiments attention was given to the food of young chickens, and it is recommended that cracked grain and cracked wheat and other similar food should be sifted, so as not to offer too coarse or too fine material for the chickens. In addition to the usual food of this sort and of an animal nature, grass, lettuce, or other green material is highly recommended. The author considered the question of whether artificial incubation has any effect upon the vigor of the chickens. It is believed by the author that chickens which come from the egg in a fully developed condition do not die on account of weakness due to incubation. Of the incubated eggs examined by the author, in which dead embryos were found, death had occurred in most cases after the fourteenth day of incubation. When insufficient moisture is furnished during incubation, it was found that a considerable percentage of chickens failed to hatch. It is believed that an incubator that furnishes air nearly saturated with moisture, so as to prevent drying of the embryo, will furnish the largest and strongest chickens.

Attention is called to the desirability of further investigation on the subject of blackhead of turkeys. A report is made on several serious outbreaks of goose cholera. One dealer in geese lost about 3,200 between July and October. The course of the disease is usually about 36 hours, and the chief symptoms were an unsteady gait, peculiar movements of the head, and formation of considerable quantities of mucous in the throat and nasal cavities. In some cases a catarrhal condition of the intestines was observed. Feeding experiments with the internal organs of dead geese demonstrated that the disease may be communicated in this way. The symptoms of geese fed upon this material were the same as those which had become diseased under natural conditions, and post-mortem examination revealed the same pathological changes. Details of bacteriological work, in cooperation with Dr. Theobald Smith, will be given in a future publication. A similar outbreak occurred in another locality, where about 20 per cent of the geese were lost. It is recommended that geese raisers should divide the birds up into small lots in order that the disease may be more readily controlled when outbreaks occur.

The author made experiments to determine the effect of hothouse brooding on the vitality of chicks. The birds subjected to these conditions appear to develop in a strong and vigorous manner, and, judging by the appearance of their feathers and by their weight and color, they were equal in vigor to hen-raised chickens. It is considered possible, however, that such birds might not be able to compete in the open field with chickens raised by their natural mothers.

AGRICULTURAL ENGINEERING.

Report of irrigation investigations in California (*U. S. Dept. Agr., Office of Experiment Stations Bul. 100, pp. 411, pls. 29, figs. 16*).—This is an account of investigations made during 1900 by the Office of Experiment Stations in cooperation with the California Water and Forest Association under the direction of Elwood Mead, expert in charge of irrigation investigations of this Department, assisted by eight specialists in irrigation. These specialists and the streams on which they studied irrigation conditions were as follows: W. E. Smythe, Susan River; Marsden Manson, Yuba River; J. M. Wilson, agent and expert in irrigation investigations, Cache Creek; Prof. Frank Soulé, of the University of California, San Joaquin River; Prof. Charles D. Marx, of Stanford University, Salinas River; C. E. Grunsky, city engineer of San Francisco, Kings River; Edward M. Boggs, Los Angeles River; James D. Schuyler, Sweetwater River.

The report reviews the agricultural situation in California and shows that in many of the principal portions of the State agricultural development is greatly hindered by the inadequacy of irrigation laws. It is claimed that the chief obstacles to such development in the State are an unremitting production of cereal crops in the great interior valley and a lack of more diversified farming; opposition to irrigation in districts which the census shows to be measurably decreasing in wealth and population; a too great zeal on the part of advocates of the Wright district law, followed by unwise investments which have led to loss and disappointment and a consequent opposition to irrigation laws of whatever nature; overappropriation of streams, resulting in confusing uncertainty as to the number and extent of valid appropriations; the conflicting nature of the water laws, and the existence, side by side, of the two opposing doctrines of appropriation and riparian rights; absolute private ownership of water in face of the fact that all leading countries where irrigation is necessary recognize only the rights of use and attach them not to the owner of land or to canal companies, but to the land itself, from which they are inseparable, and finally, and most important of all, the absence of any State control of streams or of any State administration of rights to their use.

The conclusions of the special agents and experts who made the investigations are that the State should ascertain the volume of available irrigation water, define all rights to its use, whether already acquired or to be acquired hereafter, and provide an efficient system of water administration. The definite recommendations for attaining these ends embody, among other measures, the creation of a State board of control of waters, similar to that in existence in Wyoming for the past 10 years, the making of unappropriated waters State property, the limitation of all appropriations to actual beneficial use, and the attachment of all rights to water to the land irrigated.

Irrigation in field and garden, E. J. Wickson (*U. S. Dept. Agr., Farmers' Bul. 138, pp. 40, figs. 18*).—The instructions given in this bulletin are intended for the individual farmer and not for the engineer or manager of an irrigation system. They deal with simple methods of determining levels and constructing ditches, the measurement of small streams, sources of water supply and their use, distribution of irrigation water, methods of applying water, choice of irrigation method, and time of applying water.

The open range and the irrigation farmer, R. H. Forbes (*Forester, 7 (1901), Nos. 9, pp. 216–219; 10, pp. 254–258*).—This article discusses the injury done by overstocking and the improvement that may be brought about by rest, control of flood water, judicious planting, etc.

Trials of agricultural machinery at Ultuna, H. Juhlin-Dannfelt (*Landtmannen, 11 (1900), Nos. 40, pp. 633–636; 43, pp. 684–687*).—Report of trials of 11 mowers, 11 horse rakes, and 1 hay turner, the machinery being of domestic or American manufacture.—F. W. WOLL.

Comparative trials of threshing machines at Ultuna experiment station, G. Timberg (*Landtmannen, 11 (1900), No. 41, pp. 651–657*).—Five different firms furnished 12 threshing machines which were scored as to power required, capacity, general applicability, etc.—F. W. WOLL.

Comparative trials of seed-cleaning machinery and of sweep powers, G. Timberg (*Landtmannen, 11 (1900), No. 42, pp. 667–673*).

Proceedings of the International Good Roads Congress held at Buffalo, N. Y., September 16–21, 1901 (*U. S. Dept. Agr., Public Road Inquiries Bul. 21, pp 100*).—A condensed report of proceedings and the text of the following papers presented: Importance of the road question, by A. H. Longino; Rural road naming and house numbering, by Rachel J. Davison; State aid in New York, by E. A. Bond; State aid in New Jersey, by J. E. Owens; Pennsylvania's road system, by J. Hamilton; History of highway legislation in New York, by J. A. C. Wright; Road laws and road building in Massachusetts, by C. M. Ross; Functions of the Government, the State, and the county in American highway improvement, by J. A. Holmes; Road making from the engineer's standpoint, by A. W. Campbell; Good roads work for the new century, by R. Stone; The highways of commerce, by L. C. Haupt; Progress of road improvement in Florida, by W. S. Jennings; Shall the farmer have aid for highway improvement from the wealth of the nation, by S. S. Bailey; The road situation in Iowa, by I. G. Heaps; A question of education, by E. Daniels; A farmer's views on the road question, by J. F. Bean; Steel-track roads, by S. C. Dickinson; The brick wheel-track road, by D. N. Long; The Government road system of the Yellowstone National Park, by H. M. Chittenden; Farmers' views of good roads, and how to get them, by W. T. Creasy; Organizations for good roads in Kentucky, by J. C. Van Pelt; What is our duty, by W. H. Moore; The road problem, by A. Patullo; The roads of Belgium, by M. V. Valliant; Facts and suggestions, by H. S. Earle; Work of the press for good roads, by A. H. Battey; Use of convict labor, by F. W. Lyon; Rural free mail delivery in relation to road improvement, by A. W. Machem; Methods of construction and cost of good roads in Hennepin County, Minn., by G. W. Cooley, and A simple plan for a better road system, by F. A. Polsley.

Earth roads, M. O. Eldridge (*U. S. Dept. Agr., Farmers' Bul. 136, pp. 24, figs. 20*).—This bulletin gives the simple, and in the main, inexpensive, methods of earth road construction and maintenance which are generally practiced by the most successful road builders, and which "are based entirely on a thorough system of drainage."

A modern dairy barn, A. A. Brigham (*Rhode Island Sta. Bul. 80, pp. 17–38, pls. 10*).—A general description and detailed drawings, plans, and specifications are given for a barn recently constructed at the station for the "purposes of sheltering a herd of dairy cows and furnishing storage room for hay, grain, straw, and fodder." It consists of an octagonal storage barn 60 ft. in diameter and 21 ft. in height to the plates, with a circular silo 14 ft. in diameter and 34 ft. high in the center; and wing on the south side 100 ft. long east and west and 37 ft. wide, designed for a cow barn. The capacity of the silo is 80–100 tons and the storage space of the octagon around it will accommodate 100 tons of hay. A steel track for a horse fork used in handling the hay is carried around under the roof of the octagon.

The cow barn "is provided with rows of swinging stanchions and box stalls and will readily accommodate 40 head of cattle. Sectional plank flooring is provided for

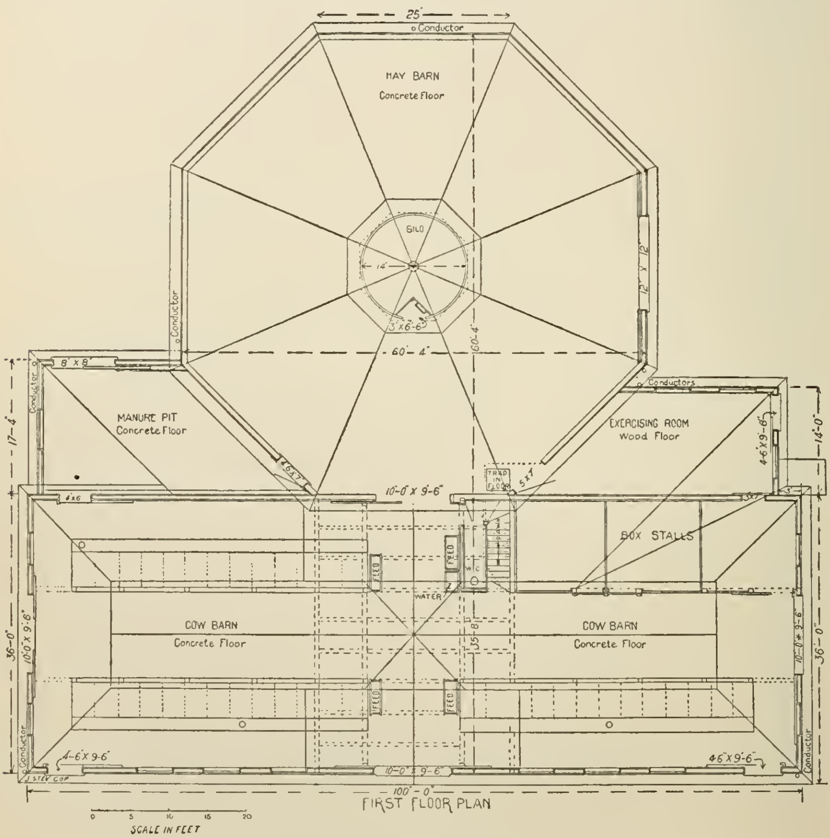

FIG. 3.—Rhode Island Station dairy barn—floor plan.

the cows to stand upon. The floor is concreted. Deep gutters behind the cattle connect with an adequate sewer system, which takes all of the drainage and roof water and carries it, together with any seepage from the gutters, to a cistern situated about 500 ft. down the slope to the west of the building. This structure has a monitor roof, except in the middle where the granary is located in a second-story room. Here, over the south entrance and passageway through the cattle barn to the octagon, is provided ample room, furnished with bins, for storing grain in large quantities. A stairway leads from near the octagon door to the granary above. . . . Large windows on the south side of the cow barn admit abundance of light. The sides of the monitor roof are mainly windows which, when necessary, are opened by means of rods operated from the floor to provide ventilation. These windows also admit a large amount of light. Large doors are placed in the east and west ends of the structure, and a team can be driven through in front of the rows of stanchions from one end of the barn to the other. On the north side of this structure are the east and west wings, which fill in the space between the cow barn and two sides of the octagon. The west wing has a lower floor than the main building and is used mainly for the storage of sawdust, which is used for bedding. At its west end stands the manure spreader into which the dung and soiled bedding can be dumped through a door behind it, opening directly from the cattle barn. The east wing is the only part of the structure which has a cellar underneath it. This room is provided with a strong plank floor, and has been used, in the absence of other shelter, for a small flock of sheep, and some of the time for calves and yearlings, and for storage of straw. The cellar is for the storage of roots. It has two

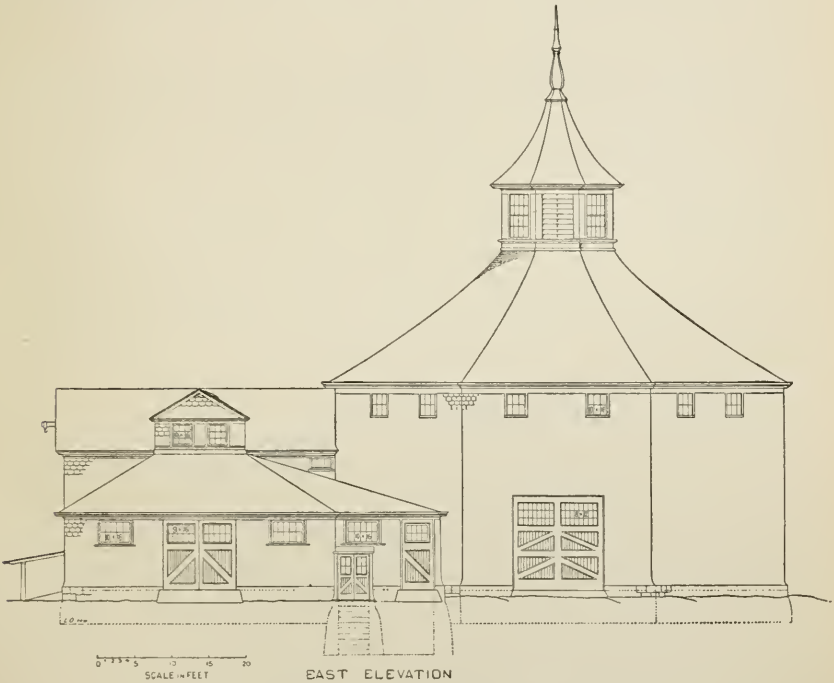

FIG. 4.—Rhode Island Station dairy barn—east elevation.

entrances, one at the east end of the building, and one inside near the center of the cattle barn, both being provided with suitable stairways. The cellar is thoroughly underdrained and has a concrete floor."

Figures 3 and 4 give the ground plan and general appearance of this barn.

STATISTICS—MISCELLANEOUS.

Fourteenth Annual Report of Kansas Station, 1901 (*Kansas Sta. Rpt. 1901, pp. XXII*).—This gives the organization list of the station, a financial statement for the fiscal year ended June 30, 1901, a review of the work of the different departments during the year, and a subject list of station publications.

Annual Report of New Jersey Stations, 1900 (*New Jersey Stas. Rpt. 1900, pp. XVII + 572*).—This includes the organization lists of the stations; a financial statement of the State Station for the year ended October 31, and of the College Station for the fiscal year ended June 30, 1900; a report of the director reviewing the different lines of station work; and reports of the chemists, assistant in horticulture, assistant in dairy husbandry, biologist, botanist, and entomologist noted elsewhere.

Annual Report of Pennsylvania Station, 1900 (*Pennsylvania Sta. Rpt. 1900, pp. 432*).—This includes the organization list of the station, a financial statement for the fiscal year ended June 30, 1900, a brief review of station work by the director, several articles noted elsewhere in this issue, and reprints with the addition in some cases of detailed data of articles already abstracted from different sources as follows: The agricultural use of lime (E. S. R., 12, p. 627), analyses of rose soils (E. S. R., 11, p, 625), effect of various systems of fertilizing upon the humus of the soil (E. S. R., 13, p 330), a contribution to the chemistry of butter fat (E. S. R., 11, pp. 308, 615, 616), the chemical analysis of the apple and some of its products (E. S. R., 12, p. 554), variety tests of wheat (E. S. R., 13, p. 449), methods of steer feeding (E. S. R., 12, p. 875), and the manurial value of the excreta of milch cows (E. S. R., 12, p. 927).

Fourteenth Annual Report of Rhode Island Station, 1901 (*Rhode Island Sta. Rpt. 1901, pp. 183–389*).—This includes the organization list of the station, a report of the director reviewing briefly the work of the station during the year, departmental reports and miscellaneous articles noted elsewhere, a financial statement for the fiscal year ended June 30, 1901, and lists of donations, exchanges, and station publications.

Memoranda of the origin, plan, and results of the field and other experiments conducted on the farm and in the laboratory of the late Sir John Bennet Lawes at Rothamsted, England, J. H. Gilbert (*Report to the Lawes Agr. Trust Committee, 1901, pp. 123, figs. 2, dgms. 7*).—This is a report on the work of the Rothamsted Experiment Station, containing summarized results up to the present time.

The Rothamsted experiments (*London: William Clowes & Sons, Ltd., 1901, pp. 17, figs. 2, dgms. 7*).—Summarized data from the above report.

Crop Reporter (*U. S. Dept. Agr., Division of Statistics Crop Reporter, Vol. 3, Nos. 7–9, pp. 8 each*).—Among a large number of short articles of a statistical nature contained in these numbers are the following: The report of the Statistician for November, the raisin industry of California, the 1901 flaxseed crop, preliminary estimate of the cotton crop of 1901–1902, annual report of the Statistician for the fiscal year 1901, exports of wheat, the United States bean crop, production of peas and potatoes in Russia since 1883, the foreign trade of the United States in hides and leather, the beet-sugar industry, receipts at primary markets and exports of wheat, the vegetable-oil trade, the export of the United States and Canada in dairy products, Russian crops in 1901, official estimate of German crops, 1901, and potatoes in the United States.

Cotton ginning—crops of 1899 and 1900, D. C. Roper (*Twelfth Census United States, Census Buls. 58, pp. 16; 98, pp. 21, figs. 5*).—Statistics as collected from ginning establishments by correspondence and through enumerators show that the cotton crop of 1899 was 9,645,974 commercial bales, amounting to 4,672,695,500 lbs.; and the crop of 1900, 10,486,148 commercial bales, equivalent to 5,061,513,294 lbs. The most significant feature is considered the extraordinary increase in the crop of Texas—from 2,658,555 commercial bales in 1899 to 3,536,506 in 1900. "Texas grew 34 per cent of the total crop of 1900 and one-fourth of the world's crop in that year." Bulletin 98 concludes with an historical and descriptive account of ginning cotton.

Cotton-seed products, D. C. Roper (*Twelfth Census United States, Census Bul. 129, pp. 10, dgm. 1*).—From this report on the manufacture of cotton-seed products for the year ended May 31, 1900, it appears that there were 357 establishments engaged in the extraction of cotton-seed oil and that the total amount and value of the several products were as follows: Cotton-seed oil, 93,325,729 gals., valued at $21,390,674; oil-cake and meal, 884,391 tons, valued at $16,030,576; hulls, 1,169,286 tons, valued at $3,189,354; and linters, 57,272,053 lbs., valued at $1,801,231.

Manufacture of beet sugar, G. L. Spencer (*Twelfth Census United States, Census Bul. 59, pp. 15, figs. 5*).—This is a report on the development and present condition of the beet-sugar industry in the United States. "From this report, it appears that there were 31 beet-sugar factories in the United States in the census year, distributed among 10 States and 1 Territory, representing an invested capital of $20,958,519, and producing 71,427 long tons of beet sugar, valued at $7,323,857."

Salt, E. W. Parker (*Twelfth Census United States, Census Bul. 116, pp. 16*).—The total value of salt products manufactured in the United States in 1899 was $7,966,897. There were 159 establishments representing a capital of $27,123,364.

Statistics on the fruit industry of California, E. S. Holmes, Jr. (*U. S. Dept. Agr., Division of Statistics Bul. 23, misc. ser., pp. 11*).—A brief statistical presentation is given of the acreage and number of fruit and nut trees and their distribution in California. Figures are also given on shipment of fruits by rail and by sea and the increase of these shipments for the years 1890 to 1900. In 1900 there were 16,192,876 bearing fruit trees and 13,209,411 nonbearing trees, covering an area of 452,252 acres. The State shipped 88,189.2 tons of green deciduous fruit by rail in 1900 and 84,899.9 tons of dried fruit, 34,217.5 tons of raisins, and 45,679.9 tons of canned goods. The bulk of these shipments was from the northern part of the State. The larger amount of citrus fruits was shipped from the southern portion of the State. The total shipment for the whole State in 1900 by rail amounted to 226,456.6 tons. The annual shipments of various fruits and canned goods have increased from 161,170.1 tons in 1890 to 519,380.8 tons in 1900.

Agricultural monograph of the Jurassic region of Belgium (*Monographie agricole de la région Jurassique. Brussels: Ministry of Agriculture, 1901, pp. VI+77*).—The region included in the study here reported occupies the southern extremity of Luxemburg, bounded on the west and south by France, on the east by the Grand Duchy of Luxemburg, and on the north by the Ardennes. The subjects treated are climate and soil (see p. 723) agricultural operations (plant and animal production), agricultural manufacturing industries, permanent improvements, and the agricultural régime.

Agricultural monograph of the clay and sandy clay region of Belgium (*Monographie agricole de la région limoneuse et sablo-limoneuse. Brussels: Ministry of Agriculture, 1901, pp. 270*).—The region embraced in the study of which this is a report extends across the country from France on the west to Limburg in Hollaud on the east, and from the Escaut and Demer on the north to the Sambre and the Meuse on the south. The report deals with climate and soil, see (p. 723), agricultural operations, including the methods and results of the culture of various crops and the production of animals, as well as the manufacturing industries closely allied to agriculture; permanent improvements, and the agricultural régime. This is one of a series of monographs which are designed to give the results of a systematic study of all of the various agricultural regions of Belgium.

The practical results obtained in the experiment fields at Lauchstädt (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 25, pp. 144, 145*).—A brief review of the results obtained at Lauchstädt, calling attention to their practical value. A paper read at the meeting of the German Agricultural Society at Halle.

Twentieth century of inventions, G. Sutherland (*London, New York, and Bombay: Longmans, Green & Co., 1901, pp. 286*).—This is a discussion of the present tendencies of invention and a forecast of the probable line along which greatest development is likely to occur in the future, the forecast being based on actual records of the trials of inventions. A chapter is devoted to inventions of interest to agriculture. In this is discussed the substitution of portable motors (electric) for muscular power and of skilled labor using machines for hand labor; the development of cheap sources of power (water wheels and windmills) to produce electricity, which is to be stored and transmitted as needed to different parts of the farm for plowing, etc.; the improvement of pumps and other means of lifting water for irrigation; and the use of electricity in the production of nitrates. "Modern improvements in agriculture will probably be, in the main, such as are based upon fundamental processes unknown to the ancients. By the word 'processes' it is intended to indicate not those methods the scientific reasons for which were understood—for these in ancient times were very few—but simply those which from long experience were noticed to be beneficial," such as rotation of crops and the enrichment of the soil by legumes. A great development of irrigation is predicted, and methods of raising and applying water for this purpose are discussed at some length. It is also predicted that the expert in plant diseases, equipped with apparatus for fumigation on a large scale, will be a person of increasing importance in the future.

NOTES.

Connecticut College.—William H. Hall, of Willington, has been appointed a trustee of the college, *vice* William D. Holman, deceased.

Iowa College and Station.—James Atkinson, instructor in agriculture in the college and agriculturist of the station, has resigned to accept a position as editor in Des Moines, Iowa. An extensive feeding experiment with cattle has been undertaken by the station in cooperation with A. E. Cook, of Odebolt, Iowa. Various rations are being fed to 11 lots of 20 steers each, and it is expected that the experiment will cover a period of five or six months.

Kansas College and Station.—At a recent meeting of the board of regents, J. G. Haney, a graduate of the college, was appointed superintendent of the Fort Hays Branch Experiment Station. G. A. Dean, also a graduate of the college, has been appointed assistant entomologist of the station, to succeed J. B. Norton, who has resigned to accept a position as scientific aid in the Bureau of Plant Industry of this Department. A. T. Kinsley, assistant in the veterinary department of the college and station, has resigned to accept a position as instructor and to pursue advanced work in the Kansas City Veterinary College. He will enter upon his new duties about September 1.

Maryland College and Station.—The legislature of Maryland, at its recent session, passed a bill appropriating $5,000 per annum for the maintenance, repairs, and insurance of the buildings of the experiment station, to aid in the printing of its bulletins and making exhibits showing the results of its work, and to contribute toward its investigations on tobacco, meat production, and in irrigation. The agricultural college receives $5,000 for the enlargement of the mechanical buildings, $25,000 for dormitory accommodation for students, and $3,000 for renovating the main college building.

Massachusetts College and Station.—D. L. Cleaves has resigned his position as instructor in chemistry in the college and has been appointed assistant chemist in the fertilizer division of the chemical department of the station, to succeed S. W. Wiley, resigned. Mr. Cleaves will enter upon his new duties about April 15.

Michigan College and Station.—J. D. Towar, formerly agriculturist of the station, sailed for South Australia April 10, under a five-year contract with the Roseworthy Agricultural College. Professor Towar will succeed the late William Lowrie as principal of the agricultural college and professor of agriculture. A. M. Brown, of Schoolcraft, has been elected secretary of the State board of agriculture and of the college and station to succeed A. C. Bird, resigned.

Missouri University and Station.—George M. Tucker, Ph.D., a graduate of the Rhode Island College of Agriculture and Mechanic Arts, has been elected instructor in agriculture, to have special charge of work in agronomy. He will enter upon the position next September, and in the meantime he will carry on some investigation work in the chemical laboratory of the station.

Cornell University.—The winter course in agriculture just completed has been one of the most successful ever held at the university. Nearly 100 students were enrolled, the courses in dairying and in general agriculture being about equally attended.

Oklahoma College and Station.—W. H. Merten, of Guthrie, Okla., has been appointed a member of the board of regents, *vice* W. H. Coyle.

Porto Rico Station.—The legislative assembly of Porto Rico has appropriated $15,000 for the purchase of a suitable tract of land for the experiment station established by this Department in that island. Proposals have been asked for and the bids will be opened the first of May.

South Carolina College.—An act was passed by the general assembly, at its recent session, requiring the board of trustees to provide for investigations in the coast region of the State. An inquiry is being made as to the lines of work needing attention.

Texas College and Station.—R. H. Price, horticulturist and mycologist to the college and station, has resigned to engage in truck farming and fruit growing in Virginia. His resignation will take effect in June.

Washington College and Station.—E. E. Elliott, associate professor of agriculture, has been elected professor of agriculture in the college and agriculturist of the station, *vice* W. J. Spillman, resigned. H. S. Davis has been made assistant zoologist.

Reorganization of the Experiment Station at Gembloux.—This station has by recent royal decree been reorganized and extended under the name of the State Chemical and Bacteriological Institute of Gembloux. A. Petermann remains as director. The head of the chemical section is A. Grégoire. The head of the bacteriological section, which is the main new feature, is L. Remy. The institute proposes to undertake on broader lines than heretofore researches in chemistry, physiology, and bacteriology as related to progress in agriculture and hygiene, and will be relieved of control analytical work.

School of Horticulture, Hartford, Conn.—The School of Horticulture established at Hartford, Conn., by the trustees of the handicraft schools of that city has been in operation less than two years, and yet it is compelled to keep a "waiting list" for applicants who can not yet be accommodated. The school is located just outside of the city on a farm of 75 acres donated to the Handicraft Schools by Rev. Francis Goodwin, who also provides all funds for carrying on the work. The buildings used by the school include a greenhouse, potting room, class room, library, office, storeroom, tool room, sheds, stables, etc.

The students received include apprentices and pupils from the Watkinson Farm School and from the city schools. Pupils from the Farm School spend two and a half hours each day at the school of horticulture and receive instruction in horticulture, floriculture, botany, forestry, entomology, market and landscape gardening, and orchard management. About half or three-fourths of an hour is spent in the class room, and the remainder of the time is devoted to practical work in greenhouse, potting room, orchard, or garden. This work includes practice in grafting, budding, layering, and other horticultural operations.

Pupils from the city schools are received daily for school garden work. There is one class in the afternoon of each school day and several on Saturday. Each pupil is given a plat of ground to work and is allowed to keep the products of his labor. He takes charge of his plat about the first of May and cares for it until the crop is harvested. In case any pupil neglects or abandons his plat it is given to some one on the waiting list.

In the spring of 1901, out of some 70 applicants, 34 boys were given garden plats, and of this number 25 carried on their work throughout the season. The cost of the experiment, including everything but rent and the salary of an instructor, was $48. Each plat was 4 by 25 ft. and produced on an average the following articles: Lettuce, 15 heads; radishes, 250; beets, 20; wax beans, 8 qt.; shelled beans, 6 qt.; squashes, 10; corn, 18 ears; verbenas, 1,000 blossoms. The average age of the boys was 13½ years, and the average attendance 84 per cent. The attendance during the summer vacation of the city schools was kept up by the Vacation Schools Committee which has undertaken with considerable success "to provide other influences than those of the streets and alleys of our tenement districts for the children during the long summer vacation."

The school garden experiment was the most successful work undertaken at the School of Horticulture last year. This fact led the director of the school, Mr. H. D. Hemenway, to broaden his plans for that feature of the work during the season of 1902. For those who had garden plats last year he provided preliminary greenhouse work during March and April in propagating plants for transplanting. The size of the plats this year will be 10 by 30 ft. for second-year boys and 10 by 20 ft. for first-year boys. Provision has been made also for a class of girls who will receive instruction and be given garden plats like those provided for the boys.

Agricultural Education in the British West Indies.—The subject of agricultural education received considerable attention at the West Indian Agricultural Conference held recently at Bridgetown, Barbados. As reported by Dr. Morris, commissioner of agriculture for the West Indies, the system of education now in vogue in those islands comprises (1) lectures to teachers in charge of elementary schools, (2) agricultural teaching in secondary schools and colleges, and (3) itinerant instruction to planters. The entire system is in charge of the Imperial Department of Agriculture for the West Indies, which employs for this work a staff of 2 lecturers in agricultural science, 1 traveling instructor in agriculture, and 5 agricultural instructors. The lectures to teachers in charge of elementary schools are given in courses at the leading towns on the different islands in the group. Classes of teachers are organized by the lecturers or instructors in agriculture and meet daily for several weeks (usually four) to receive instruction in elementary science and agriculture, subjects which they are then required to introduce into the elementary schools. Such courses of lectures have been given by the board of agriculture at two places on the island of Jamaica, at British Guiana, Trinidad, Barbados, the Windward Islands, and the Leeward Islands. At Barbados and in the Windward and Leeward islands practically all the teachers have attended these lectures. As a further aid to this work the Imperial Department of Agriculture has published a text-book for teachers entitled Nature Teaching, and a pamphlet containing hints for laying out and planning school gardens. Agricultural instruction of a higher grade is given in secondary schools and colleges, among which are agricultural schools located at St. Vincent, Dominica, and St. Lucia. Attached to the agricultural schools are experiment stations where the students assist in farming operations. The course of study lasts for three or four years, according to the age of the student at admission. Seven scholarships in agriculture, including two of the annual value of £75 each for the Windward and Leeward islands, are maintained by the department. Itinerant instruction is of recent origin. In September and October last a series of seven lectures to planters was delivered by the officers of the Imperial Department of Agriculture on such subjects as sugar cane, soils, and manures in relation to the cultivation of certain varieties of cane; hints on the planting and cultivation of sugar cane; insect pests on sugar cane, and the fungoid diseases of the sugar cane. These lectures were attended by about 120 to 140 planters and were greatly appreciated.

Instruction in Agriculture in the Primary Schools of Russia.—At a meeting of Russian school instructors at Moscow, the diffusion of popular agricultural information through the medium of primary schools was discussed. The congress expressed itself opposed to the introduction of the study of trades in primary schools, believing that special schools should be established for that purpose; but, on the other hand, it expressed the opinion that it is very desirable to diffuse agricultural information among the teachers of this grade of schools by means of periodical special courses for their benefit.

Nature Study.—A nature study exhibition will be held at the gardens of the Royal Botanic Society, Regent Park, London, S. W., beginning Wednesday, July 23.

The promotion and management of the exhibition is in the hands of the executive committee of the Nature Study Exhibition Association, of which Sir John Cockburn is chairman and John C. Medd honorary secretary. The exhibition will include 9 groups, comprising exhibits from agricultural or horticultural colleges and schools, experimental farms, agricultural departments of universities and university colleges; secondary schools (public and private); primary day schools (public and private); continuation schools; normal training colleges and day training departments of the university colleges and public teachers' schools; schools for the deaf and blind; home office schools and workhouse schools; horticultural and other societies, as well as individuals that encourage nature study or nature lore as a subject of education, and exhibits from the colonies of Great Britain and from the United States. Each group may include any or all of the following 5 classes of exhibits for which certificates of merit or medals will be offered: (1) Statistical information—printed reports, leaflets, etc., bearing on nature study, natural history object lessons, school gardens, school excursions, and similar topics, and catalogues of books suitable for a school library on these subjects; (2) pictorial illustrations—plans and photographs of school gardens, school excursions, schoolrooms in which pupils are at work on nature-study topics, etc.; (3) organization—courses of instruction in nature study; (4) apparatus for teaching—diagrams, apparatus, models in clay, plaster, etc.; (5) work done by pupils—drawings, models, paintings, notebooks, drawing books, collections of plants and insects, etc. The funds necessary for defraying the expenses of the exhibition, including prizes and medals, are being raised by voluntary contributions from members of the Nature Study Exhibition Association.

The New Hampshire College Agricultural Experiment Station has begun the publication of nature-study leaflets, the first number of which, the Pollination of Plants (pp. 12, figs. 10), by C. M. Weed, appeared in March, 1902. This leaflet is intended for teachers, to show them "how easily they can utilize in the spring the subject of the relation of flowers to wind and insects for nature study in any grade above the fourth." The examples chosen are familiar trees, grasses, and wild flowers.

In *Nature* for February 20, 1902, appears a review of the first number of the *Nature Study Journal*, published by the Southeastern Agricultural College, Wye, Kent, and maintained by a society of teachers known as the Nature Study Society. "The object of the journal," as set forth in the preface and introduction, "is mainly to facilitate the teaching of 'nature knowledge' in rural schools by enabling the teachers to interchange ideas and schemes of instruction and to be in communication with the Wye College as a central organization." It is to be largely devoted to the publication of specimen lessons, the first number containing two such lessons: "Leaves and their veining," by H. Brooker, of the Ewhurst National School, and "Dodges of nature," by A. E. Chandler, of Puttenham.

The school garden as an educational feature in the public school is the subject of much discussion, both in the United States and countries of Europe. *Nature* for February 20, 1902, contains an account of a conference on school gardens held February 15 at Reading College under the auspices of the Berkshire County technical education committee, in which is pointed out the prominence given to outdoor training in the schools of Great Britain and the Continent. In this country school gardens have not received so much attention as in Europe, but the movement for their general establishment is gaining ground. As an evidence of this we have only to refer to the programme of the fifth annual conference of the Eastern Public Education Association at Baltimore, May 1 to 3. One-half of the programme is given up to papers and discussions on the subject of "School and home gardens for children as an opportunity for industrial and æsthetic training."

Organization of Pacific Northwest Economic Entomologists.—The entomologists of the experiment stations of Montana, Idaho, Washington, and Oregon met for conference at Moscow, Idaho, March 14, continuing in session through the following day. The principal insect pest of the section, the San José scale and the codling moth, were fully discussed. Many other insects were more briefly taken up. The relation of station entomologists to the State horticultural inspection work was one of the topics considered, the unanimous opinion being that the entomologist should keep in touch with this for the sake of the assistance it would give him in planning his experimental work, but that he should not act as an inspection or quarantine officer. The most threatening insect pests at present are the Hessian fly, already introduced about Portland, Oreg., and the plum curculio, which was reported as existing in the Bitter Root Valley of western Montana, on the west side of the continental divide. Plans were made for the coming season, involving among other things a fuller study of the codling moth at all the stations, to determine the number of broods and to test the efficacy of sprays. An organization was effected under the name "Pacific Northwest Economic Entomologists," and it was decided to hold a meeting annually. The membership being necessarily small, a secretary was the only officer elected, J. M. Aldrich, of Idaho, being chosen to that position.

Nebraska Academy of Science.—At the twelfth annual meeting of the Nebraska Academy of Science G. A. Loveland presented a paper on The Relative Humidity in Dwelling Houses, giving the results of experiments upon the humidity of houses heated by various means, and the results of experiments with various expedients to increase the degree of moisture, and G. D. Swezey described A New Form of Sunshine Recorder, capable of registering not only the total amount and hours of sunshine during the day, but also the varying intensity. G. R. Chatburn presented a paper of considerable practical importance on The Strength of Nebraska-Grown Catalpa and Osage Orange, and C. E. Bessey noted Some Recent Changes in the Nomenclature of Nebraska Plants, which have been rendered necessary by the modifications of nomenclature introduced in recent botanical text-books.

Reclamation of the Zuider Zee.—Interest in the proposed reclamation of the Zuider Zee has been revived by the publication of a number of articles upon the subject of late, and by the introduction in the second chamber of the States General of a bill granting authority for inaugurating the work and raising the necessary funds. As is generally known, about two-thirds of the area of Holland consists of reclaimed lands intersected by a system of main drains and navigable canals of a combined length of over 2,000 miles. The annual budget for the maintenance of its dikes and canals amounts to about $2,500,000. The reclamation of Haarlem Lake about sixty years ago, furnishing about 42,000 acres of rich land, upon which are now the great market gardens of Amsterdam, suggested the reclamation of the Zuider Zee, and in 1892 a commission was appointed to investigate and report upon the project.

The inundation which resulted in the formation of the Zuider Zee occurred in the latter part of the thirteenth century, and was caused by the North Sea breaking through the embankments in several places. The water uniting with Lake Flevo formed the Zuider Zee, a vast inland salt-water sea, 80 miles long and in places 30 miles wide, but quite shallow in many places. Several plans have been advanced for the reclamation of this tract by means of dikes, and the commission, which rendered its report several years ago, traversed the whole ground and outlined a plan which is held to be practicable. The old plan of entirely reclaiming the Zuider Zee by uniting the islands marking the former coast line has been abandoned as impracticable. The present plan contemplates the erection of a great sea dike 18 miles in length, extending from the north Holland coast, near the island of Wieringen, to the Friesland coast near Pianm. This dike is estimated to cost about $15,000,000, and to require ten years for its construction. The plan is to reclaim only those portions of the sea which have a clay bottom, leaving free the mouths of the rivers and the present lines of water communication. For this purpose four inclosing banks are to be constructed, and the areas inclosed pumped out. For the present it is proposed to build only the sea wall and to reclaim two large areas of land on the west side, which are now entirely covered by water, containing together over 131,000 acres, of which 115,000 will be available for cultivation. The reclamation of these two western "polders," together with the indemnities to the fishing interests and other incidental expenses, is estimated to cost about $40,000,000, and would occupy about fourteen years. The area of the two other "polders" to be reclaimed later is 365,000 acres. The total cost of reclaiming the 480,000 acres of cultivable land is estimated at about $75,000,000, and would occupy some thirty-three years. The rental value of the reclaimed land is placed at $10 an acre. Aside from providing a large body of land suitable to cultivation, it is urged that the project will be of great economic advantage in effecting a saving in the present cost of pumping and maintenance of sea banks, as well as by providing direct communication by road and railway along the top of the dike between Holland and Friesland, shortening the distance materially.

It is understood that the consideration of the bill for inaugurating this work has been temporarily postponed, owing to the condition of the finances of the country.

Personal Mention.—Dr. K. von Tubeuf, chief of the biological division of the German department of health, has been appointed professor of forestry in the University of Munich.

Prof. W. H. Brewer, for thirty-seven years professor of agriculture in the Sheffield Scientific School of the Yale University, will, according to a note in *Science*, retire from the active duties of the professorship at the end of the present academic year.

Oscar Clute, LL. D., a graduate of the Michigan Agricultural College in the class of '62, president of the Michigan Agricultural College from June, 1889, to August, 1893, and of the Florida Agricultural College from 1893 to 1897, died January 23, 1902.

EXPERIMENT STATION RECORD.

Vol. XIII. No. 9.

The agricultural appropriation act for the year 1902–3, passed by Congress the latter part of May, carries an increase of $626,540 over that of the previous year, the total amount now aggregating $5,208,960. The largest increases are for the Weather Bureau, the Bureau of Animal Industry, and the four new bureaus formed last year. The latter are recognized in the act in place of the former divisions which they represented, and special provision is made for the continuance of the new bureau organization.

Two new lines of work are provided for, which the Department has given little attention to in recent years, namely, the study of the proper treatment and processes for securing uniform grade and quality of table sirup and investigations in silk culture. For the investigations in sirup making $20,000 is appropriated and for silk culture $10,000. The former will be assigned to the immediate charge of the Bureau of Chemistry and the latter to the Division of Entomology.

The Weather Bureau appropriation amounts to $1,248,760, an increase of about $100,000, $50,000 of which is for the purchase of sites and the erection of six new station buildings for use as observatories. There is also provision for extending its cable and telegraphic connections. The Bureau of Animal Industry receives an increase for its inspection and investigation work of $93,000, out of which $10,000 may be used for the purchase of additional land in connection with its experiment station at Bethesda, Md. The total amount named for the Bureau is $1,247,180.

The total increase for the Bureau of Plant Industry aggregates $116,000, making the total for that Bureau $612,730, including the $270,000 for the purchase and distribution of seeds. The largest increase is for vegetable pathological and physiological investigations, $50,000. The new lines of work mentioned are the investigation of cañaigre and other tannin-bearing plants, the cause of decay in forest timber, the practical application in agriculture of the fixation of atmospheric nitrogen by bacteria and other micro-organisms, and the cultivation and distribution of these "nitrogen fixers." The appropriations for botanical, pomological, and grass and forage-plant investigations are increased by $10,000 in each case, being now $55,000 for botanical investigations and $30,000 each for the other two branches. The Arlington Farm receives an additional $5,000, making the total $15,000, and the fund for tea-culture investigations is increased to $10,000. The allowance of $20,000 for seed and plant introduction, out of the $270,000 for the purchase and distribution of seeds, is continued, and $10,000 additional is authorized from this fund for the construction of a seed warehouse.

The Bureau of Forestry receives an increase of $106,420, mostly for general operating expenses, making the total for that Bureau $291,860. The increase for the Bureau of Soils is $60,540, including $21,540 for additional salaries placed upon the statutory roll. The total for the Bureau is $169,680. In the case of both of these bureaus the increased appropriation is principally to enable an extension of the operations along lines already approved, rather than to enter upon new lines.

The appropriation for the Bureau of Chemistry is more than doubled, including that for sirup investigation mentioned above, and a number of new duties are imposed. Among these are the establishment of standards of purity for food products and the determination of what shall be regarded as constituting adulteration, the investigation of dairy products and the adulterants of the same, a study of the influence of environment upon the chemical composition of wheat and other cereals, suitability of barley for brewing, etc., and the investigation of the chemical composition of sugar-producing plants in the United States and its possessions, together with the effect of environment upon the same. The total for the Bureau is now $73,700.

The appropriation for agricultural experiment stations is $796,000, which includes an increase of $4,000 for this Office and $3,000 for the Alaska stations. The fund for irrigation investigations (assigned to this Office) is increased from $50,000 to $65,000, and in addition to its other duties provision is made for a study of the laws as affecting irrigation and the rights of riparian proprietors, the making of plans for the removal of seepage and surplus water by drainage, and the use of different kinds of power for irrigation and other agricultural purposes. An attempt to secure an increase for the stations in Hawaii and Porto Rico, giving them the same amount as is received by each State and Territory, was unsuccessful; and an increase of $7,000 in the appropriation for this Office to enable it to enter into cooperation with the farmers' institute work of the country, which was granted by the Senate and retained by the conference committee, was later reduced to $4,000 by a concurrent resolution introduced to correct a clerical error in the total appropriation. The appropriation of $20,000 for nutrition investigations remains as before.

The Division of Entomology receives $57,450, together with the $10,000 for silk investigations previously mentioned, a total increase of $31,250; and the Division of Biological Survey receives $45,850, an increase of $13,050.

The fund for the Division of Publications is increased from $198,020 to $228,820, of which $107,500 is for farmers' bulletins. This is aside from the general printing fund for the Department of $175,000.

The appropriation for the Division of Statistics remains the same as last year, except that the $15,000 for the Section of Foreign Markets is deducted, making the total for the Division of Statistics $141,160, and the Section of Foreign Markets is raised to an independent division. A clause is inserted calling upon the Secretary of Agriculture to report to the next Congress upon the advisability of consolidating with the Weather Bureau all of the work of the Department relating to the gathering and compilation of crop reports and statistics.

The fund for Public Road Inquiries is increased from $20,000 to $30,000, and that for the Library is raised from $16,000 to $18,000. Other appropriations are as follows: Office of the Secretary, $74,410; Division of Accounts, $24,100; Museum, $2,260; and contingent expenses, $37,000.

The provision for a new agricultural building is contained in a separate bill, which at this writing is still in the hands of the Senate committee on public buildings. In this connection, as showing the great need of additional accommodations, it may be mentioned that the appropriation act cited above authorizes the expenditure of about $22,000 for the rent of buildings, to be used almost exclusively for laboratory and office purposes. Moreover, permission to rent quarters was denied several branches for which it was asked, and the growth of whose work makes it practically a necessity. The new appropriation for rented buildings is more than double that authorized in the last act, not to mention the increased incidental expense for watchmen, heating, etc.

The administration of ex-Secretary J. Sterling Morton, whose death occurred April 27, was marked by a number of important events which contributed in no small degree toward the reorganization and development of the Department. While nothing like a general reorganization was undertaken, a number of changes were made in the direction of a more compact organization, and several new lines were inaugurated which materially strengthened the work of the Department. The Divisions of Soils and of Agrostology, for example, were established in his time, as was also the Dairy Division in the Bureau of Animal Industry. Congress appropriated funds for the collection and distribution of information relating to public roads, out of which grew the Office of Road Inquiry; and the Section of Foreign Markets was reorganized and placed under the Secretary's immediate supervision.

Through Secretary Morton's recommendation the experiment stations and the Department were brought into much closer relations. In his first annual report he called attention to the lack of any Federal supervision of the funds given for experiment stations, and advocated an amendment of the law placing such supervision in the hands of the Secretary of Agriculture. In response to this, Congress empowered the Secretary to prescribe the form of the annual financial statements and directed him to ascertain whether the expenditures conformed to the requirements of the Hatch Act, which has taken the form of an annual inspection. The advisability of this step is universally accepted, since, aside from safeguarding the funds, it has brought the Department into much closer relations with the stations, and has strengthened the organization of the whole movement.

Secretary Morton also obtained the first appropriation for nutrition investigations, which carried the first legislative provision for cooperation with the experiment stations, a feature which has since assumed more importance every year and has proved of mutual benefit in working out practical problems in the application of science in agriculture.

The Yearbook, which supersedes the former annual report and has become one of the foremost agricultural annuals of the world, was started in the second year of Secretary Morton's administration; and he secured the first appropriation from Congress for the publication of farmers' bulletins, which he hoped to substitute for the Congressional seed distribution. Failing in this effort and in his attempt to bring about the abolition of the seed distribution, he set about improving the quality of the seed furnished, by establishing a laboratory for testing the purity, viability, and genuineness of the seeds which were purchased for that purpose. This laboratory has been continued and its duties and scope materially enlarged.

Secretary Morton appreciated the inadequacy of the present Department quarters and the great desirability of a commodious and appropriate building. In his last annual report he pointed out that over $2,066,000 had been covered back into the Treasury during his administration, and strongly recommended that the amount so saved be applied to the erection of an agricultural building.

Mr. Morton's deep interest in tree planting and practical forestry is widely known, and he will be remembered especially as the author of arbor day legislation.

Upon the receipt of the news of the ex-Secretary's death a committee was appointed to draw up appropriate resolutions, which were subsequently adopted at a meeting of the officers and employees of the

Department. Secretary Wilson has directed that a portrait of Mr. Morton be inserted as a frontispiece in the forthcoming Yearbook, now in press.

The Seventh Annual Report of the Director of the Office of Experiment Stations brings out the fact that much progress has been made in the direction of cooperation between the agricultural experiment stations and this Department. The lines in which the stations can most effectively cooperate with the Department are being determined, and encouraging progress made in working out the methods of arranging and conducting cooperative operations. Since both the stations and the Department have had enlarged resources it has been possible not only to increase the number of cooperative enterprises, but also to conduct them on a larger scale. At present the stations in 43 States and Territories are cooperating with the Department. This cooperation covers a very broad field, including tests of varieties of grasses and forage plants in many localities, special experiments with grasses and forage plants for the arid regions and the improvement of range lands, breeding experiments with plants, especially cereals, experiments with hybrid orange trees, the culture of sugar beets, dates, and tobacco, the planting of forest trees, the nutrition of farm animals and of man, the gluten content of wheat as affected by various conditions of environment, plants poisonous to stock, injurious insects, soil studies, and irrigation problems.

In some cases it has been found desirable to form groups of stations to investigate some problem affecting a large region. Thus, for example, a group of stations, in cooperation with the Bureau of Plant Industry, is engaged in investigations on the breeding of varieties of cereals adapted to the Northwest In other cases a single station is sufficiently aided by the Department to enable it to undertake the thorough treatment of problems in a special line. Thus, the Pennsylvania Station, in cooperation with the Bureau of Animal Industry, is preparing to make elaborate researches in animal nutrition, and for this purpose has devised and built a respiration calorimeter for experiments with large animals, which in size and complexity surpasses any apparatus hitherto used for such experiments. In other cases, two or more branches of the Department combine to work in conjunction with a station on some complex problem. Plans have been made, for example, for an extensive experiment on the problems of range conservation and improvement, in which the Arizona Station will unite with the Bureaus of Forestry and Plant Industry and the Office of Experiment Stations (irrigation investigations). It is evident that a very great variety of effective combinations can be made, which will result in a union of forces thoroughly acquainted with local conditions with those having broad views and relations. Such a strong combination of forces for attacking the problems of agriculture exists nowhere else. It is believed, therefore, that largely increased benefits will soon accrue to agriculture from this union of the stations with the Department. At the same time the stations were never so strong locally, and are better equipped than ever before to work by themselves on problems of immediate importance to their own constituencies.

Instances of governmental activity for the advancement of agriculture in the old world as well as in the new are more numerous than formerly, indicating that greater enlightment on the practical value of the results of experiment station work is having a marked effect. The Russian Department of Agriculture and Imperial Domains is displaying considerable activity in its soil and forestry investigations and in the establishment of stations for the investigation of special subjects, such as the growing of flax, cotton, olives, etc.

In Australia the Victoria Department of Agriculture is undergoing reorganization. The Victoria Royal Commission on Technical Education has brought to a close its study of Australian, European, and American departments of agriculture, agricultural schools, and experiment stations, and published its final (sixth) report. The Minister of Agriculture is now seeking a director of agriculture, who will proceed to reorganize the Department and put it on a better working basis.

In England the Board of Agriculture has made larger grants than formerly to agricultural colleges and societies for conducting agricultural investigations. The Agricultural Education Committee is doing important work for agriculture and agricultural education by publishing circulars on various topics and nature-study leaflets for teachers. During the year Messrs. John S. and T. M. Remington have established the Aynsome Experiment Station at Lancashire, a private institution.

The Austrian Government has recently established several experiment stations, notably the station for plant culture at Brünn, the station for investigations in plant and animal production at Otterbach, and an agricultural physiological station, with divisions of chemistry, physiology, and bacteriology, at Prague. In Hungary an experiment station for the analysis and study of wines was established last year at Fiume.

France has established at Nogent-sur-Marne a colonial garden to have administrative control over French colonial stations and botanic gardens in different parts of the world and to furnish these institutions with seeds and plants. During the year œnological stations have been established at Toulouse and Beaune and an agricultural station at Besançon.

In Germany five years of successful work at the Lauchstädt Experimental Farm, which is connected with the Agricultural Chemical Experiment Station at Halle, has given so much evidence of the value of experimental farms in connection with experiment stations that there is a movement in that country toward the extension of the so-called "American system" of field experiments, conducted on a large scale and in a more practical way than has hitherto been customary in that country. Two new stations have been established during the year, a flax-culture station at Sorau and a viticultural experiment station at Weinsberg.

In the West Indies and South America also the claims of agricultural education and research have received much attention. The Department of Agriculture in the West Indies has established three new stations at Montserrat and one at Tortola, and has conducted several meetings of planters and investigators, at which great interest in the advancement of agriculture was displayed. The Bolivian Government has established an agricultural college at Cochabamba and an agricultural school for Indians at Umala. Brazil has recently established a botanical garden and experimental demonstration field at San Vicente; and Argentina, which hitherto had no stations, has decided to establish four experiment stations on the same general plan as those in the United States.

An irrigation experiment station has been established at Calgary, Canada, a dairy station at Gembloux, Belgium, and a veterinary pathological institute and animal vaccine institute at Christiania, Norway; and a department of agriculture, with a small staff of experts attached, has been organized at Bangalore by the government of Mysore, India.

Thus the organized effort for the advancement and improvement of agriculture increases year by year, the example and experience of one country seeming to stimulate others to action or to increased activity. The well-deserved reputation of the American stations for doing work of practical bearing and quite direct application to agricultural practice is causing them to be looked to by the newer countries, and the so-called American system is finding many imitators.

THE STATION FOR PLANT BREEDING AT SVALÖF, SWEDEN.

David G. Fairchild,
Agricultural Explorer of the U. S. Department of Agriculture.

In connection with an expedition for plant introduction the writer had the pleasure in the summer of 1900 of visiting the Station for Plant Breeding at Svalöf, Sweden. This station is so unique and promises so much for the agriculture of Sweden that it is worthy the serious consideration of American agriculturists.

The object of the station is the development by systematic breeding and selection of new, better, and more productive varieties of agricultural plants. So far, it has confined its attention to the improvement of wheat, oats, rye, barley, peas, and vetches.

The institution is the outcome of private enterprise and owes its origin to the farsightedness and liberaiity of B. Welinder, a wealthy landowner of the province of Schönen. Mr. Welinder became convinced, through his travels in Germany and England, of the importance to agriculture of cultivating the best varieties of cereals; and in 1884, or thereabouts, he imported into South Sweden and grew on his own estate a number of different foreign varieties of grain. Among this number was the Scottish variety of wheat known as Square Head.

Mr. Welinder distributed seed of this Scottish sort among his neighbors, who discovered upon growing it that with the same amount of labor they were harvesting nearly 2,000 kg. per hectare of this new variety, instead of 1,200 kg., the ordinary yield of wheat.

The success of this introduction, together with other arguments, induced Mr. Welinder to form in 1886 the South Swedish Society for the Breeding and Selection of Seeds. In this he was heartily seconded by Freiherr F. G. Gyllenkrook and other large landowners of the province of Schönen. The object of this society was to raise the standard of Swedish agriculture thro gh the introduction and origination of better varieties of grain and forage plants. In connection with the society, and the breeding station which was the outcome of it, there was established in 1891 a seed company, which at present is capitalized at $100,000. This company is a business concern for the purpose of growing in large quantities and distributing advantageously and economically seeds of the cereals and fodder plants which have been originated or tested by the breeding station and proved of special agricultural value. In the early years of the breeding society the attempt was made to combine these two related objects, but it was found that too much time of the plant breeders was absorbed in the purely business transactions of selling and shipping seed.

The effort of Mr. Welinder and his associates soon attracted attention in other parts of Sweden and resulted in the formation of the General Swedish Breeding Society, which later, by absorption of smaller institutions in middle Sweden, became the Swedish Seed Breeding Association.

Although owing its origin to private initiative, the association has received since 1891 an annual government appropriation, which now amounts to 18,000 crowns, or nearly $5,000. This sum, together with 700 to 800 membership fees, subscriptions from various Swedish agricultural societies, receipts from the sale of grains from the experimental plats, etc., makes the total fund for maintenance of the institution nearly 53,000 crowns, or $14,300.

Until recently the business relations between the association and the company have been somewhat complicated. Seeds of new varieties originated by the breeding station have been appraised by a joint committee and sold outright to the company. Under the present arrangement the association receives a royalty of 1 per cent of the gross receipts of the company on the sales of seed originated by the breeding station.

Although it was not expected in the formation of the company that any profit would result in the first few years from the sales of seed, the books already show a small credit balance, and it seems assured that from a business standpoint the company will be a success.

From 1886 to 1892, unproductive methods of selection were employed and not a single really superior variety of grain was developed. Since 1892, when Director N. H. Nilsson introduced an original method of selection which has proved very important, several new and valuable sorts have been distributed on a large scale and many more promising ones are on trial. As it requires about five years to grow a sufficiently large quantity of the seed to justify putting it on the market, it was not until 1897 that the company could really begin to get any benefit from the work of the plant breeders.

Upon receiving seed of a new and thoroughly tested variety from the breeding station, the company sows it at once on its own land, which is adjacent to the grounds of the station; and when a sufficiently large quantity has been harvested, the company distributes it to correspondents under the simple agreement that the latter shall sell the whole crop harvested from this seed to the company, receiving for their extra pains a price somewhat in advance of the market price for ordinary grains. No special precautions are considered necessary to prevent the grower from stealing a small quantity for his own use and subsequent sale. So much depends upon the inspection of the growing grain and harvested product and the certificate furnished by the breeding station that Swedish farmers evidently prefer to pay the extra price charged for the certified seed.

Throughout both Sweden and Finland the Svalöf varieties of grain are spoken of in the highest terms. As far north as the sixty-sixth parallel they yield better returns than native sorts whenever the season is sufficiently long. In short seasons, when the frosts come unusually early, the southern varieties do not ripen. It could not be expected that sorts from southern Sweden would prove well adapted in this respect to the northernmost localities.

The seed company carries in stock a limited number of standard seed varieties that have not been bred at the Svalöf station. These are, however, all subjected to inspection by the experts of the station, and every sack of seed sold by the company bears the stamp of the latter and contains a certificate as to its purity. All pedigreed grains which are purchased by the company from its correspondents must, before purchase, be inspected in the field and officially recommended by an expert of the breeding station.

In a brochure[1] for the guidance of a committee of the German Agricultural Society, published on the occasion of its visit to Svalöf in 1898, Dr. Nilsson describes in more detail than the limits of this article will allow the organization and scientific principles of the institution. This brochure is worthy the careful perusal of every American plant breeder.

The breeding station at Svalöf is housed in a modern laboratory of attractive exterior and conveniently arranged interior, and is surrounded by a small neatly kept park. (Pl. II, fig. 1.) The experimental plats, of which there are more than 2,000, are scattered among the larger fields of pedigreed grain and cover in all about 25 acres.

Special stress is laid by Dr. Nilsson upon the fact that all of his experimental plats are under as nearly as possible natural conditions, and to insure still further accuracy, each variety is tested on not less than three different plats.

The work of the station naturally runs along two lines, i. e., the search for mother plants for starting new varieties, and the elimination of all but the very best of the varieties started.

All selection of mother plants is based upon (1) the general qualities of the plant itself, (2) its ability to produce plants of high average quality, and (3) its ability to produce plants of nearly absolute uniformity in botanical characters.

The method of work is practically the same for all crops handled.

[1] N. H. Nilsson, Einige kürze Notizen über die schwedische Pflanzen-Veredlung zu Svalöf. Malmö, 1898.

FIG. 1.—STATION FOR PLANT BREEDING, SVALÖF, SWEDEN.

FIG. 2.—INCREASE PLAT OF PEAS, THE PROGENY OF A SINGLE PLANT.

and in Pl. II, fig. 2, is shown a small plat of peas which is the product of the single best plant grown in a similar plat the year before.

As soon as one of the plats seems to warrant it, i. e., when its uniformity of type and general excellence of yield have been demonstrated, a number of the best yielding plants, excepting of course the single best one, are chosen to plant an increase plat. From the seed obtained from this increase plat, providing the uniformity of type and general excellence still hold good, the variety test plats are planted. Here is applied the third and final test, and all but the one or two very best are eliminated. The variety or varieties that hold out through all this process of selection are increased for distribution. The method of selection outlined has been in use at Svalöf since 1892.

Although directly productive of no novelties, the early years of activity were not lost, for they resulted in the discovery of numerous valuable methods and instruments for correctly appraising the practical value of certain characters of cereal and fodder plants. They made it possible for the investigator to express, often in statistical form, the value of a variety of grain.

The amateur plant breeder is often blinded to the real problem at issue by the ease with which a host of new forms can be produced by cross fertilization. He learns later, as Dr. Nilsson says, that it is easy enough to produce new varieties, but far more difficult to determine which of their characteristics are worth reproducing, or can be reproduced. When Dr. Nilsson hit upon the idea of conducting all experiments from the standpoint of a single plant, he was able with the aid of the experience of former years to correctly and quickly decide the value of such new varieties as he observed and selected from his fields. He was able by the same means to select from each following generation the desirable type for propagation.

The discovery of certain easily observable seed characters on the grains of barley made it possible to group the many varieties of each subspecies into 4 tolerably distinct strains, and to analyze quickly large quantities of seed of a given sort in order to determine its purity as a variety (*Sortenreinheit*). The botanical arrangement of the oat inflorescence, i. e., the number of flowers per spikelet, etc., have made a tolerable classification of the varieties of this plant possible, and the breeder can detect at a glance in his experiment plats the presence of a valuable *botanical* variation.

These purely botanical characters have correlated with them valuable economic ones, and it has been one of the services of the Svalöf station to point out some of these correlations and to emphasize the importance of this principle. For example, it has been found that the close headed wheats have the strongest straw, and the three-flowered spikelets of the oat bear the largest grains.

Too much stress can not be laid, according to Dr. Nilsson, upon the value of a pure botanical variety. In the production of a barley for brewing purposes uniformity of germination is of prime importance, and at the Swedish Brewers' Exposition at Malmö, in 1898, the varieties of barley which took the prizes were all botanically pure or nearly so. Such sorts as were mixtures of several strains were invariably of inferior quality. It can be easily understood that grains which are descended from a common parent will show a greater uniformity, even in length of time required to germinate, than those from different parentage.

Dr. Nilsson finds that none of the existing races of cereals now sold by seedsmen is pure, but rather mixtures of many different strains, which he is able to separate and identify. He holds that when a race has been produced which is botanically pure a remarkable uniformity results. The writer saw 14 acres of a new variety of wheat, not yet on the market, which had for several years been subjected to the most careful selection. Every plant in the field was the offspring of the same ancestral plant which Dr. Nilsson had discovered some 4 or 5 years before. The uniformity of color and evenness of growth were most remarkable. Two bands of dark green along the margin of the field could be seen for hundreds of yards, and were as distinct as if painted above a chalk line. Upon closer observation they proved to be formed by the dark green upper nodes of the individual plants, which were of such uniform height that the nodes stood at the same level.

It is easy enough, in Dr. Nilsson's opinion, to secure variable varieties and curious sports by crossing; but it is very difficult, once the strain is disturbed by cross breeding, to secure uniformity. At present he finds so many variations in his experimental fields without recourse to hand crossing, and he has been so successful in rendering the best of these uniform, that he has not paid much attention to the matter of artificial cross fertilization. He admits, however, that crossing must be judiciously resorted to for the production of quite new varieties of superlative excellence.

Not content merely with the production of a new variety, the station continues work upon sorts already put on the market by the company. Every year a new representative plant is selected from the trial plats, the seed from it sown, and the machinery set in motion for its multiplication. The Svalöf Princess barley of 1898 is not the same nor as well bred as that of the same pedigree, but originated in 1900. The system of records and methods of systematically studying each of the characters of these pedigreed sorts are among the most interesting features of the station. The field and record books, and the system of numbers employed to keep track of these almost countless variations, are the result of years of experience. Extensive herbaria and photographs assist in rendering the short descriptions of the various sorts intelligible, and in looking these over one is impressed with the thorough manner in which this kind of experimental work is systematized.

The station laboratory is a machine shop of specialized contrivances. Among these may be enumerated counting cases for quickly registering the grains per spikelet, specialized racks upon which the pedigreed grain is hung, tables of peculiar construction, racks and trays of convenient form, self-sorting balances, special pincers for cutting the grains of barley in two in order to examine their flour texture, abacus-like and ordinary counting machines for diminishing the labor of calculation, ingenious shaking sieves for grading and registering quickly large quantities of grain, marking boards to guide the plat planters in planting the seed, and calipers for registering the relative compactness of the wheat head.

Dr. Nilsson has two scientific assistants, Dr. H. Tedin and Mr. P. Bolin. The former is at work upon the improvement of forage plants, with which he has already had excellent results, while the latter has made a specialty of barley, and his Princess variety is rapidly superseding other sorts through southern Sweden. It is an essential of success in plant breeding that the breeder shall become so intimately acquainted with the plants he is breeding that he learns which among the host of characters constantly developed are of significance for his purpose; and the organization and specialized scope of the Svalöf station foster this intimate acquaintance.

Among the valuable varieties already produced by this remarkable breeding station are the Grenadier wheat, which is not yet on the market but has yielded over 70 bu. per acre where ordinary kinds gave only 35 bu.; the Princess barley just mentioned, which took 20 out of 28 prizes offered by the Brewers' Association at a recent exposition in Malmö, Sweden, and a variety of vetch (*Vicia sativa*) quite proof against the mildew (Peronospora), which has for several years almost completely destroyed the fields of this fodder plant at Svalöf. This vetch was found by Dr. Nilsson in a field which has been devastated by the disease. It was noticeably free from the malady, and its progeny now form a race which is quite immune to the Peronospora. Considering the short time that has elapsed since the proper method was discovered for the improvement of plants, and that the staff of the station includes only three breeders, these are certainly most worthy results. What might be done if this work were prosecuted on a large scale does not require much imagination to discern.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Method for preparing strictly tenth-normal, fifth-normal, etc., hydrochloric or nitric acid, R. K. MEADE (*Jour. Amer. Chem. Soc., 23 (1901), No. 5, pp. 343–347*).—The method described depends upon the decomposition of copper sulphate in solution by the electric current. Barium chlorid is afterwards added to the solution, a double decomposition taking place, barium sulphate and hydrochloric acid being formed. The process is carried out as follows: In making tenth-normal hydrochloric acid there is introduced into 12.487 gm. of crystallized copper sulphate in 500 cc. of water, a cylinder of copper foil attached to the negative wire and a platinum rod attached to the positive wire of an electric circuit with a current of from 1 to $1\frac{1}{2}$ amperes. The beaker is covered with a watch-glass perforated for the rod, and the current passed through the solution for from 6 to 8 hours, or longer. After removing and rinsing the apparatus, 12.215 gm. of crystallized barium chlorid, dissolved in water, is added and the solution made up to 1 liter. In order to have the volume correct 26 cc. of water is added to fill the space taken up by the precipitate. After the precipitate has settled the clear liquid is siphoned through a dry tube upon a dry filter and caught in a dry stock-bottle.

In making tenth-normal nitric acid by this method, 13.076 gm. of barium nitrate should be used in lieu of barium chlorid, the quantity of copper sulphate remaining the same. Where the standard hydrochloric acid is for use with alkaline earths, it is necessary to add a little in excess of the amount stated of barium chlorid. The author prepared only tenth-normal and fifth-normal acids by this method, but states that normal acid can also probably be prepared, but that the waste caused by the loss of solution retained in the precipitate would be somewhat greater.

The determination of nitrates in water containing chlorids, R. MARCILLE (*Ann. Agron., 27 (1901), No. 12, pp. 596–600*).—The method proposed is a modification of that of Grandval and Lajoux,[1] which is based upon the coloration produced by the formation of trinitrophenol or picric acid when water containing nitrates is treated with sulphophenic acid. The chlorids are eliminated by precipitation with a concentrated ammoniacal solution of silver sulphate, the determination of nitrates being made in the solution without filtering to remove the precipitate. The method of procedure is as follows: To 10 cc. of the water in a small porcelain dish add a few drops more than enough of the silver solution to precipitate the chlorids; evaporate to dryness at a temperature not much over 120° C.; cool, add 1.5 to 2 cc. of sulphophenic acid (8.1 parts of phenol to 100 parts of sulphuric acid), and mix to a homogeneous paste; dilute to about 10 cc. with water, and add a slight excess of ammonia; pour into a glass tube, make volume to 50 or 100 cc. with distilled water, and determine nitrates by the ordinary colorimetric method. The silver solution is prepared by heating pulverized silver sulphate with a little water and adding ammonia little by little. Even small amounts of chlorids are shown to interfere with the accuracy

[1] Compt. Rend. Acad. Sci. Paris, 101 (1885), p. 62.

of the determination of nitrates, but theoretical results were obtained when the chlorids were precipitated in the manner described.

Synoptic tables for the chemical analysis of water, P. Goupil (*Tableaux synoptiques pour l'analyse chimique de l'eau. Paris: J. B. Baillière & Son, 1901, pp. 70, figs. 10*).

The quick determination of nitrates in soils, C. Montanari (*Staz. Sper. Agr. Ital., 34 (1901), pp. 690–693; abs. in Chem. Centbl., 1901, II, No. 13, p. 793*).—The author adapts the method of Grandval and Lajoux, referred to above, for the determination of nitric nitrogen in air and water to this purpose.

Methods of analyzing commercial fertilizers, F. Kretschmer (*Ztschr. Angew. Chem., 14 (1901), No. 45, pp. 1136–1138; abs. in Chem. Centbl., 1901, II, No. 24, p. 1277*).—A brief account of methods commonly employed in Germany for the determination of nitrogen, phosphoric acid, potash, and lime.

The solubility of phosphatic manures in some organic acids, W. F. Sutherst (*Chem. News, 84 (1901), No. 2187, pp. 199, 200*).—Tests are reported of the action of 1 per cent acetic, tartaric, and citric acids on Christmas Island coprolite, basic slag, basic superphosphate, and precipitated phosphate. In the method followed 1 gm. of the phosphate was digested for 24 hours with frequent agitation in 100 cc. of the solvent, phosphoric acid being determined in 50 cc. of the filtered solution thus obtained by the molybdic method. The solubilities obtained were very variable. Acetic acid gave much lower results than the other two acids tested. The author states that "though citric acid seems to be now fixed upon as the reagent in testing phosphates, it is not at all a true representative, . . . for the most satisfactory results as a general solvent are given by tartaric acid."

A suggestion regarding the modification and simplification of phosphate analysis, M. Passon (*Ztschr. Angew. Chem., 14 (1901), No. 45, pp. 1134–1136; abs. in Chem. Centbl., 1901, II, No. 24, p. 1277*).—It is recommended that such weights of material be used (12.8 gm. per liter or 6.4 gm. per half liter) that each milligram of the magnesium pyrophosphate obtained shall correspond with a definite percentage (0.1) of phosphoric acid, thus obviating the necessity of calculating the percentage. Modifications based on the same principle are suggested for the volumetric methods.

On the separation and determination of small amounts of potassium in salt mixtures, F. H. van Leent (*Ztschr. Analyt. Chem., 40 (1901), No. 9, pp. 569–573*).—For this purpose the author recommends, on the basis of his experiments with sea water, a modification of the cobalt nitrate method of de Koninck and Gilbert, converting the potassium finally into perchlorate or the platinum salt and weighing in these forms. The conclusion is reached that the method is better adapted for use with mixtures of potassium with other salts, especially when the proportion of potassium is small, than the direct platinum or perchlorate method. The reagent employed is prepared by dissolving 9.58 gm. cobalt chlorid with 25 cc. of glacial acetic acid in 500 cc. of water. Just before use equal parts of this solution and of a solution of 90 gm. of sodium nitrate in 500 cc. of water are mixed.

Estimation of sucrose and lactose in condensed milk, S. H. R. and C. N. Riiber (*Ztschr. Analyt. Chem., 40 (1901), No. 2, pp. 97–110*).—The method of Kjeldahl for estimating two sugars at the same time and in the same solution depends upon whether the copper yielded by each sugar present is in a correct ratio to the total. This method is correct when the two sugars reduce Fehling's solution with equal rapidity. This is not exact with others, like invert sugar and lactose, and the authors propose a formula for calculating an approximate result. The figures they obtained by the calculation agreed very closely with those applied to 3 samples of milk prepared with known amounts of sugar.

Determination of milk sugar by the Wollny refractometer in comparison with analytical and polariscopic methods, R. Braun (*Milch Ztg., 30 (1901), Nos. 37, pp. 578, 579; 38, pp. 596–599, figs. 4; 39, pp. 613–616*).

The determination of saccharin, F. Wirthle (*Chem. Ztg., 25 (1901), No. 77, p. 816*).

Note on the approximate estimation of formaldehyde in milk, J. F. Liversege (*Analyst, 26 (1901), No. 303, pp. 151, 152*).—A color reaction obtained by the adition of a reagent composed of 25 cc. of normal ferric chlorid in 100 cc. of pure concentrated sulphuric acid. Ten cc. of the milk is placed in a 25 cc. stoppered cylinder and the reagent added, 1 cc. at a time, from a burette and the color noted. In the presence of formaldehyde a violet color appears which increases in intensity with the amount of formaldehyde in the sample.

Detection of formalin in milk, O. Henzold (*Milch Ztg., 30 (1901), No. 40, pp. 629, 630*).—The addition of sulphuric acid to milk containing formalin gives a distinct violet color at the contact of the two layers.

The estimation of formaldehyde, Z. Peska (*Chem. Ztg., 25 (1901), No. 71, p. 743*).—A discussion of methods.

Estimation of the acidity of the fat in foods, G. Loges and K. Mühle (*Landw. Vers. Stat., 56 (1901), No. 1, pp. 95, 96*).—The authors recommend the direct extraction of the fat, carried out with 5 gm. of material and 100 cc. of water and acid-free ether. An aliquot portion of the filtrate is taken for the determination of the acidity, using an alcoholic potash solution containing 50 per cent of alcohol for titrating. The results of a series of tests of this method with various foods are shown in comparison with the ordinary method. The results are in every case higher with the former method.

The application of iodin monobromid in the analysis of fats and oils, J. Hanus (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 20, pp. 913–920*).—The author has made an extended study of the use of iodin monobromid in the analysis of fats and oils. The formation of iodin monobromid, a gray, crystalline, metallic substance, soluble in alcohol and acetic acid, is given. A table is shown, giving the number obtained with this compound, in comparison with the Hübl number. The method of obtaining the iodin monobromid number is as follows: 0.6 to 0.7 gm. of fat and 0.2 to 0.25 gm. of oil, or, in case the iodin number is above 120, 0.1 to 0.15 gm. of oil is put into a glass-stoppered flask of 200 cc. capacity and 10 cc. of chloroform added. After the fat is dissolved 25 cc. of a solution made of 10 gm. of iodin monobromid in 500 cc. of acetic acid is run in, and after 15 minutes, with occasional shaking, 15 cc. of potassium iodid solution (1:10) added. The free iodin is then titrated with sodium thiosulphate solution, using starch as an indicator.

The advantage of the iodin monobromid solution in acetic acid over the usual method of obtaining the iodin number is as follows: (1) The solution is more stable and keeps for a longer time; (2) the results with the iodin monobromid solution are more uniform and it is not necessary, therefore, to employ so many blank determinations; (3) the flask needs to stand only a quarter of an hour, so that a greater number of manipulations may be carried out in a short time; and (4) the numbers obtained by this method very closely approximate those obtained by the usual method.

A method for the quantitative separation of cholesterin from fat, E. Ritter (*Chem. Ztg., 25 (1901), No 81, p. 872*).

Concerning lecithin compounds, H. J. Bing (*Skand. Arch. Physiol., 11 (1901), Nos. 3–4, pp. 166–175*).—A chemical study of the compounds which lecithin forms with sodium chlorid, sodium acetate, platinum chlorid, salacin, amygdalin, and a number of other reagents, the purpose of the investigation being to study the chemical constitution of lecithin.

Glycogen obtained by extraction with boiling water in comparison with the total glycogen present, J. Nerking (*Arch. Physiol. [Pflüger], 85 (1901), No. 7–8, pp. 313–319*).—In the studies with the flesh of calves the author found that by continued extraction with boiling water only about $\frac{2}{3}$ or $\frac{3}{4}$ of the glycogen was obtained.

Comparison of volumetric methods of tannin analysis with hide-powder method, H. R. Procter and A. B. Searle (*Wiss. Tech. Beil. Ledermarkt, 2 (1901), p. 60; abs. in Chem. Ztg., 25 (1901), No. 80, Repert., p. 283*).—By the Jean method the results were lower than by the Löwenthal method and much lower than by the hide-powder method. There was no constant relation between the results obtained by the 3 methods.

Studies of the pentosans of jute, vegetable sponge, and brewers' grains, A. Schöne and B. Tollens (*Jour. Landw., 49 (1901), No. 1, pp. 21–28*).—The authors made a study of the pentosans of the substances named, and the application of various modifications in the methods of analysis. Comparisons were made between heating on the water bath in the usual manner and heating under pressure. Lower results were obtained by heating in an autoclave at 125 to 118°, with 1 per cent sulphuric acid, than heating with 5 per cent sulphuric acid in the water bath. By digesting jute with dilute soda solution and precipitating with alcohol 4.6 per cent of wood gum was obtained, representing 1.2 per cent of xylose. The vegetable sponge yielded 0.63 per cent of xylose. Brewers' grains heated in the water bath with 3 per cent sulphuric acid yielded 24.77 per cent of pentosans, equivalent to 28.16 per cent of pentoses. The treatment was found to have extracted the pentosans and inverted them to pentoses quite completely, although the residue continued to show the lignin reaction.

The constituents of the tea leaf, and the changes which these substances undergo during the manufacture of tea, A. W. Nanninga (*Meded. 'S Lands, Plantentuin, 1901, No. 46, pp. 60*).—This contribution treats of the quantitative determination of caffein, tannic acid, and some other soluble constituents of the tea leaf. The methods of v. Romburgh and Lohmann of extracting with alcohol, and that of Vité of extracting with water, were carefully tested with samples having a known caffein content. It was found that the alcohol method could not be used for green tea nor for freshly dried leaves because giving too low figures, while for black tea both methods gave practically the same results. Further tests showed that the cause of the unsatisfactory results obtained with the alcohol method were due to the presence of the tannic acid, and that it was not practicable to satisfactorily extract caffein with chloroform from an aqueous solution when tannic acid is present. The water method failed to return quite all the caffein present in the green and in the freshly dried leaf. The method finally adopted was that of extracting with chloroform. This method also was the most satisfactory in analyzing coffee and kola nuts. The results of the several methods with fresh, dried, and fermented tea leaves are shown in tables.

Great difference of opinion has long existed regarding the properties of the tannic acid of tea. This is probably due to impurities in the extract, and to avoid this the author devised a method for obtaining pure tannic acid from the leaves. It was found that the presence of 20 per cent water in the powdered tea made possible the complete extraction of the acid, which was impossible with dry leaves. The tannic acid of tea is very hygroscopic and deliquesces at once, assuming a yellowish-brown color and a sirup-like consistency. The characteristics of the dry powder as regards solubility, taste, and reactions with a variety of chemicals are given. The deflection of the plane of polarized light is practically constant for different samples—about 3.4°, showing that the tannic acid of tea is a pure chemical combination and not a mixture as tannin.

The peculiar property of being absorbed by hide powder was tested with the tannic acid of tea. The conclusion was reached that in the quantitative determination of tannic acid it is necessary to add the hide powder in small amounts every 10 minutes. If the entire amount is added at once there is at first a rapid absorption of the acid, followed by a decrease in the absorptive power of the hide powder, so that not all the acid is taken up, although the quantity of powder is sufficient to absorb the whole amount of acid when added in small quantities at short intervals.

The reactions of the tannic acid of tea with a number of chemicals are briefly mentioned. The molecular weights in two cases determined were 503.5 and 502.

A comparison of the properties and reactions of the tannic acid of tea with the two groups of tannic acids established by Trimble show that it belongs to neither, but occupies an intermediate position.

A substance closely resembling quercitin was found to differ from it in some reactions. This substance, which has not been named, plays no important part in the manufacture of tea.

Tea leaves also contain a glycosid which the author provisionally calls tea-glycosid. The method of obtaining it is described.—H. M. PIETERS.

An oven for igniting the precipitate of ammonium-magnesium phosphate in porcelain Gooch crucibles, SCHALLER (*Ztschr. Angew. Chem., 14 (1901), No. 32, pp. 800, 801, figs. 2*).—An oven of the Hempel pattern to accommodate 4 crucibles is described.

The C. Fresenius-Offenbach distilling apparatus for the determination of ammonia (*Bul. Assoc. Belge Chim., 15 (1901), No. 6, p. 219*).—This apparatus is briefly described and the advantages claimed for it are stated.

The foundation principles of chemistry—a guide for the use of agricultural educational institutions. I, Inorganic chemistry, G. ALTMANN (*Grundriss der Chemie. Ein Laitfaden für den Unterricht an landwirtschaftlichen Lehranstalten. Leipsic, 1900, 5. rev. ed., pp. IV+132, figs. 37*).

Agricultural chemical exercises for agricultural schools, A. MAHRENHOLTZ (*Die agrikulturchemischen Übungen an Landwirtschaftsschulen. Liegnitz: Reinersche Buchhandlung, 1901, 2. enl. and rev. ed., pp. 68, ill*).

BOTANY.

The effect of water on the maturing of woody stems, F. KÖVESSI (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 22, pp. 1359-1361*).—The author claims that an abundant fruiting follows a year of drought, and that a humid season is followed by one of small fruit production. This is due in a large degree to the maturing of the branches which carry the floral buds, and in the ripening of these branches the water which they contain plays an important part. It is stated that branches arising directly from the trunk or occurring in the interior of the top contain a large amount of water, and as a result are poorly matured at the end of the growing season. These branches suffer severely on account of the winter's cold, and as a result many are destroyed, and the tree naturally pruned. It is claimed that the location of the flower-bearing branches conforms to the same rule. They are most numerous on the slender branches in which the water conduction is limited, on account of the distance of transfer, and they are also most numerous if the branch assumes a vertical position, in which by the added action of gravity there is a diminution of water content. In this manner the form of the tree, as well as the location of the flower-bearing branches, is determined by conditions influencing the maturity of branches, and the maturing of branches, as well as the number of flowers and fruits, depends to a great degree upon the amount of water which the plant receives.

Osmotic pressure and its rôle in defending living cells against cold, D'ARSONVAL (*Compt. Rend. Acad Sci. Paris, 133 (1901), No. 2, pp. 84-86*).—Attention is called to the extreme brittleness to which animal and vegetable tissues are subject when exposed to liquid air, and also the fact that yeasts and various bacteria do not lose their vitality when subjected to the temperature of liquid air for several weeks. This resistance, the author claims, is due to the osmotic pressure existing in the yeasts. If the osmotic tension be lowered by placing the yeast or bacteria in solutions of sodium chlorid, potassium nitrate, or glycerin, they are no longer able to withstand the temperature of liquid air. It is believed possible to determine the value of the osmotic pressure for any given cell by which the temperature at which its vitality will be destroyed.

The periodicity of root growth, J. HÄMMERLE (*Beitr. Wiss. Bot., 4, pt. 2, pp. 15; abs. in Bot. Centbl., 88 (1901), No. 4, p. 107*).—The roots of *Acer pseudoplatanus* were found to make their principal growth in the spring of the year and in the autumn. During the months of January, February, and March there was an almost entire cessation of growth. During mid-summer a similar cessation of growth was noticed. Investigations were made upon a number of 1 to 5 year old trees grown in the open and in pots, the results obtained confirming previous observations. The duration and amount of growth was found to be influenced by age, soil, climate, etc. Contrary to the observations reported by others, the author was unable to find any root growth taking place in the red beech during autumn. Willows, oaks, and hazel make strong root growth in the fall of the year, and the hazel showed considerable growth during January.

The structure of the sprouts from various trees, M. DUBARD (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 22, pp. 1356–1358*).—A study is reported of the sprouts which rise from the roots of poplar, elm, hazel, etc., from dormant buds of the oak, and from the cambium layer of oak, black poplar, etc. These sprouts show by their anatomy the characteristics of herbaceous plants. Their growth is rapid, and they have elongated internodes and develop stipules which persist for a long time. There is little differentiation of tissues, particularly of the protective and strengthening tissues. There is a considerable production of cortex in proportion to wood, and the whole ripens poorly. Within the same genus of plants the structural characteristics of the shoots are most nearly alike for those species which are nearly related.

The form and manner of root growth of some trees, M. BÜSGEN (*Allg. Forst u. Jagd Ztg., 67 (1901), Aug., pp. 273–278; Sept., pp. 305–309, figs. 4*).—The root systems of a number of trees are described. The time of the most important root growth of a number of trees and shrubs, as shown by the observations of the author and others, is indicated by a chart. The principal species reported upon are ash, birch, beech, alder, oak, maple, poplars, willows, elms, locust, spruce, pine, larch, white fir, etc. Considerable variation is shown in the period of maximum root growth of the different species, as reported by the different observers. As a rule the most of the root development takes place between April and October, with little or none in December and January. Exceptions are noted, however, and there seems to have been a cessation of growth during the summer months in some species, and willows, maples, lindens, horse chestnut, and a few shrubs are shown to have increased their root development during December and January.

Concerning the proteid formation by plants, W. ZALESKI (*Inaug. Diss., Kharkov, 1900; abs. in Bot. Centbl., 87 (1901), No. 8, pp. 277–282*).—A review is given of the literature bearing upon the subject of proteid synthesis by plants, and experiments conducted by the author are described, from which he draws some conclusions. The subject is considered to be still in an indefinite state as to some of the phenomena. Proteid formation from organic nitrogen in the dark, proteid regenertion from metabolic products, and proteid synthesis from nitrates are discussed at some length. Experiments with onions, potatoes, and narcissus bulbs showed that there was an increase in the proteid content when kept in the dark, and the author claims that it was not made at the expense of asparagin, but from other little-known nitrogenous bodies. Experiments with etiolated lupine seedlings showed their ability to build up proteids from some of their metabolic products, and experiments with sunflower leaves kept in the dark showed they were able to form proteids from nitrates and sugar.

The probable function of calcium oxalate crystals in plants, A. SCHNEIDER (*Bot. Gaz., 32 (1901), No. 2, pp. 142–144*).—Calcium oxalate is said to occur in plants in 4 predominating types. Of these the least common is that called crystal sand. The prismatic and aggregate forms are about equally common and are very widely distributed. The needle-shaped or acicular crystals are very common but predominate in monocotyledonous plants. The author reviews the common opinion that calcium oxalate occurs in plants as a protective agent, and from his own and other observations concludes that its prime function is that of mechanical support, and that its rôle as a reserve product is doubtless secondary. The principal reasons favoring the mechanical support theory are given at some length. Cells containing prismatic crystals are generally associated with bast fibers. As a rule the crystal-bearing cells are thin-walled and each contains a single crystal. These cells surround the bast fibers or bast bundles, and are very abundant in the bark of many trees. In other instances the crystal-bearing cells are believed to serve as a substitute for mechanical tissues, taking the place of sclerenchyma. For example, in the seed of the quince and the ordinary garden bean, particularly in the latter, the sclerenchymatous tissue is replaced by a layer of cells containing large prismatic crystals so constructed and placed as to best resist vertical and lateral pressure. In the case of the acicular crystals of monocotyledonous plants it is quite evident that they give elasticity as well as support against pressure. The crystoliths which occur so abundantly in Ficus leaves perform a purely mechanical function. It is frequently found that cells bearing calcium oxalate take the place of mechanical cells in leaves, which is particularly true about the stomata of the leaves. It is believed to be highly probable that in many plants and plant organs calcium oxalate exists accidentally, but in the majority of instances its function is that of mechanical support, as indicated.

The sensitiveness of higher plants to the action of salts of potash, H. COUPIN (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 25, pp. 1582–1584*).—In a previous paper (E. S. R., 13, p. 620) the author has shown the remarkable sensitiveness of some plants to very small quantities of toxic substances. The present paper reports the sensitiveness of plants to some of the useful salts. Experiments were made with wheat which had been germinated. After unfolding the second leaf the seedlings were placed in solutions containing known quantities of potash salts, and comparisons made with the development of plants in distilled water. The strength of the stronger solution was 1:5,000, and this was decreased in a regular arithmetical progression through a series of 13 cultures. It was found that the plants were sensitive as shown by their growth to various salts of potash as follows: Potassium carbonate, 1:1,000,000; potassium phosphate, 1:25,000,000; potassium sulphate, 1:8,000,000; potassium chlorate, 1:300,000; and potassium nitrate, 1:400,000. These figures show the remarkable sensitiveness of the plants to the action of potash salts.

The etherizing of plants, E. CHARABOT and A. HÉBERT (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 8, pp. 390, 391*).—It is claimed that terpene alcohols are transformed into ethers in the chlorophyll-bearing organs of plants, and that the etherizing is most active when the plant is best adapted for assimilation. The etherization in the plants is produced by direct action of acids on alcohol, and it is favored by the presence of diastase, which exerts a dehydrating action through the medium of the chlorophyll.

Notes for a monograph of the phenomena of plant transpiration, A. BURGERSTEIN (*Verhandl. K. K. Zool. Bot. Gesell. Wien, 51 (1901), Nos. 1, pp. 49–64; 2, pp. 65–106; abs. in Bot. Centbl., 87 (1901), No. 7, pp. 233, 234*).—The methods of investigation are given and descriptions of intercellular and epidermal transpiration; transpiration of leaves and of the palisade parenchyma; the transpiration of halophytes and succulent plants; the influence of light, temperature, moisture, and anæsthetics upon transpiration; transpiration and the phenomena of transpiration exhibited by tropical plants, and other special variations.

Concerning symbiosis between plants and animals, F. Fedde (*Jahresber. Schles. Gesell. Vaterländ. Cultur, 1900, II, pp. 2–15; abs. in Bot. Centbl., 86 (1901), No. 2, p. 61*).—According to the relationship between the symbionts, there are 3 forms of symbiosis—that between animals, between plants, and between plants and animals. From a biological consideration one of the symbionts may be injurious to the other, which is the case in the relation between parasites and host plants. The author discusses various kinds of symbiosis and calls attention to various well-known instances where animals live in this relationship, as well as numerous plants. The symbiosis between plants and animals is said to occur in the case of certain plants requiring for their fertilization certain insects, as in the case of Yucca and Pronuba, and in the case of the mutualism which exists between ants and various plants.

The cell nuclei of Saccharomyces, C. Hoffmeister (*Sitzber. Deut. Naturw. Med. Ver. Böhmen, n. ser., 20 (1900), No. 5, pp. 251–263, pl. 1; abs. in Bot. Centbl., 87 (1901), No. 4, pp. 129, 130*).—In the first part of this work the author gives a short review of the previous investigations and theories relative to the occurrence of nuclei in the Saccharomycetes. New species are described from pure cultures made from various yeasts, and the methods of fixing and staining are given. The author concludes that so far as his investigations go species of Saccharomyces and yeast-like organisms possess nuclei. The nucleus is generally in the center of the cell or may be somewhat displaced, and is in shape more or less that of a flattened sphere.

Investigations on the fall of the leaves of dicotyledons, A. Tison (*Mém. Soc. Linn. Normandie, 20 (1900), No. 1, pp. 121–168*).

An edible fungus, J. C. Arthur (*Indiana Sta. Rpt. 1901, pp. 20, 21, pls. 2*).—An illustrated description is given of the spiny or hedgehog mushroom (*Hydnum erinaceum*).

Plants used by the Indians of Mendocino County, California, V. K. Chesnut (*U. S. Dept. Agr., Division of Botany, Contributions from the U. S. National Herbarium, vol. 7, No. 3, pp. 295–408, pls. 12, figs. 13*).—A report is given of the economic uses of plants by the Indians in Mendocino County, California, based upon investigations made by the author in 1897 and 1898.

Elements of vegetable biology, J. Pavillard (*Elements de biologie végétale. Paris: Société d'ed. Sci., 1901, pp. 589*).

Nitrogen assimilation by living bacterial cells, J. Stoklasa and E. Vitek (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 8, pp. 257–270*).—A review is given of some of the more recent literature regarding the value of Alinit as a fertilizer. The authors maintain that *Bacillus megatherium* is able to assimilate free atmospheric nitrogen when supplied with proper carbohydrates, and report a number of experiments in which it was used to inocculate oats and barley. The results, it is claimed, demonstrate the efficiency of the organism for nitrogen assimilation.

METEOROLOGY.

Monthly Weather Review (*Mo. Weather Rev., 29 (1901), Nos. 10, pp. 447–487, pl. 1, figs. 5, charts 9; 11, pp. 489–533, figs. 2, charts 13; 12, pp. 535–589, figs. 5, charts 10*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts (for the months of October, November, and December, 1901), recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 10, special contribution on The measurement of sunshine and the preliminary examination of Angström's pyrheliometer (illus.), by C. F. Marvin; and notes by the editor on Weather Bureau men as instructors, applied climatology, the barometer as used at sea, what is a storm wave? on barometric oscillations during thunderstorms, and on the brontometer, an instrument designed to facilitate their study (illus.) (by G. J. Symons), colored snow, electrical phenomena—incandescent clouds, and fake forecasts.

No. 11, special contributions on The westward movement of the daily barometric wave (illus.), by O. L. Fassig; The reduction of records of rain gages, by M. S. W. Jefferson and A. J. Henry; The temperature of the soil and the surface of the ground, by D. A. Seeley (see p. 833); and The sun-spot period and the temperature and rainfall of Jamaica (illus.), by M. Hall; and notes by the editor on relative frequency of sun spots, hailstorms on the St. Lawrence, earthquake-proof buildings, signs and weather, the equinoctial storm, the November meteors, ice caves and freezing wells, the temperature of water in wells, periodicity in climate, auroral light, establishment of the Martinique weather service, and second Mexican meteorological congress.

No. 12, special contributions on Evaporation underground, by E. S. Balch; Facilities for systematic study of corresponding weather types (illus.), by F. H. Brandenburg; A proposed classification and index of weather maps as an aid in weather forecasting (illus.), by W. V. Brown; Classified weather types, by E. B. Garriott; An auroral-lunar halo display, by H. H. Ten Broeck; and The physical basis of long-range weather forecasts, by C. Abbe; and notes by the editor on classified weather types, the influence of small lakes on local climate, meteorological observations with kites at sea, climate and crops, the Meteorological Society of Mauritius, early meteorological records, lunar halo and lunar corona, and halo of Hevelius (illus.).

Meteorological chart of the Great Lakes, A. J. Henry and N. B. Conger (*U. S. Dept. Agr., Weather Bureau, Meteorological Chart of the Great Lakes, 1901, No. 2, pp. 32, charts 13*).—This is the usual summary of observations for the season of 1901 on storms, atmospheric precipitation and lake levels, opening and closing of navigation, wrecks and casualties, fog, etc., with a paper on the use of barographs on the Great Lakes.

Meteorological observations at the Michigan Agricultural College for 1900 (*Michigan Sta. Rpt. 1901, pp. 121–145*).—Tabulated daily and monthly summaries of observations during 1900 on temperature, pressure, precipitation, humidity, cloudiness, wind movement, etc. The summary for the year is as follows: Mean temperature, 48.08° F.; humidity, 91 per cent; atmospheric pressure (reduced to 32° F.), 29.099; cloudiness, 46.1 per cent; amount of rain or melted snow, 31.02 in.; snowfall, 47.10 in.; number of thunderstorms, 38.

Meteorology in Prussia (*Rev. Sci.* [*Paris*], *4. ser., 17* (*1902*), *No. 1, p. 26*).—A note on the report for 1900 published by the National Institute of Prussia, giving summaries of observations at 200 meteorological stations, 2,200 rainfall stations, and 1,400 storm-warning stations.

Results of meteorological observations in German Southwest Africa (*Dankelmann's Mitt. Dut. Schutzgebieten, vol. 14; abs. in Meteor. Ztschr.* [*Vienna*], *19* (*1902*), *No. 1, pp. 41–45*).

Report of the Meteorological Council (*Rpt. Meteor. Council* [*Great Britain*], *1901, pp. 162, charts 4*).—An account of the work of the council during the year ended March 31, 1901, in the following lines, ocean meteorology, weather telegraphy and forecasts, climatology, and miscellaneous investigations, is given with statements regarding publications of the council and its library and finances.

Climate of the British Empire, 1900, A. Buchan (*Symons' Mo. Meteor. Mag., 36* (*1901*), *pp. 167, 168*).

Climate and mineral waters of Spain, A. Labat (*Climat et eaux minérales d'Espagne. Paris: J. B. Baillière & Son, 1901, pp. 78*).

The daily barometric wave, H. H. Clayton (*Science, n. ser., 15* (*1902*), *No. 371, p. 232*).—A brief discussion of a recent paper by O. L. Fassig on the westward movement of the daily barometric wave.

The story of the snow crystals, W. A. Bentley (*Harper's Mo. Mag., 104* (*1901*), *No. 619, pp. 111–114; noted in Science, n. ser., 15* (*1902*), *No. 368, p. 111*).—Essentially the same as the article contributed by the author to the *Monthly Weather*

Review (E. S. R., 13, p. 425). Microphotographs of snow crystals formed under different atmospheric conditions are shown and the results of a careful study of the different forms are discussed, it being claimed that "the extent and the character of a storm may be read directly from its crystals."

Hailstorm clouds, C. Kassner (*Meteor. Ztschr.* [*Vienna*], *18* (*1901*), *pp. 526–528*).

On "weather shooting" at Windisch-Feistritz in southern Steiermark, F. Klengel (*Wetter*, *18* (*1901*), *pp. 270–276*).

Hailstorm cannon, L. Dumas (*L'Ing. Agr. Gembloux*, *12* (*1902*), *No. 6*, *pp. 295, 296*).—A brief note on cannonading as a means of preventing hailstorms.

The moon and rainfall, A. B. MacDowall and H. R. Mill (*Symons' Mo. Meteor. Mag.*, *36* (*1901*), *pp. 165–167, 183–184*).

The dry moon and the wet moon, A. K. Bartlett (*Ciel et Terre*, *22* (*1901*), *pp. 433–437*).

Weather and the horns of the moon (*Symons' Mo. Meteor. Mag.*, *36* (*1901*), *pp. 184, 185*).

Influence of the moon on the barometric state of the air, N. Demtchinsky (*Ann. Soc. Météor. France*, *49* (*1901*), *pp. 246–249*).

The influence of rainfall on commerce and politics, H. H. Clayton (*Pop. Sci. Mo.*, *60* (*1901*), *No. 2*, *pp. 158–165*).—Studies on the relation of rainfall to wheat yields and pasturing of sheep in Australia, by Wills, and to sugar production in Barbados and Jamaica, by Rawson and Hall, respectively, are described and data are presented to show that every severe financial panic with its attendant political changes "has been closely associated with a protracted period of deficient rainfall." A plea is made for the more liberal endowment of institutions for the broader scientific study of the atmosphere in its relation to man.

Some economic aspects of the heat and drought of July, 1901, in the United States, R. DeC. Ward (*Bul. Amer. Geogr. Soc.*, *33* (*1901*), *Oct.; noted in Science, n. ser.*, *15* (*1902*), *No. 368*, *p. 111*).

Organization of the weather service of Mexico, E. E. Schulz (*Rev. Cient. Bol. Met.*, *4* (*1901*), *No. 1–2*, *pp. 33–37*).

WATER—SOILS.

The retention of bacteria in ice, H. W. Clark (*Massachusetts State Bd. Health Rpt. 1901*, *pp. 509–524*).—Chemical and bacteriological studies were made with ice gathered in different localities in Massachusetts. The results show that ice contains less of both suspended and dissolved matter than the water from which it is formed. The same is true as regards bacteria, particularly if there is a considerable depth of water under the ice, and the water is quiet during the process of ice formation. "When, in order to thicken ice, the ice already formed on a pond or river is flooded and the entire volume of water over the ice is frozen, bacteria will undoubtedly be retained in this ice." It is stated that when *Bacillus coli* and *B. typhosus* are frozen in the ice they retain their vitality for a number of weeks, the exact limit not having been determined. It is also stated that "if there is a considerable depth of water in portions of a somewhat polluted pond or river, and the ice is formed in these portions in comparatively quiet water, with but little matter in suspension, this ice will probably be entirely satisfactory for domestic use, although considerable drainage may enter the body of water upon which it forms. On the other hand, ice formed in shallow portions of such ponds or rivers, even during still weather, or in any portion if there is a considerable movement of the water by currents or wind while it is forming, may be rendered by these conditions entirely unfit for domestic use."

Ice supplies (*Massachusetts State Bd. Health Rpt. 1901*, *pp. 92–103*).—Statements are made concerning the quality of the ice supplied to different cities and towns in

Massachusetts. The purity of natural ice in relation to its source, and of artificial ice in relation to the process of manufacture followed, is discussed.

A soil study. III, The soil, W. P. Headden (*Colorado Sta. Bul. 65, pp. 56*).—Previous bulletins (parts I and II) contain the results of observations on the effects of the mechanical condition, the alkalis contained in, and the general properties of the soil of a plat on the college farm, upon the crops grown on it. This bulletin reports a continuation of this investigation, but deals exclusively with the chemical and physical study of the soil used in the previous experiments. The soil, which "varies in its character from a loamy soil with a calcareous, clayey subsoil, to a fine alluvium resting upon a stratum of gravel, separated from it by a rather compact clay, but with no proper hardpan," was chosen because "it was considered to be the most strongly alkalized plat to be found on the college farm." Examinations of this and other soils of the eastern slope of the Rocky Mountains and of the plains lying to the east in Colorado are reported, which show that these soils are in general very similar in chemical (mass analysis) and mineralogical composition, the principal variations in the latter respect being in the ratio of the quantities of the minerals present. "The surface soils of this section of Colorado probably owe their mineral constituents to a common source, the schists and granites of the Colorado range." Feldspar (orthoclase) is an almost universal constituent, and according to the sand cultures with oats reported "serves as a source of potash and also of hydrous silicates under ordinary cultural conditions. . . . This fact is of great importance to our western agriculture, especially to the agriculture of the eastern slope of the Rocky Mountains and eastward to the State line, as the irrigable lands are composed largely of granitic materials and consequently contain a more or less considerable quantity of feldspar, whose decomposition yields, slowly it may be, but a continuous supply of this very important compound. . . . The theory of the formation of zeolitic minerals, to serve as conveyors of the potash, etc., from the more stable minerals to the plant, can not very well be appealed to, at least as necessary. My experiments do not show that zeolitic compounds are not formed, but they do show that if they are formed their formation takes place so rapidly that perfectly fresh, but finely pulverized, feldspar becomes an available source of potash in the short period required for the growth of the oat plant. . . .

"The alkali salts in the soils and waters of Colorado are essentially mixtures of the sulphates of lime, magnesia, and soda. . . . Relative to the origin of such quantities of sulphates in these rocks and soils, the possible supply is abundant, for throughout the mountain masses we find sulphids disseminated everywhere, and we have an almost inexhaustible source of sulphuric acid for the formation of alkali in the gypsum which is so abundant in our Jurassic and other formations."

It is shown that by the analyses reported that the composition of the water-soluble portion of the soil studied differs both from that of the incrustations of alkali formed on the surface and from that of the portion in solution in the ground water. "The incrustations are formed by the evaporation of water from the surface of the soil, which, owing to the deportment of the solutions of these salts toward capillary action, and the chemical instability of the hydrated salts themselves, effects their separation from the soil solutions. . . . The predominant soluble salt in the soil is calcium sulphate, that in the alkali which effloresces from this ground is sodium sulphate, with magnesium sulphate second in quantity, while the calcium sulphate is but little greater than the sodium chlorid. . . .

"The formation of these incrustations effects a rough separation of the markedly efflorescent salts, sodium and magnesium sulphates, from the permanent calcium sulphate. Ordinary salt, sodium chlorid, which is present, is also concentrated in the alkali, but not nearly to a like extent, as those already named. The highest figure obtained for the sodium sulphate in any sample of the water-soluble is in the first 2 in. of a soil in which it amounts to 27 per cent. In the alkalis it is practically

54 per cent, or twice as much. The highest percentage of magnesium sulphate in the water-soluble is 24 per cent, found in the first 2 in. of soil, while the average for the 2 samples of alkali is 28 per cent. The decrease of the calcium sulphate from the amount present in the water-soluble to that present in the alkali, is more marked than the increase in the sodium sulphate in the alkali given above. The minimum of the calcium salt found in the water-soluble is 34 per cent, the maximum 67 per cent, while the amounts in these alkalis are 7.5 and 3.3 per cent, respectively. . . .

"The water-soluble in the soil is not identical with ground water solutions, probably due to reactions dependent upon the relative masses, which react upon each other within the soil and during the extraction. The reactions near the surface of the soil are quite different from those more remote. This is indicated by the solutions yielded by samples taken to depths of 2 and 4 in."

The efflorescent alkalis are quite different from the residues left by evaporating bodies of water; such residues seem to be intermediate between those obtained by evaporating ground waters to dryness and the salt brought to the surface by capillarity and separated as efflorescences on the ground."

Other conclusions from the studies reported are as follows:

"The readiness with which the chemical reactions take place and their character, as indicated by the salts present in the ground waters, probably have a direct and important bearing upon the fertility of the soil. The loessial soils of the plains agree with the ordinary prairie soils in the chemical composition of their mass and in the general results of the agricultural analysis, but not in the mechanical analysis.

"The analyses of the whole soil mass and of the different portions of the fine earth suggest important differences between the unchanged rock particles in the soil and the finer portions which have suffered change or are the products of alteration.

"The aggregate amount of soluble salts per acre whose movement is effected by the water falling on or supplied to the surface, or by its evaporation from the surface, is large; we make it 9 tons in one instance. The application of water, irrigation, may carry the soluble salts so deep into the soil that a long time may be reauired for them to come near to the surface again.

"There is in the samples of soil examined both free ammonia and ammoniacal salts, which we interpret as indicating unfavorable biological conditions, which view is materially strengthened by the nitrates in the ground waters.

"There is a significant gain in the total soil nitrogen during the time of the experiment which may have been favored by, but was not dependent upon, the application of manure.

"The nitrates in the first 2 in. of this soil are from 9 times to 200 times as great as in the second 2 in., corroborative of the suggested reduction in certain zones of the soil.

"Air-dried soil samples can be kept for a year or more with ordinary precautions without material change in their nitrogen content.

"The humus in this soil is nearly as abundant as in average Eastern soils, and we were unable to find anything about it markedly different from ordinary humus. It is unlike the humus of arid soils in that it is not so rich in nitrogen as they have been found to be.

"The solutions of the humus carried relatively very large amounts of silicic acid, phosphoric acid, potash, and lime. The precipitated humus did not carry much lime.

"The effect of the cultivation, manuring, etc., for three seasons, may be summed up by stating that the store of plant food in the surface soil, taken to a depth of 10 in., was actually increased. This, however, was the lesser part of the improvement, the greater part lay in the betterment of the general conditions, whose best features can not be shown by chemical analysis or expressed in any formula."

Soil survey around Imperial, Cal., T. H. Means and J. G. Holmes (*U. S. Dept. Agr., Bureau of Soils Circ. 9, pp. 20, figs. 2*).—This is an account of an examination of soil conditions (alkali content and mechanical analysis), usually to a depth of 6 ft., occasionally to a greater depth, over 6 townships in that part of what is known as the Colorado Desert, which is now being irrigated by means of a canal from the Colorado River. The Colorado Desert "is undoubtedly the site of an old inland sea which has long since dried up, leaving a basin, at the bottom of which is the Salton Sink, at a depth of 280 ft. below the present sea level, with a surface heavily incrusted with salts which are mined for domestic purposes. The rim of this basin is composed of soils which have been considerably modified by the occasional overflow of the Colorado River, which runs into this area for a short time every few years."

Five types of soil are described and mapped—namely, dune sand, which covers 27.7 per cent of the area; sand, 1 per cent; sandy loam, 21.9 per cent; loam, 28 per cent; clay, 21.4 per cent. All of these types are "in places excessively alkaline, and even where the surface 6 ft. shows no accumulation, the soil is underlaid by an alkali-bearing clay subsoil." The composition of this alkali is reported to be as follows: Calcium sulphate, 9.91 per cent; magnesium sulphate, 9.02 per cent; sodium sulphate, 0.33 per cent; potassium chlorid, 30.02 per cent; sodium bicarbonate, 9.59 per cent; sodium nitrate, 8.91 per cent, and sodium chlorid 32.22 per cent. The determinations of the alkali at 1 ft. intervals to a depth of 6 ft. in the different borings are reported in detail and the distribution of the alkali in the soil is mapped.

The results of the survey show "that of the 169 square miles surveyed about 51 per cent is either too rough for economical irrigation or contains too high a salt content for any but the most alkali-resistant plants to withstand. The remaining 49 per cent of the area it is believed can be safely cultivated, provided suitable precautions are taken in the use of a proper amount of irrigation water, in the adoption of careful methods of cultivation, and, where necessary, in the installation of underdrainage to carry off the excess of seepage waters and alkali. . . .

"The claims for the fertility of this country are based upon the experience gained from irrigation along the Colorado River below Yuma. An examination of the country reveals the fact that the conditions below Yuma are very different from those in the Imperial area, and the agriculture of the two areas is not comparable. The soils of the bottom lands below Yuma are lighter in texture, more pervious to water, contain less alkali, and are, many of them, well adapted to alfalfa."

Alkali lakes and deposits, W. C. KNIGHT and E. E. SLOSSON (*Wyoming Sta. Bul. 49, pp. 71–123, fig. 1, map 1*).—This bulletin gives a general discussion of the occurrence of alkali deposits in Wyoming, and a special treatise on their chemistry, geology, mineralogy, and origin. As regards the origin of the alkali salts, the conclusion has been reached that "primarily the alkali has been produced by the decomposition of the various rocks containing these elements. These salts appear to have been formed extensively during the Mesozoic and Cenozoic eras, but in place of being stored in deposits were carried down with the sediments. Later through the mountain-making agencies these formations were brought to the surface, and through the influence of decomposition and erosion have been converted into soil. The salts have remained in the soils so formed, since there has not been sufficient water to leach them out. The decomposition of the rocks is still in progress, and from this source and the storage already accumulated in the soils the deposits of alkali have been formed and are being increased."

Eight groups of deposits in the State are described in detail, viz, "Downey, Union Pacific, Rock Creek, Rankin, Bothwell, Morgan, Independence, and Gill. These are all located in the southeastern part of Wyoming, and are confined to Albany, Carbon, and Natrona counties." The chemical composition of only those deposits in which the alkali is of considerable depth and purity, i. e., the so-called "soda lakes," is considered in this bulletin. "The salts found in the soda lakes are the same as those which occur in the soil of the surrounding region and form alkali crusts as they are drawn up from below with the water and left on the surface as this evaporates. Of these salts the most abundant in Wyoming is sodium sulphate." The next in importance is magnesium sulphate. There are also found sodium carbonate and chlorid, as well as other salts in small amounts. A number of original and compiled analyses of samples from the deposits referred to above are reported.

The rise of alkali salts to the soil surface, E. W. HILGARD (*Science, n. ser., 15 (1902), No. 373, pp. 314, 315*).—Accumulations of alkali at and near the surface in California are considered to be largely due to leaky ditches. The difficulty of leaching out alkali is referred to.

The chemical exploration of Belgian soils, A. PETERMANN (*Bul. Agr. [Brussels], 17 (1901), No. 6, pp. 975–1006*).—The results of chemical and physical examination of 15 samples of soil are reported.

Investigations on the physical properties of soils, A. MITSCHERLICH (*Landw. Jahrb., 30 (1901), No. 3, pp. 361–445, charts 4*).—The author briefly describes the principal methods of soil analysis commonly employed in Europe, discussing the physical and chemical properties of soils and other factors of plant growth, and calling attention to the importance of studying the volume and nature of the soil spaces with reference to the water supply rather than the soil particles themselves. In treating the latter subject he distinguishes between the total surface area of the soil, which is defined as the sum of the surface areas of the soil particles, and the surface area of the soil aggregates or *micellæ*. The utilization of the determination of heat evolved when soils are moistened (*Benetzungswärme*) (E. S. R., 10, p. 423) in estimating the volume of space and water capacity, hygroscopicity, capillarity, etc., of soils is explained and tables and curves are given showing the relation between these properties in different kinds of soil, the data being calculated by a formula based on Rodewald's hypothesis.[1] The general physical characteristics, productiveness, and the *Benetzungswärme* of a large number of soils are given, showing a certain relation between the last two properties.

A comparison of the results obtained by different methods of mechanical soil analysis, H. BUCHNER (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 141–148*).—The results of a comparison of the Hilgard, Fadejeff-Williams, Kühn, and Meyer methods on very clayey, medium clayey, and sandy soils are reported. The wide differences in the results obtained indicate that the analyses made by these methods are not comparable.

Silting flask and sieves for the mechanical analysis of soils and clays, A. GAWALOWSKI (*Ztschr. Analyt. Chem., 40 (1901), No. 12, pp. 776–781, figs. 2*).—A simple apparatus for the mechanical analysis of soils, etc., by elutriation, and a device consisting of concentric sieves of different degrees of fineness for the quick separation of the different grades of soil particles are described, with results of a comparison of these pieces of apparatus with the Nöbel apparatus.

The temperature of the soil and the surface of the ground, D. A. SEELEY (*Mo. Weather Rev., 29 (1901), No. 11, pp. 501–503*).—Observations with minimum thermometers are reported which show that the temperature on the bare ground was 2.5° lower in a swale than on a hilltop about 15 ft. above; 4.2° lower in a swale without air drainage than in one having good air drainage; 4° lower in clover 2.5 in. high, and 10° lower in grass 6 in. high than on bare ground, the temperature being apparently more dependent upon the height of the plant and its thickness on the ground than on its kind; and 1.5° lower in dark-colored grass on a lawn than on light colored, and 10° lower than on a hard gravel roadbed near by.

"Temperatures taken on dark colored muck, a lighter colored loam, and a very light clay during an afternoon in summer were, respectively, 110°, 101.5°, and 97°. Readings were also taken early the next morning, and the corresponding temperatures were 61.5°, 60°, and 63.5°.

---

[1] Ztschr. Physikal. Chem., 33 (1900), p. 593.

"Another important difference in temperature was observed to result from cultivation. Temperatures were taken on soil that had been newly cultivated for seeding and upon soil that had not been worked for several days. Thermometers were placed at the surface of the ground, and at 3, 6, and 12 in. below the surface. These were read at 2.30 p. m. and 2.30 a. m. the following day. The readings are given in the table below:

Temperature of cultivated and uncultivated soil.

	Surface.		3 inches.		6 inches.		12 inches.	
	a. m.	p. m.	a. m.	p. m.	a. m.	p. m.	a. m.	p. m.
	°	°	°	°	°	°	°	°
Cultivated soil	63	108	65	72	65	68	64	61
Uncultivated soil	60	102	64	77	64	68	62	60

"The table shows, first, that the newly cultivated soil was 6° warmer at the surface of the ground than the uncultivated; second, that the temperature 3 in. below the surface was 5.5° higher on the uncultivated soil. These facts show that the newly cultivated soil conducts heat much more slowly than the uncultivated, probably because it is less compact. The amount of evaporation from each is probably about the same for a short time after cultivation, hence this can not be considered as a cause of the difference in temperature. When cultivation is carried on continuously, the surface of the soil is warmer, and the first few inches below the surface cooler, than upon the same soil uncultivated; while at a depth of 6 in. the cultivated soil has the same or a higher temperature than the uncultivated. These are all desirable conditions during the growing season. The warmer surface soil hastens the process of growth in the plant and is a protection against frost. The soil just below the surface being cooler, retards capillarity and thereby retains the soil moisture, while the temperature about the roots of the plant 5 or 6 in. below the surface is the same or a little higher than on the uncultivated soil. The plan of cultivating the soil about growing crops during the afternoon of a day when the conditions are favorable for frost at night is often recommended, and the table shows that there is much to be gained by so doing. The temperature at the surface of the cultivated soil was 3° higher than on the uncultivated at 2.30 a. m., hence the danger of frost was materially lessened. The heat absorbed during the day is held near the surface of the ground in the cultivated soil, instead of being conducted to lower depths, and the air becomes more moist from the rapid evaporation at the surface, which is a condition unfavorable for the occurrence of frost."

On a modification in the method of using the electric thermometer for determining underground temperatures at the Museum of Natural History, H. BECQUEREL (*Compt. Rend. Acad. Sci. Paris, 133* (*1901*), *No. 21, pp. 800–803*).

The soil cover of forests and the rôle of earthworms (*Gaea, 37* (*1901*), *pp. 634, 635*).

FERTILIZERS.

Report on fertilization, C. F. ECKART (*Rept. to Hawaiian Sugar Planters' Assn., 1901, Nov., pp. 45*).—This article summarizes the results of determinations at the Hawaiian Sugar Station of total and available (soluble in aspartic acid) fertilizing constituents in Hawaiian soils, and of the amounts of these constituents lost in the drainage waters, taken up by the sugar cane crop, and returned in the cane refuse (E. S. R., 10, p. 525; 11, p. 507). The total and available fertilizing constituents in the soils of the different islands of Hawaii are given as follows:

Total and available fertilizing constituents in Hawaiian soils.

Island.	Lime.		Potash.		Phosphoric acid.		Nitrogen.
	Total.	Available.	Total.	Available.	Total.	Available.	Total.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Oahu	0.380	0.01568	0.342	0.00256	0.207	0.00012	0.176
Kauai	.418	.01367	.309	.00249	.187	.00013	.227
Maui	.395	.01764	.357	.00312	.270	.00012	.388
Hawaii	.185	.00789	.346	.00156	.513	.00014	.540

It is estimated from analyses reported that a crop of cane producing 5 tons of sugar per acre requires 158.7 lbs. of lime, 509.2 lbs. of potash, 74 lbs. of phosphoric acid, and 164.7 lbs. of nitrogen. On this basis it appears that lime is the only ingredient present in the soil in sufficient quantity for the needs of the crop. Potash and phosphoric acid are much too low.

To determine the relative retentive power for fertilizers and water of the so-called "sandy soils," consisting mainly of fine coral particles, four of these soils "varying in their proportions of lime carbonate from 71.25 per cent to 91.07 per cent were placed in iron pipes 2 ft. 6 in. long and 1 in. in diameter, the pipes being filled to within 6 in. of the top. One gram each of amonium sulphate, nitrate of soda, and muriate of potash were dissolved in a liter of water and 500 cc. of this solution holding ½ gm. each of the salts mentioned were poured upon the soils and allowed to drain through. It was found in regard to the nitrate of soda that practically none was retained by any of the soils, while the other compounds were fixed in an inverse proportion to the lime carbonate content of the medium through which they filtered. . . . When the nitrate is lost from the land through the over-saturation of its soil, not only so much nitrogen is lost, but likewise a large amount of lime. . . .

"To observe the action of nitrate on lime, as well as the relative action of different salts in the same particular, tests were made at the experiment station in connection with other lysimeter investigations. Nitrate of soda, chlorid of potash, ammonium sulphate, and sulphate of potash were applied to the rows of cane growing over the lysimeter drains, and 48 hours later these rows were irrigated with 102 gal. of water, of which quantity 33 gal. leached out and was analyzed," with the following results:

Lime in drainage water of soils receiving different salts.

Drain.	Salt applied.	Lime lost.
		Grams.
No. 1	None	1.72
No. 2	Nitrate of soda	26.52
No. 3	Chlorid of potash	23.49
No. 4	Sulphate of ammonia	5.49
No. 5	Sulphate of potash	2.73

In the experiments with sandy soils in tubes referred to above none of the chlorid or sulphate of potassium was lost in the soil containing the least amount of calcium carbonate, while in the soil containing 91.07 per cent of this substance there was a loss of 65 per cent of the chlorid and 28 per cent of the sulphate. "The absorption of potash by these peculiar soils is influenced chiefly by their content of lime carbonate for several reasons. The higher the percentage of lime carbonate the lower must be that of the double silicates in the respective soils. . . . and these silicates are particularly instrumental in holding potash. . . . On account of the basic nature of Hawaiian soils, and their smaller content of double silicates as compared with American soils, as a rule, potassic fertilizers are much more readily disseminated throughout the soil mass by means of rain or irrigation water."

The methods of fertilizing practiced on the different islands is briefly explained, special attention being given to the use of sodium nitrate, which, when applied in large amounts, "has been observed in many instances to induce an abnormal and undesirable growth, which retarded the ripening of the cane, and resulted in juices of low purity and low sugar content. On the other hand, this selfsame stimulating property has been of the greatest service to yellow and 'nitrogen-hungry' cane, and with the application of small amounts of this material wonderful tonic effects have been produced in an extremely short space of time." It has also proved useful as a means of delaying tasseling.

The value of some city wastes as fertilizers (*Maryland Agr. Col. Quart., 1901, No. 14, pp. 2-6*).—The wastes considered are night soil, garbarge, street sweepings, and ashes. The method of utilizing the contents of Baltimore sinks and cesspools for fertilizing purposes is described, and analyses of 4 samples of the material are reported. "The absence of a sewage system in Baltimore renders necessary the use of sinks and cesspools. When these are filled the contents are pumped out into tank wagons and barrels made especially for the purpose. It is then hauled to the wharf and emptied into covered barges holding from 100 to 200 tons. The barges are towed to various points where reservoirs have been built, into which they are emptied by means of a powerful steam pump. The rule is to locate the receiving reservoirs on a bank at such an elevation that they may be emptied by gravity on merely opening a gate, or, at most, by only elevating the material to a trough near the top of the reservoir. The reservoirs are simply excavations in the ground, the removed earth being used to elevate the edges, and clay from the bottom lining the sides. . . . Each patron of the system has his own receiver and uses the contents when convenient. The contents of the reservoirs are drawn off into tank wagons and distributed on the land before the crop is planted. The material is locally called 'soup,' and its application 'souping.' The ease of application and ready response to this fertilizer cause it to be highly esteemed by those who are using it."

The average composition of the samples examined was as follows: Water, 97.32 per cent; phosphoric acid, 0.07 per cent; potash, 0.13 per cent; and nitrogen, 0.44 per cent. Analyses of street sweepings compiled from a bulletin of the Division of Chemistry of this Department are given and briefly discussed, and the fertilizing value of ashes is referred to.

The bacteria occurring in manure and their rôle in its decomposition, S. SEVERIN (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 11, pp. 369-386*).—The author here reports a continuation of previous studies (E. S. R., 10, p. 35) on the rapidity with which certain organisms found in manure set free carbon dioxid and ammonia from a mixture of horse manure and urine (150 gm. fresh excrement, 15 gm. straw, 50 cc. urine, and 50 cc. water). The oxidation of the manure was most rapid in fresh manure in the first stages of decomposition, the process being here due almost entirely to aerobic organisms found in the manure at the beginning of the process. After the first stages of decomposition the aerobic organisms remain more or less inactive and the process is continued by anaerobes, the activity of the latter being promoted by conditions which are unfavorable to the activity of the aerobes, such as the covering of the heap with a fresh layer of manure or the accumulation of carbon dioxid in the manure. The evolution of ammonia was as active during the last half of the period of the experiment as during the first. The total amount evolved during 7 months in the 265 gm. of manure mixture referred to above was 0.0424 gm. The activity of the different organisms in this respect was very variable.

Experiments with precipitated calcium phosphate, II. G. SÖDERBAUM (*K. Landt. Akad. Handl. Tidskr., 40 (1901), No. 2, pp. 109-121*).—The author conducted pot experiments with Probsteier oats under different systems of fertilization, for the purpose of determining the value of precipitated calcic phosphate prepared electrolytically from apatite, as compared with Thomas slag and superphosphate. The phosphate, the method of manufacture of which was invented by the Swedish chemists Wiborgh and Palmaer, forms a pure white light powder without crystalline structure. Chemical analysis showed its composition to be as follows: Hygroscopic moisture, water, fluorin, etc., loss on ignition, carbon dioxid, 12.15 per cent; phosphoric acid, 35.73 per cent; lime, 48.83 per cent; soda, 1.57 per cent; insoluble residue, 1.71 per cent.

By treating 1 gm. of the phosphate with 200 cc. 2 per cent citrate solution at 17.5° C. for 30 minutes in a rotary apparatus and determining the phosphoric-acid content of the clear filtrate, a citrate solubility of 90.96 per cent of the total phosphoric-acid content was found, thus showing a great similarity to bone meal. In a sample of steamed bone meal treated by the same method of analysis 94.76 per cent of the phosphoric acid was soluble in citrate solution. The chemical analysis of the phosphate also shows it to stand near bone meal, as it is essentially a tricalcium orthophosphate.

The pot experiments were conducted with a poor sandy soil of the kind previously used at this station in the experiments with Wiborgh phosphate (E. S. R., 10, p. 32), giving up on treatment with hot hydrochloric acid of 1.15 sp. gr. only 0.044 per cent phosphoric acid, 0.037 per cent potash, and 0.404 per cent lime. In addition to small quantities of finely-powdered marble, sodium chlorid, sulphate of magnesia, sulphate of potash (at the rate of 300 kg. potash per hectare), and nitrate of soda (at the rate of 100 kg. nitrogen per hectare), phosphates were added in three series, in the form of precipitated calcium phosphate, Thomas slag, and superphosphate, at the rate of 100, 150, and 200 kg. of citrate-soluble phosphoric acid per hectare in each case. The yields of oats obtained in these trials compared with those obtained without application of phosphoric acid (this being equal 100) are shown below:

Comparative yields of oats with different phosphates.

	Relative yield of oats with—		
Phosphoric acid applied per hectare.	Precipitated phosphate.	Thomas slag.	Superphosphate.
Kilograms.			
None.	100.0	100.0	100.0
100	111.1	401.7	417.2
150	138.9	411.7	401.7
200	107.2	432.2	417.2

In earlier comparative fertilizer experiments with bone meal and Thomas phosphate, conducted under similar conditions,[1] bone meal gave the following relative yields, when applied at the rate of 100, 150, and 200 kg. per hectare (no phosphoric acid=100): 101, 142, and 172, and Thomas slag, 427, 500, and 542. The new precipitated phosphate is therefore more like bone meal in its action than Thomas slag, and according to our present limited knowledge may be considered of approximately the same value as bone meal.—F. W. WOLL.

Comparative experiments with nitrogenous fertilizers, C. PFLAUMER (*Wchnbl. Landw. Ver. Bayern, 1901, pp. 398, 434, 437, 489; abs. in Centbl. Agr. Chem., 31 (1902), No. 1, pp. 3, 4*).

Refuse molasses solutions as a fertilizer, BARTOS (*Oesterr.-Ungar. Ztschr. Zuckerind. u. Landw., 30 (1901), p. 754*).

Phosphate rock, E. W. PARKER (*Mineral Resources of the United States. Dept. Interior, U. S. Geol. Survey, 1900, pp. 803–814*).—The production of phosphate in the United States during 1900 was 1,491,216 long tons against 1,515,702 tons in 1899, a

[1] K. Landt. Akad. Handl. Tidskr., 1892, p. 302.

decrease of 24,486 tons. "Notwithstanding this decrease in production, the total value of the product increased from $5,084,076 to $5,359,248, a gain of $275,172." There was a marked decrease in production in Florida and South Carolina and a slight increase in Tennessee. "In Florida the decreased production was in the output of hard rock and river pebble, there being an increase of about 44,000 tons in the production of land pebble. This increase in the production of land pebble was not sufficient, however, to overcome the decreases in the other two grades of rock. There has been no production of soft rock reported from Florida since 1897. In South Carolina the production of land rock increased from 223,949 long tons in 1899 to 266,186 long tons in 1900, while the production of river rock fell off 50 per cent—from 132,701 long tons in 1899 to 62,987 long tons in 1900. Tennessee's production increased from 430,192 long tons to 454,491 long tons. No production was reported from North Carolina in 1900, and the output in Pennsylvania decreased from 2,000 tons in 1899 to 900 tons in 1900. Two States, Alabama and Arkansas, each reported a small production of phosphate rock in 1900, the former having an output of 344 tons and the latter an output of 75 tons. These amounts are insignificant, and of interest only as indicating a possibility of further developments."

Gypsum, E. W. PARKER (*Mineral Resources of the United States. Dept. Interior, U. S. Geol. Survey, 1900, pp. 827–833*).—The production of gypsum has increased steadily since 1896. In 1900 it amounted to 594,462 short tons, valued at $1,627,203, as against 486,235 tons worth $1,287,080 in 1899.

The use of commercial fertilizers, P. WAGNER (*Anwendung künstlicher Düngemittel. Berlin: Paul Parey, 1901, 2 ed., pp. 172*).

Analyses of commercial fertilizers, J. HAMILTON and W. FREAR (*Pennsylvania Dept. Agr. Bul. 83, pp. 132*).—A report on fertilizer inspection in the State, including analyses of samples collected from January 1 to August 1, 1901.

Phosphates and fertilizers, E. WILLIS (*News and Courier [Charleston], 1901, Sept. 30, p. 5*).—Statistics of the production, domestic consumption, and export of phosphates and fertilizers for the United States during the year ended August 31, 1901.

FIELD CROPS.

Results obtained in 1901 from trial plats of grain, fodder corn, field roots, and potatoes, W. SAUNDERS (*Canada Cent. Expt. Farm Bul. 39, pp. 56*).—Cooperative variety tests in continuation of those previously reported (E. S. R., 13, p. 34) are recorded. The method of conducting the tests has been uniform throughout the seven years the work has now been in progress. The yields of each crop at the various experimental farms are tabulated. The varieties producing the largest crops in 1901, taking the average results obtained on all the experimental farms, were as follows:

Oats.—Lincoln, Abundance, Improved American, Wide Awake, American Triumph, Danish Island, American Beauty, Banner, Holstein Prolific, Mennonite, Early Maine, and Golden Beauty. Average yield per acre, 82 bu. 3 lbs. *Two-rowed barley.*—Standwell, French Chevalier, Nepean, Beaver, Canadian Thorpe, and Logan. Average yield per acre, 45 bu. 12 lbs. *Six-rowed barley.*—Mansbury, Odessa, Claude, Mansfield, Excelsior, and Royal. Average yield per acre, 50 bu. 30 lbs. *Spring wheat.*—Roumanian, Huron, Goose, Stanley, Hastings, Preston, Hungarian, Clyde, Australian No. 13, Speltz, Countess, and Red Fife. Average yield per acre, 39 bu. 20 lbs. *Peas.*—Gregory, Pride, Paragon, New Potter, Arthur, Nelson, Agnes, Crown, Early Britain, King, Picton, and Victoria. Average yield per acre, 43 bu. 36 lbs. *Indian corn.*—Early Mastodon, Rural, Thoro'bred, White Flint, Selected Leaming, Salzer All Gold, Pride of the North, and Cloud Early Yellow. Average yield per acre, 20 tons 330 lbs. *Turnips.*—Hartley Bronze, Hall Westbury, Imperial Swede, Carter

Elephant, Prize Purple Top, and Sutton Champion. Average yield per acre, 35 tons 365 lbs. *Mangels.*—Half Long Sugar White, Giant Yellow Globe, Giant Yellow Intermediate, Yellow Intermediate, Norbiton Giant, and Mammoth Yellow Intermediate. Average yield per acre, 31 tons 720 lbs. *Carrots.*—Half Long White, New White Intermediate, Giant White Vosges, Ontario Champion, Mammoth White Intermediate, and Improved Short White. Average yield per acre, 25 tons 357 lbs. *Sugar beets.*—Red Top Sugar, Danish Red Top, Improved Imperial, and Royal Giant. Average yield per acre, 25 tons 894 lbs. *Potatoes.*—Sabean Elephant, Burnaby Seedling, Uncle Sam, Late Puritan, I. X. L., Hale Champion, Money Maker, Clay Rose, Dreer Standard, Holborn Abundance, Carman No. 1, and American Giant. Average yield per acre, 496 bu. 1 lb.

The average results of the various crops for the last 4 to 7 years are also reported. The following varieties, taking the average of the results obtained on all the experimental farms, have given the best yields.

Oats.—Banner, American Beauty, Mennonite, Holstein Prolific, Bavarian, Buckbee Illinois, Golden Beauty, Columbus, Golden Giant, Early Golden Prolific, Abundance, and American Triumph. Average yield per acre, 72 bu. 24 lbs. *Two-rowed barley.*—French Chevalier, Beaver, Danish Chevalier, Canadian Thorpe, Nepean, and Newton. Average yield per acre, 43 bu. 27 lbs. *Six-rowed barley.*—Mansbury, Odessa, Trooper, Common, Royal, and Oderbruch. Average yield per acre, 47 bu. 34 lbs. *Spring wheat.*—Preston, Wellman Fife, Monarch, Goose, Huron, Red Fife, White Fife, Hungarian, White Connell, White Russian, Rio Grande, and Pringle Champlain. Average yield per acre, 32 bu. 36 lbs. *Peas.*—Crown, Pride, Carleton, Early Britain, King, New Potter, Paragon, Duke, Perth, Agnes, Archer, and Arthur. Average yield per acre, 34 bu. 41 lbs. *Indian corn.*—Cloud Early Yellow, Red Cob Ensilage, Rural Thoro'bred White Flint, Selected Leaming, Early Butler, and Giant Prolific Ensilage. Average yield per acre, 18 tons 1,655 lbs. *Turnips.*—Purple Top Swede, Perfection Swede, Halewood Bronze Top, Hall Westbury, Hartley Bronze, Bangholm Selected. Average yield per acre, 30 tons 853 lbs. *Mangels.*—Yellow Intermediate, Giant Yellow Intermediate, Gate Post, Selected Mammoth Long Red, Mammoth Yellow Intermediate, and Giant Yellow Half Long. Average yield per acre, 30 tons 1,771 lbs. *Carrots.*—Half Long White, Giant White Vosges, Improved Short White, Mammoth White Intermediate, Iverson Champion, and Green Top White Orthe. Average yield per acre, 20 tons 1,840 lbs. *Sugar beets.*—Danish Red Top, Red Top Sugar, Danish Improved, and Improved Imperial. Average yield per acre, 23 tons 1,075 lbs. *Potatoes.*—Seedling No. 230, Everett, Seedling No. 7, Irish Daisy, American Wonder, American Giant, Late Puritan, Carman No. 1, Carman No. 3, Rose No. 9, Seattle, and Empire State. Average yield per acre, 376 bu. 34 lbs.

In summarizing the results, the author calls attention to the importance of selecting the best and most productive varieties as demonstrated by these tests.

Report of the agriculturist, J. D. TOWAR (*Michigan Sta. Rpt. 1901, pp. 101–109*).—The results of a fertilizer experiment with sugar beets conducted under the supervision of the agriculturist by a private party showed that the use of fertilizers decidedly increased the yields. Nitrogen seemed to be most needed, followed closely by potash. Applications of lime slightly increased the yield. The sugar content of the beets was only 10.7 per cent. A general report is given on growing sugar beets on muck land, but no definite conclusions are drawn. The results obtained on the College farm indicate that wood ashes, barnyard manure, and upland soil are the best applications for the improvement of muck soils. Applications of lime were indifferent in all muck experiments.

Variety tests with wheat are reviewed. All varieties grown were injured by the Hessian fly. Dawson Golden Chaff, Poole, Jones Square Head, Gold Coin, and Early Genesee Giant gave the best results, yielding 32.73, 32.33, 32.25, 30.75, and 30.50

bu. per acre, respectively. Sowing wheat October 1 gave best results as compared with other dates. Of 7 varieties of oats, Big Four yielded 67.70 bu. per acre, the highest yield by weight. By measure the yield amounted to 63.72 bu. Hot-water treatment for the prevention of smut in oats seemed to have been effective.

Fall sowing of winter or sand vetch (*Vicia villosa*) was practiced with success. The vetch sown alone or in a mixture with wheat on light sandy and sandy loam soils gave satisfactory yields. Sand lucern (*Medicago media*) is described and the results of culture tests are reported. A plat of sand lucern was pastured with sheep and the results led to the conclusion that this crop furnishes abundant pasture, and that pasturing is not injurious to the plant. On another plat a total of 12,310 lbs. of cured hay per acre were obtained in four cuttings this season. In 1901 this same plat had yielded 4,265 lbs. of cured hay per acre by June 15. These results were obtained on a light sandy soil.

The experiments undertaken with barley, hops, clover, and sugar beets as well as a test of Alinit are briefly mentioned but no results are reported.

Winter cereals and legumes, A. M. Soule and P. O. Vanatter (*Tennessee Sta. Bul., Vol. XIV, No. 3, pp. 19, figs. 7*).—The results of an experiment in seed selection with winter barley showed an average increase of 10.6 bu. per acre obtained by the use of large grains for seed as compared with small grains. In connection with making the selection of seed it was found that in the material at hand the large heads contained on an average 53.8 grains, the medium heads 33.2, and the small heads 25.5. It required 753 grains from large heads to weigh an ounce, and 876 from small heads. A test of seeding winter barley at different dates resulted in a yield of 30.4 bu. per acre from the seeding of September 17, and of only 8.8 bu. from the seeding made November 15. Intertillage experiments with this crop indicated that sowing in narrow rows without subsequent cultivation is the most satisfactory method.

Winter barley and Fulcaster wheat grown on good soil yielded 71.1 and 44.58 bu. per acre, respectively. On poor soil the respective yields were 27.1 and 37 bu. per acre.

Among a number of varieties of winter oats Culberson was the most productive and also the earliest, ripening fully 2 weeks before any other variety. The highest yield produced by this variety was 73.7 bu. per acre. It is described as a fine, strong, thrifty grower, standing up well and producing a well-filled grain of superior quality. A seeding made October 3 matured earlier and gave better returns than seedings made later. Of 3 varieties of winter rye, Twentieth Century gave the best returns, the total weight of crop being 8,170 lbs. per acre and the yield of grain 42.5 bu. Seeding October 4 gave much better results than seeding October 25. The yields of 3 winter cereals, wheat, barley, and rye, are compared. The rye produced the heaviest total crop, 7,218 lbs. per acre.

Hairy vetch as a winter crop, grown singly, yielded 7.68 tons of green forage, or 1.85 tons of cured hay per acre. When grown with barley the yield of cured hay per acre was 3.28 tons, with wheat 3.72 tons, and with oats 1.60 tons. The experience of the station is that it combines well with oats, wheat, and barley for pasture and hay, and that it is in general of easy cultivation.

The amounts of digestible nutrients per ton of the different kinds of hay are tabulated. The cost of making a ton of hay from the different crops varied from $4.73 with wheat to $10.65 with oats and vetch. The value and expediency of growing winter cereals and legumes for hay making and pasturage is dwelt upon throughout the bulletin.

Soil improvement and forage experiments, R. L. Bennett (*Arkansas Sta. Bul. 68, pp. 51–60, fig. 1*).—Corn and cowpeas were grown on a number of plats, and when the corn was ripe the ears were harvested, and then steers fed on cotton seed were grazed on the remainder of the crop. On corresponding plats a crop of corn was cut and the stover removed from the soil. The following year cotton, corn, and oats were grown on these different plats for the purpose of determining the benefits to the soil resulting from these methods. The plats grazed by the steers produced 626.5 lbs. more seed cotton, 14 bu. more corn, and 1,188 lbs. more oat hay per acre than the rest of the plats. "The profit from the grazing paid the cost of the cowpea seed and of planting them, also the cost of the cotton seed, and a good profit besides. The manure from the cotton seed and cowpeas was therefore furnished free to the soil." In another test cotton grown 2 years in succession after peanuts, chufas, and soy beans grazed by pigs was compared with cotton following a corn crop which was cut and the stover removed. The yields in both years were in favor of the plats which had been grazed.

A comparative test of corn, cowpeas, and Spanish peanuts resulted in yields of 1,863, 3,040, and 4,460 lbs., respectively, of thoroughly dry fodder per acre. The value of these different crops for forage and soil improvement is discussed.

The relative merits for forage purposes of crops with different drought-resisting qualities were studied. Sorghum, Kafir corn, and Indian corn compared in this test yielded 7,012, 5,412, and 2,835 lbs., respectively, of dry fodder per acre. The advantages of the different crops for forage are outlined, and the method of harvesting them by means of corn binders and shredders is described.

Wheat, hairy vetch, Virginia Winter Gray oats, crimson clover, and winter vetch were tested as winter crops for soil covering and early hay. The wheat and crimson clover were cut May 25, and the other crops June 5. Wheat produced the largest yield of hay, 2,340 lbs. per acre, and crimson clover the smallest, yielding only 945 lbs.

A broken and unbroken seed bed for corn and cotton were compared. In one case the crops were simply listed on an unplowed ridge of cowpea stubble, and in the other they were planted with a planter on the same kind of land, but well prepared with the plow and harrow. The well-prepared plats yielded 4.7 bu. more corn and 268.8 lbs. more cotton per acre than the unbroken plats.

Report on certain economic experiments conducted in connection with the botanic station, Antigua, F. Watts and W. N. Sands (*Barbados: Imp. Dept. Agr. West Indies, 1901, pp. 14*).—Variety tests with millet, corn, leguminous crops, including velvet beans, cowpeas, soy beans, sweet potatoes, yams, cassava, tanniers and eddoes, castor beans, sesame, and cotton are briefly reported.

Green crops for winter fodder, P. Quirk (*Agr. Gaz. New South Wales, 12 (1901), No. 7, pp. 784–786*).—Notes on the culture of sorghum, corn, barley and vetches, oats and rape, and millet for green forage for winter feeding.

Substitutes for clover (*Wallaces' Farmer, 26 (1901), No. 40, p. 1138*).—A note on the uses of alfalfa, cowpeas, soy beans, and vetches as substitutes for clover.

Broadcasting and drilling grain, Bachmann (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 38, p. 567*).—A brief report on a comparative test of sowing rye broadcast and in drills. The results were largely in favor of drilling. Hoeing the drilled crop twice during the season gave very profitable returns.

Contributions to the Alinit question, C. Schulze (*Landw. Jahrb., 30 (1901), No. 3, pp. 319–360*).—This article reviews the experiments made with Alinit by different investigators, discusses the growth of Alinit bacteria in nitrogen-free media as shown by various experimenters, and reports the results of laboratory, pot, and field experiments in 1898 and 1899. In discussing the laboratory work, the author briefly describes the apparatus employed and the process of disinfecting the grains used for seed. The effects on the germination of disinfecting the grains of wheat and barley with corrosive sublimate solutions and alcohol are given in a table. The results of the different experiments showed that the application of Alinit in no case had produced an appreciable increase in the yield of the cereals grown in connection with the tests, and that the claims of Stoklasa that the addition to the soil of suitable carbohydrate substances such as xylose and dextrose insure the effectiveness of

Alinit can not be confirmed. Chemical analyses of the solutions and soils which had produced plants subsequent to inoculation with Alinit did not reveal an increased nitrogen fixation or assimilation.

The effect of secondary growth on the chemical composition of chicory roots, E. Carpiaux (*Bul. Inst. Chim. et Bact. Gembloux, 1901, No. 70, pp. 17–21*).—Chicory roots were studied 2 years in succession to determine the effect of secondary growth on the chemical composition of their reserve material. The results of analyses are shown in tables. The figures obtained show that 20.6 per cent of the inulin of the root was used in the production of the second growth. It is stated that levulose resulting from the saccharification of the inulin is formed in the roots in sufficient quantity for the requirements of the plant before growth begins. The quantity of potash used in the growth of the sprouts was greater than of any other mineral element. This fact is considered as evidence that potash is a transporting agent of the carbohydrates in the plant organism.

The albuminoid and nonalbuminoid nitrogenous substances in the root diminished appreciably during the growth of the sprouts. It is further stated that the nitrogenous matters do not undergo an appreciable modification during the growth of the sprouts and that they are transported from the root to the young growth without any transformation of the amid bodies into albumin. The new growth was found to have drawn only slightly on the reserve of phosphoric acid. The lime content of the root increased to an appreciable extent during the activity of the growing portion, and this is explained as due to the lime taken up from the soil by the root for the purpose of neutralizing the organic acids formed during the hydrolysis of the inulin.

Corn culture, R. J. Redding (*Georgia Sta. Bul. 55, pp. 97–118*).—This work is a continuation of previously reported experiments (E. S. R., 13, p. 39). Meteorological data for the years 1890 to 1901 are tabulated. Among 17 varieties of corn tested in 1901, Marlboro, Cocke Prolific, Sanders Improved, Gedding Improved, Bradberry Improved, and Tennessee Yellow, given in the order of their productiveness, yielded from 20.69 to 27.38 bu. of shelled corn per acre. All other varieties yielded less than 20 bu. per acre, Shaw Improved ranking last with a yield of 14.32 bu. The average yield for all varieties was 19.73 bu.

It was observed that the varieties producing the largest ears were not necessarily the most productive. In this test Marlboro, Cocke Prolific, and Sanders were the earliest varieties. In a special test of 4 early varieties, Hickory King gave the highest yield, followed by Weekley Improved, Blount Prolific, and Golden Dent in the order given. The yields for these varieties ranged from 22.74 to 30.46 bu. of shelled corn per acre, with an average of 27.49 bu. Hickory King required the smallest weight of ear corn, 63.8 lbs. to shell a bushel. The difference in the yields obtained in the 2 tests is considered as possibly due to the closer planting of the 4 early varieties. A comparison of several methods of harvesting showed that the greatest value of total product was obtained on the plats where the leaves were harvested August 8, and the stalks cut when dry and shredded. The differences in the yield of shelled corn for the various series of plats was in all cases less than 1 bu.

Applying 672 lbs. of fertilizer per acre broadcast produced only 2.95 bu. more than half this quantity applied in the drill. This increase was produced at a cost of $1.08 per bu. From the results of this and previous tests, the author infers that heavy applications should be applied broadcast in view of probable droughts, and applications of less than 300 or 400 lbs. should be made in the drills.

As in previous years, nitrate of soda, cotton-seed meal, and dried blood were compared as sources of nitrogen. The results this season were in favor of nitrate of soda, but the differences in the yields were inconsiderable. Even in the general average for 4 seasons the dried-blood plats yielded only 0.15 bu. more than the nitrate plats, and these only 0.91 bu. more than the cotton-seed meal plats. "For all practical purposes it may be safely concluded that the corn plant has no preference as to the source of the nitrogen, as between nitrate of soda, cotton-meal and dried blood." Fertilizer formulas for corn on different Georgia soils are given.

Planting corn in the water furrow as compared with planting on the bed did not prove advantageous, due, to a large extent, to a heavy rainfall shortly after planting. Deep planting gave slightly better yields than shallow planting, although the weather conditions were unfavorable to this method. A test of thorough and ordinary soil preparation is reported. Ordinary preparation consisted in plowing under on February 14 a catch crop of rye after cotton to the depth of 6 in., and harrowing the soil; while for thorough preparation the soil was again plowed 10 in. deep and harrowed on March 14. The results showed an increase of only 1.10 bu. per acre in favor of thorough preparation. In a tillage test cultivating thrice in succession every 3 weeks, twice every 2 weeks, and once every week, resulted in yields of 32.65, 31.25, and 32.55 bu. of shelled corn per acre, respectively. From a number of 2-eared stalks both ears were used for seed to determine the influence of position of the ears on the stalks on the progeny. The plats planted with seed from the lower ears produced the larger number of ears, and, therefore, the larger proportion of 2-eared stalks. The yield of these plats was 0.85 bu. per acre greater than the yield of the plats planted with seed from the upper ears.

Effects of renewing the humus in continuous corn culture, W. C. Latta (*Indiana Sta. Rpt. 1901, pp. 22–25*).—An experiment in restoring humus was conducted on soil which had its humus supply reduced by growing corn and entirely removing the crop for 10 successive years. The methods of restoring humus to the soil consisted in (1) passing the corn stover through a feed cutter and returning it to the soil at the time of plowing, (2) applying wheat straw equal in weight to the stover produced, and (3) sowing crimson clover in the fall, to be turned under the following spring. The results obtained on the different plats from 1894 to 1900, inclusive, are given in tables. Taking the yields obtained on the plats during the 3 years preceding these experiments as a base, the stover, wheat straw, and crimson clover increased the production of grain during the last 3 years of this test by 39.78, 18.19, and 17.92 per cent, respectively, as compared with the yields of the check plats.

Corn culture, G. d'Utra (*Bol. Agr. São Paulo, 2. ser., 1901, No. 5, pp. 298–303*).—A report on culture and fertilizer experiments with corn.

Fertilizers for corn, C. Giner (*Abono del maiz. Valencia: La Agricultura Española, 1900, pp. 28*).—A brief treatise on corn culture, with a report on fertilizer experiments.

Cotton and cotton oil, D. A. Tompkins (*Charlotte, N. C.: Author, 1901, pp. 500, figs. 100*).—This work treats of the planting, cultivation, harvesting, and marketing of cotton; the organization, construction, and operation of cotton-seed oil mills, and the uses of cotton seed in cattle feeding and soil fertilization.

Cowpea experiments, C. L. Newman (*Arkansas Sta. Bul. 70, pp. 85–123, figs. 2*).—This bulletin contains a discussion on the value and importance of cowpeas and a report on a number of experiments in their culture.

Fourteen varieties were grown for 2 and 3 years in succession, and their yearly and average yields are given in a table. The average yields for 1899, 1900, and 1901 were 12.58, 22.84, and 29.53 bu. per acre. New Era produced the largest average crop of peas, 39.95 bu. per acre, and Lady the largest average yield of hay, 4,919 lbs. per acre. The proportion between peas and hay varied from 22.4 lbs. to 128.2 lbs. of peas to 100 lbs. of hay in Red Ripper and Old Man, respectively. The proportion of hay to total weight of the dry plant ranged from 36.62 to 76.49 per cent and of peas to the entire pods from 65.6 to 75.6 per cent.

The results of sowing at different rates show that 12½ lbs. of seed per acre gave heavier yields of hay and peas than 18¾ lbs. or more. The author recommends 10 to 20 lbs. of seed per acre for peas and 30 to 60 lbs. for hay, ensilage, pasturage, or green manuring. Heavy seeding gives a greater proportion of hay and light seeding a greater proportion of peas and a heavier total yield. In 1900 and 1901 cowpeas were planted the first week in May, June, July, and August. The results for the May and June plantings were practically the same, and the July plantings gave 5.15 bu. of peas and 448 lbs. of hay per acre less than the plats planted in June. Less than one-half the quantity of hay and less than one-third the yield of peas produced by the early plantings was obtained from the crop planted in August.

A number of experiments were made to test the value of the cowpea for soil improvement. Cowpeas were drilled and broadcasted between the rows of corn at the time of the last cultivation. The best yield of peas and hay was obtained from the drilled seed. The cowpeas had no appreciable effect on the corn crop growing at the time, but the next year's crop was increased by 3.2 bu. per acre. The results of experiments showing the fertilizing effects of plowing under cowpea stubble or cowpea vines upon crops of wheat and oats, and the yield and value of cowpeas and other crops planted after oats were harvested, are republished from former bulletins (E. S. R., 12, p. 1034; 13, p. 545). The value of cowpea culture for eradicating weeds, such as nut grass and Johnson grass, is briefly discussed.

Breeding flax, W. M. Hays (*Farm Students' Rev., 6 (1901), No. 6, pp. 85, 86, fig. 1*).

Hemp (Cannabis sativa), a practical treatise on the culture of hemp for seed and fiber, with a sketch of the history and nature of the hemp plant, S. S. Boyce (*New York: Orange Judd Co., 1900, pp. 112, figs. 13*).

Assimilation in the oat plant as affected by different conditions of soil moisture and fertilization, L. Langer and B. Tollens (*Jour. Landw., 49 (1901), No. 3, pp. 209–229; abs. in Deut. Landw. Presse, 28 (1901), No. 82, pp. 688, 689, figs. 3*).—For the purpose of experiments here reported oats were grown in 36 pots divided into 9 groups of 4 pots each, receiving the elements of plant food in different combinations, with the exception of the check group, which received no fertilizing elements. Nitrogen and phosphoric acid were supplied at the rate of 1 gm. per pot, in the form of nitrate of soda and calcium phosphate, respectively, and potash was given in the form of potassium carbonate, the quantity being 1 gm. calculated as potassium oxid. Lime was furnished in the form of marl, supplying 2.652 gm. of calcium oxid per pot, and magnesia was given as magnesium sulphate in solution, the quantity being 0.5 gm. of the sulphate per pot. In each group the plants from 2 of the pots were harvested when the grain was in the milk stage, and from the remaining 2 when it was fully ripe. As regards plant food, the pots in each group were treated alike. Each pot contained 15.475 gm. of dry soil, having a water-holding capacity of 22.8 per cent. In 2 pots of each group the quantity of water in the soil from April 15 to May 15 was brought down from 59.43 and 47.19 per cent of saturation; from this time until the 5th of June it remained stationary, and then was held at 53.29 per cent until the plants were harvested. The soil in the other 2 pots of each group contained from the 15th to the 26th of April about 59.43 per cent of the quantity of water held at complete saturation, and from this time until harvest, 83.90 per cent. The results are given in tables and discussed.

The increase in the water content of the soil caused an increase in the plant substance, affecting the quantity of grain as well as the quantity of straw and chaff. The percentage of phosphoric acid in the grain, straw, and chaff was increased by an increase in soil moisture, while the percentage of nitrogen was decreased. The quantity of potash in the plants was subject to greater fluctuations than the quantity of phosphoric acid. An application of phosphoric acid alone, when no nitrogen had been given, increased the yield of grain, straw, and chaff in the pots which had received the larger quantity of water. The percentage of potash in these same parts of the plant increased with the moisture supplied to the soil, but only when this element was present in considerable quantity; otherwise the percentage of potash in the plant was lowered. A surplus of lime in the soil in connection with a high-water content increased the production of straw and chaff, but decreased the yield of grain. The percentage of lime in the plant was highest where the quantity of potash in the soil was high, and lowest where it was low. The quantities of nitrogen, potash, and phosphoric acid removed from the soil by the plants were increased by increasing the soil moisture. It was further shown that the amount of soil moisture has a marked influence on the development of the roots, for an increase in soil moisture favored root development, while a decrease retarded it. The percentage of phosphoric acid in the roots seemed to increase with the water content of the soil, but the percentage of nitrogen decreased. Heinrich's conclusions that the lack of plant food is indicated by the roots were confirmed in general by the results of these experiments. The authors also state that the conditions of soil fertility may be determined in some cases as well or even better by the analyses of the oat plants grown than by an analysis of the soil itself. In these experiments, owing to the difference in weight of the plants harvested, the percentage of phosphoric acid was the highest in the plants which had received no phosphoric acid in the fertilizer.

The potato crop, O. M. Morris (*Oklahoma Sta. Bul. 52, pp. 1-14*).—A general discussion on commercial potato growing, including notes on planting, cultivation, harvesting, and storing is given, and the results of experiments in different lines are briefly reported. The yields of 37 varieties tested in 1900 and 1901 are given in a table. The first year Early Six Weeks headed the list with a yield of 213 bu. per acre, and the second year Early Fortune, with a yield of 111 bu.

The results of several experiments at the station confirmed the opinion of practical growers in that region that the land should be plowed in the fall before the potatoes are planted in the spring. It was further observed at the station that potatoes planted March 14 came up as early and matured as early as potatoes planted February 27. Comparisons of yields from cultivated and mulched plats were largely in favor of the mulched plats. Of a number of methods of keeping potatoes, mulching with straw and leaving them in the soil till fall, proved most effective. In tests made of this method the losses due to decay were nearly 5 per cent in one instance and about 15 per cent in another.

Culture of the potato in field experiments at Grignon in 1900, P. P. Dehérain (*Ann. Agron., 27 (1901), No. 2, pp. 90-94*).—In 1900, 3 varieties of potatoes, Richter Imperator, Prof. Maercker, and Peach Blow, were grown after different crops and received different fertilizer applications. Entire tubers and sets were used for seed. The detailed results are shown in a table. Richter Imperator yielded 21,500 kg., Prof. Maercker, 19,300 kg., and Peach Blow, 18,400 kg. of tubers per hectare. The starch content of the tubers of Richter Imperator was 22.6 per cent; of Prof. Maercker, 25.6 per cent; and of Peach Blow, 18.8 per cent, with a total yield of 5,758, 5,438, and 4,902 kg. of starch per hectare, respectively.

Old potatoes made new (*Florida Agr., 28 (1901), No. 37, p. 607*).—Description of a California process of renovating old potatoes so that they have the appearance of new potatoes.

The international ramie congress, Paris, 1900 (*Congrès international de la ramie, Paris, 1900. Paris: Bureaux de la Revue Cultures Coloniales, 1901, pp. 107, figs. 14*).—This publication contains the proceedings of the international ramie congress held in Paris at the Exposition of 1900. The culture, preparation, and utilization of ramie are discussed. The preface to the proceedings is written by M. Cornu, president of the congress.

Rice growing in the Logan district and its preparation for market, F. W. Peek (*Queensland Agr. Jour., 9 (1901), No. 2, pp. 231-238, pls. 4, fig. 1*).—This article is a general discussion on the culture of rice and its preparation for market. The prospects of the rice industry in Queensland are considered.

Rice culture, G. D'UTRA (*Bol. Agr. São Paulo, 2. ser., 1901, No. 5, pp. 281–291*).—A report on culture experiments with several varieties of rice.

The rice industry in Queensland, F. W. PEEK (*Queensland Agr. Jour., 9 (1901), No. 4, pp. 414, 415*).—This article discusses the soil and climatic conditions of Queensland in their relation to rice culture.

Saltbushes, R. W. PEACOCK (*Agr. Gaz. New South Wales, 12 (1901), No. 7, pp. 791–793*).—General notes on the culture of saltbushes, with brief descriptions of several species.

The sugar beet in Indiana, H. A. HUSTON (*Indiana Sta. Rpt. 1901, pp. 89–106*).—This report summarizes the sugar-beet tests in Indiana from 1888 to 1900. The conditions necessary for the success of a beet-sugar factory and the requirements for the profitable culture of the sugar beet are discussed. Meteorological data for different sections of the State are tabulated, and the average sugar content and purity of the samples grown in different countries are given, with brief comments on the results.

Chemical changes in the composition of the sugar beet during the period of ripening, K. ANDRLIK (*Vestnik III Sjezdu Ceske. Prir. Lék Praze, 1901, p. 310; abs. in Chem. Ztg., 25 (1901), No. 70, 256*).—The variations in the sugars and other organic substances and the ash constituents during the ripening period of the sugar beet are shown in tables.

The growth of the German sugar industry from 1850 to 1900, E. O. VON LIPPMANN (*Die Entwickelung der deutschen Zuckerindustrie von 1850 bis 1900. Leipsic: Hesse & Becker, 1900, pp. 341*).—A treatise published on the occasion of the fiftieth anniversary of the German Association for Sugar Industry.

Work of the Hawaiian [Sugar Planters'] Experiment Station, R. E. BLOUIN (*Honolulu: Hawaiian Gazette Co., 1901, pp. 25*).—Fertilizer, culture, and irrigation experiments are reported. Fertilizers were applied in different quantities and various combinations to a rattoon crop of Lahaina and Rose Bamboo varieties of sugar cane. The quantity of nitrogen used varied from 179 to 227 lbs. per acre, and the phosphoric acid from 145 to 194 lbs. The quantity of potash was kept constant at 255 lbs. per acre. One-third of the fertilizer application was applied at each of 3 different times, July 26 and October 10, 1899, and March 29, 1900. The highest average yields of sugar were obtained from the use of nitrogen and potash. The lowest average yield was produced by the unfertilized plats. Similar results were obtained the year before with a crop of plant cane. Taking the results with each variety of cane separately, the Rose Bamboo plant which received nitrogen and phosphoric acid gave the highest yield in weight of cane and amount of sugar. Nitrogen and potash applied together in this case gave next to the lowest yield. With Lahaina cane the nitrogen and potash gave the highest yield, both in weight of cane and sugar. Where these elements were used singly they produced but a small increase, but in combination the results were very pronounced.

Cane trash used as a fertilizer increased the yield of both cane and sugar. A test was also made of planting cane in rows 4, 5, 6, and 8 ft. apart, with the result that the plat with the rows 5 ft. apart produced about 4 tons of sugar more per acre than any other plat, followed by the 4, 6, and 8 ft. rows in the order given. The 5 ft. rows also gave a juice of higher purity than any of the other plats.

Irrigation experiments were carried on with special attention to the time of applying the water and the quantity used. Water was applied at the rate of 1, 2, and 3 in. per week, 2 in. every 2 weeks, and 3 in. every 3 weeks. The results were decidedly in favor of applying 2 in. of water weekly. The application of 2 in. every 2 weeks produced a good yield of cane, but with a markedly low sugar content which brought the yield of sugar below that of other plats receiving the same amount of water. The results indicate that the intervals between irrigation should not be more than one week.

The results of experiments in previous years are compared with this season's results, and the treatment of the rattoon and the plant crops considered separately. It is shown that the amount of water used ranges from 93.5 in. for the crop of 1897–98 to 283.46 in., the maximum amount used for the crop of 1899–1900. In the rattoon crop of this season 75.2 gal. of water were required to produce 1 lb. of sugar. This was the maximum sugar production from a limited supply of water, but it was shown that the use of over 5,500,000 gal. per acre, which represent 101 gal. per pound of sugar produced, was much more profitable.

Distance and fertilizer experiments with sugar cane, J. D. KOBUS (*Meded. Proefstat. Oost Java, 3. ser., 1901, No. 28, pp. 23*).—The experiments here reported were cooperative. The results of the distance experiments showed that on heavy soils rows 3½ ft. apart produced the largest yield and the highest percentage of sugar. Four ft. between rows gave nearly as good results, but 3 or 4½ ft. were distinctly less satisfactory distances. On light soil the influence of distance was less marked but the results were again in favor of 3½ ft. between rows.

The fertilizer tests confirmed previous results in indicating sulphate of ammonia to be the most advantageous source of nitrogen for sugar cane. A test was also made with superphosphate and potash on lands not subject to flooding and hence not supplied with these substances by sediment. The tabulated results show that the use of fertilizers improved the quality of the cane and increased the yield by 40 per cent.—H. M. PIETERS.

Cane-sugar industry of Australia, W. MAXWELL (*Brisbane, 1901, pp. 16*).—This publication is a report upon some factors relating to the cane-sugar industry of the country, and deals mainly with labor and factory problems.

Proceedings of the sugar cane and cassava convention held at Brunswick, Ga., April 9, 1901 (*Atlanta: Foote & Davies Co., 1901, pp. 48*).

Studies on the culture and biology of tobacco, C. J. KONING (*Der Tabak; Studien über seine Kultur und Biologie. Leipsic: W. Engelmann; Amsterdam: J. H. & G. Van Heteran, 1900, pp. 86, figs. 15*).

The production of tobacco in Italy from 1890 to 1899 (*Rappresentazione grafica della produzione del tabacco in Italia, 1890–1899. Rome: Ministry of Finance, pls. 19*).—This is a series of plates illustrating graphically the tobacco production of Italy for the years 1890 to 1899, inclusive.

Wheat culture, I. GIGLIOLI (*Ann. Regia Scuola Superiore Agr. Portici, 2. ser., 1901, No. 2, pp. 159*).—This publication presents the results of culture and fertilizer experiments with wheat on the experiment field of the agricultural school at Portici.

Studies and researches on the wheat grain, and a process of sterilizing and bleaching cereals and their flours, E. FRICHOT (*Études et recherches sur le grain de blé, suivies d'un procédé de stérilisation et de blanchiment des céréales et de leurs farines. Dreux: Author, 1899, pp. 235, figs. 24*).

HORTICULTURE.

Cyclopedia of American horticulture, L. H. BAILEY (*New York: The Macmillan Co., 1900–1902, vol. 1, A–D, pp. XXII + 510, pls. 9, figs. 743; vol. 2, E–M, pp. XIV + 511–1054, pls. 10–19, figs. 744–1453; vol. 3, N–Q, pp. XV + 1055–1486, pls. 20–30, figs. 1454–2059; vol. 4, R–Z, pp. XXX + 1487–2016, pls. 31–50, figs. 2060–2800*).—This cyclopedia, recently completed, presents the status of American horticulture at the close of the nineteenth century. There have been many publications in this country on particular phases of horticulture, and in 1881 Henderson's one-volume cyclopediac work entitled Handbook of Plants and General Horticulture appeared, but the present work is the first and only publication to treat exhaustively of American horticulture in its entirety as it exists to-day. The matter included in the work deals with the culture of fruits, shrubs, flowers, and vegetables; with all plant species known to be in the horticultural trade in North America or that are mentioned prominently in horticultural writings of other countries; with the possibilities of horticulture in the different States, Territories, and provinces; and gives the biographies of men who have contributed most to the horticultural development of North America. All general subjects related to horticulture, like insects, spraying, landscape gardening, manures, soils, etc., are also treated. All the plant species cultivated horticulturally in this country, from Alaska to Florida, are compared, contrasted, and described; and whenever the genera consist of several species they have been classified and keys given. Brief notes are also given on the more important farm crops and such economic plants as cinchona and India rubber. Forage and medicinal plants are noted only incidentally. Special attention has been paid to tropical fruits and vegetables. The word horticulture has been interpreted broadly.

All prominent subjects in the cyclopedia have been written up from different standpoints, usually 2 or more authors contributing who represent different sections of the country and different climatic and cultural conditions. These articles are signed by the authors, thus giving credit and fixing responsibility. More than 450 persons, including the more prominent botanists, horticulturists, and specialists in the country have contributed to the cyclopedia. There are 4,357 separate articles, and 2,255 genera are described, including 8,793 species. The total number of plant names accounted for is 24,434. The articles are fresh. They are written from the standpoint of the growing plants. In general, the broader spirit of the outdoor commercial plant culture, which is the dominating characteristic of American horticulture, has been clearly presented. References to the prominent literature on the different subjects are cited freely. A cut is seen wherever the book is opened; most of these are new.

The cyclopedia marks an epoch in the horticultural literature of this country. The author hopes it may never be revised but be supplemented with annual volumes of the same size pages as the cyclopedia, which will record the progress made each year. These volumes are promised if there is sufficient demand for them. The manuscript for the first 2 is already prepared.

In the making of this cyclopedia the author has had associated with him Dr. Wilhelm Miller, who has had particular charge of indexes, trade lists, bibliographical matter, and the editing of manuscripts.

Gardening for the South, or how to grow fruits and vegetables, W. N. WHITE, revised by P. H. MELL (*Richmond: B. F. Johnson, 1901, pp. 683, pls. 20, figs. 280*).—This is a revised and enlarged edition of this work on Southern gardening, which was first issued in 1856. The second edition was issued in 1868. This makes the third edition. It purports to take into account the changes and development along horticultural lines during the last 30 years, bringing the work up to present ideas and methods. Recommendations of the experiment stations and the results secured in experiment-station work are seen throughout the book. In its revised form it will undoubtedly take a prominent place in the literature of Southern gardening.

Some portions of the work might profitably have been revised more thoroughly. The statements allowed to stand that squashes, melons, cucumbers, and pumpkins readily cross and contaminate each other when planted together, when considered in the light of the crossing experiments made with cucurbits at the New York Cornell, Iowa, and Nebraska experiment stations (E. S. R., 2, p. 509; 4, p. 726; 12, p. 449), need modification. The old exaggerated idea of the value of common salt as a fertilizer for different vegetables and fruits is frequently seen throughout the work, as evidenced by the following statement: "From the analysis of the stones, bark, leaves, and wood, it is evident that common salt is one of the most essential manures to apply to the soil in which the plum is cultivated." In the revision of plums, the valuable work of Waugh and other station investigators with this fruit seems not to have been taken into account.

Gardening for beginners, a handbook to the garden, E. T. Cook (*London: George Newnes Ltd., 1901, pp. VII + 496, pls. 89, figs. 80*).—More than half this elementary garden book is devoted to the description and culture of flowers and shrubs. Different chapters deal with the flowers most suited for different purposes, as the mixed border, annuals, climbing plants, bulbous plants, roses, ferns, rock gardens, etc. The care and management of the small greenhouse and conservatory, and of the flowers and plants that grow in them are considered; methods of fruit growing, including orchard fruits, grapes, and small fruits, are described at some length, and directions given for the culture of all the more common vegetables. Chapters on manures and soils, insects and fungus pests, town gardening, monthly work, etc., are also given. A compact gardening chart of useful information completes the work. The book is profusely illustrated. It is particularly adapted to English gardening, and in America to the use of flower growers.

Report of the horticulturist, L. R. Taft (*Michigan Sta. Rpt. 1901, pp. 110–115*).—This is an outline of the work of the central station and South Haven Substation for the year. The best early crops of tomatoes were secured by pruning to single stems and training to stakes. Oats seeded alone as an orchard-cover crop grew 15 to 18 in. high. They held snow and leaves well during the winter, lessened the freezing and thawing of the soil, and also prevented the soil from freezing to as great a depth as on uncovered soils. The lessening of the injury from frost is considered one of the most vitally important results to be secured with orchard-cover crops. Where oats were used as a cover crop the ground in the spring was practically free from weeds and remained moist considerably longer than where other crops were used. The oats were easily worked in with a disk harrow, and it is estimated that the cost of cultivating the orchard when oats were used was fully one-third less than when crimson clover was sown. Rape and turnips used as cover crops, while fairly satisfactory, were unsightly during the winter and gave off an offensive odor. Crimson clover seeded with oats was less satisfactory than either sown alone. Cankerworms and the tent caterpillar were controlled in the orchard by spraying with Paris green and white arsenic boiled with lime.

Use of commercial fertilizers in vegetable growing, J. Aeby (*Cong. Nat. Agr. Namur, 1901, Sec. 2, pp. 15, pls. 4*).—The results are here given of some cooperative experiments at 10 different horticultural schools and institutions in Belgium in the use of nitrate of soda, superphosphate, and sulphate of potash, for growing 16 of the more common garden vegetables. In each experiment 1 plat was used as a control, 1 received all 3 fertilizers combined, and on 3 plats 1 of the elements of a complete fertilizer was omitted. The plats were duplicated in another series, except that like amounts of barnyard manure were used on each plat in connection with the commercial fertilizers. Each plat occupied an area of 10 meters square. The results secured with the different vegetables are tabulated and the good effects of supplementing barnyard manure with commercial fertilizers shown in a series of illustrations. The best yields were obtained when a complete commercial fertilizer was used with barnyard manure. Where the barnyard manure was used alone, not nearly so good results were obtained, but they were about equal to the yields secured when commercial fertilizers were used alone. Both exceed considerably the yield on the control plat. It is concluded that in order to obtain the largest yield of vegetables chemical fertilizers should be employed simultaneously with barnyard manure.

The service of soils, F. A. Huntley (*Idaho Sta. Bul. 30, pp. 39–51, pl. 1, figs. 3*).—Sugar beets, parsnips, and onions were grown on fertilized and unfertilized soil and the results here recorded were obtained during the third and fourth seasons following the application of barnyard manure on the fertilized plats. The chemical analyses of the soil from the fertilized and unfertilized plats are reported. The results with sugar beets showed but little difference in the richness of the beets in favor of the unfertilized plats. Where parsnips were grown on unmanured soil the growth of the plants almost ceased during the driest part of the season, owing to the cracking of the soil along the line of the row, while on the manured plats well supplied with humus the soil did not crack and the plants continued to grow. Experiments with onions indicated that a well-manured soil, early planting, and good cultivation produce a bulb typical of the variety, while a poor soil and late planting tend to produce bulbs poor in quality and of undesirable forms. Irrigation increased the yield in 2 out of 3 instances over 100 bu. per acre. A general note on tomato culture concludes the bulletin

Some muskmelon experiments, E. Walker (*Arkansas Sta. Bul. 69, pp. 63–80*).—Herewith are reported the detailed experiments and results of transplanting muskmelons, the different methods of manuring the crop, and a test of various cultural methods and of varieties. The results secured along these various lines with muskmelons at other stations are given throughout the work and the methods of growers generally noted, thus making the bulletin quite a complete guide as regards muskmelon culture.

In the transplanting test, 6 seeds were sown April 18 in 5-in. pots and these placed in frames. The plants were thinned from time to time and transplanted to the open field May 13, and 2 plants finally left in each hill. On the same day that the plants were set in the field seed of the same varieties was also sown in hills, thus making the difference between the dates of sowing the seed for transplanting and seeding in the open field 25 days. Three hills of each variety were used for the transplanted melons, 2 of which in each case were manured with a couple of shovelfuls of well-rotted manure, and the third left unmanured. With the field-planted melons, only 2 hills were used for each variety and but one manured.

The transplanted manured melons on the whole averaged 20.82 days earlier than the manured field-planted melons. The transplanted nonmanured melons averaged 8.88 days earlier than the manured field-planted melons. It required 90 days from the time the seed of the transplanted melons was sown until the first fruits on the manured plats were gathered, and 85.6 days from seed sowing to the first gathering of the crop in the case of the field-planted seed, thus showing that transplanting had no hastening but rather a retarding effect on the period of growth of the melons. In every instance with the transplanted plants, manuring increased the earliness of the crop and on the average about 12 days.

In these tests, while the earliness of the crop was hastened, the greatest number of melons per hill and the largest melons were obtained from the field-sown seed. Thus, the unmanured transplanted plants averaged 5.21 melons per hill, weighing 24.11 oz. each, the manured transplanted plants 7.11 melons per hill, weighing 20.88 oz. each; and the field-grown plants 8.43 melons per hill, weighing 31.1 oz. each.

The earliest melons grown were Golden Netted Gem, Rockyford, Emerald Gem, Paul Rose, and Jersey Belle. These vines matured on the average in 82.57 days, whether transplanted or field grown. The first 4 matured fruit by July 11. Emerald Gem and Paul Rose are considered less desirable shipping sorts than the others.

In the fertilizer experiment 37 plants of 8 hills each were used and 34 different varieties grown. Thoroughly mixed well-rotted barnyard manure was used. Two hills in each plat had the manure applied in a circular trench, leaving a worked space of soil in the center of the hill 18 in. across and free from manure. Two had the manure applied on the surface and well worked into the soil. With 2 others a hole spade-deep was dug and manure placed in the bottom to within 4 in. of the surface and covered 4 to 5 in. with soil. Two other hills were left unmanured. The data obtained are summarized in the following table:

Effect of different methods of manuring muskmelons.

Method of manuring.	Time to maturity.	Average number of fruits per hill.	Average weight of fruits.
	Days.		*Ounces.*
Manure in circular trench	95.35	7.92	32.97
Manure well worked into the soil	85.60	8.22	29.63
Manure placed under the hill	89.62	7.27	30.00
Unmanured	103.11	5.33	32.54

The table shows that the earliest melons and the largest number per hill were obtained when the manure was applied to the surface of the ground and well worked into the soil. This method of manuring is also the most feasible for commercial growing, since, instead of hills, continuously manured furrows 8 to 10 ft. apart can be used and the manure thoroughly worked into the soil with a bull-tongue or single-shovel plow passing back and forth. The furrows should finally be thrown into a low, broad ridge with a light plow and thoroughly dragged and harrowed. Melons can be planted on this ridge about 18 in. apart in the row. Placing the manure in circular trenches or underneath the hills is too expensive except for limited areas.

The necessity of warm, light sandy soil for commercial muskmelon growing and the use of vegetable nitrogenous manures are pointed out by the author, and citations given from various writers on muskmelon growing to substantiate these views.

For commercial purposes netted melons are most in demand. The smooth-skinned, green-rind types are considered undesirable for culture in the region of the station on account of their greater liability to sun scald. Productiveness, firmness, high quality, uniformity in size, attractive appearance, and keeping quality are the points necessary to consider in good shipping melons. The following melons are considered best for shipment: Golden Netted Gem, Rockyford, New Jersey Improved Button Strain of Extra Early Jenny Lind, Early Netted Gem. For local market the varieties Early Hackensack, Emerald Gem, Paul Rose, Kinsman Queen, Montreal Green Nutmeg, Bay View, and New Orleans Market are considered preferable.

Additional notes are given on harvesting and shipping melons.

Indoor tomato culture with chemical fertilizers, W. STUART (*Indiana Sta. Rpt. 1901, pp. 26–50, pl. 1*).—A study was made with chemical fertilizers to determine the particular element or elements of plant food necessary to the development of a maximum crop of fruit. The crop was grown in both benches and pots indoors. Subwatering was practiced in both cases and a black loam soil of medium fertility used. The phosphoric fertilizers used were mixed with the soil before setting the plants; other fertilizers were either lightly stirred into the surface soil or applied in solution by the subwatering method. The Stone, Lorillard, and Sutton Best of All varieties were used. The plants were trained to a single stem and the blossoms pollenized by jarring the flowers over a piece of glass $2\frac{1}{2}$ by 5 in., and touching the stigmas to the pollen collected on it or by transferring the pollen by means of a camel's-hair brush to the stigmas.

In the bench experiments the 3 essential fertilizer elements were used alone and combined in 2's and 3's. The average product obtained in 3 years on an area of $3\frac{3}{4}$ by $4\frac{2}{3}$ ft., when no fertilizers were used, was 18 lbs.; when nitrate of soda was used, $21\frac{3}{4}$ lbs.; nitrate of soda and acid phosphate, $27\frac{5}{16}$ lbs.; nitrate of soda, acid phosphate, and muriate of potash, $29\frac{1}{4}$ lbs.; and acid phosphate and muriate of potash, 21 lbs.

In the pot experiments the addition of nitrate of soda increased the yield 16 per cent over the control pot; nitrate of soda and muriate of potash, 35 per cent; nitrate of soda and acid phosphate, 70 per cent; and nitrate of soda, muriate of potash, and acid phosphate, 325 per cent. When raw bone meal was substituted for acid phosphate, the increase over the controls for 2 seasons averaged 345 per cent. When sulphate was substituted for muriate of potash, the yields were slightly decreased. The addition of raw bone meal alone increased the yield over the checks 32 per cent, or was nearly as effective as a combination of nitrate of soda and muriate of potash.

In these experiments the average yield per square foot of bench space with complete fertilizers was 3.4, 3.1, and 3 lbs. for the first, second, and third crops respectively, and 2.6, 2.9, and 3.2 lbs. for the first, second, and third years' crops, respectively, in pots.

In a study of the relation of the percentages of small fruits to the chemical fertilizers applied, it was found that in all instances save one the greatest percentage of small fruits occurred on the control plats, and in general it is stated that the proportion of small fruits decreased according to the completeness of plant food supplied.

The Stone variety proved more desirable in cloudy weather than the Lorillard, owing to its maturing more pollen than the Lorillard. It was used in later experiments in preference to that variety. In a comparison of Stone with Sutton Best of All, the yield on a certain area was 178 fruits, averaging 4 oz. in weight each for the Stone variety, as compared with 238 fruits of but 3 oz. each of Sutton Best of All. The total weight of the product, however, was about the same in both cases. The Stone is a rougher fruit than the Sutton Best of All, and for pot experiments the latter is believed to be the more satisfactory of the two.

In a test of surface *vs.* subwatering there was 6.5 per cent increase in yield of fruit in favor of subwatering.

Forcing dwarf tomatoes under glass, F. W. RANE (*New Hampshire Sta. Bul. 84, pp. 59–68, figs. 2*).—The purpose of this bulletin is to emphasize the value of dwarf varieties of tomatoes for forcing. The methods of growing dwarf tomatoes under glass and the yields obtained with 3 varieties are recorded. Seed was sown in the greenhouse September 27 and the plants transplanted and kept in pots until December 27, when they were set 18 in. apart each way in beds in the forcing house. They were pruned to single stems and trained to stakes. Although dwarf varieties, under this treatment they grew to the height of the house—7 ft. or more. Dwarf tomatoes are shorter jointed and produce fruit clusters much closer together on the stem than the taller growing or standard sorts. They also grow slower and therefore do not reach the glass as quickly, thus prolonging the period of fruit production. Hand pollination was practiced by taking the corolla from the flower as soon as it began to lose its bright yellow color, cutting it along one side, and turning it inside out, thus exposing the pollen, which was readily dusted on the stamens. This method of pollination does away with the necessity of a receptacle to catch the pollen. One blossom was sufficient to pollinate a number of flowers. The size and yield of the fruits obtained with the 3 dwarf varieties used in this test are shown in the table below.

Yield of dwarf tomatoes under glass.

Variety.	Average number fruits per plant.	Average weight fruit per plant.	Average weight of individual fruits.	Weight of fruit to May 1.	Weight of fruit from May 1 to June 15.	Total weight to July 15.
		Pounds.	*Ounces.*	*Lbs. oz.*	*Lbs. oz.*	*Lbs. oz.*
Dwarf Champion	$28\frac{1}{3}$	5.4	3.0	34 9	50 7	98 0
Golden Dwarf Champion	$19\frac{7}{9}$	4.3	3.5	11 7	34 6	80 0
Lacross Seedling	$26\frac{3}{11}$	5.6	3.4	31 4	45 12	124 6

The results secured in this test are compared with results secured in tests with tall-growing or standard tomatoes at the Maine station (E. S. R., 7, p. 863), and the number of fruits per plant and the weight of the product per plant are shown to be about double those secured with the tall-growing or standard varieties. It is noted, however, that the dwarf varieties had $2\frac{1}{4}$ sq. ft. of soil-surface space each, while with the tall-growing sorts the range was from $1\frac{1}{2}$ to 2 sq. ft.

Aleyrodes, or "white flies," were present to some extent during the test, and it is predicted that they might be very destructive if allowed to become well established early in the season.

From these tests the conclusions are drawn that dwarf tomatoes mature fully as early and bear longer than tall-growing or standard sorts, and that where the tall sorts like the Lorillard can be produced profitably the dwarf tomatoes under like conditions will bear more, area for area, and be more profitable.

Variety tests of cabbage, O. M. MORRIS (*Oklahoma Sta. Bul. 52, pp. 15, 16*).—Tabulated data are given for the yields of 35 varieties of cabbage for the 2 seasons of 1890 and 1891, with brief descriptive notes on some of the more important varieties.

Some points on fruit culture, C. B. WALDRON (*North Dakota Sta. Bul. 49, pp. 23, figs. 7*).—Fruit conditions in North Dakota differ from those in the eastern United States in the winters being colder, the growing season shorter, and the rainfall less. These conditions necessitate different cultural methods. Instead of stopping cultivation of the orchard in August to ripen up wood, as is done in the East, it should be continued much longer during the season, in order to retain the moisture in the soil. Mulching the trees in late fall to maintain moisture during the winter has been found to be of the greatest importance. South slopes for orchards, where the sun is hot and the drying process active, must be avoided. It is stated that only one species of plum (*Prunus americana*) can be grown at present with any success in the State. For general cultivation De Soto, Forest Garden, Weaver, Cheney, Wolf, Rolling Stone, and Wyant are recommended. Directions are given for the culture of plums, apples, currants, gooseberries, raspberries, and strawberries. Currants and gooseberries are quite successfully grown. Raspberries require winter protection, and should be bent over in the fall and covered with manure. The strong drying winds of early spring are a serious drawback to the culture of strawberries, and it is thought that these may be successfully cultivated with the protection of windbreaks.

Apple growing in Addison County, F. A. WAUGH and M. B. CUMMINGS (*Vermont Sta. Bul. 90, pp. 31–36, figs. 3*).—A farm-to-farm canvass of the orchardists of Addison County was made, and data secured as to the number of fruit trees, yield of fruit, cultural methods employed, etc. Addison County produces more apples than any other county in the State. The number of bearing trees approximated 26,500. The crop in 1900 was 30,660 bbls. and in 1901 it was 10,870 bbls. Methods of apple culture observed throughout the county were found to be rather slack. Out of 42 representative apple growers whose orchards were personally examined, only 8 practiced any cultivation of the soil. The remainder grew their orchards in grass. Ten out of the 42 growers used some fertilizers on their orchards, but only 2 or 3 in adequate amount. Only 4 sprayed their orchards. Five or 6 orchards were protected in a measure by windbreaks, but the windbreaks were there accidentally and not by design. A very large number of varieties of apples were found to be grown throughout the county.

The authors offer many suggestions regarding improved methods of apple growing. Proper cultivation "consists of plowing the land early in the spring and in following this with a surface cultivation with spring-tooth or cutaway harrow every 10 days till July 1. By that time the wood is done growing and cultivation should be stopped. Then a cover crop of clover, 8 lbs. to the acre, or of peas, 2 bu. to the acre, or of buckwheat, 1 bu. to the acre, should be sown. The cover crop holds its place untouched till the following spring, when it is turned under at the annual plowing."

Annual applications of good barnyard manure at the rate of 20 loads per acre are advised. Where barnyard manure is not available an application of 400 lbs. each of ground bone, acid phosphate and muriate of potash per acre is recommended for full bearing orchards. The varieties Baldwin, Rhode Island Greening, Northern Spy, Ben Davis, and Fameuse are especially recommended for market purposes. Where an orchard is made up of a large number of varieties it is recommended that these should be grafted over with 3 or 4 of the better sorts.

Apple growing on grassy hillsides (*Rural New Yorker, 60 (1901), No. 2702, pp. 753, 754*).—An account is given of the successful culture of apples on hillsides near Syracuse, N. Y. The trees are grown in sod and no cultivation given. With this method of treatment 11-year-old trees were found bearing 15 to 18 bu. of fruit, and apple trees bearing paying crops at 6 years from setting. The first 10 years the trees are mulched with the hay cut between and around the trees; after that the grass is allowed to lie where cut. The trees are headed low, 18 to 24 in. from the ground. No pruning is practiced. The advantages of this method of culture are briefly summed up as follows: Early bearing, easy picking, easy spraying, easy to fumigate if necessary, high color, annual crops on young trees, a short fall for the fruit upon a mulch, almost all windfalls salable as picked apples, less labor and attention.

Plum culture, F. A. Waugh (*Vermont Sta. Bul. 89, pp. 19–28, figs. 5*).—In this bulletin the author has summarized his extensive investigations with plums as applied to the cultural practices, varieties, etc., best suited for Vermont. Practically all portions of the State are suited to plum culture. Strong 1-year-old trees are satisfactory, but 2-year-old trees are generally advised, especially of Domesticas and Damsons. Spring setting is generally recommended, and trees should be set 15 ft. apart each way, with the exception of Burbank, which should have 20 ft. or more. When the trees come from the nursery the loose and broken roots should be cut off, the top pruned to a straight whip, and the whip cut back to a height of 2 or 3 ft. The first year 4 to 6 of the side branches, which come out and are well distributed around the trunk, are preserved, while the remainder are removed. The tips of these branches are cut back late in August or the first of September to stop growth and harden them up. All water sprouts are removed. The second spring the branches should be cut back to a length of 6 to 18 in., the pruning being closest with the weaker trees. From 1 to 3 new branches are allowed to grow on each primary branch. The third year the trees should bear a moderate crop. The orchard should be thoroughly cultivated by plowing the soil between the trees every spring and keeping it thoroughly cultivated until the middle of summer and then sowing to some cover crop or allowing weeds to grow. A moderate amount of barnyard manure should be applied every other year, and wood ashes used on soils deficient in lime. The work of the station has shown that it is absolutely essential, in order to secure good crops of plums, to mix 2 or 3 varieties in the orchard. Most plums are self-sterile to their own pollen, and in order to secure pollination of the blossoms and a set of fruit this mixing of varieties is necessary. Black knot should be cut out of the orchard as soon as it appears. Brown rot or ripe rot of the fruit can be controlled by spraying. For shipment to distant markets the 6-basket carrier is recommended. For market purposes Burbank, Abundance, Red June, Lombard, Bradshaw, and Chabot are recommended for planting in the Champlain and lower Connecticut valleys. For the colder portions of the State Stoddard, Hawkeye, Smith, De Soto, American Eagle, Cheney, and Surprise are recommended.

Prunes and prune culture in Western Europe, with special reference to existing conditions in the Pacific Northwest, E. R. Lake (*U. S. Dept. Agr., Division of Pomology Bul. 10, pp. 23, pls. 10*).—Some 50,000 acres of prune orchards are now under cultivation in the States of Oregon, Idaho, and Washington. About 20 per cent of the trees belong to the Agen (California, Petite, or French) variety, while the remainder are largely Italian prunes.

With a view to ascertaining whether there were any European varieties possessing better qualities than the Italian, and adapted for culture in the Northwest, a study was made of the prune industry of France, Germany, and Austria. The report covers European varieties and methods of culture, evaporating, utilizing, and marketing prunes. The following table, showing the chemical composition of French and Oregon prunes, is appended:

Composition of evaporated prunes grown in France and Oregon.

Variety.	Country.	Number per pound.	Flesh.	Pits.	Moisture.	Ash.	Acid as sulphuric.	Reducing sugar.	Cane sugar.	Total sugar.
			P. ct.	*P. ct.*	*P. ct.*	*P. ct.*		*P. ct.*	*P. ct.*	*P. ct.*
Agen	France	65–70	84.7	15.3	27.92	1.65	0.99	35.73	1.69	37.32
Agen	France	50	87.8	12.2	25.14	1.75	.56	38.25	3.31	41.56
Agen	Oregon	128	78.0	22.0	25.78	2.35	1.51	33.28	1.87	35.15
Italian *a*	Oregon	38	84.8	15.2	27.24	1.95	1.51	32.54	Not determined.

Willamette	Oregon	21	88.3	11.7	25.96	2.06	1.66	34.00	1.18	35.18

a Steamed, and packed hot. *b* Not steamed.

In general, Europeans give much less attention to the culture of their prune trees than is observed on the Pacific coast. The trees are mixed with other fruits and crops, planted along roadsides and in isolated patches. Only in Bohemia do large orchards of 20 acres or more occur. All the prunes in France, Germany, and Austria are grown on plum stock instead of the peach, as is common in the Northwest. St. Julien is the usual stock. The universal European practice is to head plum trees high so that some crop may be grown underneath. The leading plums of France are the Agen and Mirabelle; of Germany, the common German prune, Mirabelle, and Italian; and of Austria, the common German prune. The Italian seems to be grown only to a limited extent in any place.

The Mirabelle type is held in high esteem in France and is believed to be worthy of more attention by Pacific coast growers. With the exception of the Reine-Claude type, which is grown for consumption in both the fresh and conserved state, the Mirabelle is the type receiving most attention by French growers. It is dried and canned and used in preserves, jams, and jellies, and distilled to make plum brandy.

Europeans prefer prunes preserved in jars, cans, or bottles to the evaporated product, and there is a steadily growing demand for pitted prunes, especially of the larger sorts like the Italian. As in America, there is a large quantity of second-grade fruit unfit for drying. Nine-tenths of this low grade fruit is distilled and put upon the market as "Prunelle" or "Quetsche" liquors (plum brandy). This low grade of fruit also enters into jams, jellies, marmalades, and fruit butters, either alone or mixed with other fruits.

The European methods of marketing are described. The plan of having large factories rather than small evaporators is favored by the European dealers. A more uniform grade and better use of the crop can be made at less cost. An objection to the prune product of the Northwest is that it is not uniform in size, quality, or pack. The use of better packages and cleaner methods of handling are advocated. One feature in which European plum growers excel American commercial growers is in the better provisions made for utilizing all the inferior fruit, and the preparation of various secondary products, as noted above.

The fig: Its history, culture, and curing; with a descriptive catalogue of the known varieties of figs, G. Eisen (*U. S. Dept. Agr., Division of Pomology Bul. 9, pp. 317, pls. 15, figs. 93*).—This is an exhaustive account of the fig. The history of this fruit in various Old World countries is traced from the earliest times, and an account given of its introduction and cultural development in America. Methods of fig culture and commerce now observed in Smyrna and Asia Minor, Greece, Northern Africa, Italy, Portugal, Spain, France, England, Southern United States, Mexico, and California are given in detail. Methods of caprification are explained at length; the necessity of this practice with some varieties, especially Smyrna varieties, pointed out, and the life history of *Blastophaga grossorum* explained. Different chapters are devoted to climatic conditions under which figs will thrive, methods of fig propagation, planting the orchard, pruning, irrigation, diseases and insect injuries, drying and curing, packing, shipping fresh figs, and describing figs. All the known varieties of figs, including Smyrna and caprifigs, are catalogued alphabetically and briefly described, synonyms being noted and illustrations given of some varieties. Following this are chapters on the chemical analysis of a large number of fig soils and food analysis of figs, statistics on the production and importation of figs, together with tables of temperature, precipitation, and humidity in the principal fig regions of the world; and household recipes for preparing and using figs. The bulletin closes with a bibliography consisting of 173 references to fig literature.

The fig in Australia (*Queensland Agr. Jour., 9 (1901), No. 4, pp. 405, 406*).—The writer states that a few trees of the Smyrna fig have been planted in Australia, two of which at least have borne fruit. Relative to the caprification of Smyrna figs the article states as follows:

"The blastophaga being so minute, it is impossible for it to carry sufficient pollen into the fig to cause fertilization. Its entrance simply causes decay or premature ripening, such as a grub will do when it has entered a pear or apple, producing decay by its own death. The custom of caprification is fast becoming a thing of the past. According to the investigations of modern science, it is proved to be not only unnecessary but positively injurious to the fig. May not the cause of figs falling off the trees before they reach the stage of maturity be improper kinds, unsuitable localities, and, last but not least, the absence of knowledge of proper and judicious pruning? And the cause of not placing them upon the markets equally as good as those imported is the want of knowledge and experience as to their proper treatment during the process of drying."

Notes on fig drying, C. H. Gorman (*Agr. Gaz. New South Wales, 12 (1901), No. 3, pp. 367–369; abst. in California Fruit Grower, 26 (1901), No. 676, p. 3*).—The experience of the author in drying figs in New South Wales is recorded. The figs are cut from the trees and placed on trays similar to raisin trays as soon as the figs begin to milk and show small white seams. They are dried in the sun and turned every day like raisins. The crop is considered sufficiently dry when the figs have the same appearance in the morning as in the evening. Should they show a swelled appearance in the morning they require further drying. They must not, however, be over dried, as this gives them a cooked and earthy taste which can not be removed and which greatly injures their value. It requires from 5 to 12 days to dry the figs, according to the weather. After the figs are dry they may be dumped in sweat boxes, but it is desirable to pack as soon as possible. Before packing, the figs are dipped in a kettle or tub of boiling water in which has been dissolved coarse rock salt. Sea water may be used if available. About 3 big handfuls of rock salt per gallon is considered enough. Immediately after dipping the figs are thumbed, working the eye of the fig downward and the stalk upward, to give the appearance of Smyrna figs as packed in 1 lb. boxes.

Grafting with summer shoots, K. Fetisch (*Deut. Landw. Presse, 28 (1901), No. 68, pp. 584, 585*).—The author states that the general opinion that grafting is suited only for spring operations and that budding must be practiced in summer instead, needs qualification. In his own experience summer-grafted trees have not only united well, but have produced an especially good growth the following season. Apples and pears are especially suited to summer grafting, but good results have also been obtained with stone fruits, more particularly Mirabelle and Reine-Claude plums. Caution is advised in summer grafting apricots and peaches. These do not succeed well. Summer grafting often enables a better distribution of time than spring grafting, when all farm work is pressing. In summer grafting, the scions should be taken from good healthy wood, preferably the under portion of the summer's growth. Any of the usual methods of grafting may be practiced. As soon as the scion is cut it should be wrapped in moist cloth to prevent the bark from drying out. All the leaves should be removed from the scion as in budding. Usually no more leaves will be put out during the season. August is considered the best time for summer grafting. Earlier grafting is not recommended, since the hot weather of July is apt to seriously injure the young grafts and force new growth, which seldom ripens up before winter sets in, and is almost certain to be destroyed.

Second report on grapes, A. L. QUAINTANCE (*Georgia Sta. Bul. 53, pp. 35–70, pls. 13*).—The earlier report of the station on grapes was largely concerned with the culture and pests of grapes (E. S. R., 7, p. 767). The present bulletin includes the results of tests of 302 varieties, with notes on the specific and varietal parentage of each variety, State of origin, vigor, blooming period, condition of stamens as to whether upright or reflexed, size and compactness of bunch, size of berry, color, susceptibility to black rot, date of ripening, and average yield of fruit per vine in 1900. A succession list of 12 red, 18 black, and 13 white varieties recommended for cultivation in Georgia is given. These varieties are described, their self-fertility or sterility noted, and the effect of ringing on the size, earliness, and quality of the fruit, as determined by experiments, recorded in tabular form.

The succession list of grapes recommended for Georgia is given below:

Succession list of grapes for Georgia.

Variety.	Ripe.	Variety.	Ripe.	Variety.	Ripe.
RED.		BLACK.		WHITE.	
		Early Ohio	July 4		
Presly	July 8	Janesville	July 8		
		Moore Early	July 12		
		Hartford	July 16		
Brighton	July 18	Ives	July 20	Winchell	July 20
Delaware	July 24	Cambridge	July 28	Bell	July 22
Brilliant	July 26	Concord	Aug. 1	Annie M	July 24
Agawam	Aug. 2	Beacon	Aug. 2	Moore Diamond	July 25
Rochester	Aug. 7	Liney	Aug. 9	Grein Extra Early	July 28
Venango	Aug. 9	Norton Virginia	Aug. 11	Rommel	July 29
Lindherbe	Aug. 10	Carman	Aug. 12	Niagara	July 30
Catawba	Aug. 14	W. B. Munson	Aug. 15	Lightfoot	Aug. 4
Goethe	Aug. 14	Perry	Aug. 15	Guinevra	Aug. 6
Diana	Aug. 15	Herbemont	Aug. 18	Gold Coin	Aug. 7
		Thomas	Aug. 20	Triumph	Aug. 12
Roanoke Red	Aug. 25	Eden	Aug. 25	Pocklington	Aug. 25
		Neva Munson	Aug. 29	Scuppernong	Aug. 27
		Flowers	Sept. 1		

Of the varieties above recorded, the best for market purposes are Presly, Delaware, Agawam, and Catawba, of the red varieties; Early Ohio, Moore Early, Ives, Concord, Carman, and Neva Munson, of the blacks; and Bell, Moore Diamond, Rommel, Niagara, Triumph, and Pocklington, of the white varieties. For red wine, Norton, Virginia, Lenoir, Clinton, Concord, Ives, and Thomas are recommended; and for white wines, Missouri Riesling, Catawba, Delaware, Elvira, Herbemont, Noah, and Scuppernong. In the station tests the varieties Maxatawney, Whitehall, and Salem were found completely self-sterile, and Goethe was practically so, and hence these varieties should never be planted alone.

One of the 2 canes of each of the varieties in the above table was ringed 3 or 4 joints distant from its base, thus leaving 3 or 4 shoots to support that part of the vine the fruit of which was removed. The ripening period of Diana, Lindherbe, Neva Munson, and Rommel were not hastened at all by ringing; the other varieties matured from 1 to 18 days earlier. With 16 varieties the size of the berry was not increased by ringing, while with 21 others the size was increased from 5 to 40 per cent, averaging 18 per cent. The quality of fruit does not appear to have been injured in a single instance by ringing.

Rubber planting in the West Indies, J. H. HART (*West Indian Bul., 2 (1901), No. 2, pp. 100–113, figs. 6*).—This article discusses the subject of rubber culture in the West Indies, the best kind of rubber trees to grow, cost of establishing a plantation, the best methods of planting the trees, harvesting and marketing the product, etc. Some trees of *Castilloa elastica*, planted in the Royal Botanic Gardens of Trinidad 25 or 30 years ago, are reported as having a height of 75 ft. with a girth of 6 ft. 3 ft. from the ground. A tree planted in 1888 now measures 40 ft. in height and 55 in. in girth. These trees produce quantities of good seed from April to June. The best 5 trees of a group planted in 1898 now average 18 ft. in height and 12 in. in girth. One of the largest trees in the garden was tested by tapping. It yielded 2.14 lbs. of rubber fluids and 0.69 lb. or 32 per cent of clean rubber. The rubber produced was of excellent quality. The fluid taken from young trees gave 25 per cent of rubber; this was hard and brittle and of a very inferior quality.

The bleeding of Castilloa trees by light wounds is reported to be tedious and expensive, and is believed to be economically performed only on large trees when planted closely together. In order to make the cultivation of this rubber tree profitable, the author believes that it will be necessary to grow it on large areas by itself.

Para rubber trees (*Hevea brasiliensis*) also grow well at the botanic gardens. Trees planted in 1898 averaged in 1901 6½ in. in girth 3½ ft. from the ground, and most of them were over 18 ft. high. One of the largest trees in the garden has a girth of over 5 ft. and is 50 ft. high. It is supposed to have been planted over 25 years ago. The rubber made of this species is of excellent quality and it appears to keep better than any other kind and may be taken from the trees at less expense than from the Central American rubber trees. Several trees of *Hevea confusa* have been planted at the gardens, but the rubber of the young trees is of poor quality. Ceāra rubber (*Manihot glaziovii*) seems suitable only for dry hillsides or mountain lands. In its later stages it grows slowly and seems to produce but little rubber. Another species growing in the garden which promises well is the West African, Iré, or Lagos silk rubber tree (*Funtumia elastica*). The trees planted in 1898 are now 13½ ft. high and average 7 in. in girth. Even now these trees bleed freely and the rubber made from the fluids obtained is of good quality, approaching Para in value. The species grows well either in the shade or in the sun. It has not been sufficiently long under observation to warrant conclusions regarding it.

A number of other rubber plants are mentioned which will also grow in the West Indies, but the Central American rubber tree appears to be the one best suited for general cultivation. Para, it is thought, while taking longer to grow may prove more profitable in the end than Central American trees. Thick, close planting, to secure straight stems, is advised. The cost of planting has varied between $30 and $40 per acre. Relative to yield, the author states as follows:

"Our trials show that at least half a pound of dry rubber can be taken at one time from a single tree of Castilloa, without affecting the seed-bearing powers of the tree. Trees of *Hevea brasiliensis*, still more carefully treated, and operated on within easy reach of the hand when standing on the ground, have given a gross weight of 2.26 lbs. of rubber, the major portion of which, weighing 15.8 oz., is of excellent quality."

Further notes on the growth of rubber trees, particularly *Castilloa elastica*, are given in an appendix by M. Short, together with a general discussion of the subject.

Rubber culture in Nicaragua, G. WALDRON (*U. S. Consular Rpts., 67 (1901), No. 254, pp. 431–433*).—The methods of growing rubber trees in Nicaragua and the cost of growing are briefly noted and suggestions given to intending rubber planters. Rubber in Nicaragua is grown entirely without shade. Trees are set from 6 to 20 ft. apart, but opinions seems to be fixing on 10 ft. as the best distance for a permanent plantation. In clearing a plantation for rubber, the primeval forest is felled during March and April. When the whole has become dry enough, it is fired and everything burned but the trunks and larger branches. No attempt is made at logging or clearing away the remains of the forest; neither is the land plowed nor cultivated any way except by repeatedly cutting down the weeds and vegetation, so as to allow the foliage of the young rubber to be completely exposed to the sun. Many trees grown from seed planted in June, 1898, measured in August, 1900, 17½ in in circumference. A few of these same trees measured in July, 1901, showed an increased diameter of from 1 to 2½ in. It is believed that trees carefully grown and cared for will be large enough to bleed safely and profitably at 5 years of age. It is calculated that the cost of a large plantation for the first 5 years is about 50 cts. per tree, taking into account land, administration, labor, buildings, and equipment. Owing to excessive bleeding of rubber trees in Nicaragua since 1855, but few good native trees can now be found. The author states that sane and modest rubber planting enterprises in Nicaragua promise well.

The artificial cultivation of the rubber tree for industrial purposes, E. Brown (*Sci. Amer., 85 (1901), No. 19, p. 293, figs. 2*).—Methods of rubber culture observed by a San Francisco company operating in Mexico are outlined. In planting, only the underbrush is cleared away, the larger trees being left to afford shade, which is considered essential to the growing rubber trees. The nursery trees are set out 14 ft. apart, or 200 to the acre. The young trees are grown from native seed. The planting season lasts from May to January. The temperature of the region seldom rises above 93° or falls below 60°. The rainfall is from 100 to 150 in. annually.

Mexican rubber plant, F. de François (*Agr. Prat. Pays Chauds, 1 (1901), No. 1, pp. 105–109, figs 2*).—A technical description of *Parthenium argentatum*, known in Mexico as "Guayule."

Ornamentals for South Dakota, N. E. Hansen (*South Dakota Sta. Bul. 72, pp. 97–206, pls. 26*).—Following some introductory remarks on reasons for planting ornamentals, the financial aspect of the problem, and right methods of ornamental gardening is an extensive list of deciduous ornamental trees, shrubs, and evergreens that have been grown at the station. A list is also given of native species of plants worthy of cultivation, with notes on the outdoor flower garden and plants best suited to it in South Dakota, followed by a list of trees, shrubs, and hedge plants best suited to South Dakota conditions.

The replanting of bulbs that have once flowered, W. T. Thiselton-Dyer (*Gard. Chron., 3. ser., 30 (1901), No. 759, p. 22*).—The author states that at Kew the bulbs are lifted while still green to make room for bedding plants and "heeled in" in beds of ashes. This allows the foliage to slowly ripen off. The nutriment contained in the leaves is gradually transformed to the bulbs. The process is considered complete when the leaves have dried up to the consistency of thin paper. The bulbs are then lifted again, cleaned, and placed on shelves in a dry and airy shed, where they remain until they are planted in the autumn.

A new tender Nymphæa, H. S. Conrad (*Amer. Gard., 22 (1901), No. 358, p. 745*).—A description is given of a new hybrid water-lily obtained by crossing *Nymphæa cærulea* with *N. zanzibariensis*.

Directions for the culture of saffron (*Crocus sativus*) (*Bol. Agr. y Granadería, 1 (1901), No. 13, pp. 28, 29*).—Soils, preparation, cultivation, harvesting, etc., are considered.

Report on the culture of roses in the Balkan Mountains, J. Gravereaux (*Bul. Min. Agr. [France], 20 (1901), No. 3, pp. 585–593*).—The author visited Austria and Turkey, and made a collection of the wild roses of these countries, more particularly in the Balkan region. A horticultural and industrial study was also made of perfume roses and of the production of rose essence in Bulgaria. An account and outline is given of this work. The manufacture of rose essence in Bulgaria is carried on by the peasants in a crude manner, and it is believed that the industry can be profitably extended in France and her colonies under more scientific methods. It is proposed to undertake experimental work along this line.

Different methods of making rose cuttings, VIVIAND-MOREL (*Rev. Hort.*, *73* (*1901*), *Nos. 15, pp. 357–360; 17, pp. 413, 414; 18, pp. 435, 436; 19, pp. 459, 460*).—The various methods of propagating roses by means of cuttings are described from a practical standpoint.

The sweet pea and its failings (*Amer. Florist*, *17* (*1901*), *No. 691, pp. 161, 162*).—The opinions of several prominent sweet-pea growers and seedsmen are given as to the cause of the failures in recent years in growing sweet peas, especially in Massachusetts. W. T. Hutchins is of the opinion that the failure is due largely to loss in the vigor of the seed, and that before success can be obtained a new race of peas must be bred up which will be more hardy and vigorous than those now in cultivation. W. Atlee Burpee & Co. have tested the sweet-pea seed from France, England, Germany, Oregon, California, and northern New York, and have been able to detect absolutely no difference in the growth of vines from these seeds of widely different origin, and are of the opinion that the trouble is due to some blight disease. Peter Henderson & Co. have had similar results with seed from different localities, and attribute the failure to local conditions, complaints coming from some sections and not from others. R. & J. Farquhar & Co., of Boston, are of the opinion that the blight can be prevented by injecting bisulphate of carbon at the roots whenever the first sign of the blight appears. The method of use suggested is to bore a few holes around the roots of each plant, drop in the bisulphate, and cover up the hole again so that the fumes permeate all through the soil.

Intensive horticulture in California, C. H. SHINN (*Land of Sunshine*, *14* (*1901*), *Nos. 2, pp. 96–110, pls. 6, figs. 6; 3, pp. 182–189, pl. 1, figs. 4; 4, pp. 276–289, pls. 6, figs. 4*).—A biographical sketch of Luther Burbank, noting in some detail many of the more important fruit, flower, and vegetable creations originated by him by hybridization and selection; and of Carl Purdy, the California specialist on the culture and botany of Pacific Coast bulbs. This article is also reprinted as a separate.

FORESTRY.

A planter's notes on trees and shrubs, E. A. POPENOE (*Industrialist*, *28* (*1901*), *No. 5, pp. 60–62*).—Notes are given on the behavior of trees and shrubs drawn from nearly 20 years' experience in planting, chiefly on the trial grounds of the Kansas Agricultural College and Experiment Station. Among the trees the tulip tree or poplar is said to have proved fairly satisfactory, while other trees of the same family, among them several magnolias, have been unable to withstand the climatic and other conditions. Notes are given on the coralberry, moonseed, Akebia, and various barberries, all of which are more or less adapted to the conditions existing in the region covered by this report.

The use of nitrate of soda in sylviculture (*Bul. Soc. Cent. Forst. Belg.*, *8* (*1901*), *No. 3, pp. 144–149, figs. 8*).—The use of nitrate of soda in seed beds for growing seedlings of a number of forest trees is strongly recommended. In the case of black pine, ash, maples, birch, hornbeam, and ailanthus, seedlings grown with and without nitrate of soda were compared. Those receiving nitrate at the rate of 200 to 300 kg. per hectare were decidedly in better condition of growth than those not receiving the fertilizer.

The succession of cuttings for deciduous high forests, PILZ (*Allg. Forst u. Jagd Ztg.*, *67* (*1901*), *Oct., pp. 341–348*).—Discusses the relative value of different periods of cuttings upon the maximum production of oak and beech forests.

The reconstitution of forests in Ardennes, J. Pollet (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 8, pp. 461–474*).—The author accounts for the deforestation of parts of the country and offers suggestions for its reforestation. It is recommended that plantings should be made of beech as an undergrowth for Scotch pine, beech plantings for coppice, and the planting of beech and spruce in mixtures.

The disappearance of beech in the forest of Cambre, C. Bommer (*Bul. Soc. Cent. Forst. Belg., 8 (1901), Nos. 4, pp. 181–189; 5, pp. 247–255, figs. 4*).—In accounting for the disappearance of beech from the forest in question, the author believes that this tree is not adapted to grow under the system of forestry pursued, which is that of high forest and coppice. The beech seems to be especially liable to disease, which also accounts for the destruction of many trees. Among the enemies to which it is particularly subject, mention is made of *Nectria ditissima* and an insect (*Cryptococcus fagi*). The old trees are also subject to other fungi such as *Phycomyces nitens, Armillaria mellea*, etc.

The Picardy poplar, N. I. Crahay (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 6, pp. 342–347, pl. 1*).—A description is given of what is called the Picardy poplar, a variety of white poplar (*Populus alba*). The tree is of rapid growth and adapted to various situations. The wood is said to be of better quality than that of ordinary forms of poplar.

Fire lines and their use in the pine forests of Germany and Gascony, P. Buffault (*Rev. Eaux et Forêts, 40 (1901), No. 22, pp. 673–683*).—An account is given of the methods pursued in Germany and Gascony in the construction and care of fire lines in pine forests. Different kinds of fire lines are described, a common form being from 40 to 60 meters wide, which is planted in vineyards, cultivated crops, or some deciduous tree. For trees to plant in such regions the pedunculate oak, locust, ailanthus, ash, and maples are recommended.

On the use of white pine, du Pré de St. Maur (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 3, pp. 155–162*).—The author gives a discussion of the white pine (*Pinus strobus*) as a forest tree for different situations in Europe. A number of plantations are described and the rate of growth indicated. The distribution of white pine in the United States and Canada is indicated and notes given upon the utilization of its timber.

Suggestions for increasing the value of nonagricultural lands in Belgium, J. Huberty (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 6, pp. 322–331*).—The author suggests, for the utilization of the nonagricultural lands of Belgium, that they be planted to Austrian pine. From estimates based on plantations which are already in existence, it is believed that these lands will pay an income amounting to between 6 and 7 per cent annually upon the investment.

Experiments in wood preservation, W. von Knieriem (*Balt. Wchnschr. Landw., 38 (1900), p. 475; abs. in Centbl. Agr. Chem., 30 (1901), No. 7, pp. 486–488*).—Experiments are reported in which the relative efficiency of a number of substances was tested for preserving wood. In the winter of 1892 spruce blocks 46 by 13 by 14 cc. were cut, and on August 27 to 30 were submitted to treatment with various tar products. The products used were carbolin oil, creosote oil, creosote tar, carbolineum, and copper sulphate. After treatment the blocks were dried, and on October 8, 1893, were placed in sand and covered with earth. After $3\frac{1}{2}$ years they were taken up and examined, at which time it was found that the blocks treated with the first 4 preparations were still sound, the fifth showed s me decay, and a control block treated in a similar way was beginning to show considerable rot. The blocks were again buried for a year and a half, when they were taken up and reexamined. The one treated with carbolineum was the soundest, followed by those treated with creosote oil, carbolin oil, and creosote tar, in the order named. The block which had been treated with copper sulphate was badly decayed, and the one which had not been given any treatment was almost entirely destroyed.

The wood pulp industry of Canada (*Bul. Soc. Cent. Forst. Belg., 8* (*1901*), *No. 5, pp. 292–305*).—A description is given of the wood pulp industry of Canada, and the forest resources of that country are compared with other regions. Each province of Canada, with the exception of Manitoba and the Northwest Territories, produces great quantities of spruce timber which is particularly adapted to the production of wood pulp. The increase in the use and production of wood pulp for the last 10 years is shown, and the possibilities of Canada for supplying this material are pointed out.

SEEDS—WEEDS.

A report on cooperative seed testing, F. NOBBE (*Landw. Vers. Stat., 56* (*1901*), *No. 2–3, pp. 177–185*).—A report is given on the fifth cooperative experiment in testing red clover, sainfoin, perennial rye grass, meadow fescue, and beet seed. The seeds used in this experiment were from single lots which were thoroughly mixed and then distributed to the 30 stations in the seed control union of Germany. The different kinds of seeds were to be tested at the different stations under identical conditions as to temperature, moisture, light, etc. Reports were received from about half of the stations, which show wide variation between the maximum and minimum percentages obtained by the several observers. In the case of the clover seed there was a variation of 2.27 per cent in purity and 7.61 per cent intrinsic value. The variation of sainfoin seed reported was 1.62 per cent in purity and 21.15 per cent in intrinsic value. The perennial rye grass gave a maximum and minimum range of 3.63 per cent purity and 14.40 per cent intrinsic worth. Meadow foxtail gave 19.99 per cent as a range of purity determination and 12.38 per cent intrinsic value. The beet seed samples showed a variation of 3.43 per cent purity and 11.5 per cent in actual value. While there appears to be a wide range in these figures, except in the purity of the meadow foxtail and the intrinsic value of the sainfoin, the figures fall within the limits allowed by the regulations of the seed control union. In the results of tests of soft grass and blue grass seed departures from the normal, while large, fall within the limit of 8 per cent, which is allowed by the seed control regulations.

Report of the Göteborg and Bohus Seed Control Station for the year ended June 30, 1901, J. E. ALÉN (*Red. Göteborgs och Bohus läns frökontrollanst., 1900–1901. Göteborg, 1902, pp. 12*).—A report is given on the seed investigations conducted at the station during the year 1900–1901. In all, 356 lots of seed were inspected and the analytical data are given in detail. A schedule of charges for seed investigation is appended to the report.

Studies in weeds, W. CARRUTHERS (*Jour. Roy. Agr. Soc. England, 62* (*1901*), *pp. 249–256, figs. 8*).—Brief notes are given on a number of more or less troublesome weeds, among them *Ononis arvensis*, *Ægopodium podagraria*, *Carduus acaulis*, dog camomile, ragwort, etc. Notes are also given on the relative value of different brome grasses and bent grasses for forage and pasture.

The horse nettle and buffalo bur, J. C. ARTHUR (*Indiana Sta. Rpt. 1901, pp. 9–19, pls. 3, fig. 1, map 1*).—A description is given of the horse nettle (*Solanum carolinense*) and the buffalo bur (*S. rostratum*). The relationship of these weeds is pointed out and the distribution throughout the State is indicated. One or both species have been reported from about one-third the counties of the State. Suggestions are given for their eradication, and attention is called to the fact that the horse nettle being perennial, particular care will have to be given to prevent the multiplication of the individual plants. This weed may be eradicated by continued growing of hoed crops or by some thickly growing crop which will smother it out. The buffalo bur is an annual plant and for its extermination only requires that it be kept from seeding, which can be done by cutting or pulling plants during the early part of the season.

Destruction of prickly pear (*Queensland Agr. Jour., 9 (1901), No. 5, pp. 460–462*).—An experiment is reported in which an attempt was made to clear 145 acres of land infested with a dense growth of prickly pear. The plants were cut down and afterwards sprayed with a number of solutions, the best results being obtained where sodium arsenite was used at the rate of 5 to 8 oz. per gallon of water. Ordinarily the cutting of this plant does not destroy it, but 3 or 4 days after spraying the green succulent stems had wilted and turned brown and were drying up. Not only were the so-called leaves destroyed but the spray penetrated the stumps to the ends of the roots, causing them to rot. The application of this herbicide, while very destructive to the cactus, had no effect on the grass, and in a comparatively short time the area was covered with an excellent stand of pasture grasses. The other materials experimented with were iron sulphate, hydrochloric acid, coal tar, creosote oil, ammonium sulphocyanid, calcium sulphid, and solutions of copper sulphate, sodium nitrate, and potassium chlorate. None of these gave results at all comparable to those secured by the use of sodium arsenite.

DISEASES OF PLANTS.

An attempt to secure immunity of plants to fungus diseases, J. Beauverie (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 2, pp. 107–110*).—An account of experiments with *Botrytis cinerea* is reported, in which a form of the fungus was sought which would secure various plants immunity from attacks by the fungus. This fungus, which is said to be very common in greenhouse soils, exists in 3 forms. The ordinary form exists as a saprophyte developing upon decomposing plants. This form is the well-known normal conidial stage of the fungus. The parasitic form of the fungus is said to be completely sterile, and a third form between the two, which appears to be a sort of a transition stage, is also recognized. The author claims that by sowing sterilized soil with the spores from the conidial stage of the fungus and allowing them to grow for some time, it is possible to produce a growth of the fungus in the soil which will not interfere with the growth of seeds or cuttings, and especially with cuttings of begonia, which is ordinarily quite subject to attack by the sterile form of the fungus. In this way he claims to have secured immunity from attack. By extending this method of culture to the soils of greenhouses the author says it will be found possible to secure immunity from the very common and sometimes destructive occurrence of the sterile form of the fungus.

Cultures and attenuated forms of fungi which cause diseases of plants, J. Ray (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 5, pp. 307–309*).—A summary is given of recent investigations relative to attenuated cultures of fungus parasites of plants, with studies of rusts and smuts of cereals and other plants. The author claims to have been successful in obtaining pure attenuated cultures of the smuts of wheat and oats, and rusts of eglantine and *Euonymus europæus*. By using these artificial cultures it is believed possible that immunity to disease caused by them may be secured.

A bacterial disease of the tomato, F. W. T. Hunger (*Meded. 'S Lands Plantentuin, 1901, No. 48, pp. 57, pls. 2*).—The tomato disease caused by *Bacillus solanacearum* (E. S. R., 8, p. 895) is reported as prevalent at and about the botanic gardens at Buitenzorg, Java. The diagnosis of the disease is given for the parts of the plants above as well as for those below ground. The author describes the germ and its behavior on different culture media, and records a number of experiments with pure cultures to determine the method of infection. In connection with the diseased conditions produced by the germ, the normal anatomy of *Lycopersicum esculentum* is described. Under the discussion of species of Solanaceæ susceptible to this disease, the writer expresses the belief that the slime disease of tobacco is caused by the same germ as that which causes the tomato disease, and that this disease also occurs in *Capsicum annum*, although neither of these cases has been confirmed by inoculation.

A series of experiments to determine the manner in which *Bacillus solanacearum* finds entrance resulted in the conclusion that uninjured tomato plants can not be infected, and that when the bacteria do gain an entrance by way of the water pores, they get no farther than the air spaces immediately below the water pores. The germ gains entrance most commonly by means of injuries to the roots caused by the attacks of parasites or by careless planting. For this reason the author considers the bacillus to be a secondary rather than the primary cause of the tomato disease. A wound of some kind is believed to be in every case the primary cause. This may be caused by (1) careless planting, (2) climatological influences, (3) chemical and physical condition of the soil, and (4) attacks of parasites. In the last class are included all attacks by fungi, insects, and nematodes. Infection most commonly follows the attacks of nematodes. As preventive measures, greater care in planting and the destruction of the Heterodera are urged. Since the latter is, however, almost impossible, it is suggested that the tomato be grafted on a solanaceous stock that is resistant to the attacks of Heterodera.—H. M. PIETERS.

A bacterial disease of potatoes, G. DELACROIX (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 9, pp. 417–419*).—Attention is called to a bacterial disease of the potato which has been observed in central and western France, being more or less widely distributed through 13 departments. The disease, which is described, is believed to be that caused by *Bacillus solanacearum*, an account of which was given in U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 12 (E. S. R., 8, p. 895). This disease is said to be quite distinct from that described by the author under the name gangrene, which is said to be caused by *Bacillus caulivoris*. As suggested methods of treatment the author recommends the rotation of crops in which potatoes or allied plants shall not occupy the soil for a number of years.

A bacterial disease of beets, M. C. POTTER (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 8, pp. 282–288; 9–10, pp. 353–362, figs. 6*).—This article has been previously noted from another source (E. S. R., 13, p. 467).

The finger-and-toe disease of turnips (*Trop. Agr., 20 (1900–1901), p. 258*).—The occurrence of the finger-and-toe disease, or club root, of turnips is mentioned and the writer states that its ravages seem to be increased by the use of superphosphate manures or upon soils subject to short rotations. In his experience, land which had been sown to grass for 8 or 9 years, and afterwards cultivated in turnips, grew a crop without any diseased roots. Where the fields had been in grass for but 3 years the turnip crop was practically ruined, showing that the fungus remains in the soil for a longer time than 3 years.

Observations on root rot (Dongkellanziekte), J. D. KOBUS (*Meded. Proefstat. Oost Java, 3. ser., 1901, No. 25, pp. 11*).—Formerly many diseases were known by this name, but since 1897 the use of the name has been confined to a single well-characterized disease. At the East Java station it has been proved that the trouble is not due to differences in the chemical composition of the soil, and that the disease is not inherited. The method of working the soil is, however, of importance. Shallow planting or planting in loose soil tends to increase the disease, while a heavy application of nitrogenous fertilizer delays or prevents its appearance. Irrigation after the west monsoon has likewise been found helpful in overcoming the disease. The mud deposited from the irrigating water appears to exert a beneficial effect, but the reason for this is not understood since the amount deposited is too small to have any appreciable influence either on the fertility or on the mechanical structure of the soil. One of the most promising fields of work is the development of resistant varieties. Some varieties are already known to be nearly or quite free from the root rot, but these are poor in sugar content.—H. M. PIETERS.

Apple scab, G. P. Clinton (*Illinois Sta. Bul. 67, pp. 109–156, pls. 4, figs. 34*).—In a previous bulletin of the station (E. S. R., 11, p. 258) an account was given of investigations for the prevention of apple scab. The present bulletin records the results of botanical studies made during the years 1898 to 1900. The author has demonstrated the relationship between the parasitic form which causes the well-known apple scab and the saprophytic fungus found upon the decaying leaves. As a result of his investigations the author is led to believe that the saprophytic form is the one in which the fungus is carried through the winter. The Fusicladium or parasitic stage is described at some length, with the results of experiments in the germination of the spores and experiments with artificial cultures. The Venturia or saprophytic stage is also described at length. After the scab-infected leaves fall from the trees in the autumn they lose their green color and the mycelium contained in them undergoes slow changes. The rounded cells enlarge and gradually assume a reddish olive color and give rise to similarly colored mycelium filaments that penetrate into the interior of the leaf. In this way the Venturia stage is produced from the mycelium of the scab stage. The Venturia stage was found most abundant in the spring of the year, when the apple scab was the worst. In an especially severe winter the cold apparently destroyed many of the perithecia, as few of them were found to come to maturity. The perithecia show on the leaves as small black pustules, generally scattered about on grayish spots, which mark the place of the fall scab colony. When mature they are more or less loosely embedded in the leaf tissues, and at the time of their disappearance infected leaves often show numerous small holes where they have been embedded. The microscopical appearance of the fungus and germination of its spores are described and the results of artificial cultures, in which the 2 forms are connected, are given. In this way the author has established the identity between the 2 forms, and it is claimed that the name given to the fungus should be derived from the mature form, and this should be *Venturia inæqualis*. Moreover, should the fungus occurring on the pear prove different from that upon the apple, the specific name of the apple-scab fungus would then be *V. pomi*. An extended bibliography of apple-scab literature completes the bulletin.

On the power of some peach trees to resist the disease called yellows, E. W. Morse (*Bul. Bussey Inst., 3 (1901), I, pp. 12*).—A brief résumé is given of the various factors which have been hitherto attributed as causes of the disease known as peach yellows, and an account given which seems to show the varying susceptibility of varieties to serious injury from this cause. According to the author a seedling variety known as the White Magdalene has been grown for 150 years without showing any tendency towards disease. The author believes that the principal causes of peach yellows will be found in the atmospheric influences rendering plants more susceptible to disease, while the active agent he believes to be enzyms which may be carried from one plant to another by pollen when the plant is fertilized, and which only manifests itself after a number of years' development.

Silver-leaf in peaches (*Gard. Chron., 3. ser., 30 (1901), Nos. 769, p. 220; 770, pp. 247, 248*).—This disease of peaches, nectarines, etc., has been known in England for at least a quarter of a century. The leaves retain their normal form and are neither spotted nor blistered, but are deprived of a large portion of their chlorophyll, assuming a silvery appearance, and the whole tree becomes sickly and unproductive. No spots or pustules of any kind are detected on the leaves, nor has any fungus been found in any of the tissues, but at the same time the disease seems to be communicable. It is believed that this disease is closely allied to that known as the peach yellows in this country, and is possibly a modification of it. In a subsequent communication an account is given of this disease occurring on nectarine trees. The writer states that the disease appeared on one branch of the tree from which all the affected leaves were removed and a heavy application of liquid manure, to which half an ounce of iron sulphate per gallon was added, given to the roots of the tree. The following winter the usual dressing of air-slaked lime was given the soil about the trees. The next season the trees seemed to be affected to a greater extent than the previous year but the treatment was repeated with the result that the third year no indication of disease was observed.

The injury of fungicides to peach foliage, S. M. BAIN (*Science, n. ser., 14 (1901), No. 345, pp. 221, 222*).—The author has been conducting investigations for a number of seasons on the injury produced by fungicides to peach foliage, and a preliminary report of his observations is here given. It was found that pure copper hydroxid, copper oxid, or metallic copper placed on leaves is injurious to the foliage of the peach, but without visible injury to that of the apple or the grape. A solution of copper sulphate 0.00005 normal proved fatal to water cultures of the apple, while grapes and peaches under like conditions were not seriously injured. Peach foliage protected from rain and dew, as in a greenhouse, sustains no external visible injury from spraying with Bordeaux mixture or copper hydroxid. Under normal orchard conditions, leaves sprayed with Bordeaux mixture in situations so as to be partially protected from rain or dew are the last to show injurious action of the copper salts. The presence of deliquescent salts, such as calcium nitrate and calcium chlorid, appears to accelerate the injurious action of copper hydrate on the foliage of the peach. When grown in saturated atmosphere, peach seedlings were not injured by Bordeaux mixture, and only slightly by pure copper hydrate. Peach leaves growing in such an atmosphere possess a thinner, more easily permeable cuticle than those growing in dry or less moist atmospheres. The presence of a certain excess of lime accompanying the copper hydrate retards or possibly may entirely prevent the injurious action of the fungicide. This is true of lime applied either as hydrate or as a carbonate. The author is led to believe that the results obtained will serve to explain some of the conflicting testimony of different investigators regarding the effect of Bordeaux mixture upon peach foliage. A practical application of the results obtained is suggested in the recommendation that spraying with Bordeaux mixture be followed with one or more sprayings of milk of lime, thus preventing injury which would otherwise occur. Experiments inaugurated by the author during the present season have thus far showed this method of treatment to be successful; whether it will remain so to the end of the season is yet to be determined.

Investigations on the mulberry dwarf troubles, U. SUZUKI (*Bul. Col. Agr. Imp. Univ. Tokyo, 4 (1901), No. 4, pp. 267–288*).—In a previous publication (E. S. R., 13, p. 61) the author described the disease of mulberry, which is said to be the cause of very extensive injury. He has continued his investigations which are reported at some length, the effect of oxidizing enzyms, influence of cutting upon the decay of roots, and the quantity of reserve starch as affecting the disease being reported upon. His former views on the primary causes of the disease are confirmed and it has been shown experimentally that the poor development and ultimate decay of the roots is caused by cutting back the plants during the growing season. The small rootlets which have just begun developing lose their activity and decay, and new ones are not developed for 2 or 3 months after the cutting. The new shoots appearing depend upon the reserve materials of the roots until that time, and a deficiency of reserve material is not only a result of the disease but is considered the principal cause of its further development. There was observed an abnormal increase of oxidase and peroxidase in the diseased leaves, and at the same time the migration of starch and nitrogenous compounds was greatly retarded. It is believed that the oxidizing enzyms present exert an inhibiting action upon the diastatic and proteolytic enzyms, and thus become one of the principal causes in the retardation of growth in the diseased plants. A second cause has been lately found to be an insufficient development of the transportation tissues. These phenomena are analogous to those causing variegation or albinism in plants. The production of oxidizing enzyms in such abnormal quantity is believed to be due, to some extent at least, to the partial starvation of the cells. As the cutting of the mulberry plants in the growing season causes deficiency in the nutriment for the newly developing shoots, this seems to afford a strong support for the above assumption.

The appearance of white rot of grapes in Algeria, J. D. CATTA and A. MAIGE (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 10, pp. 444, 445*).—The occurrence in Algeria of white rot, caused by *Charrinia diplodiella*, is reported. It seems to be more severe in its attack on some varieties of grapes than others, causing the destruction of two-thirds of the crop of Aramon and Alicante, and about one-third of the crop of Carignan. For its prevention the authors recommend the thorough use of Bordeaux mixture.

Black rot and mildew, G. CAZEAUX-CAZALET (*Rev. Vit., 16 (1901), Nos. 408, pp. 393–397; 409, pp. 419–424; 410, pp. 452–458, figs. 4*).—The results of observations on the period of invasion of black rot and mildew are given. The time of appearance of these diseases in a number of localities in France have been under investigation for a number of years, and with some allowance for climatic conditions the first invasion may be noted upon the vines about the first of May; the second, about the middle of May; the third, the first of June; the fourth, about June 25; and the fifth, about July 20 to 25. The appearance of these attacks is preceded by infection about 2 weeks previous, and in treating the disease by spraying or use of sulphur advantage should be taken of these rather definite periods.

The treatment of vineyards for the prevention of mildew, N. PASSERINI and P. FANTECHI (*Abs. in. Ann. Agron., 27 (1901), No. 6, p. 294*).—On account of the high price of copper salts, the authors have investigated means for protecting grapevines against the downy mildew. A number of fungicides were experimented with and the conclusions show that a 1 per cent solution of Bordeaux mixture is efficient in preventing the attacks of the mildew. For the first treatment, when the leaves are small and tender, it may be reduced to 0.5 per cent with good results. In connection with the above experiments the authors found that spraying with a 2 per cent soap mixture containing lime was efficient in destroying insects of the genera Cochylis and Eudemis.

Table grapes and fungicides, E. CHUARD (*Chron. Agr. Canton Vaud, 14 (1901), No. 18, pp. 445–447*).—In reply to numerous correspondents, the author states that the use of properly prepared fungicides upon table grapes need not be followed with any serious consequences. During the present year, on account of a severe attack of mildew, it was necessary to spray the grapes later than usual. Examination of a large number showed that while slight traces were present upon the outside of the grape, the author failed to find any trace of copper in the pulp. The very small quantity that is found on the skin of the grape is not sufficient to be a source of any danger. In wine made from sprayed grapes in which fermentation has been completed, the copper is said to be in an insoluble and innocuous state.

A means for the prevention of shelling of grapes, H. DAUTHENAY (*Rev. Hort., 73 (1901), No. 17, p. 402*).—The author describes a disease of grapes in which the fruit falls from the cluster, similar to the disease known in this country as shelling or rattles. For the prevention of this disease he recommends the pinching or cutting off of the shoots after the development of 6 to 8 leaves where grapes are borne, or 12 to 15 on those shoots not carrying any grapes. In this way the material elaborated by the vine is carried to the grape clusters instead of being utilized for greater growth of shoots. This method has been employed a number of times with complete success.

A tea eelworm disease in South India, C. A. BARBER (*Dept. Land Records and Agr., Madras, Vol. II, Bul. 45, pp. 227–234, pls. 3*).—A nematode disease of tea plants was first called to the author's attention as occurring on a single estate in Madras. The plants were badly attacked by the nematode *Heterodera radicicola*, and the disease has proved a very destructive one for tea seedlings. So far the attack appears to be confined to nurseries, and the disease is believed to be of recent origin. In addition to the tea seedlings, a number of weeds and other plants were attacked, and it is believed that the nematodes have been upon the plantation for a long period, being established on other plants, but only recently have found the young tea plants as suitable hosts.

A contribution to the knowledge of slimeflux of trees and some of its causes, W. Holtz (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 4, pp. 113–128; 5–6, pp. 179–189; 7, pp. 229–238; 8, pp. 274–281; 9–10, pp. 338–350, pls. 2, figs. 6*).—The author gives results of studies made upon *Oidium ludwigii*, and a number of bacteria and other fungi associated with it which are considered the cause of slimeflux on oak, maple, birch, aspen, and other trees.

The slimeflux of trees, F. Ludwig (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 9–10, pp. 350–352*).—A report is given upon observations made during the years 1899 and 1900 upon various forms of slimeflux observed by the author. The brown flux is reported as having been observed upon apple trees in various parts of Germany; upon aspen, chestnut, elm, and birch trees in parks; and upon beech and white fir in forests. The author is led to believe from correspondence that this same disease occurs in a number of parts of the United States and other parts of Europe. The white slimeflux of oaks was commonly observed upon oak trees, and there seemed to be some relationship between the phenological conditions of its appearance and that of the first flowering of elder and rye. Observations covering 15 years seem to indicate that the slimeflux and flowering of these plants occur at about the same time. Another form to which the name musk flux is given has been observed as white or reddish masses upon linden or maple trees. It is believed to be due to a fusarium form of *Nectria aquæductum*.

ENTOMOLOGY.

Proceedings of the thirteenth annual meeting of the Association of Economic Entomologists (*U. S. Dept. Agr., Division of Entomology Bul. 31, n. ser., pp. 103, pls. 2, figs. 4*).—At this meeting, held in Denver, Colo., August 23 and 24, 1901, the following papers were read:

Life history studies on the codling moth, C. P. Gillette (pp. 5–20).—The author made a careful study of the life history of this insect with special reference to the determination of the number of broods per year. In Colorado it is found that the time occupied by the codling moth for a complete cycle in the summer averages about 7 weeks. In early spring the insect was always found in a larval condition. The larvæ begin to pupate just before the apple blossoms open. The length of the pupal state of the first brood varied from 13 to 68 days. Notes are given on the numbers of larvæ taken by different people under bands of apple trees previous to time of blooming. It was found that a small percentage of larvæ seek a place for pupation in the spring after having passed through the winter in a larval condition. At Ft. Collins the earliest moths were captured April 26, and moths continued to appear in breeding cages until July 24. The moths lived but a few days. The earliest time at which eggs were observed was June 9, and by July 21 it was almost impossible to find unhatched eggs. The time between the emergence of the moth and the laying of the eggs averaged 6.7 days and the number of eggs laid by each moth varied from 2 to 50, nearly all of which hatched. The incubation period of the eggs was found to be from 6 to 8 days. The earliest date at which larvæ of the summer brood were observed was June 28, and the earliest date for the appearance of larvæ of the second brood was August 3. The first brood reached its maximum on July 25 and the second on September 12. Of 414 larvæ taken under bands 353 came to the bands during the night and the remainder during the day. The duration of the larval period varied from 12 to 24 days. Of 526 wormy apples, 424 were found to have worm holes at the blossom end, while 84 had holes at the side and 18 at the stem end. The earliest date for the appearance of a moth of the second brood was July 13 and the latest date September 16. The first eggs of the second brood were observed July 24 and they were most abundant on August 12. The time between the broods according to these observations is about 54 days. The author concludes that the codling moth is definitely two-brooded throughout Colorado and that there is no reason for assuming the existence of a partial third brood.

Jarring for the curculio on an extensive scale in Georgia, with a list of the insects caught, W. M. Scott and W. M. Fiske (pp. 24–35).—The curculio is reported as causing great annual damage to peaches and plums in Georgia, 25 per cent of the crop being destroyed. The adult beetles are also instrumental in disseminating brown rot fungus. Jarring experiments were conducted in a large orchard containing 200,000 peach trees and 50,000 plum trees. These trees were all jarred several times between April 18 and June 1, some of the trees being jarred 6 days per week. The jarring was done from 3 a. m. until 9 a. m. and from 2 p. m. until dark. The best results were obtained in the morning. The beetles were caught on rectangular frames covered with canvas. The total cost of the work for the season was $1,000. Of the 325 species of insects which were thus caught, a list of which is given, over 67 per cent were curculios, the total number of curculios being 137,000. The amount of curculio damage on the jarred trees was 4 per cent, while in an adjacent orchard of 130,000 trees where no jarring was done, the damage was 40 per cent.

A simple form of accessions catalogue, E. D. Ball (pp. 37–39).—According to the scheme proposed by the author an accession catalogue is recommended containing one entry for each trip or special collection, this entry being in the form of a date giving the year, month, and day. Every specimen as it is labelled bears the place of capture and the date on a single small label. The advantage of the system lies chiefly in the great saving of time.

A preliminary report on the San José scale in Japan, C. L. Marlatt (pp. 41–47).—Evidence is presented supporting the conclusion that the San José scale is not native to Japan but was introduced from America. A related species, *Diaspis pentagona*, is native to Japan and is prayed upon by a beetle, *Chilocorus similis*, which also feeds to some extent on the San José scale. The latter species is attacked by a fungus disease and by one or two parasitic insects.

Further notes on crude petroleum and other insecticides, E. P. Felt (pp. 49–51).—Trees were not injured by spraying with 20 or 25 per cent mixtures of oil. Experiments with a 10 and 15 per cent mixture of crude petroleum in combination with a mixture of whale-oil soap containing 1 lb. to 4 gals. showed that no injury was done to the trees and the San José scale was thoroughly checked. Spraying with whale-oil soap solutions gave good results, but it was not quite so effective as crude oil.

Notes on some Colorado insects, C. P. Gillette (pp. 51–55).—Notes on the habits, life history, and means of combating *Nysius minutus*, *Aspidiotus howardi*, *Chermes abietes*, grain plant louse, the apple aphis, beet army worm, cabbage Plutella, bean ladybird, cabbage aphis, and a species of Phytoptus which attacks cottonwoods.

A preliminary note on a new species of aphis injurious to plums and peaches in Georgia, W. M. Scott (pp. 56–60).—A brief account is given of a species of aphis believed to be new and reported as injurious to plums and peaches in different parts of Georgia. Observations were made on a part of the life history of the insect.

Fighting insects with fungus diseases, L. Bruner (p. 59).—The author reports that a fungus was received from this Department supposed to be a South American locust disease, but which proved to be a species of Mucor. The material was distributed in Nebraska, but was not found to be effective. In the author's experiments none of the locust diseases proved successful.

Insects detrimental and destructive to forest products used for constructing material, A. D. Hopkins (pp. 60–62).—Brief notes on *Eupsalis minuta, Lymexylon sericeum, Prionus laticollis*, and other injurious insects.

Observations on forest and shade tree insects in New York State, E. P. Felt (pp. 63–68).—Short notes on *Anisota senatoria, Cacœcia argyrospila, Chalcophora virginiensis, C. liberta, Dentroctonus terebrans, Tomicus calligraphus, T. balsameus, Monohammus confusor*, elm-leaf beetle, forest tent caterpillar, carpenter moth, and other species.

Review of the white-fly investigations, with incidental problems, H. A. Gossard (68–74).—*Aleurodes citri* is reported as infesting 75 per cent of the orange groves in Manatee County. Two fungus diseases were observed on the insect. The white fly is not always fatal to orchards, as is shown by the fact that one grove has been infested for at least 10 years and is still in a vigorous condition. Notes are given on the life history of the insect and on treatment with resin wash, kerosene, and hydrocyanic-acid gas. It was found that when 1 oz. of sulphuric acid and 1 oz. of water mixed together and cold were added to 1 oz. of potassium cyanid, 428.4 cu. in. of gas were produced, while the same quantity of water and acid mixed and added immediately to the cyanid of potash yielded 467.9 cu. in. of gas. Fumigation was done at all hours of the day and in sunshine and cloudy weather. Little injury was done to trees or foliage if fumigated at night or during cloudy weather, but when trees were fumigated in sunshine during the middle of the day some injury resulted. Observations were made on the affect of fumigation on ladybirds and it was found that the majority were destroyed.

Hydrocyanic-acid gas notes, C. P. Lounsbury and C. W. Mally (pp. 75–80).—This insecticide has been successfully used in destroying lice and other insect pests in railroad coaches, jails, and private houses. Experiments showed that when 1 oz. of potassium cyanid was used to 450 cu. ft. of space it was uniformly fatal to scale insects. Cockroaches were destroyed by 12 hours' exposure to the gas, when 1 lb. of potassium cyanid was used to every 100 cu. ft. of space. Bedbugs and various species of ticks were found to be most resistant to the action of this gas. In treating infested grain, 1 oz. of potassium cyanid to 12 cu. ft. of space was found inefficient in the destruction of *Calandra oryza* and *C. granaria*.

The use of hydrocyanic-acid gas for exterminating household insects, W. R. Beattie (pp. 80–84).—From experiments with gas in combating cockroaches (*Periplaneta americana*), it is concluded that 0.1 gm. of 98 per cent cyanid of potassium per cubic foot is sufficient to kill all roaches within a period of 3 hours.

Insects of the year in Ohio, F. M. Webster and W. Newell (pp. 84–90).—Notes on chinch bug, Hessian fly, strawberry weevil, cankerworm, western corn-root worm, pea louse, cabbage bug, San José scale, southern turkey gnat, and various other insects, together with a brief report on the use of arsenate of lead, green arsenoid, Paris green, whale oil soap, and tobacco dust.

Summarizing the results of experiments with *Sporotrichum globuliferum* since 1894, it is stated that this fungus gives no evidence of its value in protecting the country from an annual recurrence of an attack of chinch bugs. Observations on the spread of San José scale from infested fruit indicate that infestation from such sources takes place slowly.

Fruits seriously injured by moths, C. W. Mally (90–93).—A report is made on the injury to apples, pears, plums, grapes, peaches, figs, citrus, and other fruits by a moth (*Ophiuza lienardi*). The moth was observed making punctures in fruits by means of its proboscis, through which the juices were sucked.

Notes on four imported pests, A. H. Kirkland (pp. 93–97).—Observations on the distribution and injurious attacks of the gypsy moth, brown-tail moth, imported elm-leaf beetle, and imported willow weevil (*Cryptorhynchus lapathi*). During the year a new colony of gypsy moth was discovered at Providence, R. I. The colony extended over an area of about 2 square miles. During 1900 it is stated that practically no damage by the moth occurred throughout the whole infested district. The numbers are increasing, however, and more serious damage is expected. Many complaints were made of the brown-tail moth, partly on account of the poisonous effect of the hairs of caterpillars when coming in contact with the skin.

Drought, heat, and insect life, Mary E. Murtfeldt (pp. 97-99).—During the unusually dry season of 1901 in the vicinity of St. Louis it was observed that cutworms, plum curculios, bollworms, codling moths, horseflies, and grasshoppers were very badly affected by the excessive drought and heat and rapidly disappeared as the season advanced. A few other insects seemed to be favorably affected by these conditions. Among these, mention may be made of ants, crickets, and *Lepisma domestica.*

The codling moth, W. W. Froggatt (*Agr. Gaz. New South Wales, 12 (1901), No. 2, pp. 1354-1365, pl. 1*).—Notes are given on the habits and life history of this insect and on its distribution in New South Wales. In combating the pest the author recommends scraping the loose bark from the trunks of trees, spraying with Paris green, painting the trees, destruction of windfalls, and removal of all rubbish from infested storehouses. Notes are given on legislation adopted against the codling moth in Tasmania, South Australia, Victoria, Queensland, and West Australia.

A report is given on experiments extending over 2 years in combating the codling moth. The trees upon which the experiments were made were 335 in number and some of them were also attacked by canker and woolly aphis. All orchards in the vicinity were badly infested with codling moth. Paris green was applied soon after the blossoms fell and later the trees were banded with burlap and the bands removed and examined at regular intervals. The number of larvæ killed under the bands during the 2 years is tabulated, showing the dates of the different inspections. During the first year 18,505 larvæ were captured under the bands, and during the second year 25,796 were captured in this way. The maximum number of larvæ captured under the band of a single tree for the season was 673.

Codling moth, G. Quinn (*Jour. Agr. and Ind., South Australia, 5 (1901), No. 4, pp. 327-329*).—Brief notes on the habits and life history of this insect, together with recommendations regarding insecticide treatment. The remedies recommended for the codling moth include destroying the eggs and young caterpillars by kerosene emulsion, by scraping the stems of trees, applying bands to the trunks of trees, collecting infested and foreign fruits, destruction of rubbish in orchards, disinfection of fruit houses and packing cases, and spraying with arsenites.

Insects injurious to the muskmelon, E. Walker (*Arkansas Sta. Bul. 69, pp. 81-84*).—The melon louse (*Aphis gossypii*) is considered the most important injurious insect on muskmelons. When the vines are sprayed with a strong decoction of tobacco before the leaves have become badly curled the insect may be effectively checked. In the author's experiments the tobacco decoction was applied with a knapsack sprayer to which a bent extension pipe was attached; the under surface of the leaves could be readily sprayed. No injurious effects from tobacco decoctions were observed. It is suggested that weedy areas in the vicinity of melon patches should be burned over.

The striped cucumber beetle appeared in considerable numbers in 1900, but was not early enough to affect young melons badly. In combating this insect a number of repellent substances are recommended, including air-slaked lime, tobacco dust, land plaster impregnated with kerosene, and Bordeaux mixture. Brief notes are also given on the habits and life history of the melon worm and pickle worm, and the usual remedies for these insects are recommended.

The pickle worm (Margaronia nitidalis), A. L. Quaintance (*Georgia Sta. Bul. 54, pp. 71-94, pls. 3*).—While the pickle worm is injurious to a number of cucurbit plants, special attention is given in this bulletin to treatment of muskmelons to prevent its injuries to this plant. The insect is injurious in the larval stage only. The larvæ bore cylindrical holes into the fruit during any stage of its growth. Flowers are frequently attacked, especially in squashes. The vines may also be injured, long cavities being eaten up or down in the stem, sometimes beneath the surface of the ground. The food plants of the insect include nearly all of the cultivated cucurbits. It is a species of American origin and is quite widely distributed throughout the United States. A description is given of the various stages of the insect. The moth is probably strictly nocturnal, flying mostly after midnight. Oviposition occurs also at night. The eggs are laid, either singly or sometimes in clusters of from 3 to 8, on flowers or flower buds or on young and tender parts of the plant. On hatching the larvæ work their way down through the stem or leaves, eating out channels. When the eggs are laid on flower buds of squash the larvæ may remain in the plants until fully grown. The older larvæ crawl about from one plant to another and attack the fruits; a number of larvæ may be found in a single muskmelon. Several broods appear during the summer and fall until checked by cold weather. The length of the life cycle in the months of July and August is from 24 to 27 days. No parasite was bred by the author from this insect. In preventing the injuries of pickle worm to muskmelons it is well to remember that early muskmelons largely escape injury on account of the late appearance of the moth. In general, a serious attack may be expected only upon late muskmelons. After harvesting the plants should be removed and destroyed, or if it is not done at that time, all plants and rubbish should be raked up and burned in late fall or winter, in order to destroy the pupæ of the insect in such situations. The use of Paris green, arsenate of lead, and other arsenical poisons is of little value in combating this insect. The pickle worm shows a decided preference for squash blossoms, and the most successful remedy for the insect consists in planting rows of squashes through the melon fields and removing the squash blossoms after the larvæ of the insect begin to appear. In 1900 1,640 larvæ were captured in this way on an experimental plat, and in 1901 5,519 larvæ were taken in the same manner. It is believed that by planting squashes at different times, so as to have a succession of flowers from the middle of June until the first of August, and by carefully removing wilted squash blossoms from time to time, the majority of the larvæ of the pickle worm may thus be captured and destroyed.

Asparagus beetles, K. Sajó (*Prometheus, 13 (1901), No. 635, pp. 166–171, figs. 3*).—Notes are given on the habits, life history, and means of combating the common species of asparagus beetles, including *Crioceris asparagi, C. 12-punctata, C. 14-punctata, and C. 5-punctata.*

Three orchard pests, E. D. Sanderson (*Delaware Sta. Bul. 53, pp. 19, figs. 11*).—The apple-bud borer (*Stenagoptycha pyricolana*) injures the terminal shoots of young apple trees in orchards and nursery stock, and attacks the tips of water sprouts on old trees. A description is given of the larvæ and moth. The insect winters in a larval condition in the terminal twigs. The moths appear about the middle of May, another brood late in August, and probably another early in October. The whole life cycle apparently occupies about 6 weeks, and it is believed there are 4 broods. The worst injury is done by the second and third broods, especially in August. The eggs are probably laid singly among the unfolding terminal leaves. Many of the larvæ are found to be parasitized. Arsenical sprays are of little value in combating the insect. The most effective preventive remedy consists in removing infested water sprouts and terminal twigs of orchard and nursery trees; all such prunings should be gathered and burned in order to destroy the larvæ.

Fruit-tree bark borer (*Euzophera semifuneralis*) bores beneath the bark of apple, pear, plum, and other fruit trees. It gains entrance in the cracks of the bark on the trunk or at the stumps of pruned branches. In some cases the trees are badly girdled and killed. The insect hibernates in cocoons beneath the bark. The adult moths appear late in May or early in June, and a second brood of larvæ appears in September. A description of the insect in its larval and adult conditions is given.

The remedies recommended for this species consist in painting abrasions in the bark, with a slight addition of Paris green; scraping loose bits of bark from the trunk and applying a wash of whale-oil soap, caustic soft soap, or other substances in winter; in the summer the borers may be cut out.

Brief notes are given on the periodical cicada with special reference to the brood which will appear during the present season. It is urged that orchards should not be pruned too closely, and that where possible budding and grafting should be postponed until after the appearance of the cicadas.

The cherry fly, K. Sajó (*Prometheus, 12 (1901), No. 614, pp. 663–668, fig. 1*).—Detailed notes are given on the habits and life history of *Spilographa cerasi.* In breeding experiments with this insect it was found that the species lives over in the pupa condition until the second year, and it is believed that in some cases it may remain in that state until the third year. It was found impossible to secure the emergence of the adult insect from the pupa during the first year, although the temperature and moisture conditions were made as favorable as possible. As a result of the author's observations it is recommended that the soil around infested trees should be removed to a depth of a few inches and covered in such a manner that the insects can not escape. This soil should be left undisturbed during the summer of the second year in order to make it certain that all insects contained in it are destroyed. Infested cherries when detected should be thoroughly cooked or otherwise treated so as to destroy the fly larvæ contained in them.

Remedies for the cankerworm, C. M. Weed (*New Hampshire Sta. Bul. 85, pp. 69–76, figs. 5*).—The cankerworm is reported as having done an unusual amount of injury in the past 2 or 3 years. Brief notes are given on the habits and life history of this insect. In combating the cankerworm, banding the trees and spraying with arsenicals are recommended. Good results are reported from the use of Bodlime in painting trees. This substance is placed around the trunks of old trees and is removed after danger from the cankerworm is past. Brief directions are given for applying arsenicals for destroying the cankerworm. Mention is made of arsenate of lead, Paris green, and Scheele's green in this connection.

Currant aphides (*Jour. Bd. Agr. [London], 8 (1901), No. 3, pp. 306–312, figs. 2*).—Descriptive, biological, and economic notes are given on species of plant lice affecting currants, including *Rhopalosiphum ribis, Myzus ribis* and *M. cerasi.* Brief mention is made of the natural enemies of these insects. As a treatment for currant-plant lice it is recommended that infested bushes should be cut back and the pruned twigs be destroyed. A caustic alkali wash may be applied for destroying the eggs of the plant lice. Besides this wash, kerosene emulsion and a decoction of quassia, alone or in combination with kerosene emulsion, are recommended.

Thrips on cacao trees, H. Maxwell-Lefroy (*West Indian Bul., 2 (1901) No. 3, pp. 175–190, figs. 3*).—It is reported that cacao trees in Barbados suffer to a greater or less extent from the attack of thrips. The insect injured the leaves of young and old trees and attacked pods in all stages. The pods turned to a deep brown color as the result of injury from thrips. It is suggested that not all of the damage to cacao trees which has been attributed to thrips is really due to these insects. In controlling the thrips it is recommended that after the beans are removed infested pods should not be allowed to remain on the ground where the young thrips mature, but should be burned, or otherwise destroyed. Pods and leaves may be sprayed with kerosene emulsion, resin wash, or other similar insecticides. Other native food plants of the insect in the vicinity of cacao plantations should be destroyed. Formulas are given for the preparation of resin wash, resin compound, kerosene emulsion, resin and whale-oil soap combined, and whale-oil soap.

Combating the coffee borer (*Rev. Agr. Réunion, 7 (1901) No. 10, pp. 412–417*).—Notes are presented on the habits, life history, and appearance of *Botys coffealis.* The insect slightly resembles in its life history the codling moth, and it is recommended that coffee plants be sprayed with Paris green, beginning with the first application about 20 days after flowering. One application is usually not sufficient.

The caprification of figs, K. Sajó (*Prometheus, 12* (*1901*), *Nos. 622, pp. 788–792; 623, pp. 807–811; 624, pp. 823–827, figs. 11*).—In this article the author gives a general account of the agency of the fig insect in the fertilization of Smyrna figs. The discussion is based partly on publications of this Department.

Experiments in the destruction of Diaspidæ injurious to fruit trees, P. Marshal (*Ann. Inst. Nat. Agron., 24* (*1897–1900*), *No. 16, pp. 587–598*).—The species of scales upon which these experiments were made were *Aspidiotus ostreæformis* and *Diaspis piricola*. Experiments with undiluted kerosene were made under a number of conditions. On February 26, 5 apple trees were sprinkled with kerosene. All of the scales were destroyed and no injury was done to the trees. On March 25 plum, apple, and pear trees were sprinkled with crude petroleum. The trees were not infested with scales and the experiment was made for the purpose of determining the effect of the oil on the trees. The trees were in bloom at the time of the experiment. No injury was done to the trees except to the inflorescence of the pears. The flowers of the apple appeared not to be injured. Similar experiments were made on other trees, with like results. In one experiment made on April 9 the leaves of apples were somewhat burned by the use of pure kerosene. An experiment with Russian oil of naphtha, which was applied to pear and plum trees on March 25, showed that this substance was very injurious to the trees. A kerosene emulsion was used in the following proportions: Boiling water 1,500 parts, black soap 400 parts, petroleum 1,000 parts. This mixture was sprayed on apple trees on April 9, with the result that nearly all of the scales were killed and only a few of the apple blossoms were injured. Crude vaselin diluted with kerosene was sprinkled upon apple trees on April 8. It formed a thick and persistent coat on the trees and killed all the scales, but greatly injured the tree. An experiment with pure oil of sesame showed that this substance, while destructive to the scales, was very injurious to vegetation. An emulsion of oil of sesame and kerosene was made in the following proportions: Black soap 200 parts, water 600 parts, oil of sesame 150 parts, and kerosene 100 parts. This mixture was sprinkled on apple trees on April 8. All of the scales were destroyed and little injury was done to the trees. Experiments were made with mixtures containing heavy oil of coal tar. One mixture was prepared in the following proportions: Water 1,500 parts, heavy oil of coal tar 900 parts, black soap 400 parts. Pear trees sprayed with this mixture diluted in 6 parts of water, on April 22, were uninjured, but the mixture had no effect upon the scales. Similar negative results were obtained from a mixture prepared as follows: Heavy oil of coal tar 1 kg., brown naphthalene 1 kg., quicklime 6 kg., and water 25 kg. Another mixture was prepared in the following manner: Heavy oil of coal tar 1 cc., brown naphthalene 1 cc., quicklime 6 cc., water 20 cc., black soap 50 gm. A considerable proportion of the scales were destroyed by this mixture and vegetation was uninjured. An experiment with black soap mixed with water in the proportion of 250 gm. of soap to 500 gm. of water showed that this substance caused no injury to the trees and destroyed a considerable proportion of the scales. Pure pyroligneous acid was sprinkled on apple trees on April 1; nearly all of the scales were killed and the tree was not seriously affected. Several experiments with hot water were also conducted by the author. It is considered that kerosene and crude petroleum are the most efficient insecticides in the destruction of scale insects, and do not seriously injure apple or pear trees, even in bloom. Heat is effective in the destruction of scales, if the superficial parts of the trees can be brought to a temperature of 60 to 65° C., but the difficulty of applying water to all parts of the tree at this temperature is so great that this method for the destruction of scales is practically impossible.

Certain European species of Lecanium and species collected from introduced plants, G. B. KING and L. REH (*Bot Mus., Abt. Pflanzenschutz, Hamburg, 3 (1900–1901), pp. 9*).—Descriptive and biological notes on each species of this genus. A table is presented showing the food plants of different species.

Inspection and certification of nursery stock, W. M. SCOTT (*Georgia State Bd. Ent. Bul. 3, pp. 12, figs. 3*).—In this bulletin instructions are given to Georgia nurserymen concerning the requirements of the Georgia law and rules and requirements of the board governing inspection and transportation of nursery stock. Information is also furnished to outside nurserymen who desire to sell stock in the State of Georgia. Brief notes are given on woolly aphis and crown gall, which are considered dangerous and prevent the issuance of certificates.

How to make a fumigating house so as to distribute the gas, E. D. SANDERSON (*Rural New Yorker, 60 (1901), No. 2699, p. 707, figs. 3*).—A brief description is given of some details of structure of a fumigating house designed for the purpose of distributing the gas as equally as possible throughout the space.

Report on the work of the Section for Plant Protection from January 1, 1900, to March 31, 1901, C. BRICK (*Bot. Mus., Abt. Pflanzenschutz, Hamburg, 3 (1900–1901), pp. 10*).—Of the apples which were introduced from America during this period 4 barrels, 1 basket, and 931 crates were found to be infested with San José scale. Tables are given showing the localities from which the apples were shipped and giving the comparative infestation of different varieties of apples. San José scale was found for the first time in Hamburg on apples shipped from Canada. Besides the San José scale, *Chionaspsis furfuris*, *Aspidiotus camelliæ*, *A. forbesi*, and *Mytilaspis pomorum* were found on apples. Two crates and one basket of pears were found infested with San José scale, and other scale insects were also found on this fruit. Brief notes are given on the importation of dried fruit from California, Eastern United States, and South America, with notes on the condition of this fruit and parasites found upon it. Large quantities of living plants imported from Japan and the United States were inspected. The San José scale was found on a number of species from Japan, but was not discovered on living plants coming from America.

The use of calcium carbid in the destruction of phylloxera, F. VASSILLIERE (*Bul. Min. Agr. [France], 20 (1901), No. 2, pp. 222–228*).—The author carried out a series of experiments in combating phylloxera by applications of pure calcium carbid mixed in various preparations with lime and the residues of calcium carbid. In one series of experiments the residues alone were used; in the second, a mixture was used containing 80 per cent of residues and 20 of calcium carbid; in the third, a mixture containing 80 per cent of lime and 20 per cent of calcium carbid; and in the fourth, a mixture containing 25 per cent of residues, 25 per cent of lime, and 50 per cent calcium carbid. The various experiments indicate conclusively that phosphorated hydrogen and ammonia are the insecticides and fertilizing constituents of calcium carbid. The pure carbid was found to be less effective than the residues from its manufacture for the destructiou of phylloxera. It was found that as much as 2,000 kg. of the residues per hectare were applied without injury to the vineyards. It is recommended that 500 kg. per hectare be adopted as a safe and effective treatment.

During these experiments it was found that success or failure from the use of calcium carbid and its residues depended largely upon the condition of the soil with regard to moisture. Treatment was successful only when the soil was in a normal state of humidity, and failed when the soil was very dry and also when it was excessively moist. This treatment was found to be equally applicable to all soils. The results obtained from these experiments were fully as satisfactory as those obtained from the use of bisulphid of carbon, and the treatment does not in any way endanger the life or vitality of the grapevine.

Important details of spraying, A. V. STUBENRAUCH (*Illinois Sta. Bul. 68, pp. 157-188, figs. 15*).—The author presents a detailed description of certain points in the preparation and application of spraying materials frequently not considered in bulletins on this subject. A classification of spraying mixtures is given, together with brief notes on the nature of parasitic fungi and the action of fungicides upon them. Spraying mixtures are arranged in 3 classes, (1) in which insoluble substances are held in suspension, (2) simple solutions, and (3) emulsions and mechanical mixtures. Paris green and Bordeaux mixture are the chief representatives of the first class, ammoniacal carbonate and sulphate of potash of the second class, and mechanical mixtures of kerosene with water of the third class. Directions are given for the selection and use of proper agitators, the placing of pumps on barrels, and the method of applying the spray. In spraying with Paris green it is urged that the liquid should be thrown in a fine mist, and that the leaves should be covered with small globules which do not run together. When too much fluid is used the individual drops run together and fall off the leaves; a portion of the poison is thus lost and the leaves may be injured where large drops accumulate. The same directions apply to the use of simple solutions, except where they are used for insecticide purposes. In the use of emulsions and mechanical mixtures the author obtained better results with larger nozzles than those used for simple solutions. Especial discussion is given to the proper character of Paris green, Bordeaux mixture, and ammoniacal copper carbonate solution. It is stated that Paris green has proved very unsatisfactory and sometimes harmful in Illinois. The requirements for good Paris green are mentioned, together with the usual tests, including that of color, ammonia, and with a microscope. The objections to Paris green are generally so serious that the author recommends the use of home arsenicals to replace Paris green. Arsenate of lead and arsenite of lime are especially recommended. Detailed notes are given on the method of preparing the liquid constituents of Bordeaux mixture and of combining these constituents in order to make a stable mixture. It is urged that the concentrated solutions of lime and copper sulphate should never be mixed, but that these materials should be combined only after being diluted and being allowed to cool. Precipitation is much less apt to take place under these conditions. Directions are also given for the preparation and use of ammoniacal copper carbonate.

The fowl tick (Argas americanus), W. W. FROGGATT (*Agr. Gaz. New South Wales, 12 (1901), No. 11, pp. 1349-1353, pl. 1*).—A brief account is given of the geographical distribution of this insect, and the literature of the subject is discussed in connection with a detailed bibliography. According to the author's observations, this tick avoids damp places and is usually not found in wood on the ground, but rather in dry nesting boxes or in cracks of the building. In order to prevent attacks of this pest it is recommended that chicken houses be built in such a manner that they may be easily cleaned. The house might profitably be painted with coal tar in order to prevent the tick from securing a foothold. Old unused sheds loosely constructed should be destroyed or removed to some distance from occupied chicken houses. Tree trunks in the neighborhood of chicken quarters should be scraped and sprayed with kerosene in order to kill any ticks which may be hidden under the bark.

Silk culture, G. MCCARTHY (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 11, pp. 7-29, figs. 6*).—In this article the author gives a brief popular discussion of the history of silk culture; the habits, life history, and food plants of the silkworm; and various details concerning the rearing of silkworms; the preparation of the silk threads from the cocoon; and on the possibilities of silk raising in the United States.

Wintering of bees, U. GUBLER (*Rev. Internat. Apicult., 23 (1901), No. 12, pp. 238-242*).—A general discussion is given to the subject of hibernation of bees. Experiments have shown that bees subjected to a temperature of 7 to 8° C. can live but a short time. The 3 means by which heat is lost from colonies of bees are by conduction, radiation, and by currents of air. Honey is known to be a poor conductor of heat and gives off very little heat by radiation. It is considered, therefore, that loss of heat from the hive takes place largely by currents of air. In providing for a successful wintering of bees it is urged that special attention be given to securing a proper amount of fresh air with the least loss of heat by air currents. In order that bees may be successfully hibernated it is necessary that the colonies be of sufficient size to produce the required degree of heat without special effort, that the bees be not subjected to any disturbance from outside interference, and that a proper amount of food be readily accessible.

Foul brood, C. D. SMITH and J. M. RANKIN (*Michigan Sta. Spec. Bul. 14, pp. 11, fig. 1*).—The authors give a general discussion of this disease, based mainly on the investigations of N. E. France, W. McEvoy, and F. C. Harrison. A copy of the Michigan law relative to foul brood is given.

FOODS—NUTRITION.

The cost of food: A study in dietaries, ELLEN H. RICHARDS (*New York: John Wiley & Sons; London: Chapman & Hall, 1901, 1. ed., pp. 161*).—The principles of nutrition are discussed, and also the diets suited to persons of different ages and occupations and under different surroundings. Sample diets are given, costing from 10 to 60 cts. per day, a method of computing dietary studies is explained, and a dietary made at the School of Housekeeping reported. From her previous publications, the author quotes the results of 4 dietary studies of workingmen's families[1] and other investigations.

The volume also contains a glossary of terms and a selected bibliography.

Douglas's encyclopædia (*London: W. Douglas & Sons, Ltd., [1901], pp. 403, ill.*).—As stated in the subtitle, this is designed as a reference book for bacon curers, bacon-factory managers, bacon agents, meat purveyors, meat inspectors, meat salesmen, abattoir superintendents, city, county, or local authority officers, cold-storage proprietors and managers, sausage and pork-pie makers, and all other industries associated with the meat, pork, provision, and general food trades.

The digestibility of pentosans, J. KÖNIG AND F. REINHARDT (*Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 3, pp. 110–116*).—Experiments with man are reported in which materials rich in pentosans were added to a simple mixed diet. The articles selected were canned green peas, dried peas, purple cabbage, canned string beans, army bread, Graham bread, zwieback, and beer. The conclusion was reached that pentosans are very thoroughly assimilated and utilized.

The effect of mastication upon the digestibility of foods, LEHMANN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 24, p. 1168*).—Experiments by methods of artificial digestion showed that finely divided proteid material was much more thoroughly digested in a given time than large pieces of the same material. Tests are also reported with raw and cooked apples, and raw and cooked potatoes. The finely divided material digested more thorougly than that which was coarser, and the cooked more thoroughly than the raw. These experiments were reported in a paper presented at the seventy-third meeting of German Naturalists and Physicians at Hamburg, September, 1901.

Foods, feeding, and prepared foods, H. ZELLNER (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 24, pp. 1173, 1174*).—In a paper presented at the seventy-third meeting of the German Naturalists and Physicians held at Hamburg in September, 1901, the author describes and discusses a number of peptones and similar preparations.

---

[1] Rpt. New Jersey Bd. Health, 17 (1893), p. 425.

Observations on the digestion of proteids with papaïn, L. B. MENDEL and F. P. UNDERHILL (*Reprint from Trans. Connecticut Acad. Arts and Sci., 11 (1901), Oct., pp. 14*).—In the authors' opinion the observations reported by them "indicate that papaïn belongs to a class of enzyms which differ somewhat in type from the two proteolytic enzyms that have received most careful investigation in the past, viz, pepsin and trypsin. While the products of the papaïn digestion of proteids resemble quite closely those of pepsin so far as these have been examined in detail, the enzym differs from ordinary animal pepsin in that it acts readily in both neutral and alkaline media. On the other hand, although papaïn is comparable with trypsin in exerting a solvent action in fluids of various reactions, the failure to form leucin, tyrosin, and tryptophan in appreciable quantities—at least under conditions in which they are readily formed in large quantities by other tryptic enzyms—places it in a class of its own for the present."

Bread made from sorghum, J. FINKELSTEIN (*Wojenna Med. Jour., 79 (1901), pp. 309–327; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 1, p. 31*).—Bread made from sorghum seed was fed to soldiers from 15 to 24 days. It was not very readily eaten, and in a few cases caused digestive disturbances. No definite effect on the weight of the men was observed.

Some specimens of flour and bread from the Russian famine district, A. MAURIZIO (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 22, pp. 1017–1020*).—Analytical data are reported. To the article are appended analyses of similar materials by J. Bettels and A. Olig.

The composition and nutritive value of Russian famine bread, ERISMANN (*Ztschr. Untersuch. Nahr. u. Genussmlt., 4 (1901), No. 24, pp. 1166, 1167*).—The composition of a number of sorts of bread in use in Russia in times of famine was reported and discussed by the author in a paper presented at the seventy-third meeting of German Naturalists and Physicians at Hamburg, September, 1901.

The densimeter as a means of determining the value of flour for baking purposes, E. FLEURENT (*Compt. Rend. Acad. Sci. Paris, 132 (1901), pp. 1421–1423*).—A method of estimating gliadin is described, which consists in determing the specific gravity of an alcoholic extract of flour. An apparatus for this purpose, called a gliadimeter, is described, which, according to the author, gives satisfactory results.

Determining the quality of wheat gluten, L. LIEBERMANN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 22, pp. 1009–1016, figs. 5*).—A method of determining the quality of gluten by measuring its increase in volume on heating is described.

Analyses of oat meal, B. DYER (*Analyst, 26 (1901), No. 303, pp. 153–155*).—A number of analyses of fine and coarse oat meal and rolled oats are reported.

Concerning banana flour (*Jour. Agr. Trop., 1 (1901), No. 5, pp. 143–145*).—A number of articles on this subject are briefly abstracted. Analyses of banana flour, manioc flour, etc., are quoted.

Analyses of Jamaica honey, H. H. COUSINS (*Jour. Jamaica Agr. Soc., 5 (1901), Nos. 10, p. 407; 11, p. 450*).—The composition of 3 samples of honey is reported, the corrected figures appearing in the later publication.

The composition of a number of Coniferæ seeds, E. SCHULZE (*Landw. Vers. Stat., 55 (1901), No. 4–5, pp. 267–307*).—Proximate analyses are reported of the seeds of *Picea excelsa*, *Abies pectinata*, *Larix europæa*, *Pinus silvestris*, *P. maritima*, and *P. cembra*. Studies were also made of the constituents of the different groups.

Alcohol as a protector of protein, R. O. NEUMANN (*Arch. Hyg., 41 (1901), No. 2, pp. 85–118, dgm. 1*).—Experiments which are described and discussed in detail led the author to the conclusion that alcohol may act as a protector of protein.

A new method for measuring body temperature, F. G. BENEDICT and J. F. SNELL (*Arch. Physiol. [Pflüger], 88 (1901), No. 9–10, pp. 492–500*).—An electric thermometer is described with which a continuous record of body temperature may be obtained. According to the authors this instrument, which may be inserted for long periods in the rectum, under the arm, etc., gives very accurate results.

ANIMAL PRODUCTION.

Concentrated commercial feeding stuffs in Pennsylvania, W. Frear (*Pennsylvania Dept. Agr. Bul. 81, pp. 135*).—Cotton seed, linseed, wheat, rye, barley, oat, corn, and buckwheat products are discussed, together with special poultry feeds and condimental feeds. The bulletin also contains information of a general nature regarding different feeding stuffs, reprints a table of the composition of a number of feeding stuffs, and summarizes the laws which have been enacted in various States regulating their sale.

Analyses of commercial feeding stuffs, J. L. Hills, C. H. Jones, and B. O. White (*Vermont Sta. Bul. 88, pp. 16*).—In the execution of the State feeding-stuff law 386 samples of feeding stuffs collected in 1901 were analyzed. These included cotton-seed meal, linseed meal, gluten meal, gluten feed, oat feed, corn-and-oat feed, corn-and-oat provender, calf and poultry feeds, corn and oats, ground oats, wheat bran, wheat middlings, and mixed wheat feed.

"No cases of adulteration were found among the cotton seed or gluten products, although some brands do not grade as high as others and are open to improvement. In many cases the guaranties of the manufacturers were not made good. One linseed meal was found to be adulterated.

"Some brands of oat feeds, corn-and-oat feeds, provenders, and the like were found to contain considerable quantities of oat hulls, more than they should carry were the goods made from 'pure grains ground together.' A few brands were found to be extremely low in protein. Such feeds are of inferior quality, and their purchase is of doubtful advisability. Two adulterated mixed (wheat) feeds were found.

"It is thought that on the whole the grade of goods, particularly the provenders, is better than it was prior to the enactment of the law."

The composition of molasses made from light-colored peat, H. Bornträger (*Ztschr. Analyt. Chem., 40 (1901), No. 12, pp. 787–789*).—Molasses made from peat is briefly described and 3 analyses reported.

Pepton feed, A. Shmid (*Fühling's Landw. Ztg., 50 (1901), No. 22, pp. 808–811*).—Feeding tests with horses and draft oxen are reported, which the author believes show the high feeding value of "pepton feed."

The harmful effects of cotton-seed meal as a feeding stuff, L. Namêche (*L'Ing. Agr. Gembloux, 1900, p. 712; abs. in Centbl. Agr. Chem., 30 (1901), No. 5, pp. 328, 329*).—Experiments with young cattle, rabbits, a goat, cow, and pigs led the author to the conclusion that cotton-seed meal in itself is not harmful. He attributes the poisonous properties which have been observed to carelessness on the part of the feeders, ignorance in the use of cotton-seed meal, or a lack of cleanliness.

Removing spines from prickly pear (*Agr. Gaz. New South Wales, 12 (1901), No. 6, p. 697*).—In a brief note on the subject it is stated that when prickly pear is ensiled, the spines soon become soft and harmless. The silage is regarded as nutritious and palatable.

Ricinus-oil cake, O. Nagel (*Jour. Soc. Chem. Ind., 21 (1902), No. 1, pp. 30, 31*).—The author proposes the following method for removing the poisonous properties of castor pomace, which is based upon the fact that ricin or ricinin is soluble in 10 per cent cold solution of sodium chlorid, and is precipitated out of this solution by heating: Mix the powdered castor pomace with 6 to 7 times its weight of 10 per cent salt solution and allow to stand for 6 to 8 hours, with thorough stirring. Remove the solution by means of a filter press, washing with 10 per cent salt solution until a sample of the filtrate heated in a test tube shows no precipitate. Remove the cakes from the filter press and dry. The filtrate is heated to boiling to precipitate the ricin and the filtered salt solution may be used again. Attention is called to the fact that ricin has no poisonous effect on chickens, as shown by experiments in which they were fed exclusively on castor pomace for 8 days without injury.

The cost of shredding fodder (*Wallaces' Farmer, 26 (1901), No. 43, p. 1241*).—Estimates of $2.28 and $3.08 per acre and $2.50 per ton are given by practical farmers. The estimate of $2.50 per ton is accompanied by the statement that an acre of corn yields about 2 tons of shredded fodder.

Chemistry of the animal body in relation to cell life, especially the blood, L. H. Warner (*Dietet. and Hyg. Gaz., 18 (1902), No. 1, pp. 17–19*).—A discussion summarizing some of the general principles of the subject.

On the resorption of substances insoluble in water, H. Friedenthal (*Arch. Physiol.* [*Pflüger*], *87 (1901), No. 8–9, pp. 467–472*).—Fatal results showing the characteristic symptoms of quicksilver poisoning followed the administration of metallic quicksilver to rats and cats. In the author's opinion the quicksilver must have been absorbed. This investigation was discussed in relation to the passage of fat through the intestinal wall.

The passage of protein through the intestinal wall, O. Cohnheim (*Ztschr. Physiol. Chem., 33 (1901), No. 5–6, pp. 451–465*).—Experiments by the author led to the conclusion that the disappearance of peptone when in contact with the intestinal wall as observed by Hofmeister, Neumeister, and Salvioli, does not depend upon assimilation or rebuilding of albumen, but rather upon its cleavage to simpler products. This cleavage, the author believes, is brought about by a ferment secreted by the mucus membrane of the intestine for which the name erepsin is proposed. This acts upon peptone and some albumoses, but not upon albumen itself.

The formation of glycogen from protein, B. Schöndorff (*Arch. Physiol.* [*Pflüger*], *88 (1901), No. 6–8, pp. 339–345*).—A controversial article.

The influence of gall on metabolism, A. Landauer (*Math. u. Naturw. Ber. Ungarn* [*Berlin u. Budapest*], *15 (1897), pp. 75–114*).—Experiments with dogs are reported, also a bibliography of the subject given.

The feeding of animals, W. H. Jordan (*New York and London: The Macmillan Company, 1901, pp. XVII+450, figs. 10*).—This volume includes a summary of the principles of nutrition with special reference to the feeding of farm animals. It contains chapters discussing the composition and requirements of the animal body, nutrients, feeding stuffs, digestion and assimilation, rations for growth, meat and milk production, production of force, the management of farm animals, and related topics. Tables showing the composition and digestibility of the more important American feeding stuffs are included, as well as the commonly accepted feeding standards, and a comprehensive index is a noteworthy feature. The author has embodied in this work the conclusions drawn from investigations made at European and American experiment stations, as well as the results of his own extended experience as an investigator and teacher, and the work constitutes a valuable summary for students and for general readers. The chapter on the feeding of poultry was contributed by W. P. Wheeler.

Stock feeding in the South, D. R. Pillsbry (*Tradesman, 46 (1902), No. 9* [*23. annual*], *pp. 131–133, figs 3*).—A discussion with reference to local conditions.

Study of breeds in America; cattle, sheep, and swine, T. Shaw (*New York: Orange Judd Co., 1901, pp. 371, pl. 1, figs. 53*).—The available information regarding the different breeds of cattle, sheep, and swine is arranged in systematic order and supplemented by much information regarding the general subject of breeds and breeding. The volume is especially designed to suit the needs of students of agriculture.

Methods of steer feeding, G. C. Watson and A. K. Risser (*Pennsylvania Sta. Bul. 57, pp. 11; Pennsylvania Dept. Agr. Bul. 84, pp. 16*).—Continuing previous work (E. S. R., 12, p. 875) on different methods of confining steers, as well as different methods of supplying drinking water, 2 tests with steers are reported, which were carried on by the State department of agriculture in cooperation with the Pennsylvania station. The first test was made with 3 lots. Lot 1 consisted of 10 animals kept in a large box stall, 20 by 21½ ft.; lots 2 and 3 each contained 6 steers, all of which were kept in separate stalls. Lots 1 and 2 were supplied with water by means of automatic water basins. Lot 3 was turned out for an hour or two each day in yard and watered at a large trough. All the steers were fed a ration consisting of corn meal and wheat bran, 9:1, in such quantities as were readily consumed, and were given native hay and corn stover in addition. The average daily gains per steer in the 3 lots during the 104 days of the test were as follows: Lot 1, 2.05 lbs.; lot 2, 2.18 lbs., and lot 3, 1.89 lbs. Lot 1 consumed 3.62 lbs. hay, 1.46 lbs. stover, and 8.39 lbs. grain per pound of gain. Similar values for lot 2 were 3.21, 0.94, and 7.82 lbs., respectively, while the values for lot 3 were 3.47, 0.79, and 8.39 lbs. Caring for the steers in lot 1 required on an average 7.96 hours per steer; for lot 2, 14.8 hours, and for lot 3, 15.55 hours.

A second test was made with 3 lots of 2 steers each, under practically the same conditions as noted above. The average daily gain per steer in the 3 lots was 2.71, 2.92, and 2.70 lbs., respectively. The amount of hay consumed per pound of gain in the 3 lots was 4.44, 3.76, and 3.45 lbs., the corresponding amounts of grain being 5.91, 5.24, and 4.95 lbs.

As regards gains in weight and food required per pound of gain, the authors note that neither method gave markedly superior results.

"It was observed in each experiment that those animals which had a supply of water before them all the time had a somewhat better appetite and consumed their food with greater relish than did those that were turned into the yard to water once each day. Any advantage that one method may show over another is chiefly due to the difference in the amount of labor of attendance."

Practically the same amounts of straw were required for bedding under the different experimental conditions.

Shorthorn cattle (*Kansas State Bd. Agr. Quart. Rpt., 1901, Mar. 31, pp. 216, figs. 36*).—This bulletin contains a series of articles on the origin, history, and characteristics of the Shorthorn breed of cattle and related topics, as well as a report of the meeting of the Kansas State board of agriculture in January, 1901.

Hereford cattle (*Kansas State Bd. Agr. Quart. Rpt., 1901, Dec. 31, pp. 233, figs. 154*).—A number of papers on the history of Hereford cattle in America, their proper management, and related topics are included in this bulletin, as well as statistics bearing upon the general subject.

Cattle rearing, C. M. BRUCE (*Jour. Khediv. Agr. Soc. and School Agr., 2 (1900), Nos. 4, pp. 176–181; 6, pp. 261–268; 3 (1901) No. 2, pp. 77–82*).—A general discussion with special reference to local conditions.

Feeding cotton-seed meal to hogs, F. C. BURTIS and J. S. MALONE (*Oklahoma Sta. Bul. 51, pp. 15*).—To study the effect of feeding cotton seed, 16 pigs, 11 weeks old at the beginning of the trial and weighing from 25 to 67 lbs., were divided into 4 equal lots. Each lot was fed in pens with small yards for 126 days. Lot 1 received corn meal, lot 2 corn meal and middlings 1:1, and lot 3 corn meal and cotton-seed meal 4:1. Lot 4 was fed the same ration as lot 3 alternated with a ration of corn meal only, the feeding periods being respectively of 4 and 2 weeks duration. The grain ration was heavy at the beginning of the trial and lighter at the end. In addition to grain, all the pigs were fed about 2 lbs. per head daily of sugar beets and were supplied with a mixture of charcoal, ashes, and salt. Two pigs in lot 3 and 1 in lot 4 died shortly after the first month of the trial. The average daily gain of the pigs in the 4 lots was 0.62, 1.15, 1.07, and 1.06 lbs., respectively. The corresponding grain eaten per pound of gain, was 4.7, 3.7, 3.57, and 3.68 lbs. The cost of food per pound of gain, taking into account the grain only, was 2.61, 2.87, 2.24, and 2.14 cts. According to the authors, the pigs which were fed cotton-seed meal and survived were fattened with most excellent results.

"The amount of grain required to produce a pound of gain was practically the same with the pigs getting cotton-seed meal as it was with the pigs getting middlings, but was much less than that required by the pigs getting corn meal. The pigs getting one-fifth cotton-seed meal and four-fifths corn meal alternating with corn meal required 34.5 per cent less grain to produce a pound of gain than the pigs did that were getting only corn meal for their grain.

"More economical gains, disregarding losses caused by death, were obtained by feeding rations containing cotton-seed meal than by feeding either corn meal or a mixture of corn meal and wheat middlings. . . .

"The gain of the pigs getting one-fifth cotton-seed meal and four-fifths corn meal alternating with corn meal cost 23.5 per cent less than the pigs getting two-thirds wheat middlings and one-third corn meal (84 days). The cost of the gain of the corn meal fed pigs was a trifle more than that of those getting middlings in their ration, but the outcome of the former should be considered a failure and unprofitable while the latter was a success and profitable."

The authors emphasize the fact that a light ration of cotton-seed meal should be fed, and that it should be alternated with a ration free from it. The advisability of allowing the pigs to range and of supplying them with some green feed is also noted.

Pig-feeding experiments with Ohlendorff's meat meal, Lilienthal (*Deut. Landw. Presse, 27 (1900), Nos. 41, p. 510; 42, p. 519; abs. in Centbl. Agr. Chem., 30 (1901), No. 5, pp. 329, 330*).—Pigs fed meat meal made greater gains than those fed ground barley in a comparative test.

Pork production in Tunis, P. Robinet (*Bul. Dir. Agr. et Com., 6 (1901), No. 21, pp. 327–358*).—This industry is discussed with special reference to local conditions. Many statistics are quoted.

The substitution of maize for oats in the ration of horses, H. Blin (*Jour. Agricole [Paris], 12 (1901), No. 139, pp. 173–177*).—In an article quoted from *L'Acclimation*, the author discusses maize which he regards as inferior to oats for horses, though of value when properly fed.

Fatigue in army horses, J. Kryembiehl (*Ann. San. Med. Buenos Aires, 1901, July; abs. in Sanitarian, 47 (1901), No. 384, pp. 455, 456*).—Favorable results were obtained when sugar was added to the ration of horses subjected to unusual strain.

Feeding horses and cattle with carob beans, J. F. Audibert (*L'Art de nourrir et engraisser chevaux et bestiaux par la caroube. Marseilles: Author, 1901, 5. ed.; rev. in Ann. École Nat. Agr. Montpellier, n. ser., 1 (1901), No. 2, p. 186*).—This volume treats of the cultivation of the carob bean and its employment as a feeding stuff and for the manufacture of alcoholic beverages.

Ostrich farming in New Zealand (*Agr. Jour. Cape Good Hope, 19 (1901), No. 10, pp. 648–651*).—In an article quoted from the *Pastoralists' Review*, ostrich farming and management in New Zealand are described.

Recent progress in feeding fish, Knauthe and Guntz (*Centbl. Agr. Chem., 30 (1901), No. 8, pp. 537–539*).—A brief summary of some of the recent literature of the subject.

Concerning carp feeding at Sunder in the summer of 1899, E. von Schrader and F. Lehmann (*Hannover Landw. u. Forstw. Ztg., 1900, p. 216; abs. in Centbl. Agr. Chem., 30 (1901), No. 5, pp. 330–333*).—Feeding experiments are reported which led to the conclusion that maize is not satisfactory for fattening carp, and that too much or too concentrated feed should not be supplied when it is desired to produce carp cheaply.

DAIRY FARMING—DAIRYING.

Individual differences in the value of dairy cows, W. J. FRASER (*Illinois Sta. Bul. 66, pp. 95–108, figs. 5*).—A weekly record for 1 year is given of the food consumed and the milk and butter fat produced by each of 2 grade cows. The cows were fed the same ration and were otherwise treated alike in every respect. During the year one cow (Rose) consumed 6,477.92 lbs. of digestible dry matter and produced 11,329 lbs. of milk and 564.82 lbs. of butter fat; and the other cow (Nora) consumed 6,189.06 lbs. of digestible dry matter and produced 7,759.4 lbs. of milk and 298.64 lbs. of butter fat. "Reduced to a like feed basis, for every 100 lbs. of milk given by Nora, Rose gave 139.5 lbs., and for every 100 lbs. of butter fat produced by Nora, Rose produced 180.7 lbs." On the same feed basis the difference in the value of the butter produced was $47.09. The cow Rose also made a greater gain in live weight.

In discussing briefly a profitable standard of production the author states that in general cows producing less than the equivalent of 250 lbs. of butter annually can not be kept at a profit in Illinois. Methods of testing cows and grading up dairy herds are also discussed.

The production of milk and butter—variations in the fat content of milk, L. MALPEAUX and E. DOREZ (*Ann. Agron., 27 (1901), No. 10, pp. 449–461*).—The results of experiments on the influence of breed, individuality, time of milking, heat, stage of lactation, and atmospheric conditions upon the fat content of milk are reported and the different subjects are discussed at some length. The breed is considered as having a very marked influence upon the percentage of fat in milk. Records of cows in the same stage of lactation, fed the same ration, and giving approximately the same yield of milk are given to show variations in the fat content of milk considered due to individuality. The last milk drawn was much richer in fat than that obtained at the commencement of milking, but was slightly poorer in other elements. During 6 days one cow, milked 3 times a day, gave 82 liters of milk containing 36.5 gm. of fat per liter, and during the following 6 days the same cow milked twice a day gave 76 liters of milk containing 34 gm. of fat per liter. When cows were milked morning, noon, and evening the milk was richest at noon and poorest in the morning, and when milked morning and evening, the milk was generally slightly richer in the evening. Only a slight diminution in the yield of milk and fat was observed in 4 cows during the period of heat. A mild humid atmosphere was the most favorable for milk and butter production.

The production of milk and butter—the influence of food upon the fat content of milk, L. MALPEAUX and E. DOREZ (*Ann. Agron., 27 (1901), No. 12, pp. 561–593*).—The influence of carbohydrates, fats, and proteids in foods upon the fat content of milk was studied in a number of experiments here reported, and numerous feeding stuffs were tested. The results of experiments with sugar and molasses showed no marked increase in the fat content of milk due to an excess of carbohydrates. The addition of linseed meal to the ordinary ration in an experiment with 4 cows in no case increased the fat content of the milk. In an experiment with 1 cow sesame cake was fed for 3 months in quantities increasing from 1 to 5 kg., during which time the fat content of the milk decreased from 32.1 to 23.8 gm. per liter. Cotton-seed cake and linseed cake were also used in other experiments. The authors conclude that foods rich in fat produce no appreciable increase in the fat content of the milk. Rations having nutritive ratios varying from 1:8 to 1:3 were compared, the nutritive ratio of 1:6 giving the best results.

Considerable tabulated data are given for the feeding tests with the various forage and root crops, grains, and by-products. Among the conclusions drawn are the following: Succulent forage like beet leaves, fodder corn, and mustard should form only a small part of the ration for dairy cows. Potatoes are ot to be recommended. Carrots are superior to beets, but the increased yield of butter due to carrots is not sufficient to pay for the cost. Oats and wheat bran are satisfactory feeds. Horse beans are not suitable for butter production. Malt sprouts and brewery residue may enter into the dairy ration, the latter to be fed with concentrated feeds. Sugar-beet pulp, well ensiled, may be fed without inconvenience to the animals and without bad effects on the quality of milk and butter. Of the oil cakes, cotton seed, cocoanut, linseed, sesame, colza, and poppy rank in the order named.

Danish experiments on the feeding of dairy cows, A. Mallèvre (*Ann. Inst. Nat. Agron., 24 (1897–1900), No. 16, pp. 217–240*).—This is a review of investigations in Denmark on the feeding of dairy cows based largely on reports of the laboratory of agricultural experiments of the Royal Veterinary and Agricultural High School of Copenhagen. Methods employed in feeding experiments with dairy cows are described in detail, and résumés are given of experiments on the addition of root crops to ordinary rations for dairy cows, the substitution of root crops for concentrated feeding stuffs, and the effect of root crops on the quality of butter.

The physiology of milk secretion, A. W. Bitting (*Indiana Sta. Rpt. 1901, pp. 51–88*).—The author discusses this subject in detail under the following headings: The characteristics of milk, quantity and quality of milk secreted, influences affecting milk production, influence of food upon milk secretion, and comparisons of grains and by-products. The article includes compiled data relating to the composition and properties of milk and a review of considerable experiment-station work.

Different theories of milk formation are given. "The latest theory is to regard milk as a product of metabolism of the cells of the mammary gland. It is in all essential characters a secretory product, and not an excretory product. In reviewing the physiology of the formation of milk in such a light, it is only regarding it in the same way as saliva, gastric and pancreatic juices. It may be argued that these glands secrete a special product to be used in the animal economy, while milk is not so used. All excretory glands, as the kidneys, liver, and sweat glands, find their material already prepared in the blood, the result of activity in other parts of the body, and they serve as a means of eliminating it. Secretory glands, as the pancreas, salivary glands, etc., do not find their active principles in the blood, but construct them within their own especial cells. The mammary gland does not find fat, casein, and lactose in the blood, but constructs them within its own tissues. The recognition of the mammary gland as an organ having a special function will explain fully all the difficulties met in trying to reconcile all other theories with the facts as they are observed."

Under the influences affecting milk production are considered breed, heredity, age, pregnancy, and food. In this connection are given brief summaries of the results of experiments at a number of stations considered typical of the work done to determine the effect of food upon the quantity and quality of milk. "In all cases the influence is within narrow limits, and can all probably be accounted for by the general effect upon the body, or by one food being more palatable than another and therefore more agreeable to the animal. The effect upon milk is probably no greater than it is upon the body as a whole The discrepancy between the results obtained by different experimenters may often be accounted for by the difference in the method of conducting the experiments. The usual length of time given to each period in a feeding experiment is 10 days or 2 weeks. Many foods have a temporary stimulating effect, which food naturally shows in such short period experiments, and which would disappear if the period were continued for a longer time."

The author also discusses milk secretion as affected by drugs, certain foods containing volatile substances, watering, weather conditions, methods of milking, exercise, excitement, abortion, sickness, tuberculin, dehorning, and spaying.

The composition of milk, H. D. Richmond (*Analyst, 26 (1901), No. 309, pp. 310–318*).—The average composition of 13,798 samples of milk analyzed during 1900 was as follows: Specific gravity 1.0323, total solids 12.57 per cent, fat 3.64 per cent, and solids-not-fat 8.93 per cent. The lowest fat content occurred during May and June and the highest during October and November. The fat was determined usually by the Gerber method and the solids-not-fat calculated. Results obtained in this way agreed closely in comparative tests with results obtained by the Adams method for fat and the asbestos method for total solids. The chrysotile method of Macfarland (E. S. R., 4, p. 983) was found unsatisfactory.

Determinations were made of the milk sugar, proteids, and ash in a large number of samples of milk to ascertain if an excess or deficiency of solids-not-fat is due to an excess or deficiency of any one of these constituents. The following conclusions were reached: "Any deficiency of solids-not-fat below 9 per cent is chiefly due to a deficiency in the milk sugar. Any excess of solids-not-fat above 9 per cent is chiefly due to an excess of proteids. The ash may be deduced with very fair accuracy from the proteids by the formula $A = 0.36 + 0.11\ P$."

A study was made of the relation between the proteids and salts of milk. The average results of analyses of whole milk, milk serum obtained by filtration through porcelain which removed all the proteids, and of whey produced by the action of rennet are reported and discussed. The author considers that one-third of the base with which casein is combined in milk is soda, and also that casein forms a molecular compound with calcium phosphate.

Daily variations in the fat content of milk, M. Siegfeld (*Molk. Ztg., 15 (1901), No. 50, pp. 907–910*).—Determinations made almost daily for 1 year of the fat content of the mixed milk of 10 dairies, which delivered during that time from 18,000 to 140,000 liters of milk each, are reported in tabular form. The most common daily variation was from 0.1 to 0.3 per cent. The daily variation in the milk of the two largest dairies did not exceed 0.45 per cent during the year. The greatest and most frequent daily variations were observed in the milk of the smallest dairies, amounting in some cases to 1 per cent and over. Causes of variations in the fat content of milk, such as the health of the cows, heat, weather conditions, changes in feeding and attendants, etc., are discussed.

Causes of variation in the butter-fat percentages of milk and cream, G. S. Thomson (*Jour. Agr. and Ind. South Australia, 5 (1901), No. 5, pp. 445–450*).—The author points out that variations in the yield and quality of milk may be due to methods of feeding cows, irregularity in milking, rough treatment, exposure to cold, stage of lactation, etc. Results of experiments in substantiation of some of these points are given. Factors affecting the separation of milk, such as temperature, degree of acidity, etc., are noted. The butter returns of cream are shown to be seriously affected by the age of the cream and by the mixing of sweet and acid samples. Practical suggestions are given throughout the article.

The relation between specific gravity, fat, and solids-not-fat in milk, N. Leonard (*Analyst, 26 (1901), No. 309, pp. 318, 319*).—The author has deduced a new formula for calculating fat from specific gravity and total solids, which, however, is not considered as accurate as the formula previously noted (E. S. R., 12, p. 186).

A method of determining the specific gravity of milk serum and fat, E. Gutzeit (*Milch Ztg., 30 (1901), No. 33, pp. 513–515*).—From the specific gravity and fat content of whole milk and of the skim milk the author has deduced formulas for determining the specific gravity of milk serum and of fat.

Pasteurization and sterilization of milk, H. de Rothschild (*Pasteurisation et stérilisation du lait. Paris: Octave Doin and Ch. Béranger, 1901, pp. 91, figs. 33*).—The different phases of this subject are discussed in detail in chapters entitled: The chemistry and bacteriology of milk production and rational treatment of milk, pasteurization of milk, sterilization of milk, and the value of sterilized milk—its digestibility and objections which have been raised against its use. A bibliography of the subject is appended.

Pasteurization of milk for butter making, H. H. DEAN and F. C. HARRISON (*Ontario Agr. Col. and Expt. Farm Bul. 117, pp. 16, dgms. 2*).—Methods of pasteurization are briefly discussed and 6 series of experiments are reported, the results of which are embodied in the following summary:

"(1) Milk as ordinarily delivered at a creamery may be successfully pasteurized. The milk used in these experiments was largely furnished by patrons who had but ordinary facilities for taking care of it. In the winter we receive our milk but three times a week; in summer it is delivered daily.

"(2) On but two occasions was the acidity of the milk over 0.2 per cent. The acidity averaged about 0.17 per cent. There is danger of the milk coagulating when heated, if it contains more than 0.2 per cent of acidity.

"(3) It was noticed that the lots heated at from 185 to 195° produced more foam than those heated to the lower temperatures of 140 to 160°. This was most noticeable in the samples heated to 195°. At 185° the foam was not sufficient to cause much trouble in handling.

"(4) By cooling the skim milk with water to a temperature of about 65° immediately after it comes from the separator we were able to return it to the patrons in excellent condition for feeding, even in hot weather.

"(5) The use of 10 to 15 per cent of culture in the pasteurized cream enabled us to ripen the cream without any difficulty. The culture used was a lactic-acid bacillus.

"(6) Pasteurization of milk at 185° and the use of a pure culture is the best method of securing uniformity, keeping quality, and the mild flavor requisite for export butter.

"(7) The cooked flavor which was present in the butter made from milk heated from 185 to 195° usually disappeared at the end of about 2 weeks. In one or two lots heated to 195° the cooked flavor remained for some time. There is apparently no danger of cooked flavors on butter made from milk pasteurized at 195° at the end of 2 weeks, or by the time it would reach the British markets.

"(8) The species of bacteria present in the milk when the animals were kept in the stable were very undersirable. Many putrefactive and fecal bacteria were present, hence the necessity of keeping the stable walls and rafters well cleaned. A good coat of whitewash increases the amount of light, and gives a general clean effect to the stables.

"(9) The average number of bacteria per cc. found in milk pasteurized at 140° F. was 631,046, at 160° was 12,848, at 185° was 81, and at 195° was 40."

The influence of high temperatures on tubercle bacilli in milk, C. BARTHEL and O. STENSTRÖM (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), 11, pp. 429-432*).—The authors briefly review the literature on this subject and report upon a number of different experiments which they have carried out. For this purpose a cow in the last stages of tuberculosis of the udder was obtained and the secretion from the anterior or badly affected half of the udder was mixed with the milk from the posterior quarters of the udder, which were not as yet badly attacked by tuberculosis. It was found that a temperature of 65° C. for periods of 5, 10, and 20 minutes was not sufficient to destroy the tubercle bacillus. Milk maintained at 70° C. for periods of 5, 10, and 15 minutes remained in each instance tuberculous. The same results were obtained with experiments at a temperature of 75° C. At a temperature of 80° C. the milk remained tuberculous after exposure for periods of 1, 5, and 10 minutes. The milk upon which these experiments were made, on account of the advanced stage of tuberculosis, had already suffered great physical and chemical changes. The reaction was decidedly alkaline, and this probably accounts for the fact that tubercle bacilli resisted the highest temperature for such long periods. Attention is called to the well-known fact that tubercle bacilli show greater resistance to heat in a neutral or alkaline solution than in an acid solution. It was found that in milk which had not yet suffered any chemical changes a momentary exposure to a temperature of 80° C. was sufficient to kill tubercle bacilli. It is urged that in order to reduce the results of all experiments along this line to a standard, attention should be given to the reaction of the milk before the experiment is made, in order to determine whether it is alkaline, neutral, or acid.

Report of the Chemical Control Station at Christiania, Norway, for 1900, H. GREGG (*Aarsbr. Offent. Foranst. Landbr. Fremme, 1900, pp. 208–246*).—The report gives accounts of routine analytical work done at the station during the year and of investigations of more general interest. Among the latter that of the composition of Norwegian creamery butter is more fully described. The investigation was begun in 1898, bi-weekly examinations of the products of nine different creameries being made. The samples examined were taken by authorized agents of the station and were in all cases genuine butters. Limits so far observed were: Specific gravity (at 100° C.) 0.8636 (minimum), Reichert number 21.1 (minimum), and refractive index 43.7 (maximum), while Hübl numbers ranged between 28.8 and 45.1. The influence of the season on the composition of the butter fat is shown in the Reichert numbers, iodin numbers, and refractive index. In general, maximum figures were obtained for Reichert number from November to February, and a decided minimum in June.—F. W. WOLL.

Payment for milk and cream according to the yield of butter, J. FROST (*Milch Ztg., 30 (1901), No. 35, pp. 545–547*).

The manufacture of Gruyère cheese, M. BEAU (*Jour. Agr. Prat., n. ser., 2 (1901), Nos. 27, pp. 12–14; 29, pp. 71–73; 30, pp. 105–108*).—A description of methods employed in the manufacture of this cheese.

Common-sense ideas for dairymen, G. H. BLAKE (*Elgin, Ill.: The Elgin Dairy Report, 1900, pp. 281, figs. 27*).—The subtitle states that this is "an exposition of the methods pursued by the most practical and successful dairymen in the Elgin district." The book is largely compiled and is designed to present in a simple and concise manner the most important principles underlying successful dairy farming and dairying. Chapters are devoted to the following: Selection of dairy stock, feeding and care of dairy stock, corn and clover culture, milk and cream testing, care of milk, butter makers and butter making, cheese making, creamery building, farmers' dairy clubs, and miscellaneous facts.

Bibliography of milk, second supplement, 1901, H. de Rothschild (*Bibliographia lactaria, deuxième supplément, 1901. Paris: Octave Doin, 1902, pp. 106*).—This second supplement to de Rothschild's extensive bibliography of milk is similar to the one previously noted (E. S. R., 13, p. 690) and contains a classified list of 1,578 titles of papers which appeared during 1901 or have been discovered since the first supplement was issued. Many of the papers noted are not recent, a considerable number dating back from 10 to 25 years, and several to the seventeenth and eighteenth centuries.

VETERINARY SCIENCE AND PRACTICE.

The toxin of tapeworms, E. MESSINEO and D. CALAMIDO (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), Nos. 8, pp. 346, 347; 9, pp. 374, 375*).—The authors undertook experiments to determine whether the injurious effects from the presence of tapeworms were due to chemical irritation or to the production of a poisonous substance. Extracts were made from tapeworms which were ground up in a mortar with distilled and sterilized water, and rabbits, guinea pigs, and dogs were inoculated with samples of this extract. In all cases poisonous effects of uniform character were produced. These effects included trembling of the body, paralysis, especially of the hind legs, and lowering of the body temperature. As a rule the animals recovered from the effects of the injections after about 24 hours. It is believed, therefore, that the injurious effects of tapeworms are to be ascribed to the action of a special toxin which is produced by the worms.

Further experiments were conducted for the purpose of isolating, if possible, the toxin which was believed to be present in the extract obtained from crushed tapeworms. Experiments were made for this purpose with a large number of chemical substances, and precipitates were obtained in a number of these experiments. All precipitates were amorphous without any indication of crystalline forms. The precipitate which was obtained from the treatment of the extract with sulphate of magnesia produced certain lowering of the temperature, paralysis of the hind legs, and contraction of the muscles in the rabbits and guinea pigs, even when administered in small doses. Experiments with these precipitates were made for the purpose of determining their hæmolytic action. It was found that the red blood corpuscles of rabbits and guinea pigs maintained at a temperature of 37° C. were entirely dissolved within 10 hours by the action of precipitates. When a small quantity of the precipitate was injected directly into the substance of the liver of rabbits and guinea pigs, a fatty degeneration of the liver was noted within 48 hours.

The three species of armed palisade worm, A. STICKER (*Deut. Tierärztl. Wchnschr., 9 (1901), Nos. 33, pp. 333–336; 34, pp. 346, 347, figs. 9*).—The author gives detailed notes on the life history, habits, and parasitism of *Sclerostomum edentatum, S. bidentatum,* and *S. quadridentatum.* From a critical review of the literature on this subject it appears that the points requiring further study at present are as to which of the 3 species occur in any given region, in what numbers and in what month are they found, at what time do they become mature, and what is the proportion between the numbers of the 2 sexes.

Tetanus infection supposed to follow the absorption of toxin by the intestinal wall, RÉMOND (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), No. 13, pp. 412–414*).—The author gives a description of a case of well pronounced tetanus in a horse in which the symptoms were characteristic. The animal was given an injection of antitetanic serum, but died within 20 hours after the first marked symptoms were observed. A careful post-mortem examination indicated rather conclusively that the infection in this case had taken place by means of the alimentary tract. The author believes that this mode of infection must be taken into consideration in accounting for epidemics of tetanus.

Cerebro-spinal meningitis, J. WILSON (*Vet. Jour., 53 (1901), No. 313, pp. 34–37*).—The author discusses briefly the symptoms ordinarily manifested in cases of this disease. According to the experience of the author, recovery will not take place in more than 40 or 50 per cent of the cases. After recovery from the disease, where there is a loss of coordination of muscular movements, with atrophy of the muscles, good results were obtained by the application of cantharides to the loins and the administration of small doses of nux vomica.

Agglutination reaction in infections of various grades, S. J. GOLDBERG (*Centbl. Bak. u. Par., 1. Abt., 30 (1901), No. 16, pp. 605–617*).—The significance and value of the agglutination test as proposed by Widal has been thoroughly interpreted by different authors, and the present study was made for the purpose of gaining more evidence on some of the doubtful points concerning this problem. The results of inoculation experiments and blood tests indicate that in a fatal infection the reaction of agglutination remains the same as before infection. When non-fatal doses of the virus were given, an increase of the agglutinating power of the blood was noted, but this reaction was by no means the same in different animals. While in the rabbit the agglutinating power became much more pronounced, no such reaction was observed in guinea pigs. The reaction increases gradually in intensity, reaches a certain maximum, and then returns to the normal. The increase of the agglutinating power of the blood is to be regarded as an indication of successful self-protection on the part of the animal.

Artificial production of experimental spore material of a fixed degree of resistance to living steam, for the purpose of testing the value of disinfection methods, R. WEIL (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), Nos. 13, pp. 500–504; 14, 526–536*).—For the purpose of testing the influence of various disinfecting materials anthrax spores have been extensively used. The author calls attention, however, to the great difficulty of obtaining a sufficient number of anthrax spores for such experiments and to the practical impossibility of maintaining any quantity of spores at the same degree of resistance to unfavorable influences. Even when anthrax spores of a known degree of resistance are protected from the light and kept at a constant low temperature, they gradually lose their resisting power, and thus become useless for the purpose of continued tests with known strengths of various germicide substances. Better results were obtained by the author in making use of the spores of *Bacillus mesentericus ruber*. Spores of this bacillus which were maintained at a boiling temperature for ¼ hr. did not show a sufficient reduction in their resisting power. After being maintained at the same temperature for ½ hr. the desired degree of reduction in resisting power was obtained. After such exposure the spores were found to withstand the action of living steam for about 10 minutes. In some cases, however, spores were much more resistant, and it was found, therefore, that for the most resistant examples of these spores an exposure to a boiling temperature for ¾ hr. was too short and for 1½ hr. was slightly too long in order to obtain the desired results. After determining the fact that spores of a known degree of resistance could be produced by artificial means, it was desirable to ascertain whether these spores were modified by desiccation or other external influences to such an extent that they could not be depended upon to maintain the same degree of resistance for any considerable period. Experiments along this line showed that for seven months spores were unchanged in their resisting power by desiccation. Experiments were undertaken for the purpose of determining whether cultures made from spores in which the resisting power had been artificially reduced would develop spores of a correspondingly weakened resisting power. It was found that such was the case to a considerable degree, and it is believed that this fact may help to explain the existence in nature of races of the same bacillus of varying degrees of virulence.

The technique of micro-biology and serotherapy, A. BESSON (*Technique microbiologique et sérothérapique. Paris: J. B. Baillière & Sons, 1902, 2. ed., pp. 686, figs. 289*).—This volume contains an elaborate discussion of sterilization, culture media, isolation of bacteria, incubation, bacteriological microscopy, staining of spores, capsules and cilia, inoculations, observations of inoculated animals, technique of autopsies, and demonstration of pathogenic bacteria in the fluids and organs of the body. A large portion of the volume is devoted to a special study of the more important bacteria which are concerned in the production of infectious diseases in man and animals. Special chapters are occupied with the study of the organisms of anthrax, blackleg, swine erysipelas, fowl cholera, hog cholera, tetanus, glanders, tuberculosis, and protozoan parasites.

Morphology of the blood of the fœtus of the rabbit and guinea pig and the influence of infection of the gravid female on the blood of the fœtus, N. TSCHISTOVITSCH and YOUREWITSCH (*Ann. Inst. Pasteur, 15 (1901), No. 10, pp. 753–768*).—In a study of the normal blood of the rabbit fœtus it was found that the various white blood corpuscles exist in the following proportions: Polynuclear eösinophilous corpuscles, from 41.3 to 62.7 per cent; ordinary leucocytes, from 2.9 to 12 per cent; large mononuclear corpuscles, from 11.8 to 28 per cent; lymphocytes, from 4.2 to 5 per cent. In the normal fœtus of the guinea pig the proportions of the different kinds of leucocytes were as follows: Polynuclear leucocytes with granular protoplasm, 0.7 to

9.9 per cent; polynuclear leucocytes with clear protoplasm, 0 to 6.7 per cent; large mononuclear corpuscles, 9.9 to 42.5 per cent; lymphocytes, 53.2 to 88.2 per cent. Inoculation experiments were conducted with bouillon cultures of the diplococcus of Fränkel, *Staphylococcus aureus*, and with diphtheria toxin. As a result of the authors' experiments it was found that as a rule pronounced morphological modification of the fœtal blood at the time when under the influence of infection or intoxication, the blood of the mother showed the hypoleucocytes or hyperleucocytes were absent. The absence of these modifications is explained by the fact that there is no passage of the bacteria or toxin into the blood of the fœtus. The pure cultures of toxin were introduced directly into the blood or into the lymphatic system of the mother. These materials were rendered harmless in the blood of the mother, or at least did not pass through the placenta. Occasionally intra-uterine death of the fœtus occurs during the infection of the mother, and in such cases the toxin or bacteria effected a passage into the blood of the fœtus. The number of leucocytes found in the blood of the fœtus was small and the authors believe that the defense of the organism by means of phagocytes is not well developed until after birth.

The group of Pasteurella, J. LIGNIÈRES (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), No. 13, pp. 414-416*).—This article is of a controversial nature, the purpose being to justify the establishment of a systematic group of ovoid bacteria which produces various forms of hemorrhagic septicæmia. It is not considered that the generic name adopted by the author is of vital importance, but the objections to its use are not considered of great weight.

Contagious diseases of animals and man, L. BAILLET (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), Nos. 13, pp. 417-423; 17, pp. 553-561*).—Special attention is given to a discussion of glanders and tuberculosis, as being among the most important contagious diseases which are common to man and animals and which may be transmitted from one to the other. The use of mallein and tuberculin for detecting incipient cases of glanders and tuberculosis is considered of great importance from the standpoint of general hygiene, since by this means the existence of the diseases in animals may be made known and precautions may be taken to prevent their transmission to man.

Diagnosis of tuberculosis in animals during life, DEWAR (*Vet. Jour., 53 (1901), No. 314, pp. 92-96*).—An elaborate discussion is presented of the tuberculin test, its efficiency, and the means of arriving at a practical judgment concerning the significance of reactions which are obtained by its use. Statistics are given from the experiences of the author and other writers relating to the percentage of tuberculous animals in different herds. The rules for the application of tuberculin laid down by the author are as follows: The tuberculin must be thoroughly reliable; the herd to be tested must be kept quiet and undisturbed, without great change of food, pasture, surroundings, or management during the experiment; and all special conditions which influence the reaction in individual cases must be taken into consideration. The author considers all animals which react with an elevation of temperature of more than 2½° F. as tuberculous.

Relation of bovine to human tuberculosis. Tuberculin tests of the college herd, G. H. GLOVER and B. C. BUFFUM (*Colorado Sta. Bul. 66, pp. 26, pls. 3*).—A large portion of this bulletin is of a controversial nature. An attempt is made to summarize evidence which tends to disprove the contention of Koch that human and bovine tuberculosis are distinct diseases. The tuberculin test was applied to the college herd for the purpose of determining whether or not any of the animals were affected with tuberculosis. The tuberculin test was made on 31 head of cattle, and of this number 10, or 32¼ per cent, reacted. Of the 31 head, 11 were Jerseys and 20 Shorthorns, and 5 of each breed reacted, with 2 additional doubtful cases among the Shorthorns. Post-mortem examinations were made on 5 of the animals and the details of pathological changes are given. It is concluded that while tuberculosis may be less common in Colorado than in humid States, it is nevertheless present and should receive attention.

Tuberculosis of man is transmissible to cattle, THOMASSEN (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), No. 17, pp. 529–538*).—A critical review of the recent literature of this subject is presented by the author. Inoculation experiments were made on 2 calves and 2 two-year-old heifers, during which tubercle bacilli of human origin were used. The bacilli came from cases of tubercular meningitis, tubercular arthritis, and tuberculous kidneys. Hypodermic intraperitoneal and intratracheal inoculations were made. Great care was exercised to be certain that the animals were not infected with tuberculosis before the experiments began. In only one case was a generalized form of tuberculosis developed. In one other of the 4 experiments local tubercular lesions were produced. The author concludes from these experiments that it is difficult but not impossible to produce tuberculosis in cattle by means of pure cultures of tubercle bacilli from man. It is considered, therefore, that tuberculosis of man and of cattle are identical. The author believes that the transmission of tuberculosis from cattle to man is much easier than that from man to cattle, on account of the greater virulence of tubercle bacilli of bovine origin. It is urged, therefore, that the precautions which have usually been recommended should still be observed in preventing the transmission of tuberculosis to man through the medium of infected milk and meat of tuberculous cattle.

The communicability of human tuberculosis to cattle, S. DELÉPINE (*British Med. Jour., 1901, No. 2130, pp. 1224–1226*).—The author undertook inoculation experiments for the purpose of determining whether tuberculosis could be transmitted from man to animals. The material which was used for inoculation was prepared by mixing the sputum of 6 tuberculous patients. The bacilli in the sputum from different patients were of different types, including long slender forms, thick, uniformly staining forms, and short forms in clumps. As experimental animals the author made use of 4 calves which were apparently healthy, but which were not previously tested with tuberculin. One of the calves was inoculated directly into the lung, the second subcutaneously, the third into the peritoneum, and the fourth was fed 2 qts. of milk containing ten times as much tuberculous material as the other calves had received by inoculation. The first calf, which was inoculated in the lung with 5 cc. of mixed tuberculous sputum, died on the sixth day of generalized tuberculosis, which was not due to the inoculation. The second calf, inoculated with the same amount of sputum, subcutaneously, died on the sixth day with a conspicuous enlargement of the gland at a distance of 5 in. from the point of inoculation. This experiment was considered of doubtful result. The third calf, which received 5 cc. of mixed sputum in the body cavity, showed no definite reaction after 26 days, but reacted 68 days after inoculation and exhibited, on post-mortem examination, marked tuberculosis of the peritoneum. The fourth calf, fed with 50 cc. of mixed sputum with its food, died 26 days afterwards with tubercular lesions along the alimentary tract, but no evidence of tuberculosis in any other organ.

Detailed notes are given on the history of each of these experimental animals. It is stated that there was no evidence of any tendency toward resolution in any of the tubercular lesions. They were all fresh and in a progressive condition, and the evidence was considered conclusive by the author that the disease, in 2 of the 4 cases, was communicated by feeding and inoculation into the peritoneum respectively.

Tuberculosis in dairy cattle, J. E. DEAN (*Queensland Agr. Jour., 9 (1901), No. 1, pp. 122–124*).—The author discusses the relationship of tuberculosis in dairy cows to the disease in man. Attention is again called to the fact that 36 out of the 40 cows which composed the dairy from which the queen and her household obtained milk were found to be tuberculous. The milk of this dairy was used freely, but no cases of tuberculosis developed in any persons who used the milk. Cases are cited from the literature of the subject which indicate the general healthful effect upon man and animals from drinking milk freely, whether such milk comes from tuberculous or nontuberculous animals. The author believes that the good results which are supposed to accrue from a free use of the tuberculin test are much exaggerated by the advocates of this process for exterminating tuberculosis. It is considered that the losses occasioned by the application of the tuberculin test and the enormous expense, in connection with serious doubts as to the necessity for guarding against the transmission of tuberculosis from animals to man, are serious obstacles to the general use of tuberculin. The author suggests a method by which veterinary surgeons are appointed in control of specified districts for the purpose of inspecting all cattle, and destroying or quarantining those which show outward signs of tuberculosis.

Tubercle bacilli in cows' milk as a possible source of tuberculosis disease in man, J. McFadyean (*Vet. Jour., 53 (1901), No. 314, pp. 83–91*).—The author presents a review of the subject, calling attention especially to the arguments which tend to prove the identity of bovine and human tuberculosis. An attack is made upon the arguments of Koch before the British Medical Association, and it is urged that no relaxation should be allowed in the measures to prevent the transmission of tuberculosis from lower animals to human beings. It is admitted that tuberculosis of cattle is usually contracted from tubercle bacilli of bovine origin, while that of man is similarly transmitted, for the most part, by means of bacilli of human origin, but the identity of human and bovine tuberculosis is still maintained as highly probable.

Tuberculosis and the milk supply, J. A. W. Dollar (*Vet. Jour., 53 (1901), No. 314, pp. 100–106*).—The literature of this subject is carefully reviewed, with especial reference to the extent to which tubercle bacilli are found in the milk of dairy cattle. The author believes that milch cows and goats should be placed under regular and periodical inspection, that the sale of milk from tuberculous animals for human use should be forbidden in all cases where physical evidence of tuberculosis is present and in cases of tuberculosis of the udder.

Tuberculosis in the State of Victoria, G. Pentland (*Vet. Jour., 53 (1901), No. 315, pp. 176–183*).—The author reviews the history of the origin and distribution of tuberculosis in Victoria. Statistical tables are presented showing the extent of tuberculosis. No indemnity has been granted for condemned animals, but no trouble in this line has been experienced, since the owners have considered such animals valueless. The present districts over which inspectors have charge are considered too large for the most effective inspection and quarantine.

Legislation suggested for controlling and eradicating tuberculosis in animals, D. McEachran (*Vet. Jour., 53 (1901), No. 314, pp. 116–131*).—In this article the author discusses heredity, diagnosis of tuberculosis, tuberculin test, its reaction, various objections which have been urged against the tuberculin test, the different methods of making the test adopted by different countries, quarantine regulations for breeding stock, fat cattle and settlers' cattle, State legislation with reference to bovine tuberculosis in the United States, the danger from milk and meat of tuberculous animals, means for preventing the introduction of tuberculosis into the herd, disinfection of premises, and the payment of indemnities for condemned animals.

The relationship of tubercle bacillus to other acid-proof bacteria and actinomyces, A. Moeller (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 14, pp. 513–523*).—It has for some time been considered impossible to definitely identify the tubercle bacillus by a simple microscopic examination, for the reason that this bacillus can no longer be considered the only acid-proof and alcohol-proof species of bacteria. Similar properties are possessed by the smegma bacillus, leprosy bacillus, and the organisms which cause tuberculosis of cold-blooded animals and of birds. It has been shown, furthermore, that the tubercle bacillus is not always acid-proof, even when taken directly from sputum or from tubercles of bovine origin. The author isolated a bacillus from the tubercles taken from an animal suffering from a typical form of pearl disease, and found that this organism was absolutely acid-proof and alcohol-proof. The bacillus differed in some respects from the ordinary tubercle bacillus, but produced the pearl disease when inoculated into guinea pigs. Attention is called to the acid-proof bacteria which have been found in considerable abundance in milk and butter, and which differ in several particulars from the true tubercle bacillus. The butter bacillus, however, is ordinarily acid-proof. When inoculated into the common experimental animals, the acid-proof bacteria have the one common characteristic, that they produce tubercles. The tubercles produced by the true tubercle bacillus may a ways be distinguished, however, by careful examination from those caused by the bacillus of pseudotuberculosis. The latter tubercles show a less active proliferation and are more of an exudative character, with a tendency to the formation of an abscess. A bibliography of the subject is appended to the article.

Staining tubercle bacilli and spores by means of percarbonate of lime and peroxid of hydrogen, A. Müller (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 20, pp. 791–794*).—As a result of the use of these substances as decolorizers the author comes to the conclusion that the use of acids in treating cultures for identification of tubercle bacilli stained with fuchsin may well be avoided, and replaced to good advantage by the use of percarbonate of lime, or, still better, with alkaline peroxid of hydrogen. Preparations of tubercle bacilli were not injured by prolonged exposure to these decolorizing materials. The method is recommended as especially adapted to the demonstration of tubercle bacilli when they exist in unusually small numbers. For staining and demonstrating the presence of tubercle spores it is recommended that the percarbonate of lime and alkaline peroxid of hydrogen be used to replace the ordinary method with acids. The method as adopted by the author includes the making of cover-glass preparations, staining with fuchsin, and then subjecting to the action of percarbonate of lime in a 5 to 10 per cent solution for 15 minutes or longer. The preparation is then washed with water and stained with methylene blue. The process of decolorizing with peroxid of hydrogen is much more rapid than with percarbonate of lime, and occupies only a few minutes.

Studies on cattle plague, M. Nicolle and Adil-Bey (*Ann. Inst. Pasteur, 15 (1901), No. 9, pp. 715–733*).—Observations on this disease by the authors indicate that infection may pass from the mother to the young before birth. It was found that inoculation with virulent cultures was uniformly fatal to high-bred cattle and black races of cattle, but was not fatal to native races of cattle. The latter race was able to resist inoculation, whether by the subcutaneous, intravenous, or intratracheal methods. It appears, therefore, that a considerable difference of susceptibility to the disease exists between different races of cattle. A buffalo which was inoculated failed to develop the disease. With regard to the virulence of various fluids from infected animals, it was found that aqueous humor produced the disease when inoculated in quantities of 1 cc., and sometimes when used in smaller doses of from $\frac{1}{4}$ to $\frac{1}{2}$ cc. The serum from the brain and spinal cord was of similar virulence. Serum from the body cavity produced a fatal disease in quantities of $\frac{1}{4}$ cc. Of the various methods of inoculation it was found that the most severe and rapidly fatal cases were produced by inoculation into the brain cavity. Several experiments were tried in testing the influence of dilution upon the virus. It was found that $\frac{1}{50}$ cc. of blood diluted in 1.5 cc. normal salt solution produced fatal disease when hypodermically injected. It was found that the virus of cattle plague was not very susceptible to the action of acids and was not readily attenuated under their influence. On the other hand, desiccation reduced the virulence rapidly. When the virus was maintained for four days at a temperature of 37° C. it was found by experiment on calves that 1 cc. of virus thus treated produced no infection, but was not sufficient to cause any immunity. Experiments with Asiatic races of sheep showed that ordinary inoculations in these animals produced only a slight fever reaction, but no serious infection. Experiments with inoculation of the bile of diseased animals gave results which varied to such an extent that no definite conclusions could be drawn. The application of serum treatment for curative purposes was successful in about 50 per cent of cases. When the serum was employed for preventive purposes it was found that a subsequent exposure to the disease or direct inoculation produced merely a slight fever without a regular course of the disease.

Contribution to a study of Texas fever, J. Lignières (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), No. 15, pp. 478–483*).—During extended studies of this disease the author discovered 2 forms of the blood parasite which causes the disease, and it was shown that these forms vary to such an extent that vaccination with blood from an animal infected with one form of the parasite does not produce immunity against an attack of the other form. Both forms of blood parasite may be carried in the same species of tick (*Rhipicephalus annulatus*). Several inoculation experiments were made to gain evidence on this point, and the experiments were quite conclusive in demonstrating the two forms of blood parasites. The author concludes that these forms are not merely variations in the virulence of one variety of blood parasite, but are distinct varieties. This would offer an explanation for the observed fact that immune animals when moved to other localities may become infected with a fatal form of the disease. In such cases it would be only necessary to assume that the animal had become immune to one form of the parasite, and that upon being removed to another location became infected with the other form. Further studies along this line are promised by the author.

Anthrax and preventive inoculation in Louisiana, W. H. Dalrymple (*Jour. Comp. Med. and Vet. Arch., 22 (1901), Nos. 10, pp. 613–618; 11, pp. 708–713*).—This paper was read before the thirty-eighth annual meeting of the American Veterinary Medical Association. The author devotes special attention to a discussion of the various methods by which anthrax becomes disseminated. Among these means of distribution, mention should be made of horseflies and animals that feed on carrion. The necessity of destroying all carcasses of animals dead of anthrax is urged by the author.

Spore formation of anthrax bacillus in an atmosphere of nitrogen, E. Jacobitz (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 6, pp. 232–239*).—Experiments were undertaken by the author to test the soundness of conclusions which had been stated by Klett that spore formation is a regular phenomenon in cultures of anthrax bacillus maintained in an atmosphere of nitrogen. The author conducted his experiments with great precaution so as to prevent the possible introduction of hydrogen, oxygen, or other gases during the period of the experiment. All these experiments showed uniformly that the anthrax bacillus in an atmosphere of pure nitrogen never forms spores, at least when grown on agar, but that spores are readily formed when oxygen is allowed to gain entrance.

The danger of anthrax from the manipulation of horsehair, and its prevention, A. Scott (*British Med. Jour., 1901, No. 2116, pp. 136, 137*).—The author reports several cases of anthrax which arose from handling infected horsehair from Russia. Attention is called to the necessity for great precaution in handling hair which may possibly be infected. The disease may be transmitted by the dust which arises from the hairs by discharges which may be dried on infested hairs, and such hair is a constant source of danger, even when all the processes of manipulation have been completed and the hair is made up into various articles of furniture. In order to prevent the development of this disease among employees in furniture factories, it is suggested that all operators should wear overalls or other outside garments which may be removed upon leaving the factory; that no one with any cut or abrasion of the skin should be allowed to work unless such abrasions may be perfectly protected from contamination; that all suspicious cases of illness be immediately reported to competent physicians in order that proper diagnosis may be made, and that bales of hair should be immediately immersed in water upon being received, and should be boiled for about 30 minutes in order to destroy anthrax germs which may be upon the hair. It is also recommended that all dust and refuse from such factories be burned in order to prevent further spread of the disease.

Immunity of pigeons and guinea pigs vaccinated against anthrax, and the properties of their serum, J. DE NITTIS (*Ann. Inst. Pasteur, 15 (1901), No. 10, pp. 769–784*).—Successful vaccination of both of these animals was accomplished, in spite of the fact that the pigeon is especially refractory to anthrax, and guinea pigs are so susceptible that it has been considered impossible to vaccinate them. The vaccination of the pigeon offers no difficulties on account of its possession of natural immunity. An actual vaccination was accomplished, however, as proved by the fact that vaccinated pigeons survived an injection of a fatal dose of anthrax culture. The vaccination of guinea pigs was found to be a long and difficult operation. By means of a method in which two attenuated vaccines were used the desired result was obtained, only after two or three months, and many animals were lost in spite of all precautions. The chief difficulty was in passing from one vaccine to another, and especially from the second vaccine to virulent anthrax cultures. As the result of numerous experiments it was found that the anthrax bacillus introduced hypodermically in vaccinated pigeons preserved its virulence. The virulence of the bacillus when grown in immune serum was found to be diminished. The serum of vaccinated pigeons protects guinea pigs and mice against death by anthrax. The anthrax bacillus, when introduced hypodermically in vaccinated guinea pigs, is attenuated, but when grown in the serum of vaccinated guinea pigs seems to preserve its virulence. The serum of strongly vaccinated guinea pigs is without action on mice and guinea pigs inoculated with anthrax.

Parturient paresis, R. C. HILL (*Amer. Vet. Rev., 25 (1901), No. 4, p. 281*).—A summary is given of the results of applying the Schmidt treatment to 12 cases of this disease. Directions are given for preparing the udder previous to making the infusion. Under this treatment 75 per cent of the cases recovered, and all but one of these were able to walk within 6 hours after treatment.

The Schmidt treatment for parturient paralysis, J. J. REPP (*Jour. Comp. Med. and Vet. Arch., 22 (1901), No. 9, pp. 545–556*).—A brief account is given of the history, distribution, causes, pathological anatomy, symptoms, course, and treatment of this disease. Circular letters were sent to practicing veterinarians in Iowa for the purpose of obtaining statistics regarding the prevalence of the disease and the results of treatment by various methods. The statistics thus obtained are carefully tabulated. From these reports it appears that 76.5 per cent of cures was obtained by the use of iodid of potash.

Experiments to prove the immunity of cattle to glanders, M. PRETTNER (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 2, pp. 80–82*).—Previous experiments had indicated that cattle were immune to glanders, but the author undertook further experiments in order to demonstrate the fact more absolutely. Two calves were chosen for the experiment. One calf received 10 gm. of a bouillon culture of glanders bacilli in the auricular vein. A slight elevation of temperature was noted in the animal, but after 3 days the animal had entirely recovered from the inoculation. The calf was killed 2 months later, and upon a post-mortem examination no evidence was found of any pathological changes of a glanderous nature. The second calf received the same quantity of bouillon culture in the body cavity. No infection was produced. Since, however, it had previously been shown that the glanders bacillus loses a part of its virulence in artificial culture, one more experiment was made in which material for inoculation was taken directly from virulent glanderous pus. This experiment was conducted on a young calf, and the same result was obtained as in the other two experiments. The author believes, therefore, that cattle may be considered absolutely immune to glanders.

Dehorning of stock, C. F. DOANE (*Maryland Sta. Bul. 78, pp. 39–49, figs. 3*).—A general account is given of the history of dehorning, its various advantages and disadvantages, together with a summary of the results obtained in dehorning at different experiment stations. A report is made on dehorning a number of cattle at the station. In the first experiment 15 milch cows were dehorned. The effect of the operation on the yield of milk is shown in tabular form. A loss in the quantity of milk was observed in 11 cows and a gain in 2. The average loss during the 4 days after dehorning was 4.5 per cent. In another experiment 9 cows were dehorned, and the decrease in the quantity of milk in the 4 days after dehorning was much greater, averaging 30.8 per cent. The cows failed to regain the normal flow of milk for about 8 days. The reason for the unusual decrease in the quantity of milk after dehorning in this case was not apparent.

A description is also given of the details of the operation for preventing the growth of horns in young calves by means of caustic potash.

Forage poisoning: Ergotism, J. HELMER (*Jour. Comp. Med. and Vet. Arch., 22 (1901), No. 7, pp. 446–449*).—An outbreak of forage poisoning occurred in a herd of 38 head of cattle. The pulse became frequent and weak. The animals plunged considerably and the legs were stiffened. There was a noticeable vertigo and delirium at intervals. An examination of the surroundings, water supply, and food indicated that the cause of the trouble was feeding fermented and moldy cornstalks. When this food was withheld no further cases of the disease developed. The author investigated 3 cases of ergotism, in which the usual symptoms of this disease were developed. Samples of redtop hay (*Agrostis alba*) were submitted for examination and proved to be infested with species of ergot (*Claviceps microcephala*).

Parasites in New Zealand live stock (especially sheep), J. A. GILRUTH (*Vet. Jour., 53 (1901), No. 313, pp. 26–34*).—Notes are given on the life history, habits, and injurious effects of *Œstris ovis*, *Strongylus*, *filaria*, *S. ovis pulmonalis*, *S. contortus*, *S. cervicornis*, *Amphistoma conicum*, and species of tape and fruit worms. The most injurious animal parasites of sheep in New Zealand are considered to be the lung and stomach worms. Several predisposing causes of infestation by these worms are enumerated, including stagnant drinking water, swampy undrained lands, excessive raintall, improper or insufficient forage, acquired or congenital weakness of lambs, and overstocking. The preventive remedies named are the use of pure water, salt and iron tonics, and careful attention to dietaries. Several experiments were tried in direct treatment for these worms. While apparently satisfactory results were obtained by intratracheal injections of turpentine in warm milk, equally good if not better results were secured by a complete change of diet to hay, other dry food, and pure water. In the experiments of the author nearly all lambs, including badly infected ones, recovered after being put upon a proper diet, and the author believes that in infestation by lung and stomach worms the change of diet is more important than any system of treatment.

Brief notes are also given on botflies of horses. Several proprietary medicines were experimented with. It was found that the bots remained alive for days in saturated solutions of these medicines.

Investigations of swine diseases in Arkansas, R. R. DINWIDDIE (*Arkansas Sta. Bul. 67, pp. 25–47*).—It is sometimes suggested that the native half-wild hogs of the State might be used as a basis for breeding a race of hogs more resistant to infectious diseases. This idea is discredited by the author. Studies of infectious hog diseases have been made for a number of years at the station. The bacillus of hog cholera was isolated from the spleen of an infected hog, and was fed in milk to healthy hogs for the purpose of determining its agency in the production of the disease. The experimental hogs became sick within a few days and died soon afterwards of hog cholera. Similar tests with the same results were made with pure cultures of hog-cholera bacillus obtained from other sources. Subcutaneous inoculation of hogs with pure cultures gave results which indicate that the disease when thus induced is less acute than when caused by injection of the bacillus into the alimentary tract. In some cases subcutaneous inoculations did not cause death until after a period of 4 weeks, or rarely produced any effect whatever. It was shown that artificial cultures of the hog-cholera bacillus may become attenuated after several months growth on nutrient media in the laboratory. With regard to the problem of possible recurrence of the disease in hogs which have recovered from one attack, it is suggested that tests should be made in exposing recovered animals to infection from fresh sources. No such tests, however, have thus far been made. It was found impossible to produce the disease artificially in a hog which had recovered from an attack, and the evidence is in favor of the belief that one attack produces immunity. Hog cholera and swine plague are usually combined in the same attack. In bacteriological studies made by the author no cases were found in which it was possible to assert that hog cholera was not combined with swine plague, but in some cases the organism of swine plague was found unassociated with that of hog cholera. In several cases the bacillus of swine plague was found where the hog cholera bacillus could not be demonstrated. It is possible, however, that one disease may partly run its course, but later be obscured by the predominance of the other associated disease. The author considers it unsafe, therefore, to assert that swine plague occurs in Arkansas as an independent disease, spreading by contagion like cholera.

Notes are given on the occurrence and injurious effects of lung worms, Ascarides, and Echinorhynchi. Attention is called to the difficulties of diagnosing hog diseases from the symptoms on account of the fact that such great variations in symptoms are observed and on account of the similarity of symptoms in different diseases. With regard to the treatment of hog diseases the author found all direct remedies unsatisfactory. Even in treatment of hogs for worms the use of vermicides, such as naphthaline, santonine, and various purgatives, were not effective. The chief effort of hog raisers should be in the line of prevention of hog diseases. The application of the vaccine method in the control of infectious hog diseases has been tried and favorably reported upon by this Department. With the author, however, this method yielded no results whatever. It was also found that the vaccine which protected against hog cholera had no effect against swine plague. A double vaccine was therefore introduced which fulfilled all requirements of a vaccine in tests on laboratory animals. No opportunity, however, has been had for proper testing of the matter in natural outbreaks of hog cholera.

The influence of cold on the development of pneumonia of the horse, J. Bourgès (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), No. 16, pp. 336–340*).—Observations on the prevalence of pneumonia in horses in various countries were made for the purpose of determining the influence of cold on the etiology of pneumonia. As a result of observations on 2,850 horses and mules it is concluded that cold has no effect on thoracic diseases. The prevalence of long periods of severe cold may weaken the animal to some extent, provided a corresponding increase in fodder is not given to the animals. The practice of protecting horses to too great extent against cold in winter is condemned. In order to secure artificial heat it is frequently necessary to maintain the animals in quarters which are not as well ventilated as they would be if less attention were given to the temperature.

Report on the surra disease of horses, Schilling (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 15, pp. 545–551*).—The author gives a detailed description of the symptoms of this disease in a horse suffering from a natural infection. A purulent discharge was noted on the eyelids and in the nasal cavity, and an œdematous swelling extended from between the forelegs backwards for some distance on the inferior surface of the body. The animal had a ravenous appetite until shortly before death. The hemoglobin content of the blood was determined at from 25 to 30 per cent; body temperature varied between 38.2 and 40° C. Two other cases were observed with slightly different symptoms. Inoculation experiments were made on horses, an ass, cattle, goats, hogs, and dogs. Hogs were refractory to the disease, but the other animals became infected. Trypanosoma was found in large numbers and in an active condition in the blood of affected animals. The various stages in the development of the parasite are described in detail.

"Staggers" among horses in the northeastern counties of North Carolina, T. BUTLER (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 9, pp. 25–35*).—During August and September about 500 horses died in the northeastern part of the State from this disease. An investigation was made of the symptoms, cause, and pathological changes of the disease. The author considers the disease to be the same as what is commonly referred to as cerebro-spinal-meningitis, mold poisoning, or forage poisoning. The cases which were studied indicated that the disease was caused by poisons produced by molds or bacteria in decomposing vegetable matter, and gained entrance to the animals in their food or water supply. In a few cases moldy corn fodder was plainly indicated as the cause of the trouble. Other cases seemed to be developed as the result of eating moldy oats, and it is stated that oats were generally moldy during the season throughout the State. A detailed description is given of the clinical symptoms and post-mortem findings in cases of the disease. Treatment is usually unsatisfactory for the reason that the exact nature of the poison which causes the disease is still unknown and the disease ordinarily runs its course too rapidly to allow effective administration of medicines. Aloes or calomel may be given during the first stages of the disease, in conjunction with cold applications to the head and internal administrations of bromid of potash or iodid of potash. In preventing the development of this disease, attention is called to the desirability of avoiding the use of moldy fodder. The author gave some attention to the supposed connection between mosquitoes and the disease, which has been suggested by some stock owners. No foundation was discovered for this belief. It appears also quite improbable that any poisonous wild plants were concerned in producing the trouble.

Chickens and their diseases in Hawaii, T. F. SEDGWICK (*Hawaii Sta. Bul. 1, pp. 23*).—In the introduction by J. G. Smith attention is called to the high prices demanded for eggs and poultry in the Honolulu markets. The cause of these high prices is chiefly the prevalence of a number of diseases among poultry. The most important disease among poultry in the Hawaiian Islands is chickenpox, locally known as sorehead. The symptoms of the disease are described in detail and attention is called to the difficulty of recognizing it in its earlier stages without careful examination. In treating the chickenpox the use of disinfectants is recommended, among which mention may be made of carbolic acid, Bordeaux mixture, turpentine, and whitewash. Infected fowls may be treated with local applications of potassium permanganate, nitrate of silver, sulphur, sulphate of copper, carbolic ointment, or oxid of mercury. A discussion of the subject of chickenpox by J. J. Green is reprinted in the bulletin. Brief notes are given on diarrhea, cholera, colds, distemper, roup, intestinal worms, and lice. A historic account of the origin and introduction of domestic fowls into Hawaii is given, and it is suggested that by improvement upon the native chickens valuable breeds could be obtained which would have some resisting power to chickenpox and other local diseases. Brief suggestions are made regarding the kind and quantity of food and suitable shelter for chickens.

Bacteriological studies on the etiology of an epidemic disease among chickens in Tyrol, A. LODE and J. GRUBER (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 16, pp. 593–604*).—A serious outbreak of an infectious disease among poultry was observed in a number of small towns and an investigation of these outbreaks seemed to indicate that the disease was introduced from Italy. The death rate in outbreaks of the disease was very high, reaching, in some cases, 95 per cent. The course of the disease was in most cases run very rapidly, the fowls sometimes dying within a few minutes after the first symptoms were observed. After a thorough disinfection of infected chicken quarters, a practical control was obtained over the disease. The authors undertook a bacteriological study of material from fowls which had died of this disease, but were unable to isolate any specific organism. The symptoms are described as fairly well marked. A striking weakness is observed about 24 hours after infection, the wings are allowed to droop, and the birds appear sleepy. Occasionally a discharge from the nose is observed. The body temperature exhibited a wide range during the progress of the disease, reaching 43° C. in some cases and falling as low as 27.5° C. shortly before death. One of the most characteristic symptoms is a dark blue color of the comb and wattles, and from this symptom the authors propose the name cyanolophiea gallinarum. An organism was isolated, but it was shown afterward that this had nothing to do with the disease. Experiments demonstrated that the organism of the disease easily passes through a Berkefeld filter.

Text-book of veterinary medicine, J. LAW (*Ithaca: J. Law, 1896, Vol. I, pp. 411; 1900, Vol. II, pp. 574; 1901, Vol. III, pp. 601*).—In this general treatise the purpose of the author is to present a compendium of veterinary medicine with special reference to animal industry in America. In Vol. I the subjects treated are general pathology and diseases of the respiratory and circulatory organs, including the lymphatic system, in all domesticated animals. In Vol. II a discussion is given of the diseases of the digestive organs, liver, pancreas, and spleen. In Vol. III the diseases of the urinary and generative organs, skin, eye, and nervous system are considered. The fourth volume is in preparation and will discuss the subjects of parasites and parasitism. The volumes thus far published contain a discussion of all the important diseases which affect the various domesticated mammals and birds.

AGRICULTURAL ENGINEERING.

Irrigation in the United States, F. H. NEWELL (*New York: T. Y. Crowell & Co., 1902, pp. XIX + 417, pls. 62, figs. 94*).—This book is one of the Library of Economics and Politics series and is stated to be "a somewhat elementary and popular description of irrigation and of the devices for obtaining and distributing water, including details of interest to persons who are beginning to give attention to the subject. More space is devoted to the crude but effective home-made contrivances than to the elaborate or expensive machinery purchased from manufacturers, for the success of irrigation depends most largely upon the rough-and-ready ingenuity of the first settlers in a new country in adapting their ways to the environment." It includes a summary of the author's twelve years' study and experience in various fields of irrigation inquiry.

The book treats of the reclamation of the public lands; precipitation, frosts, and grazing and cultivated lands of the arid region; surface waters and their measurement; conveying and dividing stream waters; construction, management, and use of reservoirs; methods of irrigation; underground waters; pumping water; advantages and disadvantages of irrigation; irrigation law; accounts of irrigation in the States and Territories of the arid and semiarid regions; and irrigation in the humid region.

Irrigation of the Delta of the Colorado, W. W. CAMPBELL (*Sci. Amer., 85 (1901), p. 358*).—The areas which it is estimated may be irrigated in this region from the waters of the Colorado River are 150,000 acres in Arizona, 300,000 acres in Lower California, 500,000 acres in southern California. There are also stated to be 50,000 acres in southern California which may be irrigated from artesian wells.

Hydrography in the United States, H. GRAVELIUS (*Ztschr. Gewässerkunde, 4 (1901), pp. 143–157*).

Irrigation works in Egypt (*Rev. Sci. [Paris], 4. ser., 17 (1902), No. 2, p. 61*).—A brief note.

The regeneration of Egypt. The Assouan dam, A. RIEFFEL (*Rev. Sci. [Paris], 4. ser., 17 (1902), No. 9, pp. 268–272*).

Hydrology of Sahara, LAHACHE (*Rev. Sci. [Paris], 4. ser., 17 (1902), No. 9, pp. 272, 273*).

Irrigation in South Alberta, Northwest Territories, J. McCaig (*Farmers' Advocate, 36 (1901), No. 527, pp. 332, 333*).

A few remarkable artesian wells and the uses to which they are put, E. H. Barbour (*Sci. Amer., 85 (1901), No. 2, p. 21, figs. 4*).

Graphical solution of hydraulic problems, F. C. Coffin (*New York: John Wiley & Sons, 1901, pp. 79, dgms. 34*).

A comparison of the cut-away disc harrow and the spring-tooth harrow, C. A. McClelland (*Agr. Student, 8 (1901) No. 3, pp. 49, 50*).—Comparative tests are reported in which the results favored the disc harrow as regards draft and amount of soil stirred.

The complete harvester (*Jour. Agr. and Ind. South Australia, 5 (1902), No. 6, pp. 542, 543*).—Comparative tests of 8 different kinds of combined harvesters and threshers are reported.

The pressing of fodders, M. Ringelmann (*Ann. Inst. Nat. Agron., 24 (1897-1900), No. 16, pp. 203-216*).—This article discusses the general objects, principles, and methods of pressing fodders, and reports tests of a number of hay presses.

MISCELLANEOUS.

Fourteenth Annual Report of Georgia Station, 1901 (*Georgia Sta. Rpt. 1901, pp. 119-128*).—This includes the organization list of the station, brief reports of the board of directors and the director of the station covering the operations of the station during the calendar year, and a financial statement for the fiscal year ended June 30, 1901.

Fourteenth Annual Report of Illinois Station, 1901 (*Illinois Sta. Rpt. 1901, pp. 17*).—This contains a list of station publications, an enumeration of the principal lines of station work, text of a bill providing for appropriations for the equipment of the college and the extension of the work of the station, and a detailed financial statement for the fiscal year ended June 30, 1901.

Fourteenth Annual Report of Indiana Station, 1901 (*Indiana Sta. Rpt. 1901, pp. 112*).—This includes the organization list of the station, a report of the director on the work and publications of the station during the year, several articles noted elsewhere, a list of acknowledgments, and a financial statement for the fiscal year ended June 30, 1901.

Fourteenth Annual Report of Michigan Station, 1901 (*Michigan Sta. Rpt. 1901, pp. 95-310*).—This includes a financial statement for the fiscal year ended June 30, 1901, reports of the director and heads of departments reviewing the work of the station during the year, meteorological observations, and reprints of Bulletins 186-192 and Special Bulletin 14 of the station on the following subjects: First report of the Upper Peninsula Experiment Station (E. S. R., 13, pp. 224, 233, 240, 259, 264, 290), report of South Haven Substation (E. S. R., 13, p. 349), experiments with sugar beets (E. S. R., 13, p. 343), notes on strawberries (E. S. R., 13, p. 456), vegetable tests for 1900 (E. S. R., 13, p. 452), shrinkage of farm products (E. S. R., 13, p. 548), fertilizer analyses (E. S. R., 13, p. 540), and foul brood (see p. 877).

Papers by directors of New England agricultural experiment stations (*Rhode Island State Bd. Agr. Rpt. 1900, pp. 85-178*).—The work of the Rhode Island Station during 1900 is reviewed at some length by A. A. Brigham, the work of the Connecticut Storrs Station by R. D. Milner, the Connecticut State Station by E. H. Jenkins, the Maine Station by C. D. Woods, the Massachusetts Station by H. H. Goodell, and the Vermont Station by J. L. Hills.

Annual Reports of the Department of Agriculture, 1901 (*U. S. Dept. Agr. Rpts. 1901, pp. CXV+344*).—Executive reports.

Report of the Agricultural Chemical Experiment and Seed Control Station of Riga, G. Thoms (*Ber. Landw. Chem. Vers. und Samen-Control-Stat., Riga, No.*

10, pp. 258).—This is a detailed account of the operations of this station during the years 1897–98 and 1899–1900, including articles on the importance of nitrate of soda for Baltic agriculture, a contribution to the knowledge of the wood of the yew (*Taxus baccata*), as well as a discussion of the results of the fertilizer control conducted by the station and reviews of recent literature relating to the subject of fertilizers. A table of contents of Nos. 1 to 9 of the reports of this station is also given.

Papers selected from those read at farmers' institutes and other meetings during the year (*Pennsylvania Dept. Agr. Rpt. 1901, pt. 2, pp. 119–335*).—Following are some of the subjects treated: Ideal standards in farming, nature study in the public schools, botany on the farm, education for the adult farmer, the silo an economic, the relation of the wholesomeness of the stable to the health of its inmates, the soil our partner, soil improvement the keynote of agriculture, management of dairy cows on the farm, farm fences and ways over the farm, hygiene on the farm, nature study, the birds and the farmers, some suggestions for furnishing and decorating country homes, curing clover, lighting, heating, and ventilating the home, intensive farming, public roads, live stock in western Pennsylvania, floriculture as a profession, progressive poultry raising, our farm garden, farming on a large scale, a plea for better live stock in Pennsylvania, geological relation of soils, the Holstein-Friesian breed, Ayrshires, the Jersey cow, growing *Primula chinensis* for exhibition, twelve best herbaceous plants for the amateur, culture of *Calceolaria hybrida*, the cultivation of sweet peas, how to prepare and plant a permanent asparagus bed for private use, report of general fruit committee, strawberry culture, is it advisable to grow small fruits in young orchards, some points in door-yard planting and decoration, advancement of floriculture in Allegheny County the past forty years, Pennsylvania as a fruit-growing State, ornamental horticulture, the packing and shipping of fruit from a commission merchant's standpoint, some points in potato culture, and selection of varieties, how to plant, pick, and store the apple.

Changes in the rates of charge for railway and other transportation services, H. T. Newcomb, revised by E. G. Ward, jr. (*U. S. Dept. Agr., Division of Statistics Bul. 15* (*rev.*), *misc. ser., pp. 86*).—Statistics for the years 1898–1900 are added to the original bulletin, which was noted in E. S. R., 10, p. 298. "Perhaps the most notable fact established by the addition of data for the last three years is the great increase in the aggregate volume of traffic movement."

Agricultural statistics for Belgium in 1900 (*Statistique de la Belgique recensement agricole de 1900. Brussels: Ministry of Agriculture, 1901, pp. 223*).

NOTES.

California University and Station.—The summer school at Berkeley this year will include lectures in agriculture, horticulture, entomology, irrigation, and animal feeding. Prof. W. A. Henry, of Wisconsin, will go to the coast to deliver a course of lectures on the latter subject. M. E. Jaffa, of the college of agriculture and the experiment station, has been granted a year's leave of absence for study. He will spend several months in studying the methods of food investigation under Prof. W. O. Atwater at Middletown, Conn., and later will spend some time in Europe studying the institutions for agricultural research and instruction.

Connecticut Storrs College and Station.—C. S. Phelps, agriculturist in the college and station, has resigned. At a recent meeting of the board it was decided to concentrate the work of the station at Storrs and to discontinue the work done at Middletown, this to take effect during the coming summer.

Illinois University and Station.—H. W. Mumford, recently elected professor of animal husbandry in the university and animal husbandman of the station, has been spending considerable time at the Union Stock Yards, Chicago, securing photographs and descriptions of the market grades of beef cattle. The results of this investigation will be used in the preparation of a bulletin. R. S. Woodrow, field assistant in sugar-beet investigations, has severed his connection with the station. A. V. Stubenrauch has been elected assistant horticulturist and inspector of substations at the California Station. He will enter upon his duties early in July.

Iowa College and Station.—The general assembly of the State has given the college a one-fifth mill tax to run for five years, which is expected to realize about \$600,000. This money is to be used for the erection of buildings. An additional appropriation of \$135,000 was made for the biennial period—\$35,000 annually for general maintenance, \$10,000 annually for the experiment station, \$5,000 for live stock, \$35,000 to begin the erection of the main central building to take the place of the building destroyed by fire about a year and a half ago, and \$5,000 to begin the erection of a barn for the station to replace the one destroyed by fire. The contract has been awarded for this barn, to cost \$17,280, the balance to be paid from other funds.

Kansas College and Station.—H. M. Cottrell, agriculturist in the college and station, has resigned his position to accept the superintendence of a large farm near Trenton, Mo. Professor Cottrell will enter upon his new position about July 1, in the meantime preparing the results of his experimental work for publication. C. L. F. Paull has been appointed assistant botanist, and E. H. Webster, assistant in dairying. The station has leased for five years a large bearing apple orchard in the vicinity in order to conduct certain experiments on a commercial scale. During the last half of the winter term the college conducted a very successful judging school, one week being given to each of the following subjects: Poultry, swine, dairy cattle, beef cattle, and horses. In addition to the stock belonging to the college many valuable animals were loaned by their owners. The instruction in judging each class was given by some expert of the State. The term's work closed with the slaughter of six steers which had been fed for beef during the winter, the object being to demonstrate the difference in the character of the meat. The animals were bought in the Kansas City market. A grade Shorthorn and a grade Angus represented the beef type, a grade Holstein and a Jersey the dairy type, and two others the scrub type of mixed breeds. The full results of this demonstration will be presented in a bulletin, but it may be mentioned that the best beef was produced by the Shorthorn, and that of the Jersey ranked next.

Maine Station.—Arthur B. Foster, a member of this year's graduating class of the university, has been appointed assistant chemist.

Massachusetts College.—The State legislature has appropriated $35,000 for a central lighting and heating plant for the college, $35,000 for the erection of a boarding house, and $1,000 annually for the maintenance of the latter.

Mississippi Station.—The land for the new substation at McNeill, including about 2,000 acres, has been donated and work undertaken on a small tract. Much of this land is still in woods and only a small portion will be used. It is planned to study at this station the use of fertilizers to determine the requirements of common crops on soils of that region, economy in the use of fertilizers, and similar questions. Work will also be done in fruit growing and in gardening, the region about McNeill being especially adapted to trucking. E. B. Ferris, formerly assistant chemist, has been appointed assistant director, in charge of the McNeill station.

Nebraska University.—At a recent meeting of the board of regents of the University of Nebraska the Omaha Medical College was affiliated with the university. Two years of the medical work will be given at the university and the clinical work will be carried on at Omaha as before. It is planned to materially strengthen the course with a view to furnishing better opportunities for medical study. Dr. Henry B. Ward, of the university, has been elected dean of the medical school.

New Hampshire College and Station.—Lucian A. Hill, B. S., of the University of West Virginia, has been appointed assistant chemist of the station, in place of H. A. Clark, resigned. At the April meeting of the board of control the following new investigations were authorized: (1) A series of experiments on crop rotation, including various leguminous crops, some of which may be plowed under and others removed from the land, barnyard manure being applied to cultivated crops. The object is to discover a cheap way to restore the fertility to worn-out soils, if possible, without the use of chemical fertilizers. (2) Variety tests of some early maturing kinds of corn, with the view to discovering the varieties best adapted to the climate and soil of the State. (3) Comparative yield of dry matter and digestible nutrients in corn as compared with hay. (4) Loss of nutrients in corn fodder in different methods of storing. (5) Draft and efficiency of surface-working implements. (6) Comparative feeding value of corn meal and corn-and-cob meal in milk production. (7) Comparative feeding value of timothy hay, clover hay, and corn stover in milk production. The foundation is being laid for the new agricultural building, which it is estimated will cost $30,000.

New York State Station.—The barns of the station were destroyed by fire May 7. The buildings included cattle, horse, storage, and tool barns, and 2 small poultry houses. All of the live stock was removed except 2 bulls, a young heifer, and 3 calves. Some of the vehicles and wheeled tools were saved, but the plows, cultivators, and other implements were lost. At one time the greenhouses and the new dairy building were in danger, but the fire was checked before any serious damage to them was done. The origin of the fire is unknown. The loss is estimated at about $20,000; the property was insured for about $13,000. The buildings will be replaced at once, the State authorities having authorized their reconstruction. Plans for them are now in process of preparation. The governor has appointed Jens Jensen, of Binghamton, a member of the governing board, vice A. C. Chase, of Syracuse (term expired), and Thomas B. Wilson, of Halls, *vice* Frank O. Chamberlain, deceased. The branch office on Long Island has been discontinued. F. A. Sirrine, previously in charge of the work there, has purchased a farm near Riverhead and as special agent of the station will conduct and oversee numerous experiments on his own farm and others throughout the Island, while considerable work will be under direct supervision of heads of departments at the station.

Cornell University.—The large horticultural barn, one of the oldest structures at the university, was entirely destroyed by fire early in April. Many specimens of trees, plants, and shrubs stored there by Professor Bailey were lost. At the recent session of the State legislature an appropriation of $35,000 was made to the college of agriculture for the purpose of continuing the agricultural extension work, which has grown so popular during the past five years.

North Dakota College.—The college has added a two years' course in pharmacy and a four years' course in pharmaceutical chemistry. Charles H. Kimberly, of the Ohio State University, has been elected instructor in pharmacy.

Ohio Station.—The State legislature has made the following appropriations to the station for the two-year period, 1902 and 1903: For expenses of the board of control, $783; bulletin illustration, $800; special work in entomology, botany, horticulture, and chemistry, $14,000; substations, $10,000; general repairs, labor, and supplies, $14,000; investigation of tuberculosis (unexpended balance reappropriated), $2,859; special work in animal industry, $3,000; library equipment and care, $750; general construction, $3,000; total, $49,192. At the request of the board of control of the station the legislature has transferred to the State board of agriculture the work of orchard and nursery inspection, and made a special appropriation of $15,000 for two years. The legislature has also transferred to the board of agriculture the powers and duties of the State Live Stock Commission, under a law enlarging the responsibilities of that commission. The appropriation to the station for the investigation of tuberculosis is continued. By this legislation the station is freed from inspection or police work of every description, and its province as an organization for research is more clearly defined than ever before, while at the same time its facilities for research are largely increased, the appropriations for this purpose being 60 per cent greater than for any similar period before. A. F. Burgess, who has acted as first assistant inspector of nurseries and orchards for the past two years, is continued as chief inspector under the new management. Miss Ida L. Feiel, Ph. B., has been appointed assistant botanist.

Rhode Island College and Station.—Dr. J. H. Washburn, who has been president of the college since its establishment thirteen years ago, has resigned his position to take effect at the close of this year. The State has made an appropriation of $1,500 for dormer windows, flooring, and general repairs to the chemical laboratory building of the station; also an appropriation of $1,400 for the erection of an addition and for repairs to the barn used in connection with the field experiments. This addition will furnish storage for tools and a floor for thrashing and for mixing fertilizers.

South Dakota College and Station.—James W. Wilson, son of Secretary Wilson, has been elected director of this station, and will have charge of the work in animal husbandry in the college and station. He will enter upon his duties at once.

Tennessee Station.—A very successful meeting of the East Tennessee Farmers' Convention was held at Knoxville, May 21–23, under the auspices of the college and station. The programme was a comprehensive one, and a number of prominent speakers were present from abroad. The afternoon of the last day was given up to an inspection of the university farm and the dairy school, the latter being in operation.

Texas College and Station.—David F. Houston, formerly professor of political science at the University of Texas, has been elected president of the college and will assume charge July 1. E. P. Stiles has been appointed superintendent of the new substation at Troup. About 150 acres of land near the town has been donated for this station, part of which is cleared. A station building will be erected there, and work has already commenced on the field operations. Experiments in fruit raising and general farming will be carried on. Funds have been raised by the local community for the maintenance of the station another year, as appropriation was made by the legislature for only one year. C. H. Alvord, assistant in agriculture in the college, will withdraw at the close of this session, as will also E. A. White, assistant horticulturist, who has been elected botanist at the Connecticut Agricultural College.

Vermont Station.—Extensive alterations are being made in the station building, which will provide the director and the horticulturist with more conveniently located and spacious quarters.

Wisconsin Station.—Prof. E. S. Goff, horticulturist in the college and station, died June 6, after a short illness.

Summer School of Agriculture.—Interest in this school, to be held at Columbus, Ohio, beginning July 7, is very widespread, and students from different sections of the country have announced their intention of attending. Over 70 students have already registered, and its success from point of numbers seems already assured. A programme of the school is now in preparation and will be issued shortly.

U. S. Department of Agriculture.—The University of Missouri recently conferred the honorary degree of doctor of laws upon Secretary James Wilson and B. T. Galloway, of the Bureau of Plant Industry.

W. H. Evans, of this office, has returned from Porto Rico, where he has been in conference with F. D. Gardner, in charge of the Porto Rico Station, with reference to the selection of a permanent site and the development of the station there.

O. F. Cook, of the Bureau of Plant Industry, has returned from a three months' trip to Guatemala and southern Mexico, where he was engaged in studying the methods and the problems of coffee and rubber culture.

B. M. Duggar, botanical physiologist, has been elected to the chair of botany in the University of Missouri and will enter upon his new duties in September. He will continue to carry on some of his present lines of investigation as collaborator of the Bureau of Plant Industry.

Ernst A. Bessey, in charge of seed and plant introduction, will start early in July on a trip to Russia and Turkestan for the purpose of securing seeds of certain forage and cereal plants, especially the Turkestan alfalfa. He will then proceed to Germany, where he will spend a number of years in botanical study. He will be succeeded in charge of the seed and plant introduction by A. J. Pieters of the seed laboratory, who in turn will be succeeded by Edgar Brown.

Miscellaneous.—The New York Horticultural Society has completed arrangements for holding an international conference on plant breeding and hybridization September 30, October 1 and 2, of the present year. The meeting will be held in New York City. Papers will be read by prominent men from this country, Canada, England, Scotland, Ireland, and elsewhere. In connection with the conference an exhibition of hybrid plants and their products will be made, to which every one is invited to contribute. Awards of the society in the form of medals, diplomas, and certificates will be made for plants and plant products of hybrid origin, illustrating some particular phase of this work. Thirty papers have already been promised.

The Massachusetts Institute of Technology announces a new summer school for nature study, known as the Sharon Summer School, named for the town of Sharon, where most of the field work will be carried on. Its object is to furnish teachers and lovers of nature with thorough training in the principles of natural science and a practical knowledge of the more common forms of living things. The curriculum provides for elementary work in physiography and general biology, with elective courses on trees, wild flowers, birds, insects, mammals, and seashore life. The laboratory facilities of the institute will be utilized, and opportunity for out-door study and experimentation will be afforded by the control of 300 acres of natural country in the town of Sharon. The school will open July 9 and will continue for 4 weeks.

An interesting pamphlet has been issued by Prof. F. B. Mumford, of the University of Missouri, entitled Some Lessons from European Agriculture. The article is a reprint from the Annual Report of the Missouri State Board of Agriculture for 1902, and is based upon the author's observation and study during recent travels in Holland, Germany, Switzerland, Great Britain, and other European countries. Among the lessons which the author suggests may be drawn from European agriculture are greater care in the conservation, handling, and application of farm manures, economy in feeding, and the utilization of all the products of the farm, including many which in this country are often regarded as waste products.

The Imperial Department of Agriculture for the West Indies has begun the publication of a fortnightly review, to be known as *Agricultural News*, the first copy of which appeared late in April. The publication is a quarto sheet of 16 pages. Its object is to supply, in popular form, information of an agricultural character suited to the requirements of the West Indies, with a view to instructing and assisting all classes and to promoting the agricultural interests of the colonies. It will be sold through the local agents of the department at 1d. per number, or 4s. 4d. per annum. The initial number contains contributed articles on cane cultivation, diseases and insects, preparation of commercial papain, and cassava poisoning; agricultural news items, original and quoted, on topics of interest to the islands; department news; a number of book notices; a directory of the agricultural institutions in the West Indies, and market quotations.

A new semimonthly journal for dying and textile chemistry (*Zeitschrift für Farben- und Textil-Chemie*) appeared at the beginning of this year. It is devoted to color and textile chemistry, including the related subjects of organic chemical industry and the textile industry. The journal is edited by Dr. A. Buntrock, of Karlsruhe, with the assistance of a large number of English and European collaborators.

Nature notes that the Lawes Agricultural Trust Committee has appointed A. D. Hall, principal of the Agricultural College at Wye, to succeed the late Sir Joseph Henry Gilbert as director of the Rothamsted Experiment Station. Mr. Hall is a graduate of Oxford, and has distinguished himself by his successful development of Wye College as a center of agricultural education. Although little known in the field of agricultural research, Mr. Hall's selection to succeed Dr. Gilbert appears to meet with approval.

The German Association of Naturalists and Physicians will hold its seventy-fourth annual congress at Carlsbad September 21–28. As on former occasions, papers may be presented in any of the modern languages and foreign visitors will be accorded the same privileges as the members of the association. It is estimated that between 6,000 and 8,000 men of science and physicians will attend the meeting of this famous association.

According to a note in *Forestry and Irrigation*, the officials of the Illinois Central Railroad have decided to begin planting catalpa trees along their lines from Chicago to New Orleans, a distance of about 900 miles, for the purpose of producing railroad ties. The contract for the planting has already been let.

Science states that a committee has been formed, under the presidency of Professor von Zittel, for the erection in Munich of a memorial to the late Prof. Max von Pettenkofer.

A recent number of *The Tradesman* reports that there will soon be in operation at Kenilworth Plantation, Louisiana, a mill for making wrapping paper out of bagasse. This is stated to be the first mill of its kind in Louisiana, although one has been in operation for some time at Sugarland, Texas. The mill will have a capacity of about 25 tons of paper per day.

EXPERIMENT STATION RECORD.

VOL. XIII. No. 10.

The recent successful meeting of the American Association of Farmers' Institute Workers in this city demonstrates the widespread interest felt in this form of popular education, and the earnestness and enthusiasm with which it is being carried on. The meeting was quite a representative one, delegates being in attendance from the Pacific coast, the Gulf States, and Canada, as well as from the Middle and Eastern States.

The discussion of methods employed in different States brought out many valuable suggestions, and altogether the sessions were full of interest and encouragement for those engaged in this work. The breadth of scope which the work has taken in some of the States, and the practical results which it has already achieved, were an inspiration to delegates from States where the work is not so well established. The personal contact and the mutual sympathy and inspiration which come from such a gathering are among its most important results.

The association indorsed the plan for the National Department of Agriculture to act as a central bureau for the promotion of institute work, to assist it in organization, by publications, and in various ways. An account of the meeting will be given in the next number of the *Record*.

At various stages of the meetings the discussion turned on the personnel of the institute force—the kind of men best adapted to the work and those available. At the present time this is probably one of the most important problems. Success in farmers' institute work requires a special order of ability. It is undoubtedly one of the most difficult forms of educational work, calling for intimate knowledge of both theory and practice, ability to command the attention of farmers and to present a subject with clearness and force, and the exercise of originality, frankness, and tact. The practical and the scientific or theoretical must be blended so thoroughly as to appeal to the unread farmer without repelling his better-posted neighbor, and, above all, the institute should set the average farmer to reading and thinking more for himself.

It was agreed that the institute speakers should be men thoroughly abreast of the times, who keep themselves well posted by reading, but there was some difference of opinion as to whether or not college-trained men are especially desirable. The fear that such men will be too technical and not sufficiently in sympathy with practice has led to the employment of practical farmers or breeders in many States, selected for their intelligence and success along some special lines. It was generally agreed that a certain number of speakers of this class are a valuable acquisition to the institute corps, but the advantage of thorough training in the principles underlying agriculture was recognized as greatly strengthening the man for his work. The speakers are called upon to explain the latest theories of science regarding the assimilation of nitrogen, the ripening of cheese, the changes in silage making, the breeding of plants, and similar subjects, as well as to use charts presenting scientific data. Unless they themselves clearly and correctly understand these things they are likely to fall into error and to make unwarranted deductions and applications.

As a general rule, the experiment station worker has been voted a leading place as an institute speaker the country over. Very little real objection has developed on the ground of his being too technical in his presentation or unable to make the application of his knowledge to everyday practice—a theoretical objection which is occasionally still heard in some quarters. But with the growth of the stations and colleges the experiment station worker and the college instructor are becoming less and less available for institute work, and can be relied upon only for special occasions, such as round-ups or meetings in the vicinity of the college.

As the work develops and funds for it increase, a special class of educated institute workers will be needed, who will couple with an agricultural education a certain amount of experience and a wide knowledge of agricultural conditions in the region where they work. These men will be used in addition to a certain number of workers selected from among the best farmers and breeders of the locality, the latter confining themselves to the more strictly practical considerations. Some provision might well be made by which the trained institute workers could more readily come in contact with the college and station at frequent intervals, and literature especially adapted to their needs might be provided by State or national agencies. More men are needed to make institute work their business and to give its development and methods serious consideration and study. Then it will be practicable, with more adequate support, to systematize the work to a greater degree, to make it less fragmentary in character, and to reach the great masses of our farmers who are as yet untouched by the experiment stations and the farmers' institutes.

The establishment of a system of experiment stations in Victoria. Australia, is under consideration, and a recent official publication from that country indicates that steps in that direction are likely to be taken soon. The agencies for agricultural experimentation and demonstration in the colony at present embrace the Department of Agriculture at Melbourne, the Agricultural College and Experimental Farm at Dookie, and numerous demonstration fields.

The Department of Agriculture has a staff of some 12 experts, engaged in carrying on investigations and giving itinerant instruction throughout the colony in the various branches of agricultural practice. In addition, it has the supervision of the School of Horticulture at Burnley and the Viticultural College at Rutherglen, at both of which places a limited amount of experimental work is conducted. The Agricultural College at Dookie, in connection with its educational work, conducts experiments on a large scale on wheat and other cereals, fodder plants, and vegetables, together with more restricted experiments in olive culture, in drying and preserving fruit, and in animal husbandry. The experimental farms, as they are often spoken of, which are in reality only demonstration fields, are under the control of the Department of Agriculture. They are cooperative in character, and are distributed throughout Victoria, where they have been in operation for some 12 years.

These experimental farms have led up to the present agitation for a system of institutions of a higher class, i. e., of experiment stations. They have demonstrated the great value of experimental work in promoting agricultural science and in bringing about its application in practice. As a recent article puts it, "the power of science to assist agriculture has spoken so plainly in the growing experimental crops of the many farms throughout the State that an agitation for further developments in experimental work, too complicated and continuous for the individual farmer to undertake, is now growing on all sides. As a result, we have the Minister's promise of the establishment of a number of permanent experiment stations. It is the most progressive step that has yet been taken."

The same article mentions an apprehension on the part of some farmers that the development of the experiment stations will do away with the demonstration plats as at present carried out on the farms throughout the country. This fear, however, is declared to be groundless, and the work which the farms have done seems to be highly appreciated by the officials of the Department of Agriculture.

"The purpose of the present fields must be clearly understood. They are really demonstration as much or more than experimental fields. They are necessary, both for answering the hundred and one little questions arising from local differences of soil and climate, as well as for the dissemination of facts, not as spoken words, but as truths visible in the growing crop of the farm. Instead of diminishing in numbers in countries where the experiment stations are already numerous, they are continually increasing; for, as the discoveries of an experiment station multiply, so the necessity for the expression of such facts in the demonstration field on the farms throughout the country becomes all the more obvious. The work already accomplished by them has in certain parts of our State almost revolutionized farming, and no agricultural teacher could regard their discontinuance with anything but the strongest regret."

Experiment stations were formerly thought to be especially necessary in old countries, where more intensive farming was practiced, and where the conditions of the soil and the practice of stock raising made experiments necessary to answer the many problems which were constantly presenting themselves with the development of more rational feeding and manuring. Subsequent developments have shown, however, that the experiment station is no less valuable for the new, undeveloped country, where there are no traditions to guide the farmer and where agriculture itself is necessarily of a more experimental character. The recognition of the necessity of experiment stations in the different colonies of Australia is a demonstration of this, and the form which the stations thus far established have taken is convincing evidence of the fact that in the evolution of the experiment stations the system of no European country can be taken as a model, but there must be an adaptation of the stations to the conditions prevailing in the country or State for which they are primarily intended.

The decision of Governor Hunt and Commissioner Elliot regarding a site for the agricultural experiment station in Porto Rico has been announced in favor of the Carmen estate, adjoining the town of Mayaguez. This action is in accordance with the act of the insular legislature, which made the appropriation of $15,000 for the purchase of a suitable site as a permanent location for the station. Advertisements were made for offers of approximately 200 acres of land, and twenty-three responses were obtained.

Most of the sites offered were visited and inspected by Messrs. Frank D. Gardner, special agent in charge of the Porto Rico Station, and Walter H. Evans, of this Office, who went to the island for that purpose. A report was made to the proper officials, in which the merits of the different tracts were fully set forth, and acting upon the recommendations made the above estate was selected. It adjoins the town of Mayaguez, and embraces about 230 acres, each of the principal types of land being well represented.

The purchase price of the estate was considerably in excess of the amount of the appropriation, but the city of Mayaguez has assumed the remainder.

At present most of the land is in grass and pasture, with some scattered fruit and a few acres of coffee. The place is well provided with buildings, which will probably suffice for the present needs of the station, and the whole tract is fenced. The Mayaguez River bounds it on one side, and running water is to be found in a number of places over the farm, making it especially adapted to stock raising. Adjoining the new site is the old agronomic station which was established by the Spanish Government and abandoned in 1897. The latter is now under the control of the Quartermaster's Department of the Army, but efforts will be made to have the land added to that just purchased.

The region in which the station will be permanently located is generally recognized over the island as the best for diversified agriculture, and it is sufficiently near the larger cane and coffee regions to permit of cooperative experiments being undertaken under the immediate supervision of the station officers.

Agriculture in the New World is the title of a pamphlet recently received, which records the observations made by Prof. F. B. Smith, of the Southeastern Agricultural College at Wye, on a visit to the United States and Canada. Professor Smith will be remembered at many of the colleges and stations where he visited during the summer of 1900.

The report gives a review of the systems of agricultural education and experimentation in the United States and Canada, and descriptions of the colleges and stations which were visited, together with a discussion of some of the features of the agricultural instruction and station work in this country. It is written in a vigorous and enthusiastic style, and is an unusually satisfactory and accurate presentation of the aims, methods, and work of the American institutions for agricultural education and experimentation. The writer evidently caught the spirit of American institutions, and, while he occasionally finds things to criticise, he has not been sparing in his appreciation and praise.

Speaking of this Department, he says: "The more I learned of this wonderful Department the more was I impressed with the amount of work which it was performing and with the downright practical services which it was rendering to the farmers of the country." He has the following to say regarding the experiments and publications of the stations: "There are several points in this connection which I should like to bear testimony to, and they are, firstly, the care and exactitude with which the experiments are conducted. Referring more particularly to work upon the farm, I have never seen trials carried out with such respect for practical details, and with such scrupulous regard for accuracy in every particular, as those in progress at the different stations which I visited. Secondly, to the precautions taken to avoid publishing hasty or misleading results; and, thirdly, to the definite and precise form in which they are issued to the public. In some cases, as at Geneva, the stations engage an official for the special purpose of editing the bulletins and reports."

The writer finds the efforts which are being made to develop agricultural instruction in the secondary schools "full of interest and worthy of our close attention;" and he expresses the belief that "if such education can be carried on successfully anywhere, it will be in Canada and the United States of America."

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The development of chemistry, F. W. Clarke (*Jour. Amer. Chem. Soc., 24 (1902), No. 2, pp. 117–138*).—The presidential address delivered before the meeting of the American Chemical Society at Philadelphia, December 30, 1901.

Report on progress in agricultural chemistry, A. Hebebrand (*Chem. Ztg., 25 (1901), No. 92, pp. 1024–1027*).—A brief review of progress in this field with numerous references to literature.

The status of agricultural chemistry at the beginning of the twentieth century, T. Pfeiffer (*Chem. Ztschr., 1 (1901), Nos. 1, pp. 10–12; 2, pp. 28–30*).—A brief review of what are considered the most important recent developments along the line of plant and animal production.

Annual report on the progress in animal chemistry, M. von Nencki and R. Andreasch (*Jahresber. Thier. Chem., 30 (1900), pp. 1139*).—This volume contains abstracts of the literature of animal chemistry, physiological and pathological, for 1900, with a subject and author index. The abstracts are arranged in chapters dealing with proteids, fats, carbohydrates, miscellaneous substances, blood, milk, urine and perspiration, digestion, liver and gall, bones and cartilage, muscles and nerves, other organs, lower animals, oxidation and respiration, metabolism, pathological chemistry, enzyms and other ferments, and bacterial products.

A few of the recent advances in biochemistry, A. Kossel (*Chem. Ztschr., 1 (1901), No. 6, pp. 149–151*).

Text-book of agricultural chemistry, A. Mayer (*Lehrbuch der Agrikulturchemie. Heidelberg: Carl Winters, 1901, 5. rev. ed., vol. 1, pp. 16+442, pl. 1, figs. 35; vol. 2, pt. 1, pp. 6+174, figs. 6*).—A fifth revised edition of this well-known work.

Methods of standardizing acid solutions, C. G. Hopkins (*Jour. Amer. Chem. Soc., 23 (1901), No. 10, pp. 727–740*).—The author made a study of 6 methods of standardizing acid solutions, which are designated as follows: The silver chlorid, the ammonium sulphate, the sodium, the borax, the copper sulphate, and the iron permanganate methods. The following conclusions were reached: A skilled analyst can easily and quickly make determinations of hydrochloric acid by the silver chlorid method, within a limit of error of 0.5 mg. of silver chlorid on 2 gm. of precipitate. The ammonium sulphate method of standardizing sulphuric acid is exceedingly accurate, while simple and rapid. The results obtained by the sodium method were higher than those by the two previous methods, this being due, the author states, to impurities of carbon and iron in the sodium. The results, however, agree closely with those obtained by the ammonium sulphate and the silver chlorid methods. With the borax method the results obtained at the same time agree within themselves, but the indications are that the borax is not constant. The copper sulphate method gives fairly satisfactory results, but it is considered inferior to the silver chlorid method and the ammonium sulphate method in accuracy. The iron permanganate method gave fairly accurate results in standardizing oxalic acid and it is no less accurate than the copper sulphate method. From the results of his work the author concludes that the silver chlorid method, slightly modified as described, and the ammonium sulphate method are extremely accurate and satisfactory, the former for standardizing solutions of hydrochloric and the latter of sulphuric acid.

The determination of available plant food in soils by the use of weak acid solutions, A. D. HALL and F. J. PLYMEN (*Jour. Chem. Soc. [London], 81 (1902), No. 470, pp. 117–144*).—"The authors have compared the amounts of phosphoric acid that could be extracted from 19 different soils by a 1 per cent solution of citric acid, by equivalent solutions of hydrochloric acid and acetic acid, by a saturated solution of carbonic acid, and by an ammoniacal solution of ammonium citrate, respectively. Seven of these soils were from plats on the Broadbalk Field, Rothamsted, which had been continuously manured in the same manner for 42 years previously; the remaining 12 were soils of very varied origin, which had been the subject of crop experiments and whose reaction to phosphatic manuring was well marked.

"In the same 7 soils from the Broadbalk Field, the authors determined the potash extracted by the same dilute solvents with the exception of ammonium citrate; five other soils of different origin, whose response or otherwise to potash manuring had been tested by experiment, were also examined in the same way.

"Determinations were also made of the phosphoric acid and potash dissolved after long digestion with strong hydrochloric acid, of the loss on ignition, and of the earthy carbonates present in each soil.

"The authors conclude: (1) That no sharp line of distinction can be drawn between 'available' and nonavailable phosphoric acid and potash in the soil, and that any process of determining the 'available' constituents is an empirical one, dependent on the strength and nature of the acid used.

"(2) That the weak solvents give information as to the requirements of a given soil for mineral manures of a far more trustworthy nature than that which is afforded by such a solvent as strong hydrochloric acid.

"(3) That of the acids examined, the 1 per cent solution of citric acid gives results most in agreement with the recorded history of the soil, although there is evidence that the same interpretation can not be put on results obtained from all types of soil."

Methods of analysis adopted for soils, fertilizers, feeding stuffs, wheat and flour, and some miscellaneous substances, F. B. GUTHRIE (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 905–915*).—Details are given of the methods which have been in use for several years in the laboratory of the New South Wales department.

A simple rapid eudiometric method of determining chlorin in chlorids and hydrochloric acid, silver and phosphoric acid, E. RIEGLER (*Ztschr. Analyt. Chem., 40 (1901), No. 10, pp. 633–638; abs. in Chem. Centbl., 1902, I, No. 1, p. 70*).—The method is based on the principle that when silver chlorid is treated with hydrazin sulphate and sodium hydroxid solution the silver separates out in metallic form and nitrogen is set free according to the following equation: $4AgCl+N_2H_4.H_2SO_4+NaOH=4Ag+4NaCl+Na_2SO_4+6H_2O+N_2$. The method of procedure in case of phosphates is as follows: Dissolve the phosphate in water strongly acidulated with nitric acid. To a quantity of this solution corresponding to from 0.15 to 0.16 gm. of phosphoric acid, diluted if necessary to 50 to 60 cc., first add 1 to 2 gm. of silver nitrate dissolved in about 10 cc. of water, then drop by drop a 10 per cent solution of sodium hydroxid until the silver phosphate precipitate is not completely redissolved. Add in the same manner a 10 per cent solution of ammonia until the solution is alkaline, and boil for about 5 minutes. Cool the solution, collect the precipitate on a small filter, and wash with water, removing it to a flask by breaking the filter and washing it out with about 50 cc. of water. Add about 3 cc. of concentrated nitric acid and 1 gm. of sodium chlorid dissolved in water, close the flask and shake vigorously for ½ minute, collect the precipitate of silver chlorid on a small filter, and wash until it is free from acid. Roll up the filter and contents and place in a Knop-Wagner azotometer, adding about 30 cc. of water, 0.5 gm. of crystallized hydrazin sulphate, and 10 cc. of a 10 per cent solution of sodium hydroxid. The collection and measurement of the gas evolved is carried out in the usual way.

A contribution to the determination of phosphoric acid in organic substances, F. RIEGER (*Ztschr. Physikal. Chem., 34 (1901), pp. 109–113; abs. in Chem. Centbl., 1902, I, No. 1, p. 67*).

Colorimetric method for determining oxygen dissolved in water, W. RAMSAY and IDA HOMFRAY (*Jour. Soc. Chem. Ind., 20 (1901), No. 11, pp. 1071–1074, fig. 1*).

A method for estimating fat, G. ROSENFELD (*Chem. Ztg., 24 (1901), Repert., p. 250; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 22, p. 1030*).—Chloroform is recommended instead of ether for extracting fat. The author states that 6 hours' extraction gives values which are comparable with those obtained by predigesting the material and then extracting with ether. Higher values were obtained if extraction was preceded by boiling in alcohol for a short time. After evaporating the chloroform the material remaining is placed for a short time in a drying oven, thoroughly dried in a desiccator, and taken up with cool absolute ether as long as any material is dissolved. On evaporating the ether only true ether extract remains for weighing. The fats obtained by this and the ordinary method have different iodin values.

A test for the coloring matter of butter, J. VANDRIKEN (*Ann. Pharm., 7 (1901), pp. 110–117; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 21, pp. 978, 979*).—The author gives a method for testing the coloring matter contained in butter by amyl nitrite. Butter without any artificial coloring matter is discolored, while with a number of artificially colored fats, with one exception, the color was not changed by the test. The manipulation was made as follows: Two cubic centimeters of filtered butter and a like amount of ether is treated with 6 to 10 drops of amyl nitrite.

On the temperature reaction of oils with sulphuric acid—Maumené's test, H. C. SHERMAN, J. L. DANZIGER, and L. KOHNSTAMM (*Jour. Amer. Chem. Soc., 24 (1902), No. 3, pp. 266–273*).

On the relation of the heat of combustion to the specific gravity in fatty oils, H. C. SHERMAN and J. F. SNELL (*Jour. Amer. Chem. Soc., 24 (1902), No. 4, pp. 348–353*).—"In fresh fatty oils the heat of combustion is a property quite as constant as the specific gravity, to which it bears a certain definite relation. Oxidation resulting from exposure to air decreases the heat of combustion to practically the same extent that it increases the specific gravity."

A note on the use of the Bechi or silver nitrate test on olive oils, L. M. TOLMAN (*Jour. Amer. Chem. Soc., 24 (1902), No. 4, pp. 396, 397*).—Before applying the test the author recommends treating the sample successively with 95 per cent alcohol, 2 per cent nitric acid, and water.

A study of the Bechi test for cotton-seed oil, A. H. GILL and C. H. DENNISON (*Jour. Amer. Chem. Soc., 24 (1902), No. 4, pp. 397, 398*).—Experiments seemed to indicate that the test might be due to the presence of sulphur compounds.

A study of some cotton-seed oils, J. B. WEEMS and H. N. GRETTENBERG (*Reprint from Proc. Iowa Acad. Sci., 8 (1900), pp. 2*).—The results are reported of the chemical examination of 9 grades of cotton-seed oil, the figures representing 3 determinations for each sample. The specific gravity ranged from 0.9003 to 0.9006, and averaged 0.90045. The saponification equivalent varied from 192.1 to 198.6, averaging 194.6, the better oils possessing the higher and the common oils the lower values. The better grades of oils gave lower iodin absorption numbers than the common, and crude oils gave high results.

The determination of starch in the cereal grains, LINDET (*Bul. Soc. Chim. Paris, 3. ser., 25 (1901), No. 24, pp. 1055–1057*).

Researches on cellulose, C. F. CROSS and E. J. BEVAN (*London, New York, and Bombay: Longmans, Green & Co., 1901, pp. VII+175*).—An outline of the chemistry of the structural elements of plants with reference to their natural history and industrial uses.

The determination of sulphur in plants, G. S. FRAPS (*Jour. Amer. Chem. Soc., 24 (1902), No. 4, pp. 346–348*).—The author found a considerable loss of sulphur in the preparation of ash with calcium acetate as compared with the nitric acid method. In the latter method it was found convenient to heat 5 gm. of the material with 20 cc. of nitric acid in a porcelain dish, add 10 cc. of a 5 per cent solution of potassium nitrate, evaporate, and ignite.

On the detection of small quantities of arsenic in foods, especially in beer, J. C. BERNTROP (*Chem. News, 85 (1902), No. 2207, p. 122*).—The arsenic in 1 liter of beer is precipitated as ammonium-magnesium arsenate and after the destruction of albuminoids by nitric acid is determined by the Marsh or Gutzeit test.

The titration of arsenious acid with potassium permanganate, O. KÜHLING (*Ber. Deut. Chem. Gesell., 34 (1901), pp. 404–406; abs. in Analyst, 26 (1901), No. 306, p. 247*).—The author has devised the following method: In a flask cleansed with permanganate and sulphuric acid the arsenious acid is dissolved in hot 30 to 40 per cent sulphuric acid. The solution is diluted to 100 cc. and heated to the boiling point. Potassium permanganate solution is introduced, rapidly at first, and then more slowly. After each addition the liquid is heated for 1 to 2 minutes nearly to boiling, this process being continued until the red color no longer disappears. By this method $2KMnO_4(=50)$ correspond to $\frac{5}{2}As_2O_3$. The results reported by the author with this method are quite concordant.

A hydrolytic derivative of the globulin edestin and its relation to Weyl's albuminate and the histon group, T. B. OSBORNE (*Jour. Amer. Chem. Soc., 24 (1902), No. 1, pp. 28–38*).

The basic character of the protein molecule and the reactions of edestin with definite quantities of acids and alkalis, T. B. OSBORNE (*Jour. Amer. Chem. Soc., 24 (1902), No. 1, pp. 39–78, dgms. 2*).

A type of reaction by which sodium carbonate and hydrochloric acid may be formed in the animal organism, T. B. OSBORNE (*Jour. Amer. Chem. Soc., 24 (1902), No. 2, pp. 138, 139*).

Sulphur in protein bodies, T. B. OSBORNE (*Jour. Amer. Chem. Soc., 24 (1902), No. 2, pp. 140–167; translated by V. Griessmayer in Ztschr. Analyt. Chem., 41 (1902), No. 1, pp. 25–35*).—The above four articles have been noted from another source (E. S. R., 13, pp. 520, 521).

Methods of estimating caffein, BEITTER (*Chem. Ztg., 25 (1901), No. 81, p. 869*).—A study of the various methods with different substances. The author cites the Keller method, with certain modifications, as the most efficient.

A new method of determining manganese, G. VON KNORRE (*Ztschr. Angew. Chem., 14 (1901), No. 46, pp. 1149–1162*).

Miscellaneous chemical work, R. H. SHAW (*Wisconsin Sta. Rpt. 1901, pp. 285–288*).—Analyses of 17 samples of feeding stuffs, 4 of fertilizing materials, 7 of lime rock, 3 of dairy salt, 4 of tobacco extract, 1 of clam shells, and 1 of oyster shells are reported.

An apparatus facilitating the analysis of sugar beets, R. H. SHAW (*Wisconsin Sta. Rpt. 1901, pp. 281–284, fig. 1*).—The author describes an apparatus designed to facilitate the determination of the specific gravity of the juice and its preparation for the polariscope.

A new form of alkalimeter, C. B. DAVIS (*Jour. Amer. Chem. Soc., 24 (1902), No. 4, pp. 391, 392, figs. 2*).

A new design for potash bulbs, J. N. TERVET (*Chem. News, 85 (1902), No. 2206, pp. 112, 113, fig. 1*).—The apparatus consists of 4 bulbs through which the potash is caused to circulate by the current of gas.

A nitrogen apparatus, J. A. WESENER (*Jour. Amer. Chem. Soc., 24 (1902), No. 4, pp. 388–390, pl. 1, fig. 1*).—The alkaline mixture is distilled in a current of steam, the method being considered as accurate and far more rapid than the ordinary method.

A digestion stand for nitrogen determination, R. WOY (*Chem. Ztg., 26 (1902), No. 3, pp. 28, 29, fig. 1*).—A rack for holding Kjeldahl digestion flasks is described.

New apparatus, C. B. WILLIAMS (*Jour. Amer. Chem. Soc., 24 (1902), No. 3, pp. 246–248, figs. 2*).—A device for marking volumetric flasks and a modified bulb tube for nitrogen apparatus are described.

New laboratory apparatus, F. JANDA (*Chem. Ztg., 26 (1902), No. 3, p. 28, figs. 2*).—A quick-filter funnel and a calcium chlorid desiccator for use in balance cases are described.

BOTANY.

Investigation of flower buds, E. S. GOFF (*Wisconsin Sta. Rpt. 1901, pp. 304–316, figs. 15*).—In continuation of previous investigations on the date of flower formation in fruit plants (E. S. R., 13, p. 18), the author has reported on the time of formation of flowers in the currant, gooseberry, and cranberry; the variation in the period of flower formation between different varieties of apples growing in the same orchard; the influence of irrigation on the formation of flower buds; and the extent to which flowers are formed the season before their expansion, in those plants in which no flower buds can be distinguished in autumn. The buds of the Pomona currant showed an early stage of flower formation July 8, those of the black Victoria currant on August 3, and those of the Downing gooseberry August 30. Buds of the latter taken October 20 showed ovules. This is one of the few instances that have been observed where ovules have been formed in autumn. The buds of the cranberry taken August 31 showed no positive evidence of flowers, while samples taken September 16 showed flowers well started.

Considerable differences were observed in the formation of the flower buds in different varieties of apples, the buds being formed between August 1 and September 3. After abundant autumn rains which began about September 10, there appeared to be no further formation of flowers.

The application of 2 bbls. of water per week about an apple tree during a severe drought apparently had no effect in causing the earlier production of flowers, nor did it appear to change the percentage of the buds on the fruit spurs from which the flowers were developed. It did, however, appear to reduce the size of the flower buds, and also the total number.

There seems to be evidence to show that in such plants as the quince, raspberry, blackberry, and grape, in which no flower buds can be distinguished in autumn, these plants unquestionably form their flower buds during that season.

Biological investigations on the ripening of the wood of the grape, F. KÖVESSI (*Rev. Gén. Bot., 13 (1901), Nos. 149, pp. 193–211; 150, pp. 251–264; 151, pp. 307–325, pls. 7, figs. 2, dgms. 8*).—The author has made a study of the anatomical differences which characterize well-ripened shoots of the grape, and the influence of various external characters, such as humidity, temperature, light, climate, diseases, etc., on the ripening of the shoots. The phenomena of ripening, from an anatomical point of view, consist of a differentiation of the tissues of the plant, producing cork, browning of the bark, development of annual rings, thickening of cell walls, and the formation of starch. The degree of ripening may be measured by the extent of the preceding phenomena. A well-ripened shoot always has the annual wood well developed, the pith is reduced, starch grains are abundant and of large size, and the cell walls are well thickened. In comparison to volume, well-ripened shoots contain more dry matter than those poorly ripened. The presence of a large amount of water in the tissues explains why poorly ripened branches are easily injured by cold. The existence of a large amount of starch is an indication of ripeness and may be of service in determining the value for grafting and budding.

The different factors influencing the ripening of grape shoots are discussed at some length, and among the phenomena described the effect of age, soil, fertilizers, and diseases is shown. Humidity of the soil is opposed to the well ripening, as is the excessive use of fertilizers which contain an abundance of nitrate. On the other hand, lime, phosphates, and sulphates are favorable to maturity. Among the diseases mentioned, most of those which attack the branches, leaves, and roots are unfavorable for the perfect maturity of the grapevines, but those diseases which principally attack the fruit, such as the black rot, etc., have little or no effect upon the maturity of the shoots. The author's investigations were carried out in France and in Hungary, and comparisons made with the different factors of soil, climate, variety, etc., the results in all cases being practically the same. In practical application a chemical analysis or microscopical study of stems will show their degree of ripeness. It was found that shoots of *Vitis rupestris*, grown in humid regions of northern France or under the same conditions in Hungary, are not adapted to use in other parts of the country for replanting vineyards destroyed by phylloxera. It was also found that shoots produced upon 3-year-old vines in the south of France were equal in all respects to those produced upon 4-year-old vines in the north, the climate of the two regions having this influence upon their development.

The influence of formalin on the germination of oats, F. CRANEFIELD (*Wisconsin Sta. Rpt. 1901, pp. 327–335, figs. 6*).—The results of laboratory and greenhouse experiments with formalin solutions for the prevention of grain smut are reported, together with the effects of the treatment on the germination and subsequent development of plants. Seed oats were immersed for 20 minutes in a solution of 1 pt. of formalin to 50 gals. of water, after which 40 samples of 100 seeds each were placed in the Geneva seed tester and a daily record kept of their germinations. Similar lots were planted in the greenhouse in shallow boxes, filled with soil, and their germination determined. The average germination in each case showed some injury due to the treatment. In the seed tester the injury amounted to from 1 to 20 per cent, while in the soil test the range was from 4 to 42 per cent. In a few instances the treated seed germinated better than the untreated, but the averages of the different lots showed a detrimental action. The effect of different strengths of solution was also tested, in which the stronger solutions were shown to be highly injurious. The effect of treating seed for longer periods than 20 minutes was studied, and while slight differences were observed there was no appreciable increase in injury due to the longer soaking of the seed. The growth of the plants is shown in a number of instances to have been checked by the treatment, the untreated lots being in every case more vigorous than the treated. In conclusion, attention is called to the fact that these trials were all conducted within doors, and it is possible that field conditions might prove more favorable to germination and growth.

The effect upon seedling plants of certain components of alkali soils, T. H. KEARNEY and F. K. CAMERON (*U. S. Dept. Agr., Rpt. 71, pp. 7–60*).—A preliminary report is given of experiments conducted with clover and alfalfa in which the effect of some of the more ordinary components of alkali soils was tested. The salts used in experiments were sodium chlorid, sodium sulphate, sodium carbonate, sodium bicarbonate, magnesium chlorid, magnesium sulphate, and calcium chlorid. The salts were made up in solutions of known strengths and the seedlings were suspended in the solution for 24 hours, and the amount of injury determined from the condition of the root tips. At a certain degree of dilution all the salts appeared indifferent in their action upon plant tissues, while at still greater dilution some produced stimulating effects. The injurious action of the different salts when used in greater strength is shown. The toxic effect of the injurious salts is said to be due more to the influence of cathions (derived from the basic radicle) than to the anions (furnished by the acid radicle). The authors give extensive reviews of literature relating to this subject, and an extended bibliography of the subject completes the report.

Formation of sodium carbonate, or black alkali, by plants, F. K. Cameron (*U. S. Dept. Agr., Rpt. 71, pp. 61–70*).—A study is reported of creosote bush and greasewood, in an attempt to show the effect of these plants in causing an accumulation of sodium carbonate at the surface of the soil. It seems probable that the neutral salts are brought up from the lower depths of soil, and through the agency of the plant are transformed into the carbonates or black alkalis.

Resistance to black alkali by certain plants, F. K. Cameron (*U. S. Dept. Agr., Rpt. 71, pp. 71–78*).—Notes are given on the resistant power of a number of plants to the action of black alkali. Among those described are *Distichlis spicata*, *Suæda intermedia*, and *Atriplex bracteosa*. These plants seem to be able to make a satisfactory growth on soils containing relatively large amounts of soluble carbonates. This growth is believed to be due in a large measure to the production and exudation of considerable amounts of soluble organic acids, which are capable of decomposing the carbonates and thus protecting the root crowns from the corrosive action of the alkalis.

Can leucin and tyrosin be used as plant nutrients? E. Schulze (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 97–106*).—The author quotes the investigations of a number of experimenters on the assimilability of these substances by plants and describes experiments of his own with lupines, vetches, and castor beans, which showed that tyrosin and leucin could be used as sources of nitrogen by phanerogams.

Organic nitrogen and cultivated plants, A. Thomson (*Sitzber. Naturf. Gesell. Univ. Dorpat, 12 (1899), pp. 307–322; abs. in Ann. Agron., 27 (1901), No. 12, pp. 602–604*).—A series of experiments with oats and barley grown in water cultures which were given various forms of organic nitrogen is reported upon. The organic compounds employed were sodium urate, sodium hippurate, and urea, comparisons being made with sodium nitrate. The results of the experiments show that the nitrogen of urea and uric acid have the same value, as far as the grasses are concerned, as nitric nitrogen; and the plants seem to be able to easily utilize these substances. On the contrary, the nitrogen in hippuric acid is detrimental to plant growth.

The bacteria of root tubercles of Leguminosæ, P. Neumann (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 187–202*).—A report is given of studies made with the organisms taken from the tubercles of the roots of *Vicia faba*. These were carefully removed and used to inoculate a great many kinds of culture media, the object being to determine what forms of culture are adapted to the artificial growth of these organisms. In all, about 70 kinds of culture media were used, and the formula for preparation of the media and action of the organism in them are shown. The best results were obtained in nutrient media which contained urine, plant extracts, root extracts, soil leachings, and soy bean seed extract. In these the organism made good growth and produced the branching forms. In 10 days, in the soy bean plant extract, there was a decided development of the organism which was short, compact, and in some cases showing the characteristic branching which is one of the characters of the true bacteroids.

Investigations concerning the occurrence of nitrogen-assimilating bacteria in the soils, P. Neumann (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 203–206*).—In this article the author seems to give an account of the behavior of certain inoculation materials in culture media rather than discuss the occurrence of nitrogen-assimilating bacteria in soils. Three forms of nutrient media were prepared—one from the above-ground green plant of *Vicia faba*, the second from the tubercles of the roots of the plant with its adhering earth, and the third from peat. These media were inoculated with the washings from the roots and tubercles, with the pressed juice from chopped roots and tubercles, and with juice of the above-ground parts of the plant. After 14 days' standing in room temperature of from 15 to 20° C., the results are shown. In every case but one, and that where the peat extract was inoculated with the juice from the above-ground parts of the plant, there was an increase in the amount of nitrogen present, although in all the experiments with the peat it was very slight. The experiments seem to show that the assimilation of nitrogen on the part of bacteria is dependent upon the organic nutrients offered the plant.

The North American species of Spartina, E. D. Merrill (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 9, pp. 16*).—This is a technical paper based on North American material of the genus Spartina. The various species of Spartina occur in saline soils along the coast throughout tropical and temperate regions. Two species are found in alkali soils of the interior. One species is known to thrive in soils free from alkaline or saline properties. In the present paper 9 species are recognized as growing in North America, one of which and one variety are described as new.

Inventory of foreign seeds and plants, No. 9, E. A. Bessey (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 5, pp. 79*).—This gives a catalogue of the seeds and plants received during the spring and summer of 1900, and represents the collections of the agricultural explorers of this Department and foreign countries, as well as receipts from various other sources. The numbers of the inventory are from 4351 to 5500. Brief descriptive notes are given of most of the importations.

A collection of economic and other fungi prepared for distribution, Flora W. Patterson (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 8, pp. 31*).—A list is given of species of fungi which are available for distribution to the various State agricultural experiment stations. The different State experiment stations are invited to compile their desiderata and select from the list 50 specimens, which will be forwarded upon request. This exchange is desired not only as a benefit to the stations, but also as a means for securing interesting material for this Department.

Poisonous and edible mushrooms, H. Garman (*Kentucky Sta. Bul. 96, pp. 215–222, pls. 16*).—A description is given of mushrooms in general, the different parts being defined, and a brief synopsis is given for the recognition of some of the edible species. A description is given of *Lepiota morgani*, one of the most common poisonous mushrooms occurring in Kentucky; and attention is called to a number of other poisonous species. The common edible mushroom (*Agaricus campestris*) is described at some length.

BACTERIOLOGY.

Enzyms and their application, I, J. Effront, translated by S. C. Prescott (*New York: John Wiley & Sons, 1902, pp. IV+324*).—This work is a summary of a course of lectures delivered at the Institute of Fermentations of the University of Brussels, and is designed not only for those whose interest in the subject is mainly one of scientific study, but also for those who are concerned solely in the application of fermentations to various industries. The work as a whole will consist of two volumes. The present volume treats of the enzyms of carbohydrates and of oxidases, while the second will treat of the proteolytic enzyms and toxins. The author has personally verified most of the experimental data given in this volume, and considerable hitherto unpublished information is included relative to experiments, analyses, methods of preparation, and technical processes. After discussing the general properties and action of diastases, several are given special consideration, chapters being devoted to sucrase, amylase and its industrial uses, maltase, panary fermentation, various other enzyms of carbohydrates, ferments of glycerids and glucosids, zymase, and oxidases. The translator has sought to reproduce the author's ideas and form of expression without sacrificing clearness and simplicity, and seems to have been unusually successful. To students and others in this country who are interested in enzyms and their uses, this work will prove highly valuable. For those desiring to pursue the subject further than the discussions given in the book, extensive lists of literature are appended to the various chapters.

The fermentation of tea leaves, C. R. Newton (*Indian Gard. and Plant., 9 (1901), Nos. 24, pp. 418–420; 25, pp. 437, 438*).—A study is given of the chemistry and physiology of the tea leaf, and the function of enzyms in its fermentation.

Contribution to the bacterial flora of the Sydney water supply, I, R. G. Smith (*Extr. from Proc. Linn. Soc. New South Wales, 25 (1900), pt. 3, pp. 436–462*).—An account is given of a bacteriological study made of the water supply of Sydney, New South Wales. The methods of study are given at some length and 30 species, some of which are new, are described.

Contribution to the bacterial flora of the Sydney water supply, II, R. G. Smith (*Extr. from Proc. Linn. Soc. New South Wales, 25 (1900), pt. 4, pp. 740–759*).—The author describes various methods for the separation and recognition of a number of pathogenic bacteria.

A process for inoculating the earth with soil bacteria, F. Bayer & Co. (*Bl. Zuckerrübenbau, 1901, p. 217; abs. in Jour. Soc. Chem. Ind., 21 (1902), No. 3, p. 179*).

Concerning oligonitrophilous microbes, M. W. Beijerinck (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 16, pp. 561–582, pl. 1; Proc. Sec. Sci. Koninkl. Akad. Wetensch. Amsterdam, 3 (1901), pp. 586–595*).—Under this name the author proposes to group those organisms which while occurring freely in nature develop in nutrient media containing combined nitrogen or from which combined nitrogen is not carefully excluded. These organisms doubtless have the ability of assimilating and utilizing free atmospheric nitrogen. Two classes are recognized, one of which by virtue of chromophyll is able to utilize the carbon dioxid of the air, the second group being colorless must have carbohydrates supplied them in the nutrient media. A number of plants belonging to the Cyanophyceæ are described as belonging to the first group, and of bacteria as representatives of the second.

A bacteriological investigation of the roots and seeds of sulla, K. H. Nicolai (*Inaug. Diss., Erlangen, 1900, pp. 34; abs. in Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 8, p. 301*).—A study is reported of the bacteria found in the roots of sulla, *Hedysarum coronarium*, apart from those existing in the root tubercles which are concerned with nitrogen assimilation. These different classes of bacteria can be readily distinguished by means of stains and from their action upon different culture media. They were not found present in the seeds, but were of frequent observation in the roots in which access had been gained from the soil through the root hairs of the plants.

The cleavage of butter fat by micro-organisms, O. Laxa (*Arch. Hyg., 41 (1901), No. 2, pp. 119–151*).

METEOROLOGY.

Loss of life in the United States by lightning, A. J. Henry (*U. S. Dept. Agr., Weather Bureau Bul. 30, pp. 21, pls. 4*).—This is in part a revision of Bulletins 15 and 26 of the Bureau (E. S. R., 8, p. 34; 11, p. 322), bringing the data down to the end of 1900. The purpose of the bulletin is "to furnish accurate information as to the destruction of human life annually by lightning; to point out the regions where the greatest loss of life occurs; and, so far as practicable, to call attention to the few simple precautions against danger that may be exercised by the individual. . . . In the United States, thunderstorms occur with considerable frequency over all of the territory east of the one hundredth meridian, save a narrow strip along the northern border. West of the above-named meridian, except in the Rocky Mountain region, the frequency steadily diminishes, reaching practically zero along the immediate Pacific coast. There are three regions of maximum thunderstorm frequency, viz, one in the southeast, with its crest over Florida, one in the Middle Mississippi Valley, and one in the Middle Missouri Valley. The average number of days annually with thunderstorms in the first-named region is 45; in the second, 35, and in the last 30. . . . From 700 to 800 lives are lost each year by lightning stroke. . . . The greatest number of fatal cases . . . occurred in the Middle Atlantic States, and the next greatest in the Ohio Valley and Tennessee, with the Middle and Upper Mississippi Valley a close third. The greatest number of deaths in any single State during the 5 years, 1896–1900, occurred in Pennsylvania—186—followed by Ohio with 135, and Indiana, Illinois, and New York with 124 each. . . . The greatest mortality by lightning, considering both unit area and density of population, is in the Ohio Valley and the Middle Atlantic States; if, however, density of population only be considered, it is in the Upper Mississippi Valley and the middle Rocky Mountain region. . . . The belief that the chance of injury by lightning in the cities is less than in the country is rather general. What foundation, in fact, such a belief has is hard to determine. When the combined area of the large cities is compared with the immense territory embraced in the rural districts it is not surprising that so few lightning strokes fall in cities. The modern city building, with its metallic roof and steel frame, is a fairly good conductor of electricity, and is in much less danger of receiving a damaging stroke of lightning than an isolated dwelling in the open country. The multiplication of telegraph, telephone, and electric-light wires in cities also adds to the effectiveness of silent discharges in relieving the electric tension during a thunderstorm; but should a cloud with a tremendous store of energy quickly approach, all of the wires in 10 cities would not prevent it from discharging right and left until its store of energy had been dissipated."

Report of the Chief of the Weather Bureau, 1900-1901, W. L. Moore (*U. S. Dept. Agr., Weather Bureau Rpt. 1900–1901, I, pp. 318*).—This, which is the first volume of the report of the Chief of the Weather Bureau for this year, is divided into six parts. Part 1 gives an account of the operations of the Weather Bureau during the year; part 2, a list of observing stations and changes therein during 1900, and hourly averages of atmospheric pressure, temperature, and wind from the records of automatic instruments at 28 stations; part 3, monthly and annual meteorological summaries for 174 Weather Bureau stations; part 4, monthly and annual means and extremes of temperature and dates of first and last killing frosts; part 5, monthly and annual precipitation, 1900; and part 6, miscellaneous meteorological tables and reports.

Meteorological observations, C. S. Phelps (*Connecticut Storrs Sta. Rpt. 1900, pp. 188–192*).—This is a record of observations on temperature, pressure, humidity, precipitation, and cloudiness during each month of 1900 at Storrs, and on rainfall during the 6 months ended October 31, 1900, at 23 places in Connecticut. The mean temperature for the year at Storrs was 48° F.; mean pressure, 29.95 in.; total precipitation, 48.64 in.; number of cloudy days, 94. The average rainfall for the State during the 6 months ended October 31 was 19.65 in.

"The total precipitation at Storrs for the year, 48.64 in., was about 3.2 in. more than the average for the past 12 years, but was very close to the general average for the State as computed from the records of the New England Meteorological Society covering periods of from 5 to 30 years. The rainfall was especially heavy in February and March. For the season from May 1 to October 31, the precipitation at Storrs, 19.5 in., was about 3 in. below the average for the past 12 years, and was also below the general average of observations made in different parts of the State during the same years. There was a general deficiency in the rainfall during July, August, and September, which affected all those crops that made most of their growth during that period. . . . The last killing frost, which was unusually severe, occurred May 11, with a minimum temperature of 25°. The temperature for June was about normal, while that for July and August was above the average for Storrs for the past 12 years. The first killing frost in the fall did not occur until October 18, so that the season was especially favorable for late maturing crops. The length of the growing season between May 11 and October 18, 158 days, was 12 days more than the average at Storrs for the past 12 years."

Meteorological observations (*Maine Sta. Bul. 78, pp. 189–191*).—This gives a monthly summary of observations at Orono during 1901 on atmospheric pressure, temperature, precipitation, cloudiness, and wind movement, and monthly and annual precipitation at 17 places. The mean temperature for the year was 42.81° F. (mean for 33 years 42.33°), mean pressure 29.17 in., precipitation 46.05 in. (mean for 33 years 45.30), and number of cloudy days 160.

Meteorological observations, J. E. Ostrander and H. L. Bodfish (*Massachusetts Sta. Met. Buls. 157, 158, 159, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during January, February, and March. The data are briefly discussed in general notes on the weather of each month.

Meteorological record for 1900 (*New York State Sta. Rpt. 1900, pp. 468–477*).—Tables are given which show the daily readings of maximum and minimum thermometers at 7 a. m. for each month of the year; the average monthly temperature and precipitation since 1882; the daily wind record for each month of 1900; a monthly summary of the direction of the wind for the year; tridaily readings of the standard air thermometer during each month of the year; and a monthly summary of maximum, minimum, and standard thermometer readings.

Meteorological observations, W. B. Alwood (*Virginia Sta. Rpt. 1901, pp. 9, 10*).—Tables are given which show monthly averages of observations at Blacksburg, Va., on temperature, precipitation, direction of wind, and cloudiness for the period from July 1, 1900, to December 31, 1901; and monthly means of temperature and precipitation during 9 years (1893–1901). The mean temperature for the year ended December 31, 1901 (calculated from monthly means), was 49.8° F., the precipitation 53.8 in.

A summary of meteorological observations at the National Institute of Guatemala, 1857-1898, D. González (*Resumen de las observaciones meteorológicas hechas en el Instituto Nacional de Guatemala desde el año de 1857 hasta el año de 1898. Guatemala, 1899, pp. 30*).

Total rainfall for 1901 (*Agr. Jour. Cape Good Hope, 20 (1902), No. 6, pp. 381–384*).—The total rainfall during the year at a large number of places in different parts of the province is reported.

Rainfall in the agricultural districts of Queensland, C. L. Wragge (*Queensland Agr. Jour., 10 (1902), No. 2, p. 130*).—A table is given which shows the total monthly rainfall at 41 places in Queensland during the year 1901.

Composition of Barbados rainfall (*Imp. Dept. Agr. West Indies, Rpt. Agr. Work 1900, p. 11*).—The total amount, and the chlorin, ammonia, nitrates, and total nitrogen contents (parts per million) of the rainfall of each month from December, 1898, to May, 1900, inclusive.

Forests and rainfall, W. L. Summers (*Jour. Agr. and Ind. South Australia, 5 (1902), No. 7, pp. 616–619*).—Tables give the annual rainfall at Adelaide and 5 other places in South Australia during a long period of years. It is stated that a study of the data affords no proof that the rainfall has decreased with the denudation of the timbered land.

On the climate of Tunis, G. Ginestous (*Bul. Dir. Agr. et Com., 7 (1902), No. 22, pp. 64–88, figs. 5, charts 4*).—This is a summary of observations since 1885 at different places in Tunis on atmospheric pressure, temperature, winds, cloudiness, relative humidity, dew, fogs, storms, evaporation, rainfall, and snow.

Frost injuries to the winter plantings of the year 1901, P. Sorauer (*Arb. Deut. Landw. Gesell., 1901, No. 62, pp. 8 + 205*).—This includes a summary of replies to circulars of inquiry distributed through the different provinces of Germany, as well as articles on The snow cover of North Germany and The temperature conditions of Germany in the winter of 1900–1901, by W. Lesz.

Text-book of meteorology, J. Hann (*Lehrbuch der Meteorologie. Leipzig: C. H. Tauchnitz, 1901, pp. XIV + 805, pls. 8, figs. 111, charts 15*).—The original purpose was to prepare a text-book suited to the needs of the German high schools (*Hochschulen*), but the completed work far exceeds these bounds, being adapted to the requirements of more advanced students of meteorology. The more important results of meteorological investigations up to the end of the nineteenth century are included. The book contains an introduction and 5 chapters, as follows: Temperature conditions of the air and the solid and liquid surface of the earth, atmospheric pressure, humidity of the air, movement of the air, and atmospheric disturbances.

WATER—SOILS.

Artesian water (*Agr. Jour. Cape Good Hope, 20 (1902), No. 1, p. 25*).—A brief note on a paper on artesian waters of Australia, read by J. P. Thomson before the Royal Geographical Society of Australia. It is stated that the greatest development of artesian water has been made in Queensland, where a very large and apparently inexhaustible supply has been discovered. While the water so developed has proved valuable for drinking purposes, it has not proved an important factor in irrigation.

The artesian wells of South Dakota, J. E. Todd (*Irrig. Age, 17 (1902), No. 1, pp. 12–15, figs. 2*).

Field operations of the Division of Soils, 1900 (second report), M. Whitney et al. (*U. S. Dept. Agr., Field Operations of the Division of Soils, 1900, pp. 473, pls. 51, figs. 47, maps 24*).—This report contains a general review of the field and laboratory work of the Division of Soils during 1900, by the chief of division; 12 detailed reports of soil surveys of districts located in Pennsylvania, Ohio, Maryland, North Carolina, Utah, Arizona, and California; reports of laboratory investigations supplemental to the field operations; and the results of experiments with tobacco conducted in various parts of the United States.

General review of the work, M. Whitney (pp. 19–60).—The purpose of the survey work and its organization and progress is reviewed. The total area mapped during 1900 was 4,465 square miles, which was surveyed at an average cost of $1.97 per square mile. The average rate of mapping was 4.4 square miles per day. The topography, geology, climate, agricultural conditions, etc., as well as the characteristics of the soil types, of the different areas are presented in the several reports. In all, 397 mechanical analyses of soils and subsoils are reported in tabular form, as well as numerous analyses of alkali and of irrigation waters. "Undoubtedly the most pressing demands for a soil survey arise from a consideration of special problems. It may be for the consideration of industries which could be introduced into a section of the country where, from the increased competition and the opening up of new areas, the specialization of crops at present grown in the area, or from various social problems, the industries have languished and new industries or new methods are desired to build up the locality. A very important consideration, however, lies in the introduction and spread of new industries, in the improvement and development of the different types of tobacco, of fruit production, of truck growing, of sugar beets, and of other special crops; also in the improvement of certain soil areas by the use of fertilizers, by the introduction of underdrainage, and in the West by the protection of soils against seepage waters and alkali and the reclamation of lands already injured by these causes."

A soil survey around Lancaster, Pa., C. W. Dorsey (pp. 61–84).—The district surveyed covers about 270 square miles, and was selected as being one of the most important tobacco-producing districts in the State and one of the most fertile regions in the country. Eleven types of soil are described, of which the Hagerstown loam and the Conestoga loam are the most important, each occupying about one-third of the area. "They are both derived from limestone rocks, the former from hard massive limestone and the latter from a softer schistose limestone, locally called a sandy limestone on account of the rough surface of the rock rather than from the amount of sand contained in it. The soil contains a quantity of very fine mica, which gives it a soapy or greasy feel." Analyses are reported which show that the first contains about 14 per cent of clay, 54 per cent of silt, 4 to 6 per cent of organic and volatile matter; the second, 7 to 12 per cent of clay, 42 to 54 per cent of silt, 5 to 6 per cent of organic and volatile matter.

Soil survey of Montgomery County, Ohio, C. W. Dorsey and G. N. Coffey (pp. 85–102).—This county, all of which was surveyed, covers 480 square miles and is also an important tobacco-producing district. The soils are all of glacial origin, 6 types being recognized. The Miami clay loam, a light soil of uniform texture and composition, is the most important soil formation and covers nearly 80 per cent of the county. "The Miami clay loam is a strong productive soil, adapted to general farm crops and to the type of tobacco most in favor at the present time for cigar fillers. The soil is a loose light loam, about 12 in. deep, resting on a sticky clay loam that dries out into small cubes, which work up like gravel when disturbed." In the analyses of this soil reported the clay varies from 11.62 to 37.37 per cent, the silt from 26.4 (in subsoil) to 65.8 per cent, the organic and volatile matter from 2.68 to 3.86 per cent.

Soil survey of Cecil County, Md., C. W. Dorsey and J. A. Bonsteel (pp. 103–124).—This district covers about 375 square miles and is divided into 2 distinct areas, in each of which are 5 types of soil varying in character from almost barren to highly productive. "It is situated in the extreme northeast corner of Maryland, and lies partly within the Piedmont Plateau of crystalline rocks and partly within the Coastal Plain formation with its gravels, sands, and clays."

Soil survey of St. Mary, Calvert, and Kent counties, Md., J. A. Bonsteel (pp. 125–186).—These counties, bordering on Chesapeake Bay, lie wholly within the Coastal Plain and have areas, respectively, of 360, 218, and 315 square miles. Nine types of soil, rarely occurring in continuous tracts, were recognized in St. Mary and Calvert counties, and 7 in Kent County. The soil types included loam, gravel, sand, clay, and swamp. The most extensive type of soil in St. Mary County (41 per cent) is the Leonardtown loam, which "consists of a silty yellow loam, fine and powdery when dry, but puddling to a plastic clay-like mass when thoroughly wet. On redrying, this mass usually bakes to a hard, firm surface, or if stirred before being sufficiently dried, it clods up into hard lumps. The subsoil consists of a brittle mass of clay lenses, lumps, and fragments separated from each other by seams and pockets of medium to fine sand." The most extensive type of soil of Calvert County (42 per cent) is the Norfolk sand, a coarse sand resting on a sandy subsoil 3 ft. or more in depth. The predominating type of Kent County is sassafras loam. "The soil proper consists of a fine brown loam, which is often slightly sandy, especially in the eastern part of the county. It extends to an average depth of about 9 in. and is underlaid by a uniform yellow loam subsoil. The subsoil varies in thickness from about 20 in. to a maximum of 5 or 6 ft."

Soil survey from Raleigh to Newbern, N. C., W. G. Smith (pp. 187–205).—This covered an area about 9 miles wide and 105 miles long in which a great variety of soils were found, 17 types being recognized. "Of these, the Cecil clay, derived from the weathering of crystalline rocks of the Piedmont Plateau, is a strong clay soil adapted to wheat and grass; the Selma silt loam, the finest type of bright tobacco soil; the Norfolk sand, a typical truck land; the Garner stony loam, a nearly worthless soil, and the Savanna and Pocoson, representing types of swamp lands which need extensive improvement in the way of drainage before they are of value for crops."

Soil survey in Weber County, Utah, F. D. Gardner and C. A. Jensen (pp. 207–242).—This district lies between the Great Salt Lake and Wasatch Mountain and has an area of about 310 square miles. Eight types of soil are described, the most important of which, agriculturally, is the Fresno fine sandy loam covering about 43 per cent of the area. A considerable portion of the district has, until recent years, been covered by the Great Salt Lake and contains excessive quantities of alkali. Chemical analyses of alkali crusts from 9 localities indicated an average composition of 59.83 per cent of sodium chlorid, 11.10 per cent sodium carbonate, 10.24 per cent sodium bicarbonate, 12.20 per cent sodium sulphate, 4.39 per cent potassium chlorid, 1.24 per cent magnesium sulphate, and 1 per cent calcium sulphate. The authors discuss the formation of a lime hardpan which occurs at a depth of about 3 ft. in some parts of the area, the injury done by seepage water from irrigation canals, etc., the reclamation of additional land by irrigation, and the nature of the water supply for irrigation.

Soil survey in the Sevier Valley, Utah, F. D. Gardner and C. A. Jensen (pp. 243–285).—The valley has an average width of about 5 miles and was surveyed for a distance of 45 miles. The soils being well drained and carefully irrigated are to a large extent free from injurious quantities of alkali. Ten types were recognized. "The soils as a rule are light in texture and well drained. They are mostly derived from the adjacent mountains, the material being often modified by stream action, and are underlaid in many places by gravel beds. The soils are derived from different kinds of rocks, and have well-defined physical characteristics, but these differences are not such potent factors in determining crop values and crop distribution as in the Eastern States." The average composition of 13 alkali crusts showed 39.06 per cent of sodium chlorid, 25.42 per cent of sodium sulphate, and other salts in smaller quantities. "The irrigation water is unusually good, except at a few points. . . . The best waters contain from 15 to 75 and average about 35 parts of solids per 100,000 parts of water. The alkali in the water contains nearly equal proportions of chlorids, sulphates, and bicarbonates, with but a trace of carbonates."

Soil survey of Salt River Valley, Ariz., T. H. Means (pp. 287–332).—The area mapped around Tempe and Phoenix and along the Buckeye canal embraced about 370 square miles and showed a variety of soils, 9 types being described. The irrigation water supply is generally good and no trouble from alkali is experienced when the soils are well drained. Numerous analyses of alkali salts are reported and the reclamation of alkali lands is discussed. The predominant salt found was sodium chlorid. An instance of the occurrence of a large amount of sodium and potassium nitrate in an alkali crust is recorded. The occurrence of a lime hardpan is noted. The surface and underground water supply for irrigation and systems of farming adapted to the region are discussed.

Soil survey around Fresno, Cal., T. H. Means and J. G. Holmes (pp. 333–384).—The area surveyed here covers about 625 square miles and includes foothills, plains, and bottom lands. Ten types of soils are described, the Fresno sand covering 40 per cent of the area and corresponding in texture and crop value to the truck soils of the Atlantic coast. About 84 per cent of the area is free from injurious quantities of alkali. In 20 samples of alkali crusts the sodium carbonate ranged from 5.72 to 93.35 per cent. Methods of preventing the rise of alkali and of reclaiming alkali lands and the nature of the hardpan and water supply of the region are discussed.

Soil survey around Santa Ana, Cal., J. G. Holmes (pp. 385–412).—The district surveyed extends from the foothills to the Pacific Ocean and comprises about 300 square miles. It is for the most part a delta plain and shows 9 types of soil. "The Fresno sand, a typical truck soil, formed of a coarse, loose, incoherent sand, 6 ft. or more in depth, naturally free from alkali, covers about 37 per cent of the district surveyed." The alkali salts consist principally of sodium chlorid and sodium sulphate, but are present in injurious quantities in only comparatively few areas.

Investigations on the physical properties of soils, L. J. Briggs (pp. 413–421).—Investigations on the physical properties of soils carried on during the year are briefly summarized. A marked difference was found to exist in the capillary movement of water in dry and in moist soils. In one instance the capillary rise in moist soil was over 4.5 times that in the dry soil. Sodium carbonate in solution was found to facilitate the rise of water in dry soil. Pure quartz sand was found to absorb 200 times the amount of carbon dioxid that would ordinarily be contained in a volume of air equivalent to that in the sand. A filter was devised for field use for obtaining clear soil solutions for chemical analysis. These investigations are to be reported in detail later.

Application of the theory of solution to the study of soils, F. K. Cameron (pp. 423–453).—The main features of this article have already been noted from other sources (E. S. R., 13, pp. 232, 428).

Results of tobacco experiments conducted in various parts of the United States, M. L. Floyd (pp. 455–473).—See p. 946.

Results of investigations on the Rothamsted soils, B. Dyer (*U. S. Dept. Agr., Office of Experiment Stations Bul. 106, pp. 180*).—This bulletin contains the lectures delivered under the provisions of the Lawes Agricultural Trust before the Association of American Agricultural Colleges and Experiment Stations at New Haven and Middletown, Conn., in November, 1900 (E. S. R., 12, p. 407). These lectures give a complete summary to date of the results of observations and experiments on the Rothamsted soils, extending over a number of years. They describe the method of soil sampling used at Rothamsted; give the results of mechanical analyses and determinations of nitrogen, carbon, chlorin, phosphoric acid, potash, and humus in soils which have been subjected to different systems of cropping and manuring; and discuss the nitrogen content of the humus of Rothamsted soils. The data reported have been partly published elsewhere (E. S. R., 13, p. 30), but by far the greater portion of the matter, including the results of the author's recent exhaustive studies on the phosphoric acid and potash contents of Rothamsted soils, is new.

A study of the available mineral plant food in soils, C. C. Moore (*Jour. Amer. Chem. Soc., 24 (1902), No. 1, pp. 79–116, fig. 1*).—The merits of the pot-test method of determining the available plant food in soils are discussed and the yields and fertilizing constituents of crops (oats and buckwheat) grown in a series of pot experiments during the past 5 years on 34 typical soils from different parts of the United States are compared with the results of various chemical methods of determining available plant food in the soils. The mineral constituents of the extract obtained by digestion of 10 gm. of each soil in 100 cc. of 1.115 sp. gr. hydrochloric acid for 10 hours, the total potash and phosphoric acid obtained by repeated digestion with hydrofluoric acid, the carbon dioxid, total and nitric nitrogen, carbon, hydrogen, and insoluble matter are reported for each soil, as well as their mechanical composition; and the results of tests of various methods of determining available potash and phosphoric acid by digesting in hydrochloric acid of different strengths, citric acid, and ammonium citrate are reported.

In the digestion of the soils a Wagner shaking machine, modified by Wiley to permit of digestions being made at definite temperatures, was used. "The modification comprises a well-fitted double wall sheet-iron chamber, in which the revolving shaft, together with the attached flasks, are encased. By use of a thermostat, and owing to the circulation of the air as caused by the revolving of the flasks, such a temperature as 40° may easily be maintained for hours with no more variation than 0.5°." A preliminary study of the effect of varying the time of digestion was made, which showed that 10 hours was apparently sufficient.

The total potash and phosphoric acid was determined by the following method: "Weigh out 2 gm. of soil into a 2-in. platinum dish, and ignite over a Bunsen burner to drive off organic matter. Get the soil as much as possible on one side of the dish and put in 1 or 2 cc. of hydrofluoric acid. Allow the soil to come in contact with the acid very slowly to avoid loss by sputtering, using a platinum stirring rod. After the violent action has ceased, place on a steam bath and evaporate to dryness. Repeat this operation one or two times and then take up with a little hydrochloric acid and water. Filter and wash into a 100 cc. flask, place the filter and contents into the platinum dish and, after drying over the flame, ignite the paper. There will be a small amount of the coarse mineral, which is transferred to an agate mortar to be ground, after which it is again digested in hydrofluoric acid until there is no insoluble residue left. Take up in hydrochloric acid and water, and add to the original washings."

The method of mechanical analysis used "was to some extent improvised, it being in the main the beaker decantation, or what is more generally known as the Osborne method. The radical change was a method devised for the disintegration of the sample. Instead of pestling with a rubber-tipped pestle, the sample was agitated in water by means of a shaking machine. Twenty grams of soil were put into a cylindrical bottle, the ordinary 8-oz. sterilizing bottle being used, with about 150 cc. of water, and the bottle shaken about one hour at the rate of 150 strokes per minute. . . Samples shaken one hour and one week gave constant results, disproving any grinding of particles. The siftings were made through sieves and bolting-cloth, the decantations controlled by the microscope. Below 0.006 mm., the decantation could be made with no accuracy, and resort was had to an arbitrary floating method. The period of 18 hours was selected."

In the studies of availability it was found that digestion for 5 hours in $\frac{1}{200}$ normal hydrochloric acid gave results more closely agreeing with the amounts of fertilizing constituents taken up by the crop in the pot tests than any other method tested. "In this method the ratio of substance to solvent was 200 gm. per liter. However, a liter flask was used in which 186 gm. of soil were placed, and the solvent added up to the mark. This varied only 1 or 2 cc. from 930, which was the ratio desired. After the digestion the whole was shaken and emptied on to a fluted filter sufficiently large. After draining, the volume of the filtrate did not vary 10 cc. from 800. This was shown in so many cases that the filtrate was no longer measured, but taken as 800 cc., corresponding to 160 gm. of the soil. This expedited the work greatly, and avoided the recording of figures and the chance for mistake. To this filtrate was always added 1 or 2 cc. of nitric acid for the double purpose of decomposing any ammonium chlorid which may have been formed in the digestion of organic matter, and also to oxidize any organic matter in solution. After evaporating to dryness, hydrochloric acid was added repeatedly and evaporated until there was no further evidence of the presence of nitrates. The residue was now transferred to a smaller porcelain dish, and diluted to about 50 cc. with water. To this was added 2 cc. of platinum chlorid, according to the method of direct estimation of potash (E. S. R., 10, p. 408). The solution was slowly concentrated until the potassium platinichlorid could be crystallized on the sides of the dish, after which it was set off to cool and solidify. It was then treated with acidified alcohol as described in the method referred to, washed onto a paper filter, and washed with plain alcohol and then with the half-saturated solution of ammonium chlorid, according to the usual method. After drying the salt, it was dissolved and washed through with hot water into small platinum dishes, evaporated to dryness, dried at 100°, and weighed. The filtrates were set aside after the washing with ammonium chlorid, stirred up and the ammonium platinum chlorid allowed to settle over night. Most of the liquid can then be decanted into porcelain evaporators. The residue is washed onto a filter with alcohol 3 or 4 times, the washings being added to the original solution for evaporation. A rather large dish should be used and the evaporation carried on slowly until the alcohol is completely volatilized. There is left a large residue of ammonium chlorid, which should be well diluted with water, and 2 or 3 cc. of nitric acid are added. The dish should be covered at first and warmed very gently to avoid loss by spurting. After the salt has been decomposed, the evaporation may be completed. The residue is taken up with water and a few drops of nitric acid, and the determination of phosphorus pentoxid made according to the usual molybdate method, titrating the yellow precipitate."

The results by Dyer's 1 per cent citric-acid method agreed quite closely with those of the crop tests in regard to potash, but there were wide discrepancies in the phosphoric acid. The phosphoric-acid soluble in $\frac{1}{25}$ normal hydrochloric acid agreed very closely with that removed from the soil by 3 successive crops of oats.

In order to gain some insight into the amount of plant food rendered assimilable in the soil during the growth of the crop "40 pots, holding about 1 pint each, were filled with the same soil, and in each pot, 18 grains of corn were planted. At the end of 2 weeks 6 pots were emptied, the corn plants and their roots freed of soil, all the soil put together as one sample, and all the plants and roots made into one sample. The roots were separated very easily, washed in a minimum quantity of water, the washings concentrated and mixed through the soil, which was then allowed to assume an air-dried condition before its moisture-free weight was obtained. The corn plants with their roots were then ashed and analyzed," *i. e.*, potash and phosphoric acid soluble in hydrochloric acid varying in strength from $\frac{1}{100}$ normal to 2 normal were determined. The same observations were repeated at 3 other periods thereafter at intervals of one week. The plants and roots contained practically the same percentages of phosphoric acid at each period, and in no case was it equal to that added in the seed. There was a steady increase of potash in the plants until about 4 times as much was removed by the plants as had been added in the seed. The results in general indicate "a condition wherein the mineral compounds are constantly undergoing a change into more soluble compounds, and with a tendency to revert before the compounds reach the point where they would leach out in drainage water. It is not seen how so great a change in the solubility of minerals can be brought about through so weak an acid as is contained in the sap of plants. In this case, a 5 weeks' growth so affected the more insoluble minerals as to bring 182 parts per 1,000,000 of the potash compounds into the range of solubility of 2-normal acid. As a mere question of solution, the weak acid of the sap could not possibly exert so strong a solvent effect as that shown. It is easier to believe that the changes in the mineral compounds of the soil are due to the action of bacteria, which are stimulated by the excretions from the roots.

"The complete chemical and mechanical analyses have no bearing on the immediately available plant food, in so far as the writer is able to interpret."

In sampling soils for analysis "a succession of similar depths should be taken in order to ascertain how deep the available food existed, and with this [should be] compared the depth to which the feeding roots of the intended crop are known to penetrate. For actual practice, the writer has constructed a very simple form of sampling cylinder, made out of 7-in. wrought-iron pipe. The pipe is cut 6 in. in length, and turned down to a thickness of $\frac{1}{16}$ in., leaving a collar on one end, to strengthen and drive upon, while the cutting edge is turned at the other end. This makes a strong cylinder weighing about 4 lbs. The cylinder is driven down to the top, and the inclosed soil taken out. The soil is dug from around the sides of the cylinder as it is driven down for the second 6 in., and so for a third 6 in. The separate portions are weighed and subsampled for analysis. . . . The more divisions into which a soil sample can be divided the more data there will be for study. . . .

However, if it is limited to two, or even one sample, let the total depth be that to which the intended crop is known to feed." The author suggests that in the study of soils by chemical methods it be assumed "that the available plant food rarely extends to a depth of more than 12 in., and that plants penetrating below that depth do so for the purpose of obtaining moisture." Such an assumption would simplify and increase the accuracy of sampling.

Development and distribution of nitrates in cultivated field soils, F. H. KING and A. R. WHITSON (*Wisconsin Sta. Rpt. 1901, pp. 210–231, figs. 5*).—In continuation of previous investigations (E. S. R., 13, pp. 24, 229) determinations of nitrates were made twice each month in the upper 4 ft. of the plats used in former experiments, "the object being to learn what differences may result with differences of season and with change of crop.

"The work with the total soluble salts as indicated by Whitney's electrical method has been discontinued because it was learned that while his method gave results which agreed fairly well with the gravimetric method for the surface foot of our soils, there was a wide disagreement when the second, third, and fourth feet were compared, the gravimetric method giving more soluble salts with the sands and less with the clays than the electrical method did, while there was an approximate agreement with the loams which are intermediate in texture."

It is shown that as an average for plats which were cropped last year there was 131.4 lbs. per acre more of nitrates in the surface 4 ft. in the spring of 1901 than in 1900, and 291.93 lbs. more at the beginning of September.

The nitrates in the plant (leaves and stems) grown on the various plats were determined at different stages by the following method:

"A sample of plants from the field was first chopped fine and mixed. From this mixture 20 gm. were weighed out, placed in a wedgwood mortar, thoroughly crushed, and finally worked up with 250 cc. of distilled water placed in the mortar; 20 cc. of this solution was drawn off into an evaporating dish and heated over a water bath for a few minutes, to partly coagulate the organic matter. It was then allowed to cool, after which 6 to 8 drops of subacetate of lead (U. S. P.) are added, with stirring to precipitate albuminoids. Then about 1 gm. of powdered animal charcoal, previously digested in sulphuric acid and very thoroughly washed, is added, allowed to stand for an hour with occasional stirring, and then filtered and washed with distilled water, making it finally up to 100 cc.

"The method of procuring a clear solution is that of A. Pagnoul (E. S. R., 8, p. 386), slightly modified. An aliquot of this solution is then evaporated and treated as described in [a previous bulletin] (E. S. R., 13, p. 230). . . .

"To determine the moisture content of the sample, for computation usually 100 gm. of the cut material was dried."

The results, together with those of determinations of nitrates in the surface foot of soil, made as a rule the preceding day, are reported in detail. They show "that in the case of the corn the nitrates, whether expressed in terms of the plant moisture or of the dry matter in the plant, have, in general, decreased with the degree of maturity in the crop; but with the potatoes or clover this relation is not so marked.

"Where the determinations have been made in the leaves and stems separately the results show a greater concentration of nitrates in the stems, as would be expected if the nitrates are broken down in the leaves or converted into organic nitrogen compounds.

"Everywhere the degree of concentration of nitrates in the sap of the plant stems is much higher than it is in the soil moisture. This appears very strange from the physical point of view and much more in harmony with the views formerly held by Berthelot and André, that nitrate of potash is continually formed in the stems of plants, but not accepted as correct by most authorities at present."

In view of the large amounts of nitrates found in the crops examined (as high as 12,317 parts per million of dry matter in potato stems), the authors tested the accuracy of the ordinary Kjeldahl method as applied to such materials and found a considerable error due to incomplete recovery of the nitrates by this method.

There was an average gain of 79.27 lbs. of nitrates in the surface foot of the soils during winter.

A study of the influence of temperature on nitrification was made by the following method: "From a large quantity of the field soil, thoroughly mixed in a tray out of doors, when the temperature was near 32°, about 2,000 gm. were taken and put into a 4-qt. tin pail, to be placed in another receptacle surrounded by water at the desired temperature." The temperatures maintained in different cases were about 35, 48, 68, and 90° F. "The soil was kept under conditions which permitted normal aeration, and the moisture content of the soil was maintained nearly constant by the addition of water at the time the samples were taken, to restore that lost by evaporation during the interval." The observations extended over 27 days, April 11 to May 8. Determinations of nitric nitrogen were made at the beginning and at about 2-day intervals in duplicate 50 gm. samples of each soil, care being taken "not to have the soil samples exposed to the temperature of the laboratory more than a few moments before the nitrates were washed out in the formalin solution to arrest both nitrification and denitrification."

The soil used "was in fairly good condition of fertility, but had received no manure or other fertilizers for more than 5 years. At the lowest temperature the mean daily rate of nitrification was 0.1594 part of nitric nitrogen per million of dry soil; or, expressed as calcium and magnesium nitrates, this is equivalent to 0.876 lb. per million pounds of dry soil. The surface 6 in. of an acre of this soil weighs about 1,370,000 lbs., and the above rate of increase would mean a production of 1.2 lbs. per day per acre and 120 lbs. in 100 days. The rate of nitrification at the highest temperature was 6.232 times more rapid than at the lowest temperature, the mean daily rates for the 4 temperatures being, in parts per million of dry soil, as follows: At 35° F. 0.1593, at 48° F. 0.1999, at 68° F. 0.4376, at 90° F. 0.9927."

These observations indicate that considerable nitrification may go on at as low a temperature as 35° F.

The results of observations on the influence of fall plowing on nitrification show that "if the total nitrates found in the plowed ground of August 19 and September 30 are compared, it will be seen that there has been a gain of 148.56 lbs. per acre during the 42 days. In the same way, comparing the total nitrates in the 4 ft. of the unplowed ground of the same dates, it will be seen that there has been a gain of 113.92 lbs. per acre, so that the effect of the plowing has been to increase the nitrates 34.64 lbs. per acre, or about 0.8 of a pound per day."

The total nitrates in soil which had been plowed in the fall just as the ground was freezing and again April 12 the succeeding spring "was 183.53 lbs. per acre, while that in the unplowed ground was 160.71 lbs. per acre, a difference of 22.82 lbs. in favor of the plowing; but on April 29 the nitrates on the unplowed ground had increased to 355.52 lbs. per acre, while that on the plowed ground contained only 327.97 lbs. or 27.55 lbs. per acre less. Accepting the figures as representing the facts, it appears that the ground not plowed has increased in its nitrate content faster than the plowed ground did, and at the rate of some 50.37 lbs. per acre. This is what should be expected if (1) nitrates are brought toward the surface by capillarity; (2) if there was greater evaporation from the ground not plowed than from that plowed, and (3) if the rate of nitrification was the same in both cases."

Studies on black marsh soils, F. H. King and A. R. Whitson (*Wisconsin Sta. Rpt. 1901, pp. 232-236, figs. 2*).—Experiments in continuation of those of previous years (E. S. R., 13, p. 27) were made in cylinders to determine the effect of turning under the crop as a means of improving the soils, and on the station farm to test the relative effectiveness of potash (sulphate), barnyard manure, and dried blood. The working of the preceding crops of oats and alfalfa into the soil had a pronounced effect in increasing the yield of corn. "The poorer soil is affected much more than the better soil, and the cylinders which had grown oats are affected much more than those which had grown alfalfa.

"These differences can not be due to lack of available nitrogen in the soil, since determinations of the nitrates in all of the cylinders made a few days before the crop was removed showed several times the amount which has been found in the soil on which heavy crops of corn were growing in the field. The indications are that one or more of the mineral elements were present in but limited amounts."

When the data obtained in the experiments with the fertilizers are expressed as per cent of increase due to each fertilizer, the results stand as follows: "On the north field, potassium sulphate, 34.4 per cent; dried blood, 20.1 per cent; manure, 29.2 per cent. On the south field, muriate of potash, 0.0 per cent; dried blood, 5.3 per cent; manure, 16.7 per cent."

Some geobotanic experiments, V. Nabokikh (*Selsk. Khoz. i Lyesor., 198 (1900), Sept., pp. 679–690*).—This article records observations since 1895 on the growth of a variety of plants, including corn, oats, potatoes, alfalfa, *Lathyrus sativa, Madia elegans, Carduus marianus, Atriplex hortensis, Dracocephalum moldavica, Datura ferox,* and *Calendula stellata,* on different kinds of soil, including gray sandy soil, alluvial clayey soil, alluvial sand, chernozem, loess clayey soil, pebbly clay soil, and marly soil, which had been filled in pits 1 meter deep and 6.4 meters square, in 1881. Partial chemical and physical analyses of the soils are given, and the behavior of different plants on the same soil and of the same plant on different soils are recorded and discussed, as well as observations on the growth of weeds and the survival of the plants on the different soils. The author especially discusses at some length the phase of the appearance of the first flower. He does not agree with the opinion shared by most horticulturists and agriculturists that as a rule on soils which are dry and poor in nutritive substances the flowering is hastened. Unfavorable soil conditions which retard the vegetative development may also retard the phase of flowering; such phenomena the author actually observed in the course of his 3 years' experience. The physiological peculiarities of different species also play a great part in the conditions of the phase of flowering. The other phases of the development of plants—the ripening of the fruit and the drying up of the above-ground organs—are subject to specific deviations from the normal as similar to those observed in the case of the flowering.—P. FIREMAN.

FERTILIZERS.

The fertilizing value of the nitrogen of stable manure and its analytical determination, T. Pfeiffer, O. Lemmermann, R. Riecke, and C. Bloch (*Mitt. Landw. Inst. Univ. Breslau, 1 (1901), No. 5, pp. 189–219*).—This is a continuation of previous investigations (E. S. R., 11, p. 134; 12, p. 734), and included pot and field experiments with 12 different kinds of manure from cattle, horses, sheep, and dogs. The experiments were made on heavy and light soils, the main object being to find an analytical method for determining the value of the nitrogen of manure. This was not attained with complete success, but there appeared to be a certain relation between the effectiveness of the nitrogen and its solubility in pepsin solution[1] after decomposition of the manure, although, as the table below shows, the results were not concordant or conclusive. The solubility in the pepsin solution was determined in the fresh manure and in the same manure after it had been kept in a

[1] See Landw. Vers. Stat., 55 (1901), p. 129.

thermostat at 38° C. for 3 months and moistened with water and soil extract to set up decomposition. The principal results are summarized in the following table:

Availability of different forms of nitrogen in manure.

Kind of manure.	Nitrogen in manure.			Plants utilized of—					
	Total.	Soluble in pepsin solution.		Total nitrogen.		Nitrogen soluble in pepsin solution at beginning.		Nitrogen soluble in pepsin solution after decomposition.	
		At time of use.	After decomposition.	On heavy soil.	On light soil.	On heavy soil.	On light soil.	On heavy soil.	On light soil.

Composted yard manure—Pot test	.531	.308	.260	17.7	11.0	30.6	18.9	36.4	22.5
Sheep manure (1)—Pot test	.900	.391	.494	24.4	19.2	56.3	44.1	44.5	34.9
Sheep manure (2)—Pot test	1.279	.988	.866	22.1	19.7	28.6	25.5	32.7	29.0

From the table it appears that there is sometimes a decrease, sometimes an increase, of pepsin-soluble nitrogen as a result of decomposition, showing that the setting free of difficultly soluble and the fixation of easily soluble nitrogen compounds varies with the kind of manure.

Goat manure, D. MARTELLI (*Studi e Ricerche Ist. Lab. Chim. Agr. Univ. Pisa, 1900–1901, No. 17, pp. 19–26*).—Analyses are reported as follows:

Fertilizing constituents of goat manure.

Constituents.	Fresh manure.		Old manure.			
	Collected in the open.	Collected in stalls.	Preserved under cover.			Preserved in the open.
			1.	2.	3.	
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Nitrogen	1.512	1.540	2.198	2.156	1.974	1.519
Potash	.536	.557	1.527	1.888	1.589	.650
Phosphoric acid	.593	.634	.972	.860	.445	.423

Guano collected on islands in the Red Sea near the Colony of Eritrea, D. MARTELLI (*Studi e Ricerche Ist. Lab. Chim. Agr. Univ. Pisa, 1900–1901, No. 17, pp. 107–123*).—In the analyses reported the nitrogen varies from 0.784 to 15.029 per cent, the phosphoric acid from 11.706 to 28.083 per cent, and the potash from 0.224 to 1.781 per cent.

Vegetation experiments on the fertilizing action of different phosphates, O. KELLNER and O. BÖTTCHER (*Chem. Ztg., 26 (1902), No. 1, pp. 8, 9*).—The experiments here reported were made for the purpose of determining whether the small fertilizing effect of the phosphoric acid of bone meal found by Wagner, Maercker, and others was not due to the fact that their tests were made on soils which were naturally rich in lime or abundantly supplied with it at the time of the experiment. Three series of experiments in pots of 6 kg. content are reported. In the first two series the fertilizing effect of water-soluble phosphoric acid (superphosphate), citric-acid-soluble phosphoric acid (Thomas slag), and bone-meal phosphoric acid was compared, rye being the crop grown in one series, and mustard in the other. In every case the application of lime reduced the action of the phosphates ($\frac{1}{2}$ to $\frac{2}{3}$) and even that of the soil phosphoric acid, the yield from unlimed soil receiving no phosphate being higher than from the same soil receiving lime. The yield was nearly a third greater from bone meal applied in the fall than from that applied in the spring (on rye). In the third series of experiments bone meal of various kinds (fine and coarse) was compared with superphosphate and mineral phosphates with the following results, the yield with superphosphate without lime being taken as 100:

Relative effectiveness of phosphoric acid from different sources, with and without lime.

	Without lime.	With lime.
Double superphosphate, containing 35.43 per cent of water-soluble phosphoric acid	100	89
Chinchas guano, containing 12.56 per cent total phosphoric acid, 6.03 per cent citrate-soluble, 3.14 per cent water-soluble, and 7.65 per cent of nitrogen	46	26
Lobos guano, containing 33.19 per cent total phosphoric acid, 5.62 per cent citrate-soluble, 1.66 per cent water-soluble, and 2.29 per cent of nitrogen	35	18
Algerian phosphate, containing 28.29 per cent total and 0.23 per cent citrate-soluble phosphoric acid	39	14
Algerian phosphate, containing 26.58 per cent total and 0.41 per cent citrate-soluble phosphoric acid	35	10
Raw "Indian bone" meal, containing 23.5 per cent phosphoric acid and 4.06 per cent nitrogen	55	33
Bone meal with fat and gelatin removed (finely ground), containing 22.84 per cent phosphoric acid, 5.31 per cent nitrogen, and 21.1 per cent of particles over 0.25 mm. in diameter	52	....
Bone meal with fat and gelatin removed (coarsely ground), containing 22.72 per cent phosphoric acid, 5.28 per cent nitrogen, and 87.2 per cent of particles over 0.25 mm. in diameter	31	....
Steamed bone meal (fine), containing 25.9 per cent phosphoric acid, 4.23 per cent nitrogen, and 13.4 per cent of particles over 0.25 mm. in diameter	51	....
Steamed bone meal (coarse), containing 26.01 per cent of phosphoric acid, 4.18 per cent of nitrogen, and 95.5 per cent of particles over 0.25 mm. in diameter	28	....

The effectiveness of the bone was very largely dependent upon its fineness.

On the question of the relative value of different phosphates, D. Prianishnikov (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 107–140, pls. 8*).—A brief review of previous investigations on the subject is given and sand and soil cultures in 4 to 5 kg. pots with different forms of calcium phosphate, and different kinds of mineral phosphates are reported. A variety of cereals and leguminous plants were grown. The mineral phosphates showing the lowest solubility in 2 per cent citric acid gave the smallest yields. The cereals in general (wheat, rye, millet, etc.) showed a very limited capacity for assimilating the crude phosphates. Buckwheat, lupines, peas, and mustard utilized them to a greater extent. Bone meal proved a much better source of phosphoric acid than mineral phosphates even in case of millet, which showed the lowest assimilative capacity. The freshly precipitated tricalcium phosphate was also very assimilable as compared with the mineral phosphates and dicalcium phosphate gave higher results than the monocalcium (or monopotassium) phosphate. The order of assimilability was mineral phosphate (phosphorite), bone meal, Thomas slag, freshly precipitated tricalcium phosphate, and dicalcium and monocalcium phosphate, all being assimilated to a greater extent by buckwheat, lupines, etc., than by the cereals. The experiments with mineral phosphates on black soil from southern Russia and on podzol soil from northern Russia showed that the phosphates were much more effective on the latter. This is ascribed to the acid character of the podzol soils. With regard to the use of phosphatic fertilizers soils are divided into 4 groups, as follows: (1) Those which are rich in assimilable phosphoric acid and do not respond to phosphatic fertilizers; (2) those containing little, easily assimilable phosphoric acid, but well supplied with other mineral constituents on which mineral phosphates increase the yield of cereals but not that of buckwheat, lupines, etc., (3) those generally deficient in phosphoric acid but not of acid properties, on which soluble phosphoric acid increases the yield of all plants but mineral phosphates are effective only on buckwheat, lupines, and similar crops; (4) soils generally deficient in phosphoric acid and decidedly acid in character, on which all phosphates, including mineral phosphates, increase the yield of all crops. Ammonium salts in connection with the mineral phosphates were very effective in increasing the yield but proved injurious when used with soluble phosphates.

The creator of the superphosphate industry and the work at Rothamsted, Maizières (*L'Engrais, 17* (*1902*), *No. 8, pp. 183, 184, figs. 2*).—A brief sketch of the life and work of Sir John Bennet Lawes, especially the experiments in continuous culture with chemical fertilizers alone.

Phosphates in Algeria and Tunis, Maizières (*L'Engrais, 17* (*1902*), *No. 9, pp. 206–208*).—A brief account of the various phosphate deposits in these countries.

Pot experiments with nitrogenous fertilizers, C. S. Phelps (*Connecticut Storrs Sta. Rpt. 1900, pp. 158–174*).—This is an account of a continuation in pots of experiments heretofore conducted mainly in the field (E. S. R., 11, p. 835). The pots used were made of galvanized iron, and were 18.5 in. deep and 10 in. in diameter, holding from 60 to 80 lbs. of the soil, sand, and gravel used. The soils experimented with were taken from the plats used in the field experiments. These soils apparently contained very little available nitrogen. The methods of filling the pots, applying the fertilizers, sheltering and caring for the plants, sampling and analyzing the crops, are described in detail. The data obtained in experiments with oats, Hungarian grass, orchard grass, and soy beans are reported in full, but without comment, since the experiments are being continued with smaller quantities of nitrogen and "it has been thought best to defer drawing any deductions until the results of the later experiments can be compared with those here reported."

Reports to the ministry of agriculture on sewage distribution at Gennevillieres and d'Achères (*Bul. Min. Agr.* [*France*], *20* (*1901*), *No. 5, pp. 965–968*).—Data are given as to the efficiency of the system of sewage farms at these places in purifying the sewage.

An experiment on soil improvement, C. S. Phelps (*Connecticut Storrs Sta. Rpt. 1900, pp. 61–65*).—This is a brief account of a continuation of experiments begun in 1899 (E. S. R., 12, p. 1025). The rotation adopted for this experiment was corn, potatoes, oats, and peas for fodder, and soy beans. The results with potatoes in 1900 are given. From these the conclusion is drawn "that clover had a high value when used to plow under as manure for potatoes. By sowing the clover seed amongst the corn in July, this crop was grown mainly between the seasons of the regular crop of the rotation. Although the clover at the time of plowing under was only 3 or 4 in. high, it proved to be a very valuable manure."

Analyses of commercial fertilizers, M. A. Scovell, A. M. Peter, and H. E. Curtis (*Kentucky Sta. Bul. 97, pp. 225–261*).—The results of analyses of 217 samples of fertilizers are reported. Of these 30 samples, representing 29 brands and 17 firms, fell below the guaranteed analyses in one, two, or all three ingredients. "The great majority of the manufacturers, however, have furnished in most instances fertilizers fully up to and often better than the guarantee."

Report of analyses of commercial fertilizers for the spring and fall of 1901, L. L. Van Slyke and W. H. Andrews (*New York State Sta. Bul. 201, pp. 103–168*).—The results of analyses of 465 different brands of fertilizers are reported. Of these, 334 were complete fertilizers in which the total nitrogen varied from 0.36 to 8.1 per cent, averaging 2.01 per cent. The water-soluble nitrogen varied from 0 to 6.4 per cent, averaging 0.87 per cent. The available phosphoric acid varied from 1.01 to 13.46 per cent, averaging 8.8 per cent. The potash varied from 0.26 to 11.59 per cent, averaging 4.47 per cent. In 70 out of the 334 brands examined the potash was in the form of sulphate free from excess of chlorids. The average amounts of nitrogen, available phosphoric acid, and potash exceeded the guaranteed averages by 0.12 per cent, 1.13 per cent, and 0.34 per cent respectively. The average retail selling price of the fertilizers was $25.71, the retail cost of the separate ingredients unmixed, $19.81.

Official report on commercial fertilizers inspected, analyzed, and licensed to be sold in the State of Ohio during 1901 (*Ohio State Bd. Agr. Rpt. 1901, pp. 92*).

The fertilizing value of citrus culls, E. W. HILGARD (*California Sta. Bul. 139, pp. 11, 12*).—It is estimated that 1,000 lbs. of oranges contain about 2.11 lbs. of potash, 1.25 lbs. of phosphoric acid, and 1.83 lbs. of nitrogen, worth from 30 to 40 cts. It is suggested that the culls may be composted with spent lime from beet-sugar factories with good results.

Compost formulas (*Bul. North Carolina State Bd. Agr., 23 (1902), No. 1, pp. 43–45*).—Formulas for composts of chemical fertilizers with barnyard manure, cotton seed, and cotton-seed meal are given, as well as precautions regarding the use of lime in composts.

Planting, fertilizing, and yield tables, VIBRANS (*Deut. Landw. Presse, 29 (1902), No. 4, p. 26*).

FIELD CROPS.

Influence of the right amount and the right distribution of water in crop production, F. H. KING (*Wisconsin Sta. Rpt. 1901, pp. 195–199*).—The distribution of rainfall at the station during the growing seasons of 1900 and 1901 are compared, and the yields of different crops under irrigation are reported. The yield of hay on 4.2 acres obtained in 4 cuttings was 20.59 tons, representing a gain of 3.4 tons due to irrigation. The increase in the yield of corn by supplementing the rainfall by irrigation amounted to 4.2 tons of silage, 1.09 tons of dry matter, and 35.16 bu. of ear corn per acre. In a test with potatoes, holding the soil moisture up to standard conditions by irrigation increased the yield of merchantable tubers 159.58 bu. per acre. The feasibility of establishing irrigation plants under certain conditions is discussed.

Field experiments with fertilizers, C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1900, pp. 34–60, dgms. 2*).—Some of these experiments have been in progress since 1888, while others have been added at different times. The work is repeated yearly with the same fertilizers on the same plats. The reports of former years, together with a description of the experiments, have been previously noted. This account is a report of progress for 1900. The results in general are the same as those reported in 1899 (E. S. R., 12, p. 1028).

Fertilizer experiments, J. SEBELIEN (*Norsk Landmandsblad, 20 (1901), Nos. 12, pp. 144–146; 13, pp. 158–161; 14, pp. 169–172*).—The work here reported consisted of fertilizer experiments with garden crops, and of pot experiments with barley. The plats used in the experiments with garden crops contained 37.5 square meters, and were fertilized at the rate of 1,216 kg. of kainit and 1,654 kg. of 20 per cent superphosphate per hectare in one series, and 1,333 kg. of kainit and 1,813 kg. of phosphoric acid in the form of potassium phosphate in the second series. Two plats were left unfertilized. The plats planted to peas had received stable manure 3 years previous, and those planted to carrots 2 years previous. Regarding the results of the check plats as 100, the average relative yield of peas on the kainit plats was 56 for the vines and 37 for the peas, and on the potassium phosphate plats 185 for the vines and 147 for the peas. The weights of the carrots harvested stood as 105.9 for the kainit plats, 121.6 for the kainit superphosphate plats, and 132 for the potassium phosphate plats. The excessive quantities of fertilizers applied exerted a very deleterious influence on the germination and retarded the growth of the plants at the beginning of the vegetative period. The peas did not seem to recover from the effect, but the carrots were able to do so. The results obtained on the potassium phosphate plats indicate that the injurious effect observed was not due to the amounts of potash or phosphoric acid applied, but to the impurities, such as magnesium salts, chlorids, and gypsum in the kainit and superphosphate. The potassium phosphate, although supplying a still larger quantity of potash and phosphoric acid than the kainit and superphosphate, produced no deleterious effects. The experiments were continued on the same plats during the following year, carrots being grown after peas and peas after carrots. Potash fertilizers again proved injurious to peas but carrots and cabbage were not injuriously affected.

In the pot experiments, potash tests with barley on a rather heavy soil showed that the increase in total yield was about the same, whether potassium chlorid or potassium sulphate was applied, but that the chlorid produced the most grain and the sulphate the most straw. In comparative nitrogen fertilizer experiments, the nitrate of soda produced considerably better results than ammonium sulphate. Considering the results from the use of potash and phosphoric acid as 100, the yields were as follows: With nitrate of soda, grain 382, straw 171, and the total yield 222; with ammonium sulphate 115, 162, and 140 for the grain, straw, and total yield, respectively.

The experiments were repeated the following year on a dark, sandy soil, under otherwise similar conditions as before. The comparative results are given below:

Relative yields of barley in pot experiments with nitrogen and potash fertilizers.

Nitrogen tests.	Grain.	Straw.	Total.	Potash tests.	Grain.	Straw.	Total.
FERTILIZERS APPLIED.				FERTILIZERS APPLIED.			
Phosphatic slag alone	100	100	100	Phosphatic slag alone	100	100	100
Phosphatic slag and sulphate of ammonia	174	156	164	Phosphatic slag and muriate of potash	111	123	118
Phosphatic slag and nitrate of soda	180	180	180	Phosphatic slag and sulphate of potash	102	125	114
Phosphatic slag and muriate of potash	100	100	100	Phosphatic slag and sulphate of ammonia	100	100	100
Phosphatic slag, muriate of potash, and sulphate of ammonia	164	143	152	Phosphatic slag, sulphate of ammonia, and muriate of potash	104	113	109
Phosphatic slag, muriate of potash, and nitrate of soda	163	153	157	Phosphatic slag, sulphate of ammonia, and sulphate of potash	102	127	115
Phosphatic slag and sulphate of potash	100	100	100	Phosphatic slag and nitrate of soda	100	100	100
Phosphatic slag, sulphate of potash, and sulphate of ammonia	175	160	167	Phosphatic slag, nitrate of soda, and muriate of potash	100	105	103
Phosphatic slag, sulphate of potash, and nitrate of soda	168	151	159	Phosphatic slag, nitrate of soda, and sulphate of potash	95	105	100

The soil was in poor fertility, as shown by the fact that the yield of grain and straw with phosphoric acid applied singly stood in the relation to that obtained in the unfertilized pots as 147:100, while with a complete fertilization the total yield was about 260 per cent of the yield in the unfertilized pots. The nitrogen fertilizers in all cases increased the yield of barley, but there was no appreciable difference between sulphate of ammonia and nitrate of soda except when applied with phosphatic slag alone. The soda supplied in the nitrate may have partially remedied the lack of potash in the soil. There was little difference in the results from the use of muriate and sulphate of potash, but they confirm previous observations that muriate of potash tends to increase the yield of grain and sulphate of potash the yield of straw. The following year the effect of the potash and nitrogen fertilizers, with or without the addition of lime, was studied with barley as a trial crop and on clay as well as on sandy soil. The clay soil contained 0.35 per cent of nitrogen, 0.03 per cent of phosphoric acid, 0.12 per cent of lime, and 0.02 per cent of potassium oxid, while the corresponding data for the sandy soil were respectively 0.13, 0.08, 0.07, and 0.01 per cent. Phosphoric acid in the presence of lime, potassium chlorid, and nitrogen increased the yield about 50 per cent, whether ammonium sulphate or nitrate of soda was applied, with slightly better results, however, in favor of ammonium sulphate. Lime with phosphoric acid, potash, and nitrogen produced better results than those alone on both kinds of soil, but the plants growing on clay soil and receiving ammoniacal nitrogen were evidently somewhat more benefited by the addition of lime than those receiving nitrate of soda. Sandy soil responded still better to fertilization with lime than the clay soil, as might be inferred from the chemical analyses of the 2 soils. A comparison of the results with muriate and sulphate of potash in the presence of lime and nitric or ammoniacal nitrogen does not indicate any appreciable difference between the 2 forms for clay soils, while on the sandy soil the muriate when given with sulphate of ammonia did somewhat better than the sulphate, the relative yields of grain being as 100:91 and the total yield as 100:94.—F. W. WOLL.

Field experiments with grain and forage plants, R. A. MOORE (*Wisconsin Sta. Rpt. 1901, pp. 237–254, figs. 2*).—These experiments were largely in continuation of work previously reported (E. S. R., 13, p. 36). The results of variety tests with oats, barley, emmer, peas, winter wheat, winter rye, and vetch, are given in a table. Swedish oats yielded 40 bu. per acre, while the common varieties averaged about 30 bu. Among 38 varieties tested during the past 3 seasons, Swedish and Siberian oats have shown the most commendable characteristics. Early Gothland and White Bedford have also given promising results. Manshury, Oderbrucker, and Silver King were the most satisfactory of 16 6-rowed varieties of barley. Silver King showed all the characteristics of Manshury. Two-rowed, hulless, and beardless barleys did not give satisfactory results. Of the 2 varieties of winter wheat grown, Turkish Red yielded 32.3 bu. per acre, and Kings Early winterkilled. Petkus and Schlansted, the only varieties of winter rye tested, gave good returns. The tests with peas were not satisfactory, owing to the seed being so badly affected by the weevil. Peas affected with the weevil showed a germinating power of 20 per cent, and those unaffected of 94 per cent. Russian vetch yielded only 2½ bu. of seed per acre.

In addition to the above experiments, tests with rape, alfalfa, clover, brome grass, soy beans, and cowpeas are reported. A test of seed of Dwarf Essex rape, grown near Puget Sound, in Washington, gave promise of a possibility of successfully growing rape seed in this country. Four pounds of Dwarf Essex rape and 3 bu. of oats per acre sown broadcast gave a yield of 32½ bu. of oats per acre and a satisfactory growth of rape for fall forage. The culture and uses of rape are briefly discussed. An instance is cited of injurious effects resulting from pasturing sheep on frozen rape. The results of a number of tests indicated that alfalfa can be sown with oats as a nurse crop. On several plats where only 1 bu. of oats was sown per acre the alfalfa made a vigorous and healthy growth and left a good stand for winter protection. As compared with American and European varieties of red clover, Turkestan alfalfa showed superior drought-resisting qualities. American red clovers and European clovers were grown to compare their quality, hardiness, and productiveness. The American varieties were medium and mammoth red clovers, and the European varieties, Hungarian, English, Steinmark, Transylvania, Russian, and German red clovers. The American varieties survived the winter, but all the European varieties, excepting Hungarian and Russian, were winterkilled. The American clovers gave the best yields, but the quality of hay was slightly in favor of the European varieties, being finer and comparatively free from dust. Experiments in growing clover with and without a nurse crop resulted in the best stand on the plats where no nurse crop was used. On plats where the nurse crop was cut for hay better results were obtained than on plats where it was allowed to ripen. A culture test of *Bromus inermis* resulted in a very heavy sod, but a rather light yield of hay. Sowing this grass at the rate of 32 lbs. per acre gave better results than sowing 16 or 24 lbs. of seed per acre. Soy beans grown at the station from Michigan-grown seed gave a yield of 22 bu. of ripe seed beans per acre. The yield of green forage determined on one plat was 4 tons per acre, equal to 2¼ tons of cured hay. Heavy fall frosts interfered with a culture test of cowpeas, and further trials will be undertaken.

Records of seed distribution and cooperative experiments with grasses and forage plants, F. Lamson-Scribner (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 10, pp. 23*).—This bulletin is a general report on the collection and distribution of grass and forage plant seeds by this Department through the office of the Agrostologist and on the cooperative work in grass and forage plant investigations with a number of State experiment stations. The manner of keeping the records of this seed distribution is explained in detail, and the plan of conducting the cooperative experiments and the line of work taken up with each station are fully described. Tables are given showing the seed distribution in detail. From 1896 to 1901, inclusive, 4,166 packages of seed were distributed to the experiment stations and 9,377 to individuals, or a total of 13,543 packages. During the fiscal year 1900–1901, 16,101¼ lbs. of seed, embracing 171 varieties, were distributed to experiment stations. The forms of the articles of cooperation under which the work is carried on and which are signed by the station officials and officials of this Department are presented.

Causes operative in the formation of silage, S. M. Babcock and H. L. Russell (*Wisconsin Sta. Rpt. 1901, pp. 177–184, fig. 1, table 1*).—The results here recorded are in continuation of work previously published (E. S. R., 13, p. 37). To determine the temperature produced, the loss in weight, and the amount of gases evolved in silage, cut field corn of average maturity was placed in 2 galvanized-iron receptacles 1½ ft. in diameter and 4 ft. high. These "silos" were hermetically sealed and remained closed for 25 days. The changes in weight and temperature, as well as the temperature of the room, were observed daily. The initial maximum temperature was reached the first day after filling. For 12 days the temperature remained above the room temperature, but from that time until the silos were opened it fluctuated with the temperature of the room. When opened the silage was in good condition and there was no evidence of mold or bacterial decomposition. Three days after opening, the temperature of the silage began to rise rapidly, reaching its maximum of about 50° C., or 20° above the initial heating after about 10 days, when the temperature again fell, but never reached that of the room. The total loss in the weight of silage before opening, representing the unavoidable losses, was about 1 per cent. After opening the silos the loss in weight was small until the temperature began to rise, when it increased rapidly and amounted to nearly 1 lb. per day as the maximum temperature was reached. In a separate experiment the rate and quality of gas evolved from 40 lbs. of cut corn was determined and the observations are tabulated.

"The fact that by far the larger proportion of gas evolved was thrown off in a period covered by the first 5 days is significant when considered with reference to the metabolic changes that occur in the tissues as a result of the activity of the plant cells themselves. If we assume that the gas evolved was CO_2, . . . the loss in weight due to the evolution of this gas would approximate 1 per cent, which is practically the same as determined by actual diminution in weight of silage in experimental silos.

"These results as to temperature change, loss in weight, and gases evolved are only explicable on the common hypothesis that the normal changes are due to . . . direct and intramolecular respiration of the plant cells themselves; and that normally . . . (bacteria and mold) only function in a detrimental way when air finds access to the mass of plant tissues."

In order to show the causal relation of plant-cell activity to silage formation immature cut corn placed in a receiver and immediately frozen to destroy the cell activity, was compared with a sample ensiled in the usual way. One frozen sample was treated with ether. After 22 days all samples were opened. Only the sample treated in the usual way had a distinctly silage aroma, while the other samples had a pronounced offensive odor suggestive of incipient putrefaction. A bacteriological examination of the samples was made and the conclusion reached that if the silage changes were attributable to bacteria the frozen corn should have made as good silage as the other. Practically the same amount of acidity was found to have developed in the frozen and the check samples as the result of bacterial growth, but in the frozen samples treated with ether the acidity was very much lower. From these results it is concluded that owing to the immediate destruction of the life of the plant cells the changes which characterize silage formation did not take place.

A number of samples of the same lot of corn were ensiled and opened on different dates to determine the relation of aroma production to death of plant cells. "The production of the characteristic aroma at the early stages noted, before the plant cells had died, is hardly compatible with the view that these changes are explicable on the theory that they are caused by the growth of organisms that must develop on the cells of the ensiled tissues. This observation adds probability to the conclusion already drawn that the internal processes of the living plant cell are the factors that inaugurate the series of changes that result in the production of typical silage."

Influence of close packing of corn in the silo on the unavoidable losses in making silage, F. H. KING (*Wisconsin Sta. Rpt. 1901, pp. 200–209, fig. 1*).—This experiment is the repetition of an investigation made the year before (E. S. R., 13, p. 38). Well matured corn was ensiled in pint and quart bottles in such a way as to have closely duplicate material in each bottle, but with more entangled air and looser packing in the quart than in the pint bottles. Air was prevented from entering the bottles, but the evolved gases were permitted to escape. The weight of the corn put into each bottle, together with the losses, are shown in the following table:

Losses in the weight of material in the silo.

	First pair.		Second pair.	
	1 pint.	1 quart.	1 pint.	1 quart.
	Gms.	*Gms.*	*Gms.*	*Gms.*
Weight of corn	323.7	318.7	299.6	291.7
Loss of silage after 33 days	1.0	7.6	3.8	8.5
Percentage loss after 33 days	.31	2.38	1.27	2.91
Loss of silage after 303 days	2.4	10.4	5.6	12.0
Percentage loss after 303 days	.74	3.26	1.80	4.11

The above figures show an average loss nearly 3 times as large with the loose packing as with the close packing. The closely packed pint bottles came to a constant weight in 8 and 9 days, respectively, while the quart bottles continued to lose for 28 and 30 days. The periodicity in the loss of weight after the rate of change had become small was evident in the data reported last year, and was again observed in these experiments.

The silos entering into the experiments of the previous year were left undisturbed, and analyses of the silage gases obtained from them were made in connection with these experiments, and the results are given in a table. An excess of residual gas over what should be expected if only the residual nitrogen of the air originally in the silo were present was found and its occurrence is discussed. That the air in the silo becomes rarefied was demonstrated by the development of a negative pressure in the bottles which at times produced a suctional effect quite marked. In one experiment silage exposed to the air did not mold, and lost in weight only 0.3 lb. or 0.4 per cent from May 15 to September 18. This silage although appearing normal was less acid than ordinary silage, and had a decidedly abnormal taste. Forcing fresh air through a silo did not injure the appearance of the silage, but gave it a bad odor and made it unpalatable.

From the data obtained the author draws the following conclusions:

"We know that during the early stages of the ensiling process, carbon dioxid is given off in large volumes. Hydrogen is given off from normal clover silage in both the earlier and later stages, and it is probably a constituent of the earlier gases from normal corn silage but produced only in small quantities. Nitrogen, other than that of the residual air, is likely to be proven to be a notable component of the gases from normal silage at all times. Water vapor and other volatile products escape with the gases of normal silage at all times, but their quantitative relations have not been sufficiently investigated to permit any statement as to how large the loss from these sources may be.

"Changes take place in normal silage which can not be measured by either a loss of weight or the escape of gaseous or volatile products, and these must be investigated before the changes in feeding value due to the ensiling process can be estimated and understood. The more loosely silage is packed in the silo and the larger the volume of entangled air the greater will be the unavoidable losses. The more open and porous the silo walls are, the larger will be the volume of air drawn into the silage by suction and forced in by wind pressure and barometric changes. The larger losses near the upper surface of the silage, and especially at the sides, are measurably increased by what may be designated silage breathing. The loss from this source could certainly be reduced and possibly to a notable extent by providing a metal cover under the roof which, when the silo is filled and the doors closed, would leave the silo nearly air tight. Such an arrangement would reduce the breathing and thus lessen the loss."

Growing alfalfa, W. C. Currie (*Farm Students' Rev., 6 (1901), No. 10, pp. 146, 147*).—A note on growing alfalfa in the Platte River Valley in Nebraska.

Studies on Bohemian barley, B. Procházka (*Centbl. Agr. Chem., 30 (1901), No. 10, pp. 695–699*).—This article is a discussion of Bohemian barleys. It recommends that in all breeding experiments the variability in plants and the power of transmission of the derived forms be carefully considered. The different species of barley are described and several varieties compared.

The effects of the growth of berseem on the soil, G. P. Foaden (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 3, pp. 134–140, pls. 2*).—This article discusses mainly the value of leguminous crops for soil improvement, and points out especially the adaptation of berseem for this purpose.

Some facts on the maize crop, G. P. Foaden (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 3, pp. 130–133*).—This article is a popular discussion on corn culture in Egypt.

Johnson grass, C. R. Ball (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 11, pp. 22, fig. 1*).—This bulletin gives a description of Johnson grass, and discusses its introduction, distribution, dissemination, the laws governing its control, the methods of eradicating it, and the uses to which it is adapted. Copies of statutes concerning the control of Johnson grass in Texas are given verbatim, and among the several means of eradication a cultural method of killing the grass patented by a Texas company is described. Chemical analyses of the grass at different stages of growth are quoted from Texas Station Bulletin 20 (E. S. R., 3, p. 890), and the comparative composition of timothy, redtop, Johnson grass, and red clover hays, being the average figures of a number of analyses, are given in tables. The author summarizes the bulletin as follows:

"Johnson grass is a tall, vigorous grass, closely related to the sorghums, with a very strong system of long, jointed, underground stems, popularly known as roots. Each joint of this underground stem is capable of producing a new plant.

"It is a native of the tropics of the Old World, and was first introduced into this country as a hay grass in South Carolina about 60 years ago.

"It has spread rapidly throughout the entire South to the Pacific coast and thence north to British Columbia. It thrives best in rich, moist, alluvial or irrigated soil, where it is also most difficult to eradicate.

"It is commonly spread by means of its seeds. They are widely scattered from hay cut after the seed has matured, and are often planted with seed oats. The seeds are unharmed by passing through the digestive tract of animals, and are thus widely scattered in manure.

"The grass should never be allowed to ripen its seeds in meadows, fields, or along roads, fences, or railways.

"It can be destroyed by hand labor—digging out the underground stems.

"Under field conditions it is best killed by plowing fallow land during hot, dry weather. The stems are thus exposed to the heat of the sun and soon killed. The same result follows the action of severe frosts.

"It can also be killed during the cultivation of a cotton crop by much extra hand labor.

"Various chemical substances have been tried but none has thus far proved successful and economical.

"Johnson grass makes a very good quality of hay when cut while just in flower, and it may be profitably cultivated throughout the South for this purpose. Meadows should be broken up at least every third year to loosen the matted stems. It is not necessary to reseed meadows when thus treated.

"Cowpeas may be sown in the grass when it is broken in the spring. When broken in the fall, oats may be used with it. It affords good pasture during summer when treated in the same way as meadows."

Variations in the fertilizing constituents contained in oats, A. Atterberg (*Jour. Landw., 49 (1901), No. 2, pp. 97-172; K. Landt. Akad. Handl. Tidskr., 40 (1901), No. 1, pp. 14-80*).—The work here reported was performed in the years 1885-1893, and the results have in part been previously noted (E. S. R., 6, p. 407). The investigations consist of 3 different lines of work, namely, (1) a chemical study of well and poorly developed oat plants, taken from different fields, to determine the variations in fertilizing ingredients in the plants under ordinary conditions; (2) a study of the composition of oat plants grown in sand cultures with special plant food solutions, and (3) a consideration of the results with reference to the applicability of plant analyses to practical agriculture.

For the study of plants grown under ordinary conditions 86 samples grown on different kinds of soils were obtained. Of some samples the different parts of the plants were analyzed separately, but in most cases an analysis of the entire portion of the plant above ground was made. No analysis was made of the roots. The variations in the content of nitrogen, phosphoric acid, potash, lime, magnesia, sulphur, and salicylic acid, as shown by the analyses of the samples, are presented in tables. The nitrogen content in the dry matter varied from 0.8 to 1.41 per cent, with an average of 1.02 per cent, the stems containing 0.24 per cent, the kernels 0.78 per cent. Unripe samples showed a high percentage of nitrogen in the stems and a low percentage in the grains. The figures representing the nitrogen content of the hulls and kernels, the stems, and the leaves, bear no definite relation to each other, while the nitrogen content of the kernels and the hulls and kernels, owing to the low nitrogen content of the hulls, varied in about the same ratio. Plants grown in pots in connection with these experiments contained a higher percentage of nitrogen than the field samples, but in the greater number of samples in both cases the nitrogen content in the kernels ranged from 1.30 to 1.69 per cent. A high nitrogen content in the green plants was indicative of a high percentage of nitrogen in the ripe kernels. The average for the ripe kernels was 1.64 per cent and for the green plants 1.20 per cent.

The greater portion of the phosphoric acid was found in the grains. The leaves had a higher percentage of phosphoric acid than the stems, but the absolute amount was smaller. The ripe hulls contained a very small quantity of this element. The average quantity of phosphoric acid in the dry matter was 0.427 per cent, 0.094 per cent being in the stems and 0.333 per cent in the grains. This shows that the variations are relatively much greater than the variations in the nitrogen content. The average content of phosphoric acid of the stems and the grains showed some relation to each other, although in general it was not very definite, while in the stems and leaves the relation was definitely shown. A content of more than 0.30 per cent in the stems was found only in those plants which showed a high content in the grains. All samples with a high content of phosphoric acid had been grown on soils rich in lime and liberally supplied with phosphoric acid. Plants grown in the culture pots showed a higher percentage than the field samples. In the pot-grown samples the phosphoric acid content in the green plants increased regularly with the percentage in the ripe grains, but when the content in the grains had reached 0.90 to 0.95 per cent it remained practically constant.

The greatest variations in the content of potash occurred in the stems. When the plants contained a high percentage of potash the larger portion was found in the stems, and when the quantity was low in the plants the stems and the leaves held about equal amounts. The lowest potash content was found in samples from moor soils and the highest in samples from clay soils and moor soils well fertilized with potash. The potash figures of the grains remained almost constant and bore no relation to the figures representing other parts of the plants. Fluctuations in potash content of the leaves and the grains were small. The average content of potash in the dry matter was 1.05 per cent, the stems showing 0.76 per cent and the grains 0.29 per cent. Plants grown in pots produced grains of a higher potash content than the field-grown plants. This was found to be true only in the case of potash. Green and ripe stems showed equal fluctuations.

The largest variations in the lime content occurred in the leaves, while in the grain only a small variation was noticed. All samples from soils rich in carbonate of lime contained over 0.35 per cent of lime in the stems. The average lime content in the dry matter of the plant was 0.256 per cent, the stems containing 0.198 per cent and the grains 0.058 per cent. The stems and leaves contained equal quantities. The lime content of the stems and leaves of the plants grown in pots was almost 100 per cent greater than in the stems and leaves of the plants grown in the field. Green samples fluctuated as widely as ripe ones, but the average content of the ripe stems and leaves was 0.10 per cent higher. Among the field samples those from limy soils contained 0.60 to 0.75 per cent of lime in the stems and leaves while the samples from moor soils poor in lime contained only from 0.17 to 0.20 per cent. Several samples from sandy soils showed a lime content of from 0.50 to 0.60 per cent.

The largest absolute quantity of magnesia was contained in the grains and the smallest percentage was found in the stems and hulls. The dry matter of the plants contained an average of 0.206 per cent, 0.115 per cent being found in the stems and leaves and 0.091 per cent in the grains. The stems contained two-thirds the quantity of magnesia found in the leaves. The grains of the pot and field-grown samples contained the same amount of magnesia, but the stems and leaves of the pot-grown samples contained a higher percentage than the stems and leaves of the field samples.

The highest absolute quantity of sulphur was found in the grains. The sulphur content was found to increase and decrease simultaneously in all parts of the plant. The stems and leaves showed the greatest variations. The average sulphur content in the dry matter of the plant was 0.15 per cent, of which 0.068 per cent was contained in the kernels.

The content of salicylic acid was highest in the leaves and much lower in the stems and grains. In general the distribution of salicylic acid in the plant was the same as the distribution of lime, but in most parts of the plant the salicylic acid content was about 7 times the lime content, and in the grain it was even 12 times as great. Plants grown on moor, sandy, and sandy loam soils were lowest in salicylic acid, while the plants from clay and chalky loam soils gave the highest figures. The content of salicylic acid in the stems and leaves of the plant seemed to be governed by the quantity of readily soluble salicylic acid combinations in the soil.

In studying the effect of different plant food solutions plants were grown in pots filled with sand according to the sand-culture method of Hellriegel, but in several instances different agricultural soils were used in place of sand. Each series of pots contained one element of plant food in different quantities, while the other elements remained constant. The plants from each pot were dried at 100° C., then weighed and analyzed. The roots were not taken into consideration, the analysis being limited to the grains and the portion of the plant above ground without the grains. These experiments were conducted for a series of years.

Four of the nitrogen series showed an increase in the nitrogen content of the plants as the quantity of nitrogen furnished in the plant food increased. In 2 series the nitrogen figures for the grains and for plants not fully ripe were about constant. According to the author, a definite factor which would indicate the nitrogen content associated with a maximum yield is not to be deduced from the results. In one series the best yields showed 1.81 to 1.94 per cent of nitrogen in the grains; in another series, 1.44 per cent; in a third, 1 per cent. In one instance of plants analyzed before fully ripe the maximum yield was associated with a nitrogen content of 2.03 per cent.

In studying the effects of phosphoric acid it was found that in 8 different series the increase in phosphoric acid in the plant food increased the content of that element in the grains, while in 3 series it remained constant at 0.85 per cent. The striking difference between the results of these 3 series and the others is not explained.

In all the potash series the increase of potash in the plant food increased the potash content in the stems and leaves of ripe and not fully ripe plants. Three series continued for 3 successive years with only an initial application of potash showed a decreasing potash content in the plants from year to year. The potash content was never constant in the stems and leaves when the quantity of potash in the fertilizer varied, but in the grain it remained constant or varied very slightly.

The results of 3 tests with different quantities of lime showed that a decrease in the quantity of lime furnished the plant caused a decrease of that constituent in the stems and leaves of ripe as well as unripe plants. The lime content of the plants in these series varied from 0.10 to 0.18 per cent, which proved too low a figure for their healthy development.

The magnesia content of the stems and leaves increased in these tests with the quantity of magnesia furnished the plant as food. With an insufficient supply the content in the unripe plants and in the mature haulms and grains sank to below 0.15

per cent. The lack of magnesia in the plant food manifested itself in small and many undeveloped grains, but it was noticed that the haulms could develop in spite of an insufficient supply.

The results of the sulphur series show in some cases an increase in sulphur content of the plants associated with an increase of this element given in the fertilizer, but as in the case of nitrogen and phosphoric acid it was also found constant. In this connection the grains showed only slight variations.

The influence of varying quantities of water on the composition of the plants was studied and the results show that in water and sand culture different quantities of water caused great variation in the nitrogen and potash content of the plants, but where the plants were grown on ordinary agricultural soils only the nitrogen figures varied widely, the potash and lime content varied less and the amounts of phosphoric acid, magnesia, and sulphur varied least. The results further indicate that generally an increase in the moisture content of the soil causes a relatively greater increase in the weight of the stems and leaves than in the weight of the grains. It was further noticed that close planting tended to decrease the content of plant food elements, especially in the case of nitrogen. It is stated that the season also is a strong factor affecting the composition of the oat plant, a favorable season usually lowering the figures for nitrogen and phosphoric acid and increasing them for lime. The smallest changes were noticed in the content of phosphoric acid and magnesia.

On the basis of the results of this investigation, the author draws the following conclusions: (1) When, in case of oats, the supply of an element of plant food is increased, this particular element is taken up and assimilated by the plant in increasing quantities, and the percentage content in the plant is also increased, except that nitrogen and phosphoric acid often remain constant under these conditions. (2) When an increase in a certain element of plant food increases the yield, the percentage content of the remaining elements in the plant is necessarily lowered, although in several instances in this work phosphoric acid and sulphur remained constant. (3) In case of a weak and poor development of the plants, a low percentage content is to be expected only of the element which is present in smallest quantity in proportion to the needs of the plant. Other elements, although present in the soil in barely sufficient quantities, may show a more or less high percentage content in the plants produced.

From the results of his work, the author gives the following method for determining the element which is present in the plant in minimum quantity: The percentage content as shown by the analysis is compared with the average and minimum content of oats. In general, the fertilizing ingredient whose percentage is farthest below or least above the average figure and nearest the figure representing the minimum content is present in minimum quantity. The author believes that it is possible to determine by chemical analysis of oats the fertilizing ingredient which was present in minimum quantity in the soil producing them, and the ingredients present in larger quantities, and the results thus obtained will permit of probable deductions as to the relative fertilizer needs of the soil. He explains, however, that the indications are always to be regarded with some doubt. He advises that the green plant be used for analysis. In conclusion the "normal" figures as obtained by the author in his work are summarized.—F. W. WOLL.

Studies on potatoes, A. PETERMANN (*Bul. Inst. Chim. et Bact. Gembloux, 1901, No. 70, pp. 16*).—The results of variety tests are reported and conclusions concerning the relation between the chemical composition of the tubers and their cooking qualities are given. The cultural treatment is described and the different varieties classified according to their starch content and their value for the table.

Variety tests with potatoes, C. FRUWIRTH (*Fühling's Landw. Ztg., 50 (1901), No. 4, pp. 166–168*).—A report on testing 47 varieties in 1899, and 49 in 1900.

The necessary qualities of potatoes for the manufacture of alcohol, with

notes on their culture and storage, W. KELLER (*Württemburg Wchnbl. Landw., 1901, No. 41, pp. 661, 662*).

Observations on rice culture in Argentina (*Bol. Agr. y Ganaderia, 1 (1901), No. 2, pp. 50–54*).—This article discusses the culture of rice in Argentina, mainly from a statistical standpoint.

Rice as a reclamation crop, J. H. PAULL (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 3, pp. 141–143, fig. 1*).—This article deals with Sabeini rice, as a means of reclaiming land in Egypt.

Storing root crops (*Deut. Landw. Presse, 28 (1901), No. 80, p. 676*).—A brief note on the subject.

Results of variety tests with rye, BACHMANN (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 40, pp. 603, 604*).—A table gives the yields and financial returns of 14 varieties.

Experiments in sugar-beet culture during 1900 and 1901, F. W. WOLL and R. H. SHAW (*Wisconsin Sta. Rpt. 1901, pp. 261–276, fig. 1*).—The work with sugar beets for the 2 seasons comprised investigations at the station and analyses of beets grown by Wisconsin farmers.

In 1900, 9 varieties of sugar beets were grown on 3 plats, one of which received an application of common fertilizers. The fertilizer application used consisted of 90 lbs. each of dissolved bone and sulphate of potash and 100 lbs. of nitrate of soda per acre. One-half the quantity of nitrate of soda was applied after the beets were thinned. The average sugar content for the fertilized plat was 15.30 per cent with a purity of 81.7 per cent, and for the unfertilized plats 15.03 per cent with a purity of 82.8 per cent. The use of the fertilizer increased the total yield of beets $2\frac{1}{2}$ tons and the yield of sugar 729 lbs. per acre, but this increase was insufficient to pay for the fertilizer applied. The varieties ranged as follows:

"*As to yield of beets*—Kleinwanzleben Dippe, Austrian Kleinwanzleben, Russian Kleinwanzleben (No. 1), Zehringen, Russian Kleinwanzleben (No. 2), Vilmorin France, Austrian Queen of the North, and Austrian White Improved.

"*As to yield of sugar*—Kleinwanzleben Dippe, Austrian Queen of the North, Austrian Kleinwanzleben, Russian Kleinwanzleben (No. 1), Austrian White Improved, Vilmorin France, Zehringen, and Russian Kleinwanzleben (No. 2).

"*As to the per cent of sugar in the beets*—Austrian Queen of the North, Austrian White Improved, Austrian Kleinwanzleben, Russian Kleinwanzleben (No. 1), Kleinwanzleben Dippe, Vilmorin France, Zehringen, and Russian Kleinwanzleben (No. 2)."

In 1901 the work was carried on under adverse conditions, and the results, as shown by the tables, were low. The beets were planted at a late date and in addition the climatic conditions were unfavorable.

The results of analyses of 34 samples of beets grown by farmers in 1900 and of 249 samples in 1901 are summarized by counties in a table. Sixteen samples of beets grown by members of a beet growers' association showed an average of 19.8 per cent of sugar in the beet with a purity of 85.3 per cent.

Relative composition of different varieties of sugar cane, B. BONÂME (*Bul. Sta. Agron. Mauritius, 1901, pp. 24*).—The analyses of different varieties of sugar cane are tabulated and the quantities of plant food removed from the soil by each are given.

Results of tobacco experiments conducted in various parts of the United States, M. L. FLOYD (*U. S. Dept. Agr., Field Operations of the Division of Soils, Second Report, 1900, pp. 455–473, figs. 2*).—This article discusses in detail the experimental growing of tobacco under shade in Florida, Georgia, and Connecticut, and its subsequent handling, together with tests of packing and fermenting cigar leaf tobacco in Pennsylvania. Experiments in growing tobacco under shade were begun in Gadsden County, Florida, in 1896. The cover consisted of 2-in. laths placed 2 in.

apart. At the present time a cheese-cloth shade is generally used. The author states that to-day there are at least 700 acres under shade for tobacco growing in Gadsden County, Florida, and Decatur County, Georgia. The principal advantages of cloth covering over lath covering are the protection it affords against worms and hail, the maintenance of a more even and higher temperature and the retention of soil moisture. The method of overhead irrigation as practiced in connection with tobacco culture under shade is described and figured. The curing and fermenting of tobacco are considered at some length.

A description is given of the tobacco experiments conducted in Connecticut, and the general results are presented and discussed. The types of tobacco entering into these experiments were Connecticut-Havana seed leaf and Sumatra. "In every case the Connecticut-Havana was pronounced by both packers and manufacturers to be the finest and most useful domestic wrapper leaf they had ever seen. The Sumatra leaf was pronounced to be, however, far superior to the Connecticut-Havana and quite equal in every way to the finest leaf imported from the island of Sumatra." The material required for shading an acre and its cost is given. The results of this work have been previously noted from other sources (E. S. R., 13, p. 133).

The fermentation tests made in Pennsylvania were made in the fall of 1900 with tobacco from the crop of 1898. This tobacco was made soft and pliable by means of warm water and loosely piled into a bulk 6 ft. wide, 12 ft. long, and 6 ft. high in a room kept at a temperature of about 75°. After 3 days when the temperature at the center of the bulk had reached 135° the bulk was repiled putting the tobacco at the surface of the old bulk into the center. This bulk stood for 15 days, when "The tobacco was thoroughly cured, dried out, and ready for packing, without the least sign of black rot." Water applied to a lot of new tobacco caused black rot in the bulk, but when bulked without being moistened, no loss occurred. The present method of packing and fermenting cigar leaf tobacco in the Northern States is briefly described.

The growing of tobacco under shade in Connecticut, E. H. Jenkins (*Connecticut State Sta. Bul. 137, pp. 20*).—This bulletin briefly reviews the experiments on the fertilization, curing, and fermentation of wrapper-leaf tobacco, conducted by the station during the past 9 years, and reports in detail the work of growing an acre of Sumatra tobacco under shade in 1901. The Sumatra seed required a higher heat for germination and a higher temperature in the seed beds than the domestic leaf seed. The extra cost incident to shading the crop and harvesting the leaf by picking, charging the first crop with 20 per cent of the cost of the frame and 40 per cent of the cost of lath for hanging the tobacco, was $326.68 per acre. The initial outlay for this experiment was $582.63 per acre. The entire yield of leaf about 2 months after curing weighed 1,171 lbs. In a comparative test of shade-grown wrapper leaf 2.9 lbs. of Havana seed leaf and a very small fraction over 3 lbs. of the Broadleaf were required to wrap 1,000 cigars. At least 9 lbs. of Broadleaf were required for this same purpose when the plants were grown without shade. The shaded Broadleaf was not as elastic as that grown in the open. Sumatra grown without shade did not give encouraging results. It was noticed this season that topping the plants when in full flower a few weeks before harvest, improved the crop and made it ripen more evenly on the stalk. As compared with the product of the year before the leaf was much more elastic, still, according to the author, a higher degree of elasticity would have been preferable. The color of the leaf was rather dull. It was found that 1¼ lbs. of leaf would wrap 1,000 cigars. Leaf cured on the stalk was lighter in color, but more papery and less elastic than leaf picked or primed before curing. The prices at which a portion of the crop was sold ranged from $1.40 to $2.50 per pound, the average being $1.91.

Report of the wheat experimentalist, W. Farrer and R. W. Peacock (*Agr.*

Gaz. New South Wales, 12 (1901), No. 8, pp. 936–944).—This report discusses the progress of the experimental work with wheat at the different experimental farms in New South Wales during 1900.

The selection of wheat, C. Lemée (*Bol. Ofic. Agr. Ganadera, 1 (1901), Oct., pp. 293–299*).—This article discusses the improvement of wheat by selection, and gives the results of a comparison of light and heavy grains for seed.

Culture experiments with varieties of spring and winter wheat (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 40, pp. 227–229*).—Nine varieties of spring wheat and 8 varieties of winter wheat are briefly described.

The quality of wheat grown in Upper Bavaria in 1899, R. Ulrich (*Vrtljschr. Bayer. Landw. Rath., 6 (1901), No. 2, pp. 321–328*).—Tables are given showing the conditions under which the samples were grown, the weight of the grain, and its germinative power. Deductions from these results are briefly given.

Yields of the best varieties of wheat cultivated in Northern France, R. Lavallée (*Semaine Agr., 21 (1901), Nos. 1061, p. 294; 1062, pp. 302, 303*).—Fifteen varieties of wheat are briefly described and the yields for 1900 and 1901 are given.

The improvement of Egyptian wheats, G. P. Foaden (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 4, pp. 162–169*).—This article discusses wheat improvement in general.

The Algerian durum wheats, C. S. Scofield (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 7, pp. 48, pls. 18*).—This bulletin contains a classified list of 31 varieties of Algerian durum wheats and descriptions of the same with key. The object of a descriptive classification of wheat varieties is discussed and the general character of durum wheats with special reference to the soil and climate best suited to their culture is briefly described. The classification and descriptions of the varieties are based on differences in the head and grain. The structure of the head, the characters of the grain, and the relative value of the different characters are briefly noted. In addition to the description a figure of a representative head of each variety is given.

How can Germany dispense with foreign wheats richer in gluten than those of her own production? P. Holdefleiss (*Fühling's Landw. Ztg., 50 (1901), No. 18, pp. 630–634*).—A discussion of the question.

Agriculture and plant breeding in Denmark in 1900, T. C. Westh (*Enkelte træk af landbrugets jorddyrkning og plantekultur i Danmark red aar 1900. Aarhus: L. Bech, 1900, pp. 87*).—This publication consists of a series of articles and reports by different writers and investigators. Types of Danish soils, meadows, and moorlands, and the cost of producing agricultural products in Denmark are discussed, and the results of plant breeding with sugar beets and wheat and of fertilizer experiments are reported.

HORTICULTURE.

Asparagus—its culture for home use and for market, F. M. Hexamer (*New York: Orange Judd Co., 1901, pp. 168, figs. 48*).—This purports to be "a practical treatise on the planting, cultivation, harvesting, marketing, and preserving of asparagus, with notes on its history and botany." Directions for both the field culture and forcing of asparagus are given, methods of canning and drying noted, and the insects and diseases affecting the plants described, suggestions being given regarding their control. The work of the experiment stations has been drawn on to a considerable extent in the preparation of the book, and methods of growers in different sections of the country outlined. The work does not pretend to be original, but summarizes in a popular way the methods of the best asparagus growers at the present time.

A list of American varieties of peppers, W. W. Tracy, Jr. (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 6, pp. 19*).—A list of peppers, including all the varieties catalogued by seedsmen in the United States and Canada for the year 1901, is given, together with synonyms of the different varieties and the seed firms who have offered them to the trade.

The new rhubarb culture, J. E. MORSE and G. B. FISKE (*New York: Orange Judd Co., 1901, pp. 130, figs. 37*).—This work gives in a clear and concise manner specific directions for the winter forcing of rhubarb in cellars, pits, hotbeds, cold frames, and greenhouses. The field culture of rhubarb is also dealt with at length, the methods of many practical rhubarb growers being quoted and summarized, and the work of the experiment stations with varieties and methods of growing rhubarb reviewed. A chapter is devoted to methods of cooking rhubarb and preserving for winter use.

The book of the greenhouse, J. C. TALLACK (*London and New York: John Lane, 1901, pp. 103, figs. 16*).—This is the second of the series of handbooks of practical gardening edited by H. Roberts. It contains short practical chapters on the structure of greenhouses, the culture of hard-wooded plants in the greenhouse, climbers and basket plants, bulbs, plants from seeds, foliage, and miscellaneous greenhouse plants, with a chapter on a small town greenhouse.

The fuel question in greenhouse heating, L. R. TAFT (*Amer. Gard., 22 (1901), Nos. 347, pp. 569, 570; 349, pp. 602, 603; 350, p. 622*).—In this article a discussion is given of the theoretical value of different fuels, the efficiency of different types of boilers, and the coal required for greenhouse ranges of different sizes, etc.

A study of certain conditions affecting the setting of fruits, E. S. GOFF (*Wisconsin Sta. Rpt. 1901, pp. 289–303, figs. 20*).—The work here reported with fruit is mainly from the standpoint of the pollen grain. With the Prunus apple, George Glass cherry, and seedling native plum, the anthers failed to burst in a saturated atmosphere under a bell jar after 56 hours, while in dry air the anthers on duplicate twigs had practically all burst. The experiment indicates that during periods of protracted rain, or so long as the trees are wet with rain or dew, or enveloped in fog, practically no anthers burst, and therefore no pollen is wasted. Even in damp, cloudy weather it is not likely that much pollen will be destroyed. Other experiments with blossoms placed in a refrigerator and kept in the laboratory indicate that pollen is discharged freely only in warm and dry weather.

In order to learn the influence of the weather upon the germination of pollen grains, a number of germination experiments in 3 per cent milk sugar solutions were made. Temperature was the first factor investigated, the germinative power of plum, cherry, apple, pear, raspberry, and strawberry pollen, as affected by temperature varying from 39 to 70° F. being noted. Drawings showing the germination of the pollen grains on microscopic slides are given for each of the different fruits. The Moldavka plum germinated as well apparently at 51° F. as at 65 to 70° F. Wood plum, however, germinated more freely at 65 to 70° F. than at any lower temperature. Dyehouse cherry germinated at 40° F. rather more freely than plums did. Pear pollen failed to germinate at 40° and showed only a feeble germination at 51° F. Prunus apple pollen germinated very slightly at this temperature. Strawberry pollen germinated rather freely at 51° F. but failed to germinate at 40° F. Pollen of King Amarelle cherry and Lombard and Wood plums, exposed to a temperature of 51° F. for 6 days in a saturated atmosphere under a bell jar, germinated rather freely in sugar solutions, while pollen exposed to the temperature of the laboratory for the same period failed to germinate. These facts indicate that the vitality of pollen is not likely to be injured by exposure to a prolonged rainy period if the weather remains cool. If it rises to 65 or 70° F. the vitality of the pollen may be destroyed.

Experiments to determine the effects on pollen of exposure to frosts were not satisfactory. The pollen of plum and cherry germinated slightly after exposure to 28° F. and the pollen of Wallace raspberry freely after exposure to 23° F.

The influence of the vigor of growth of the terminal buds of the cherry as related to the setting of fruit was studied, and some figures are given which show the whole number of the flowers that were produced on spurs which made a terminal growth of 1 in. or less and on spurs which made a terminal growth of more than 1 in. The percentage of flowers that failed to set fruit in each case is also noted. The figures indicate that a vigorous terminal shoot is not detrimental to the setting of fruit. A study of the causes for the failure of the pistil in native American plums tends to the conclusion that this is due to cold after the buds have become excited by warm weather.

The experimental apple orchard, A. DICKENS and G. O. GREENE (*Kansas Sta. Bul. 106, pp. 29–56, pls. 7*).—An account is given of the growth of the station apple orchard planted in 1891 with whole root and piece root grafts and budded trees. The varieties which have been found most desirable are noted and briefly described. An earlier account has been given of the growth of the trees grafted upon whole roots and ordinary piece roots (E. S. R., 9, p. 750). The average height of the trees propagated by the different methods, maximum diameter, and average diameter 18 in. above the ground are shown in the following table:

Growth of apple trees on whole roots, piece roots, and budded apple stock.

Kind of stock.	Number of trees.	Average height.	Maximum diameter 18 in. from ground.	Average diameter 18 in. from ground.
		Feet.	*Inches.*	*Inches.*
Whole root	64	$11\frac{1}{3}$	$7\frac{1}{2}$	4.9
Piece root	102	$12\frac{1}{6}$	9	4.6
Budded	30	$12\frac{1}{4}$	$7\frac{1}{2}$	4.8

These trees were all 1 year old when set in 1891 and have been cared for in exactly the same manner. "The conclusion is inevitable that the manner of propagation seems to count for little after growth commences." As great variation has occurred between trees of the same variety propagated in the same way as between those propagated in different ways. In working the station orchard clean cultivation has been practiced. This has been greatly facilitated by the use of reversible cutaway harrows having extension heads. As cover crops cowpeas and oats have been satisfactorily used. Rye and wheat also made heavy growths, but were somewhat difficult to kill by cultivation in the spring, and are therefore considered of less value than either oats or cowpeas. At the end of a protracted drought the college orchard, which had been cultivated throughout the season, contained 16 per cent of moisture in the upper 15 in. of soil, while with most cultivated field crops there was but 8 to 11 per cent of moisture, and in grass land the amount in the upper 15 in. of soil was but 6 per cent.

The station orchard was planted primarily to test the value of different varieties. The varieties generally regarded in Kansas as standards have succeeded best at the station. Of these the best early varieties are as follows: Early Harvest, Benoni, Late Strawberry, Cooper, and Maiden Blush; fall varieties, Fameuse, Grimes Golden, and Jonathan; winter varieties, Winesap, Missouri Pippin, Gano, and Ben Davis. Fifty-nine varieties of apples grown in the station orchard are described in brief paragraphs.

A study of the growth of apple trees, C. A. KEFFER (*Tennessee Sta. Bul., Vol. XIV, No. 4, pp. 16, figs. 15*).—A study is here reported of the growth of Jonathan and York Imperial apple trees. The purpose of the study was to secure a better understanding of the training of apple trees. The trees were planted in April, 1900, and data as to the buds that grew, growth of terminal branches, effect of pinching certain shoots, etc., are recorded for 1901.

Seventy-five per cent of the shoots on 16 trees made their principal growth in length before July 1. Growth continued thereafter, however, quite generally, and in some shoots as late as the following December, though no increase in length of the shoots took place after November 1. In these observations the terminal shoots or outermost branches made their principal growth in length early in the season, while the shoots lower down the branches and closer to the trunk grew through a longer period. In the case of 2 York Imperial trees, one of which was cut back in the winter from ½ to ⅔ of the new wood and the other left unpruned, 50 per cent of all the shoots on the unpruned tree completed their growth in length by August 30, while on the winter-pruned tree all the shoots continued to grow freely after that date, most of them increasing 10 in. or more. Summer pruning (July 8) in the case of the single Jonathan tree under observation gave somewhat conflicting results as to the growth of the outer and inner branches. As a general law it is stated "that the apple shoot makes its principal growth in length before July 1, and that the outermost shoots finish their growth in length sooner than the lower shoots."

An examination of the growth of buds on the various trees showed that 59 per cent of all the buds found on Jonathan in 1900 above the lowest limb had started into growth by June 30, 1901, and 15 per cent had made shoots ¾ in. long or more. With York Imperial 60 per cent had started into growth and 28 per cent made shoots. It was observed that pinching and other checks to growth also had a considerable influence on the growth of the remaining buds.

Some illustrations, with critical notes, are given of the methods of pruning young apple trees.

Orchard notes, C. F. Austin (*Alabama College Sta. Bul. 117, pp. 292–320*).—Herewith is included a list of the apple trees in the station orchard affected with rust and those free from this disease, the varieties on which the green aphis is troublesome, and miscellaneous notes on the growth of the young trees. Notes are also given on the growth of cherries at the station, Japan walnuts, peaches, and plums, with notes on varieties and the blooming period in some instances.

Orchard cover crops, J. Craig (*New York Cornell Sta. Bul. 198, pp. 97–133, figs. 23*).—In this bulletin the purpose and value of orchard cover crops are discussed. Some data are given on the influence of these crops on the physical qualities of the soil and its fertility. A number of plants used as cover crops, alone and in mixtures, are briefly described, methods of using being noted, and some reports of orchardists conducting cooperative experiments are also included in the bulletin.

Some data obtained from the Iowa Station show that bare cultivated ground contained 31.43 per cent of moisture at a depth of 6 in. in winter; ground covered with a crop of hairy vetch contained 31.87 per cent of moisture at the same depth; soy beans, 28.67 per cent; crimson clover, 21.48 per cent; and with blue grass sod, 21.75 per cent. The bare cultivated ground froze to a depth of 21 in., while under bluegrass sod it froze but 12 in. deep, under hairy vetch 16 in., under crimson clover 15 in., and under soy beans 21 in. deep, the latter crop affording no protection to the soil whatever. At the Cornell Station an examination of the soil at the close of an extended drought showed the following percentages of moisture in the first 6 in. of soil: Bare ground, 6.48 per cent; ground covered with a crop of hairy vetch, 12.15 per cent; ground covered with a crop of cowpeas, 9.30 per cent.

Mention is made of the influence of earthworms in burrowing in the soil, and some illustrations are given showing how roots of cover crops follow these worm holes down deep into the soil.

Some figures have been taken from the Canada Experimental Farms Report (E. S. R., 9, p. 825) which show the amount of nitrogen returned to the soil by 3-month-old leguminous crops to be as follows: Alfalfa (stems, leaves, and roots), 136 lbs.; mammoth red clover, 130 lbs.; crimson clover, 104 lbs.; common red clover, 87 lbs. At the Cornell Station the amount of nitrogen yielded by a crop of vetch, including vines, leaves, and roots, was 256.1 lbs. and with cowpeas 52.6 lbs. These figures show the great fertilizing value of these crops in the orchard in addition to their use as cover crops.

Of the nitrogen-consuming cover crops sometimes used in orchards, rye and buckwheat are considered of most importance. Oats are also spoken of favorably in some parts of the country, but have not been satisfacfory when used in connection with crimson clover at the Michigan Station. A mixture of alfalfa, mammoth clover, and turnips, in the proportion of 6 lbs. mammoth clover seed, 10 lbs. alfalfa seed, and 2½ oz. of turnip seed per acre, is reported as having given satisfaction as an orchard cover crop. In the cooperative experiments the necessity of preparing the soil with great thoroughness before seeding was demonstrated, as well as the fact that good surface tillage conserves moisture and does much to insure a satisfactory catch of seed. Rolling clover seeded ground has proved an excellent aid to germination.

Citrus fruit culture, J. W. Mills (*California Sta. Bul. 138, pp. 1–38, 42–46, pls. 21*).—In this bulletin 12 of the leading varieties of California oranges are described, and a discussion is given of the relative merits of sweet orange, sour orange, and pomelo stocks for oranges, together with general directions for planting out orchards, cultivating, irrigating, top-working over old orchards, pruning, diseases, etc. The scales of points used in judging oranges and lemons are also given.

The Washington Navel, with its subvarieties, constitute the principal oranges of commerce now grown in California. An examination of the root systems of different stocks resulted in showing that the sweet orange produces a shallow root system with an abundance of fibrous surface-feeding rootlets, thus making trees budded on sweet orange stock especially susceptible to drought. Sour orange stock roots, on the other hand, were found penetrating the soil to a depth of 9 ft., and the laterals were generally more sharply descending. Trees on sour stock do not appear to come into full bearing quite as early as on sweet orange or pomelo stock, but in localities where sweet orange stock fails it is thought sour stock will prove especially valuable. In an introductory note by C. H. Shinn it is stated that sour stock is more resistant to alkali than sweet stock, and that the dwarf deciduous orange of Japan (*Citrus trifoliata*) is more resistant to alkali than either. The roots of pomelo stock have been found at a little greater depth than those of sweet orange. It is more fibrous rooted than either stock and is resistant to a certain extent to the root form of gum disease. It has succeeded better at the station than sour stock, and, according to the author, is becoming the favorite stock in southern California.

The Japanese long-fruited "Cumquat," or gooseberry orange, and dwarf Oonshiu have done especially well at the Sierra Foothill Substation on *trifoliata* stock, and are recommended for gardens having an elevation of 2,000 ft.

The Reed system of transplanting is described and illustrated. It consists in thoroughly watering the trees in the nursery before removing and then lifting them with a large ball of earth attached. The most vigorous trees are used and only the longer branches cut back. The trees are set in holes 2 ft. deep and about 2½ ft. wide. Dirt is then filled in around the roots and settled with water, so that the tree stands at the same height as in the nursery. The ground should be soaked for several feet around the newly set tree, after which thorough cultivation should follow. About ¾ lb. of bat guano applied after planting to each tree has been found beneficial. It is mixed with earth and applied in the bottom of trenches on each side of the ball of earth, at right angles to the irrigation furrows and reaching to them. Trees thus transplanted are said to come into bearing one year sooner than by the usual methods.

In working over old trees the use of "cured" buds is especially recommended. "These are buds that have been cut from the tree and kept in damp sand or moss for a few weeks before using. When treated in this way they become tougher, and when inserted into a tree that has freely flowing sap they absorb it more readily. When buds are well cured, and not allowed to become either too wet or too dry, they are not easily injured in handling." The buds should be wrapped with waxed bands, which are allowed to remain from 4 to 6 weeks. By this time the buds will have united with the stock, and the whole top of the tree should be removed and the trunk whitewashed. Spring is considered the best time for budding. In frosty sections it may be necessary to protect the tops during the first winter. Palm leaves nailed to the trunks of the trees and tied about the tops have been successfully used for this purpose.

To prevent the formation of hardpan in orchards, the depth of cultivation should be varied each year. Cultivation 8 in., 12 in., 10 in., 14 in., and then 8 in. again, is recommended. The use of the subsoil plow to assist in breaking up hardpan is also advised. Irrigation water should be allowed to run slowly for a long time in deep, narrow furrows, keeping the greater part of the surface dry, and immediately following the irrigation with thorough cultivation. The spread of water from deep furrows is much greater in sandy loam soil than in clay loam.

Mangoes in India, W. T. Fee (*U. S. Consular Rpts., 67 (1901), No. 253, pp. 197–199*).—Brief notes on the botany and quality of these fruits in India.

Report of the horticultural department, C. A. Keffer (*Tennessee Sta. Rpt. 1901, pp. 7–9*).—A brief outline is given of the work of the year with small fruits. Among 60 varieties of strawberries grown, the best yielding varieties were Pride of Cumberland, Clyde, Tennessee Prolific, Stone 130, Sample, Gibson, W. J. Bryan, Glen Mary, and Greeneville. Excelsior and Michel were the earliest berries. These varieties are perfect flowered and good pollenizers. Berries first in quality were Bennett, Parson Beauty, Brownie, Downing Bride, etc. Of the best late varieties Gandy, Hunn, Michigan, Sampson, McKinley, and Downing Bride are mentioned first. Columbia was one of the best raspberries tested and was considerably superior in yield and size of fruit to Shaffer Colossal. Gregg was the best yielder among the black caps, and Cuthbert among the reds. Snyder was the best yielder out of 10 varieties of blackberries grown, and Houghton the best of 6 kinds of gooseberries tested.

Third report on experiment in pinching raspberry shoots, F. Cranefield (*Wisconsin Sta. Rpt. 1901, pp. 317–320*).—The earlier reports along this line have been previously noted (E. S. R., 13, p. 51). The details for the third year's work have been added to those of preceding years and the whole summarized. The conclusions accord entirely with those of last year in showing that pinching 18 to 20 in. high increased the yield of the Gregg raspberry, but decreased the yield of Cuthbert. Pinching 12 in. high gave decreased yields with both varieties. With the Gregg variety pinching increased the production of shoots and suckers, but decreased it with the Cuthbert variety.

An ever-bearing strawberry for culture under orchard trees and grapes, F. F. Ichon (*Deut. Landw. Presse, 28 (1901), No. 81, p. 683*).—The strawberry described is said to have originated in Greece and is known there as the "ever-bearing Grecian vineyard strawberry." It grows best in the partial shade of fruit trees and vines, and produces fruit from the beginning of May until the end of November. During this time the vines are covered with flowers and green and ripe fruit. The yearly product of one plant is said to be over 10 liters of fruit, which retails for about 20 cts. per liter. The berries are red, about the size of a grape, and are stated to surpass in quality the common cultivated and wild strawberries. The botanical name of this strawberry is not given. The variety does not seem to be particular as regards soil, and is quite resistant against either drought or long continued wet weather. When well fertilized the mother plant makes a growth of 60 cm. in diameter and 40 cm. high. In cultivation the plants are set 50 cm. apart in rows 1 meter distant. The runners should be kept cut off in summer but may be allowed to grow in the autumn. After 3 or 4 years, when the mother plant has begun to fail in fruit production, the plants are renewed by allowing the runners to take root and then hoeing away the mother plants. In starting a new plantation the plants should be set out only in cloudy and damp weather, since the rootlets are very fine and easily destroyed by the direct rays of the sun or drying winds. The fruit is said to be well suited for canning, drying, preserving, dessert, wine making, etc.

The book of the grape, H. W. WARD (*London and New York: John Lane, 1901, pp. 97, figs. 20*).—This is the third of the series of Handbooks of Practical Gardening, edited by H. Roberts, and is devoted to the practical details of growing grapes in houses in England. The final chapter treats of the diseases of the grape. The decorative value of the vine is briefly discussed in the introductory chapter by the editor.

The tendrils of grapes, E. DURAND (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 36, pp. 283–295*).—The author shows that grape clusters and tendrils are identical in their origin and anatomical structure, and may pass from one to the other naturally. In the wild state grapes need tendrils to lift the vines up into the light, but under cultivation the production of tendrils is a loss of energy, and it is a frequent custom among French grape growers to remove the larger tendrils of the branches early in the season, lest they make the grape clusters near them "run to tendrils." For the purpose of following the evolution of tendrils into grape clusters and to note clearly the effect of pinching on this transformation, the author made a series of experiments with several varieties of grapes. The results secured with the Chasselas variety are reported in detail. In one lot that portion of the tendrils which bears a little leaf at its base was removed; in a second lot, this same ramification was removed and, in addition, the extreme point of the other branch of the tendril was pinched, removing 1 to 2 mm. or more of the tip; finally, in the third lot, the tendrils were allowed to grow freely. The different operations were performed soon enough in the season to permit the formation of grape clusters. The branches under observation were differently treated. In the first case they were allowed to bear no grape clusters; in the second, 1 cluster; in the third, 2 clusters; and in the fourth, 3 clusters. The essential data obtained in this experiment are shown in the following table:

Conversion of grape tendrils into fruit clusters.

	Total number of tendrils operated upon.	Number of tendrils bearing flowers.	Total number of flower buds obtained.
Lot 1: Branch of tendril removed at node	298	58	500
Lot 2: Branch of tendril removed at node and other branch pinched	294	25	223
Lot 3: Tendrils allowed to develop freely	292	11	230

The table shows that in the absence of all pinching, the tendrils are capable of naturally producing flower buds. Pinching, however, seems to increase the number of flower buds. The greatest number in the present experiment was obtained when that portion of the tendril which bears a small leaf at its base (lot 1) was removed simply. Stated in percentages, the different methods of operating on the tendrils produced flower clusters as follows: Lot 1, 19.4 per cent; lot 2, 8.5 per cent; and lot 3, 3.7 per cent. As shown in the table, lot 1 produced 500 flower buds and lot 3, where the tendrils were allowed to grow freely, 230 buds; therefore, the number of flower buds produced by pinching in this test did not exceed 270.

The author states that on account of insects, diseases, etc., not more than half of these buds set will produce fruit. It is estimated that at harvest time this will reduce the yield so that only from 25 to 30 gm. of grapes additional will be secured per vine. This return is considered too small to pay for the trouble of the operation.

In some varieties under observation a large number of flower clusters were borne naturally on the tendrils. Thus for example with the variety Yapindjack from the Orient, 15 bunches of grapes and 26 fertile tendrils were borne on 8 shoots naturally, against only 16 tendrils which were not fertile. It is thought that with this variety pinching the tendril, as above noted, would produce a very large increase in fruitfulness.

With some other varieties the removal of the ramification of the tendril and the pinching of the point of the principal branch was practiced. The variety *Insolia bianca* had 8 tendrils out of 28 operated upon made fertile. These bore 104 floral buds or enough to make the operation advantageous. With the variety Jurançon 50 per cent of the tendrils pinched were made fertile. On one vine 17 pinched tendrils produced 8 flower clusters bearing 181 buds. Gros Riesling produced 3 flower clusters and 48 flower buds from 12 pinched tendrils. Petit Riesling gave 3 fertile tendrils carrying 21 flower buds out of the 15 operated upon.

Pinching the tendrils of the following varieties was without any effect whatever on the production of flower clusters:

Madeleine Juliette, Mélascone nera, Malvoisie de Liparî, Chardonnay, Fariné ou Gauche, Furmint, Marsanne, Bon noir de Montluçon, Noir Fleurien, Mauzac vert, Mauzac rose, Morillon rose, Morillon hâtif, Aubin blanc, Peloursin, Dureza, Corbel, etc.

Manures and the quality of wines, L. Degrully (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 42, pp. 449–452*).—Analyses of several classes of wines are given, with especial reference to the quantities of phosphoric acid and potash contained in them. There seems to be a close relationship existing between quality and phosphoric acid content, the best wines having the highest amount of phosphoric acid and the poorest wines the least.

Pruning trees and shrubs, T. Wirth (*Gardening, 9 (1901), No. 210, pp. 281–283*).—A criticism of usual methods and statement of general principles to be observed.

Storing fruit (*Deut. Landw. Presse, 28 (1901), No. 77, p. 650*).—A number of varieties of apples and pears were wrapped partly in tissue paper and partly in newspaper, and put in layers in a tightly closing box surrounded by peat dust. The layers of apples were also separated from each other by dry peat dust. The apples as thus prepared were put in storage in a cellar about November 1. The box was opened the middle of May following. Eleven out of the 14 varieties of apples thus put in storage averaged over 80 per cent perfect as regards rot. The 2 varieties of pears stored were wholly spoiled. A number of other varieties of both apples and pears, which had been layered in peat dust at the same time, kept well up into July. Not all the data are given in regard to the latter experiment. The experiment as a whole is believed to show that the more carefully the fruit is harvested and the less it is disturbed and shipped the better it will keep. The method of fruit storage here outlined is considered very satisfactory, especially for late-ripening winter apples.

A new method of preserving fruit (*Queensland Agr. Jour., 8 (1901), No. 6, p. 447*).—An apparatus, said to be patented in London for the preservation of fruit by means of sterilized air, is noted, and a report quoted of successfully storing English hothouse grapes and tomatoes for 3 weeks without decomposition or loss of flavor.

The preservation of fruits and vegetables, together with the preparation of marmalades, fruit tablets, jellies, and fruit wines, N. Noble (*Orgaan Ver. Oudleer. Rijks Landbouwschool, 13 (1901), No. 153, pp. 62–74, figs. 22*).—This is a comprehensive paper concerning the methods of drying and canning fruit, with figures and detailed descriptions of the apparatus used, including parers, corers, dryers for both home and commercial use, and special apparatus for cooking and for canning.

Fruit tablets are made by boiling down the pulp mixed with sugar until the desired consistency is reached. The residue is then poured into pans and spread about 1½ cm. thick, after which it is dried slowly, 10 hours being about the time usually required. When finished the mass is cut into circular tablets, which will keep 10 years. When the tablets are to be used they should be soaked in warm water from 1 to 1½ hours before cooking.

Cider making is described at length. Various presses are illustrated and described, and detailed instructions given for the treatment of the product at every stage.—H. M. PIETERS.

Fruit gardening, containing complete practical directions for the selection, propagation, and cultivation of all kinds of fruit, T. BRIDGEMAN (*Philadelphia: Henry T. Coates & Co., rev. ed., pp. 211, figs. 36*).—While this purports to be a revised edition of this work, which first appeared more than a half century ago, it still savors more of European gardening than of present American methods. For example, twice as much space is given to descriptions of European varieties of grapes as of American sorts. The revised list of grapes for this country fails to mention such widely cultivated varieties as Concord, Niagara, and Delaware. Other fruits have been revised in a like manner.

A review of the fruit-growing industry in Cape Colony, C. MAYER (*Agr. Jour. Cape Good Hope, 19 (1901), No. 5, pp. 317–325*).—The number of fruit trees of all sorts in the colony in 1898 was 3,773,507, and the value of the fruit exported in 1901 about $24,000.

The development and needs of the export [fruit] trade in North America, C. FOSTER (*Amer. Gard., 22 (1901), No. 356, pp. 714, 715*).—Paper read before the American Pomological Society at its meeting in Buffalo, September 13, 1901.

The freezing point of vegetable saps and juices, W. F. SUTHERST (*Chem. News, 84 (1901), No. 2190, p. 234*).—Various fruits and vegetables were reduced to a fine pulp by means of a grater, and then filtered through muslin and thick filter paper. The juices thus obtained were placed in narrow test tubes containing a thermometer, and cooled down by a freezing mixture of Glauber salts and concentrated hydrochloric acid. The results secured are shown in the following table:

Freezing point of vegetable saps and juices.

Vegetables and fruits.	Freezing point.	Vegetables and fruits.	Freezing point.
	°C.		°C.
1. Vegetable marrow—(a) Leaf and stalk	−0.75	4. Carrot—(a) Leaf and stalk	−1.2
(b) Fruit	−0.75	(b) Root	−1.0
2. Swede turnip—(a) Leaf and stalk	−1	5. Cabbage—(a) Outside leaf	−1.1
(b) Bulb	−1	(b) Heart	−0.85
3. Celery—(a) Green stalk and leaf	−1.4	6. Apple	−1.4
(b) White portion	−0.75	7. Pear	−1.75

"It will be seen from the above figures that—(1) Those vegetables easily attacked by frost, *e. g.*, vegetable marrow, have the higher freezing points; (2) the sap in the parts exposed to the air has the same freezing point, *e. g.*, fruit and stalk of the turnip and marrow; while (3) those plants which have a portion in the ground, *e. g.*, celery and carrot, or protected, *e. g.*, cabbage heart, the sap in these portions freezes sooner than the exposed. It is very possible that these differences can be accounted for by the fact that the hardy exposed parts contain a more concentrated sap, since more evaporation goes on there; also, pear juice, containing more dissolved uncrystallized matter, freezes lower than apple juice."

Report of the chemical division of the experiment station of the Royal Pomological Institute at Proskau for the year 1900-1901, R. OTTO (*Bot. Centbl., 86 (1901), No. 10, pp. 331–345*).—An outline is given of some of the chemical work of the station in the analysis of wines, ciders, and various fruits and flowers which have been grown in fertilizer experiments. The report of the composition of 1-year wood of orchard fruits grown on the north, south, east, and west sides of apple trees has been noted from another publication (E. S. R., 13, p. 137). Kohl-rabi was successfully grown in pure quartz sand fertilized with chemical manures, and the effect of increasing the amount of phosphoric acid and potash studied, but without satisfactory results. Myrtle, heliotrope, and fuchsias watered with liquid manure made up of a mixture containing 13 per cent phosphoric acid, 13 nitrogen, and 11 per cent potash, and diluted with water in the proportion of 1:1,000, have given very good results. Analyses of the parts of the plants above ground show considerable increase in the percentage of ash content of the plants receiving the fertilizer. Other experiments in fertilizing tobacco, tomatoes, coleus, and begonias with the commercial fertilizer known as "Martellin" are reported, but without striking results. In an examination of apples which had been stored in a cellar for 3 months, it was found that in 6 out of 8 cases there was a considerable decrease in the specific gravity, acid, sugar, and extract content. In the other 2 cases there was an increase in specific gravity, acid, sugar, and extract content. The changes which took place in the composition of different blueberry wines after 3½ years' storage in a cellar are tabulated.

Caoutchouc plants and their culture, O. WARBURG, trans. by J. VILBOUCHEVITCH (*Les plantes à caoutchouc et leur culture. Paris: A. Challamel, 1902, pp. XVI + 307, figs. 26*).—Attention was called to this work when it appeared first in the original German (E. S. R., 12, p. 955). In the present translation into French the text of the German has been closely followed. The translator has included such new facts regarding the value of different species of caoutchouc-producing trees and the methods of handling them as have come to light since the original publication appeared in 1900. The statistics of caoutchouc production and consumption have also been brought up to date. Many other supplementary notes have been added, besides a valuable index. These new features have increased the size of the work to nearly double that of the original volume, and have added greatly to its usefulness.

Vanilla, its culture, and some notes on apiculture as an economic auxiliary agent in its fertilization, E. D. DURÁN (*La vanilla, su cultivo, el beneficio y algunos apuntes sobre apicultura como un agente auxiliar económico para la fecundación. Guatemala: Ministerio de Fomento, 1899, pp. 36*).—A popular treatise.

Experiments in subirrigation of flower beds, F. CRANEFIELD (*Wisconsin Sta. Rpt. 1901, pp. 321–326, figs. 4*).—A comparison was made as to the cost and value of surface and subwatering flower beds. The beds were each 5½ by 8 ft. In the surface watered bed the ground was prepared by simply spading it 1 ft. deep. One subwatered bed was first excavated to a depth of 17 in. The sides were bricked 12 in. high and the bottom covered with a 2-inch layer of cement. Gravel 2 in. deep was then spread on the bottom and a little freshly cut grass spread over it to prevent the soil from working into the gravel. A vertical tile reaching into the gravel was then set up at one end of the bed to serve as an inlet for water. In the case of the other subwatered bed, the ground was excavated to a depth of 15 in., the bottom and sides puddled with clay, and a layer of glazed sewer pipe placed midway in the bed, with lines of common drain tile branching off on either side. After these beds were refilled with earth, all were planted to castor beans, Caladium, cosmos, Pennisetum, coleus, and canna plants. The growth of these plants was most luxuriant in the subirrigated beds and the plants in the cement bottom bed made a stronger growth, were more vigorous, and blossomed more freely than in the tile watered bed. The following table shows the differences in average height of plants in the different beds:

Height growth of plants in surface and subwatered beds.

	Castor beans.	Cosmos.	Coleus.	Pennisetum.
	Feet.	*Feet.*	*Feet.*	*Feet.*
Surface watered	4.8	4.7	1.7	3.7
Subwatered (cement)	8.0	5.0	3.2	4.7
Subwatered (tile)	7.0	4.7	2.5	4.5

The increased cost of construction of the cement bottom bed over the spaded bed was $5.12, and of the tile laid bed $3.42. The cement bottom bed cost the more, but was more satisfactory from the standpoint of a luxuriant growth than the bed in which tile were used.

A southern New Mexico flower garden, F. E. Lester (*New Mexico Sta. Bul. 40, pp. 27, figs. 11*).—This is a popular bulletin on flower growing in southern New Mexico. The chief difficulty in flower growing in that section is the summer heat, combined with the extreme dryness of the air and high spring winds. Owing to these peculiar conditions the best results are usually obtained from using the larger seeds, such as sweet peas, castor beans, morning glory, zinnias, hollyhocks, etc. It has been found that with a number of plants fall seeding gives much better results than the usual spring seeding. The author urges the larger use of native plants in home gardens and gives suggestions regarding the growing of trees, hedges and windbreaks, lawns, vines, shrubs and evergreens, roses, and sweet peas. Lists are also given of the annuals most successfully grown at the station, hardy plants and perennials, winter blooming bulbs, flowering shrubs, and evergreens, with suggestions in each instance regarding the planting of these.

The book of bulbs, S. Arnott (*London: John Lane, 1901, pp. 114, pls. 11*).—This is number 5 of the series of handbooks of practical gardening edited by H. Roberts. It gives a popular account of the appearance and culture of hardy bulbs, with an introductory chapter by the editor on the botanical nature of bulbs.

Old-time gardens newly set forth, Alice M. Earle (*New York: The Macmillan Co., 1901, pp. 489, figs. 166*).—Illustrations and descriptions are given of many old-time colonial gardens, with descriptions of the flowers, shrubs, and trees that grew in them, and an account of the uses, folklore, and something of the poetry connected with each. One chapter is devoted to the apple.

Prize gardening; how to derive profit, pleasure, health from the garden, G. B. Fiske (*New York: Orange Judd Co., 1901, pp. 307, figs. 93*).—This is a compiled account from 500 competitive reports on gardening and gives the actual experience of gardeners using parcels of ground varying all the way from 1,000 sq. ft. to many acres in extent in growing vegetables, flowers, etc., the tools and methods of doing the work, financial results obtained, etc.

Horticulture in Japan, T. Eckhardt (*Florists' Exchange, 13 (1901), No. 42, p. 1074, figs. 2*).—Brief popular account of Japanese horticulture, especially as regards lily growing.

Catalogue of library of the National Horticulture Society of France, G. Gibault (*Catalogue de la bibliothèque de la Société Nationale d'Horticulture de France. Paris: Société Nationale d'Horticulture, 1900, pp. 155*).—Alphabetical lists of books and brochures in the society's library on horticultural subjects, with an authors' index; and in addition a list of French and other foreign periodicals devoted to horticulture in its various branches.

FORESTRY.

The immediate future in forest work, G. Pinchot (*Forestry and Irrig., 8 (1902), No. 1, pp. 18–21*).—The author suggests as desirable the unification of the forest work of the Government and the extension of the forest reserve system. Following the creation of forest reserves, there is a necessity for more intimate knowledge concerning the reserves themselves and the character of their forests. The author mentions the interest that is now being taken in forest investigations throughout the country and calls attention to the work now in progress in tree planting.

Suggestions to prospective forest students, G. Pinchot (*U. S. Dept. Agr., Bureau of Forestry Circ. 23, pp. 5*).—This circular gives information relating to the position of student assistants in this Bureau, and the duties of such individuals. The general preparation for forestry work is outlined and attention called to the opening for trained foresters in various localities.

Forest planting and timber supply, F. E. H. W. Krichauff (*Jour. Agr. and Ind. South Australia, 5 (1902), No. 6, pp. 537–542*).—A brief account is given of the development of tree planting in the United States and Germany, after which the production and exportation of lumber and timber in New Zealand and Australia is shown. With the present rate of cutting, the author believes that before long there will be a dearth of timber throughout New Zealand unless means be immediately taken to restore the cut-over lands.

Forest planting and timber supply, F. E. H. W. Krichauff (*Jour. Agr. and Ind. South Australia, 5 (1902), No. 8, pp. 663–668*).—An account is given of the effect of forests on rainfall and temperature, and species of trees suitable for planting in various parts of Australia are described. Among the summary statements given relating to the effect of rainfall and temperature is an account of 5,000 observations which were made in Bavaria as to the influence of forests on temperature and moisture of the air, also the evaporation of water and rainfall. Observations were made twice a day for a period of 5 years of soil at depths of 6 in., 2 ft., 3 ft., and 4 ft., and at the same time the temperature of the atmosphere was taken. The mean annual temperature of the soil of the forest was found to be 21 per cent lower than that of the open field, and the air temperature 10 per cent lower. In this way the equalizing effect in lowering the extreme summer heat and lessening the winter's cold is shown.

Progress in tree planting, W. L. Hall (*Forestry and Irrig., 8 (1902), No. 1, pp. 40–43, figs. 2*).—A review is given of former attempts at tree planting in the United States and a brief description of the present endeavors in this line, not only in the Western, but also in the Eastern and Southern States. With few exceptions, the large plantations now being established are under the immediate direction of the Bureau of Forestry of this Department.

Investments in Southern forests, C. A. Schenck (*Tradesman, 46 (1902), No. 9 (23. annual), pp. 137–139, figs. 4*).—The increase in large holdings of forest areas in the South is noted and is believed to be the beginning of conservative lumbering. Foresting is not believed to be of immediate financial benefit to the small holder on account of the difficulties of marketing the produce, fire protection, time required to produce the crop, etc.

The boundary line between the desert and the forest, S. J. Holsinger (*Forestry and Irrig., 8 (1902), No. 1, pp. 21–27, figs. 5*).—The author considers the forest conditions of Arizona, calling attention to the effect of the destruction of brush lands, and suggests that greater attention be paid to their protection. By protecting the lesser growth it would be possible to secure the development of forests as generally understood.

Notes on some forest trees of Ohio, W. R. Lazenby (*Proc. Columbus Hort. Soc., 16 (1901), pp. 115–118, figs. 2*).—Descriptive notes are given of the American linden or basswood, sycamore, black walnut, and white oak, together with notes on their characteristics as forest trees and the value of their timber and other products.

Forestry in the Philippines (*Queensland Agr. Jour., 10 (1902), No. 2, p. 126*).—A brief review is given of the forest conditions in the Philippine Islands, and the organization of the forestry bureau is commented upon.

English coppices and copse woods, J. Nisbet (*Jour. Bd. Agr. [London], 8 (1901), No. 3, pp. 293–305*).—An historical statement of the beginnings of arboriculture in England.

Forestry in Sweden (*Queensland Agr. Jour., 9 (1901), No. 6, p. 570*).—The public forests of Sweden are said to embrace 18,000,000 acres, of which 12,500,000 are under scientific management. There is in Sweden a central forestry bureau, and a forestry corps for work in the field, comprising 9 inspectors and 88 chiefs of range, besides foresters and watchmen. The State forests are divided into ranges, which average 166,250 acres; and for forest management, administration, and instruction in the State college of forestry and 6 schools of forestry the annual expenditures are $480,000. In 1899 the total income to the Government from the State forests amounted to more than $2,000,000.

Forest tree planting on the estate of Nikolsko-Sergievskoye, N. SUKHODSKI (*Selsk. Khoz. i Lyesov., 200 (1901), Feb., pp. 335–344*).—Experiments in planting oak, ash, maple, birch, elm, linden, pine, larch, locust, and willow in a locality where there are no natural forests. The experiments have been continued since 1893, and extend now over an area of about 150 acres. The results are satisfactory.—P. FIREMAN.

The spruce forests of Canada (*Queensland Agr. Jour., 10 (1902), No. 2, p. 127*).—In quoting from the report of the superintendent of forest ranges of Quebec, it is stated that the world's demand for pulp wood, on the basis of its present supply of 1,500,000 tons annually, can be met by the Canadian spruce forests for 840 years. The extent of the spruce forests in the 4 provinces is given as follows: Ontario, 52,818,420 acres; Quebec, 144,363,454 acres; New Brunswick, 11,224,540 acres; and Nova Scotia, 10,853,544 acres.

Hybrid conifers, M. T. MASTERS (*Jour. Roy. Hort. Soc. [London], 26 (1901), No. 1, pp. 97–110, figs. 9*).—A number of what are believed to be natural hybrids between different species of conifers are mentioned, and a description given of a hybrid produced by the late Henry de Vilmorin, who succeeded in 1867 in producing a hybrid between *Abies pinsapo and A. cephalonica.*

Notes on the supposed hybridization among eucalypts, H. DEANE and J. H. MAIDEN (*Proc. Linn. Soc. New South Wales, 26 (1901), pt. 2, pp. 339–343*).—Hybridization among eucalypts has been a subject of considerable discussion, and attention is called to a supposed case of hybridism between known species. While not denying the existence of the hybridity of the species, the authors hold their opinion in suspense and for the time being describe an interesting new form.

DISEASES OF PLANTS.

Report of the botanical section of the experiment station of the Pomological Institute, Proskau, III, R. ADERHOLD (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 17–18, pp. 654–662*).—Notes are given upon a number of diseases which were more or less under investigation during the period covered by the report. The shot-hole and other leaf-spot diseases of stone fruits were investigated and it was found that 11 genera and 26 species of fungi were the causes of these diseases. Further notes are given upon *Mycosphærella cerasella*, the perethecial form of *Cercospora cerasella*, a preliminary account of which was noted in E. S. R., 12, p. 768. Infection experiments with *Cladosporium cerasi* seemed to point to the identity of a number of so-called species of that genus of parasites. The perethecial form of the species under investigation is said to be *Venturia cerasi*. A Monilia-like disease of cherries was investigated and found to be due to *Fusarium gemmiperda*, n. sp. The fungus was quite conspicuous upon the dead buds of cherry trees in the spring of the year. The occurrence of the brown slime flux upon young apple trees is noted. It appeared in May, 1900, upon a number of 3-year-old trees. The cause of its occurrence is believed to have been a severe frost that occurred late in April of the same year. A study was made of the morphology of the plum rust (*Puccinia pruni*), and it is claimed that 2 distinct types of the fungus were found, differing mainly in the character of their teleutospores. The typical form occurred upon *Prunus spinosa*, *P. domestica*, *P. institia*, and *P. americana;* while the other form, which by some authors is considered a distinct species, occurs normally on *Persica vulgaris*, *Amygdalus communis*, and *Armeniaca vulgaris*, and rarely upon some of the other species of allied plants. Investigations of the chrysanthemum rust (*Puccinia chrysanthemi*) showed that it was a specialized form confined to *Chrysanthemum indicum*. Inoculation experiments were conducted with the rust of cultivated and wild violets from which it was learned that *Puccinia violæ* is autœcious, the different phases in its life cycle being spent upon a single species of host plant. Experiments were conducted in preventing the rust of pinks (*Uromyces caryophyllinus*). Bordeaux mixture seems to be of little value in combating this fungus. Its spores were subjected to several fungicides, such as solutions of copper sulphate and liver of sulphur; copper acetate; sulphuric acid; zinc sulphate and borax; and copper sulphate and borax. The spores failed to grow in very dilute solutions of the first and last two, and it is believed that these fungicides could be successfully employed in combating the disease. The effect of adding sugar to Bordeaux mixture upon bees visiting trees sprayed with the mixture was studied, and it is claimed that bees failed to visit or eat any of the solutions prepared and placed accessible to them.

The effect of winter and summer spraying of apple trees for the prevention of Fusicladium was investigated. Winter sprayings, summer sprayings, and winter and summer treatments of apple trees were compared. But little disease appeared upon any of the trees and but slight difference could be seen as the effect of the treatments until the end of the season. There was little difference even then, except in those trees which had received summer applications only after the leaves had become large and well developed. These were more affected than any others. When summer applications were made while the leaves were young the effect was as good as where both winter and summer sprayings were given the trees. The author reports occasional injury to apple and pear trees when sprayed with copper sulphate solutions as dilute as 0.5 per cent. It is claimed that a 1 per cent Bordeaux mixture can be substituted for stronger ones for summer use. Adding sugar to Bordeaux mixture increased its adhesive property, and experiments showed that soda-Bordeaux mixture was less efficient than ordinary Bordeaux mixture, and that the substitution of iron salts for copper is not advisable.

Report of the government mycologist, J. B. CARRUTHERS (*Trop. Agr.*, *20* (*1900–1901*), *pp. 707–710*).—The first report of the government mycologist of Ceylon, who assumed the duties of his position during the summer of 1900, is given. The report covers investigations made during 6 or 7 months, which were principally devoted to a study of the diseases to which tea is subject. The principal study was made of the fungus causing gray blight (*Pestalozzia guepini*). Investigations have been begun in order that the life history of the fungus may be ascertained, and a series of experiments planned to ascertain the distribution of the blight. The effect of screens interposed between the tea bushes and the prevailing winds is to be investigated, as well as the effect of pruning upon the distribution and extent of the disease. The effect of removing diseased leaves was examined into and found to greatly diminish the occurrence and spread of the fungus. Where the spotted leaves were picked from the bushes soon after pruning the percentage of diseased leaves was greatly reduced, and this treatment, it is believed, will prove the most economical and effectual method for combating the disease. The leaf fungus (*Cladosporium herbarum*) was observed on leaves, but without producing a great amount of injury. The parasitic lichen *Cephaleurus mycoidea* was found occurring on the leaves of tea in a number of districts. It produces characteristic reddish or white and gray spots upon the leaf, but does little harm and spreads very slowly. A root disease of the tea, caused by the fungus *Rosellinia radiciperda*, was investigated and was found to occur most frequently in clearings where the stumps of the forest trees remained. The fungus occurring upon these stumps spread by its mycelium and spores to the tea plants, causing considerable damage. The means suggested for combating this disease is the removal of all stumps and application of lime about the place where they were formerly grown.

The author reports the occurrence of *Hemileia vastatrix* upon coffee, and reports inquiries relative to the cacao canker (*Nectria* sp.). These diseases and others are to be the subjects of future investigations.

Report of the vegetable pathological experiment station for the year 1900-1901, G. LÜSTNER (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1900-1901, pp. 127-134, pl. 1, figs. 3*).—The organization of the laboratory connected with the station and some of the lines of investigation are described. The principal investigations during the year have been on diseases of orchard trees and on grapes. Descriptions are given of the mildew of pears caused by *Sphærotheca mali*, the occurrence and distribution of the Monilia disease of stone and other fruits, and of the winter form of the grape mildew (*Oidium tuckeri*). These diseases are described at some length and suggestions given for their prevention.

Report of the station for plant protection and plant diseases at Weihenstephan, 1898-1900, J. E. WEISS (*Vrtljschr. Bayer. Landw. Rath., 6 (1901), No. 2, pp. 338-372, 496-514*).—A review is given of the various lines of investigation and instruction carried on by the station for the years 1898, 1899, and 1900. The principal part of the report was taken up with notes on fungus, insect, and other pests; their occurrence noted, injury described, and means suggested for their prevention or eradication. The various diseases and injuries are grouped under the respective headings of cereals; root, fodder, and garden crops; orchard and small fruits, etc.

Contributions to the knowledge of some undescribed or imperfectly known fungi, C. A. J. A. OUDEMANS (*Proc. Sec. Sci. Koninkl. Akad. Wetensch. Amsterdam, 3 (1901), pp. 140-156, 230-244, 332-347, 386-400, pls. 4, figs. 12*).—Descriptions are given of 108 new species of fungi and critical notes given upon a number of others. Many of the fungi enumerated are of considerable economic importance since they are found parasitically upon many economic plants.

Oat smut in Wisconsin, R. A. MOORE (*Wisconsin Sta. Bul. 91, pp. 15, figs. 2*).—The smut of grains has become a source of great annoyance to the farmers of Wisconsin, reducing the yields of their crops to a considerable extent. In order to ascertain the natural increase of smut a sample of oats which was infected to the extent of 10 per cent was sown without treatment, and by careful counting of the crop produced it was found that 20 per cent was affected. Seed was saved from this crop and the resultant crop was affected to the extent of 31 per cent. An attempt was made to determine the distribution of the smut throughout the State. Directions were sent out, giving methods for determining the amount of smutted oats in a given field, and the replies received indicate an average from all the counties reporting of 20 per cent infection. Data obtained in a somewhat similar manner from former students throughout the State showed an average percentage of smut in 124 fields examined of 15 per cent. The number of experiments which were carried out during 1901 to test the efficiency of formaldehyde as a preventive of smut are briefly reviewed, and letters are published from a number of farmers who have successfully used this treatment.

Treatment of seed oats to prevent smut, R. A. MOORE (*Wisconsin Sta. Rpt. 1901, pp. 255-260, figs. 2*).—Formaldehyde in various strengths was used as a treatment of the seed, which should be given several days in advance of sowing to enable the seed to dry sufficiently for drilling. According to the author, the treated oats seem to germinate more quickly, differences from 2 to 4 days being reported in favor of oats treated. No detrimental effect on the germination of the seed was apparent, and of 30 varieties treated not a single affected head could be found during the growing season. In order to determine the most efficient strength and time that the oats should be submerged in the solution, experiments were carried on with solutions of 1 lb. of formaldehyde to 50, 100, and 200 gals. of water, respectively, the seed being soaked from 10 to 60 minutes. The best results were obtained where the seed oats were submerged in the solution for 20 minutes in a 1-lb. to 50-gal. solution.

Investigations concerning the cereal fungus Rhynchosporium graminicola, E. Heinsen (*Bot. Mus., Abt. Pflanzenschutz, Hamburg, 3 (1900–1901), pp. 13, pls. 4*).—For a number of years a disease of cereals due to *Rhynchosporium graminicola* has been under observation. It was first noticed as occurring upon rye and later upon barley. The disease seems rather widely distributed throughout Germany, and it produces an effect upon the host plant quite similar to that caused by the mildew *Erysiphe graminis*. Inoculation experiments show the disease could be rather easily produced upon rye and barley, less easily upon wheat, and oats seem to be entirely immune from attacks of the fungus. Frost injuries and the use of certain fertilizers, such as those containing potassium perchlorate, seem to favor the spread of the disease. The different stages of the fungus are described at considerable length and its possible affinities are pointed out.

A California beet disease, Linhart (*Oesterr. Ungar. Ztschr. Zuckerind. u. Landw., 1901, p. 26; abs. in Bot. Centbl., 87 (1901), No. 10, pp. 356, 357*).—In 1899 there is said to have appeared a sugar-beet disease in California that in some localities destroyed from 10 to 100 per cent of the beets. The cause of the disease was attributed to bacteria and it was thought probable it was the same disease as that known to occur in Germany. Diseased beets preserved in alcohol were examined by the author and the symptoms of disease are described. The beets begin growth in the usual way and the first symptom of disease is shown when they have put out 6 or 8 leaves. The root puts out numerous fine roots, often the body and main root having a felted appearance. The leaves are undeveloped and die, while the crown of the beet changes color from yellow to brown, and finally becomes black and rotten. The flesh of the beet becomes discolored and with a short exposure to the air turns black. Sometimes the roots are uncolored; at other times they are discolored to the tap root. Many specimens appearing normal are found upon examination to be woody internally. The fundamental tissues are poorly developed, the cells being much smaller than in normal beets. Numerous bacteria 1.5 to 2μ in length with about half that diameter were found that resembled those occurring in diseased beets in Europe, but as all available material had been in alcohol for some time no cultures could be made. The author believes the bacteria are saprophytic in the soil and find their way to beets whose growth had been interfered with by unfavorable conditions. Attention should be given to the proper irrigation and fertilizing of the crop and as an additional precaution seed should be soaked for 20 hours in a 22 per cent solution of copper sulphate before planting.

A bacterial disease of beans, G. Delacroix (*Ann. Inst. Nat. Agron., 24 (1897–1900), No. 16, pp. 151–160, figs. 3*).—An account is given of a bacterial disease of beans which has been noted in the environs of Paris, a preliminary notice of which has already been given elsewhere (E. S. R., 11, p. 948).

Orange and lemon rot, C. W. Woodworth (*California Sta. Bul. 139, pp. 3–11, figs. 5*).—During the past year considerable loss has been reported in early shipments of oranges and lemons. The cause of the rot is said to be due to the presence of a mold, *Penicillium digitatum*. The characteristics and growth of the fungus are described at some length and the method of attack is shown. The rot of these citrus fruits is not usually an orchard disease. In lemons the infection occurs almost entirely in the curing houses, and in oranges after they are packed and usually in transit to the market. Navel oranges, however, often come to the packing house badly infected by the disease. The trouble begins at the navel end and may be scarcely visible from without, though commonly a slight split or perhaps a little exudation of gum will indicate the point of entrance of the fungus. In this case the trouble clearly began in the orchard and sometimes infection has taken place before the fruit is ripe. The conditions for the entrance of the fungus are described. A number of preventive measures are suggested, among them the use of refrigerator cars, and ventilated cars or ventilated curing houses. The practice of wrapping the fruits in tissue paper also decreases the danger from rot. As a preventive means of distribution the decayed fruit should be burned or deeply buried to destroy the spores. Packing houses should be thoroughly disinfected and where possible sulphuring should be resorted to.

Notes on diseases of the orange, J. W. MILLS (*California Sta. Bul. 138, pp. 39-42, figs. 2*).—The important diseases of the orange in California are said to be gummosis, a scaly bark gum disease, and die-back. The gummosis attacks the roots and trunks just below the surface of the ground and makes its appearance where the ground has been allowed to remain wet for long periods. It is also stated that the disease may be produced by heavy applications of nitrogenous manures, followed by irrigation close to the trees during hot weather. The scaly bark gum disease is prevalent in southern California. It attacks the trunk of the tree as well as some of the larger branches and if not checked destroys the tree. The new bark is unhealthy and the disease penetrates to the center of the limb or trunk of the tree. Thus far this form of the disease has not been observed in California on sour-orange stocks, nor upon the pomelo stock. The sour stock has not proved entirely satisfactory in southern California, and it is recommended that pomelo stock should be used in its stead. The sweet-orange stock is much more susceptible to the disease. The third disease, die-back, is quite prevalent in some parts of the State. The affected trees make an apparently healthy growth in the spring and summer, but the young shoots soon turn yellow, the leaves drop off, and the twigs die back to the older wood, from which a brown granular exudation takes place. In a season or two the older wood also dies. Experiments with fungicides in combating this disease have been attempted, but so far without appreciable results. It is claimed in most cases that die-back is due to some fault in the subsoil, such as hardpan, marl, or overirrigation. The correction of these evils will, it is believed, tend to prevent the disease. Closely related to the die-back and probably due to the same causes is a disease designated as mottled leaf. It is believed to be a partial chlorosis of the leaves. This disease has been noticed most commonly upon trees grown in soils where the tap roots reach sand or dry gravel, and it is probable that other unfavorable conditions, such as alkali or hardpan, may produce the same effect.

The fungus diseases of cacao in the West Indies, A. HOWARD (*West Indian Bul., 2 (1901), No. 3, pp. 190-211*).—This paper gives an account of work already done by the author in studying the cacao diseases of the West Indies, and also brings together the results obtained by some other investigators. The diseases of cacao are grouped under the headings pod diseases, stem diseases, and root disease. At the present time 3 distinct pod diseases have been noted in the West Indies; one is widely distributed and is believed also to occur in South America, while the other 2 appear almost entirely confined to Trinidad.

The brown rot (*Diplodia cacaoicola*) is a widely spread disease of the pods, and although investigation as to its nature appears to have been undertaken only quite recently the disease is believed to have existed for a long time. Pods attacked by this disease exhibit circular brown spots which gradually extend all over the pod, causing the complete destruction of the rind and its contents. The spread of the disease varies somewhat according to ripeness, but usually the whole pod is affected within 6 to 10 days from the time that the disease first makes its appearance. The microscopical characters of the fungus are described at some length and its parasitic nature was established by means of infection experiments. The fungus has been found living not only on the old husks but also on living pods, dead cacao trees, old prunings, and on diseased sugar cane where cane cultivation was carried on among the cacao trees. As remedial measures for the prevention of injury by this fungus the author suggests the gathering of the pods before they become too ripe, as ripe pods seem to be especially liable to attack. All hulls and husks should be buried or burned and diseased pods removed from the trees. All dead trees, prunings, and branches should be collected and burned, as the fungus can live saprophytically upon them. The pod diseases described as occurring in Trinidad are due to the fungi *Phytophthora omnivora* and *Nectria bainii.* For the prevention of injury by the Phytophthora the reduction of shade, destruction of diseased pods, and spraying the unattacked pods with Bordeaux mixture are recommended. The second fungus so far has not proved of great economic importance.

Of the stem diseases described the canker, due to *Calonectria flavida*, is one of the most important. A symptom of the presence of this fungus is the occurrence of a reddish gummy liquid oozing from the bark of the stem which gives a rusty appearance to the bark when dry. Infection experiments have readily produced the disease, and the diseased area spreading often completely rings the tree, and when this is complete the tree dies suddenly. Wounds made by pruning should be coated with tar to prevent the entrance of the fungus, and all trees which have been destroyed by the canker should be cut to the ground and burned. It appears probable that the fungus causing the rot of the pods described above occasions considerable damage to the cacao trees by causing their dying back at the extremity of the branches. Fertilizing and cultivation are recommended, together with the suggestions given for the prevention of the pod rot, for the prevention of this trouble.

A disease known as the witch-broom disease of Surinam, due to *Exoascus theobromæ*, is described as frequently causing considerable injury. By careful attention to trees and pruning out the diseased branches this can be kept in check.

The root disease described is from an unknown cause. The trees seem to die suddenly without any indication of disease in stems or branches, but the roots are usually surrounded by a matted sheet of fungus filaments. The fruiting stage of the fungus has never been recognized and its affinities can only be surmised. It seems to have some of the characteristics pertaining to the Basidiomycetes and is believed to be similar if not identical with the fungus which attacks the nutmeg trees of Grenada and many fruit trees in the West Indies. Where this disease appears it is recommended that trenches should be dug about the affected trees to isolate them from the rest of the plantation. A brief summary is given of the general means to be adopted for combating these diseases; and a bibliography, together with directions for the preparation and use of Bordeaux mixture, completes the bulletin.

Fungus diseases of cacao, D. MORRIS (*Bul. Bot. Dept. Jamaica, n. ser., 8 (1901), No. 8, pp. 113–124*).—An article by A. Howard on the diseases of cacao in Grenada is quoted. The diseases described are a brown rot of the cacao pod caused by *Diplodia cacaoicola*, canker diseases due to *Nectria theobromæ* and *Calonectria flavida*, and a root fungus which is believed to be a species of Polyporus. These diseases are described at some length and suggestions given for their repression.

Leaf curl of mulberry trees, M. MIYOSHI (*Bot. Centbl., 86 (1901), No. 11, pp. 375–378*).—According to the investigation of the author, this disease appears to be caused by faulty assimilation and nutrition, brought about by improper methods of culture, unfavorable climatic conditions, and varying resistance and hardiness of varieties.

Notes on Nematospora coryli, V. PEGLION (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 21, pp. 754–761, pl. 1*).—In 1897 the author described a disease of filberts that had become of considerable importance in parts of Italy. Continued observations have been made upon the disease, and its cause has been determined as due to the fungus *Nematospora coryli*, one of the Saccharomycetes. The fungus is a parasite, and the affected nuts are bitter, misshapen, and often more or less decayed. The characteristics of the fungus, effect upon the host, and means of dissemination are discussed at some length. The affinities of the new genus Nematospora with the other genera of Saccharomycetes are shown by a key of the genera.

A bacterial disease of strawberries, P. VOGLINO (*Ann. R. Accad. Agr. Torino, 42 (1900), pp. 11, pl. 1; abs. in Bot. Centbl., 86 (1901), No. 12, pp. 410, 411*).—In the experimental garden attached to the agricultural academy at Turin there appeared in July a hitherto unknown disease of strawberries. It spread rapidly, and by October had attacked nearly every plant and destroyed many of them. The leaves of diseased plants wilt, dry up, become white or spotted, although sometimes they are but little changed. The roots are badly affected. A section across one of the main roots shows the outer part more or less disorganized and the woody axis entirely laid bare. No fungus could be found associated with this disease, but numerous colonies of bacteria were present. The organism was isolated, cultivated, and infection experiments conducted that seem to show that the disease is due to bacteria. The morphology and physiology of the organism are described at some length. It grows readily upon a number of media and is from 0.9 to 1.5μ in length, although young specimens often occur 2 or 3 times that size.

Investigations upon the action and condition of the sulphur used in combating grape mildew, K. WINDISCH (*Landw. Jahrb., 30 (1901), No. 3, pp. 447–495*).—Various theories have been suggested as to the action of sulphur in preventing the growth of the powdery mildew (*Oidium tuckeri*) upon the grape. The efficiency of this fungicide has been attributed to mechanical, physical, and chemical action. All of these theories are stated and reviewed at some length, the author seeming to adhere to the theory of chemical action, although his experiments were not satisfactory and are to be repeated. Investigations were carried on upon various kinds of sulphur in which the questions of fineness and purity were examined and the different methods of determining these factors are described. The different kinds of sulphur found upon the market were studied, and comparisons are drawn between the efficiency of ground, sublimed, and precipitated sulphur. The author claims that nearly all investigators agree that ground sulphur is more efficient than the flowers of sulphur in preventing grape mildew. Analyses are reported of a number of trade preparations that are recommended for use as substitutes for sulphur. In nearly all of them sulphur was found to be the most abundant constituent, lime, gypsum, etc., often being added to make bulk.

A disease of carnations at Antibes, G. DELACROIX (*Ann. Inst. Nat. Agron., 24 (1897–1900), No. 16, pp. 161–201, figs. 11*).—This article gives detailed report of investigations conducted upon a disease of carnations caused by *Fusarium dianthi*. A preliminary account of this disease has been noted elsewhere (E. S. R., 13, p. 153).

ENTOMOLOGY.

The entomologist's experiment orchard, J. B. SMITH (*New Jersey Stas. Bul. 155, pp. 71*).—The author gives in detail the history of each tree in the orchard, which was planted for experimental purposes. The orchard contains 48 trees of different species and varieties. Notes are given on the method of application and effectiveness of arsenate of lead, cement and milk, kerosene, crude oil, whale-oil soap, and lime-sulphur-and-salt wash. No harm was done to any trees by spraying with arsenate of lead. Experiments covering a number of years, with the cement and milk treatment, indicate that this is an effective method for preventing the attacks of peach borers. Fuel oil with a specific gravity of 35° injured peach trees to some extent, but was safely used on plum, pear, and hawthorn. It was fatal to early Richmond cherry trees. Four kinds of whale-oil soap were used, with varying results. In some cases it seemed ineffective, in others all scale insects were destroyed. On peach trees the buds were badly injured in some cases. Detailed notes are given on experiments with mechanical mixtures of kerosene and crude petroleum with water, and with these substances undiluted. The results varied according to the time of year when the application was made and the hardiness of the trees. In general crude petroleum was found a safe and effective application on dormant trees. Biological and economic notes are given on codling moth, sinuate pear borer, pear midge, San José scale, apple-plant lice, and plum curculio.

Report of committee on entomology and report of chief inspector of nurseries and orchards, F. M. WEBSTER (*Reprint from Ohio Hort. Soc. Rpt. 1901, pp. 37, pl. 1, figs. 10*).—Notes are given on the damage caused to willows and poplars by *Cryptorhynchus lapathi*, and by the strawberry weevil (*Anthonomus signatus*). A warning notice is given concerning the brood of periodical cicada which will appear in western Ohio during the coming season. Experiments were made to determine the extent of infestation of orchard trees from apples and other fruits infested with San José scale. It was found that scales rarely left infested apples to settle upon the trees, even when the apples were placed near or in contact with the trunk of uninfested trees. During the operations of the State inspector and his assistants large quantities of fish-oil caustic-potash soap were used for spraying orchards and ornamental trees. The soap was used in the proportion of 2 lbs. to 1 gal. of water, and was found to be effective. In some cases the scale was apparently exterminated by one application. In experiments with crude petroleum it was found that a 10 per cent mixture was ineffective, and that some damage was frequently caused by the use of a mixture containing more than 35 per cent of oil. When the fish-oil soap was applied under favorable conditions 98 per cent of the scales were killed by one application. Details are given of a number of spraying experiments with this substance. It is concluded that fish-oil soap is the safest effective mixture for use against San José scale. It is, however, too expensive for general application. Crude petroleum is considered safe if applied cautiously, and has the advantage of being much cheaper. Notes are given on the location of nurseries and other premises throughout the State which were inspected or found to be infested. Brief notes are also presented on the extent of peach yellows and black knot in Ohio.

Report of the entomologist, J. M. SOUTHWICK (*Rhode Island State Bd. Agr. Rpt. 1900, pp. 20–49, figs. 17*).—Brief notes on the habits, life history, and means of combating carpet beetles, fleas, cockroaches, bollworms, white-marked tussock moth, May beetle, goldsmith beetle, San José scale, scurfy scale, oyster-shell bark-louse, and oak pruner.

Report of the entomologist, H. TRYON (*Queensland Dept. Agr. Rpt. 1900–1901, pp. 24–28*).—The author gives brief notes on a large number of injurious insects. Experiments were conducted in fumigating fruit trees with hydrocyanic-acid gas. It was found that excessive use of sulphuric acid in producing gas was not attended with any injury to the trees. Brief notes are given on certain insectivorous birds, on field work of the entomologist, and the collection of insects.

A report of the State entomologist for the year 1900, S. LAMPA (*Ent. Tidskr., 22 (1901), No. 1, pp. 1–56, figs. 4*).—The most important noxious insect during the year was *Lymantria monacha*. An outbreak occurred in the southern and eastern portions of Sweden, and after considerable damage had been caused, the insects suddenly disappeared. It is reported that the gypsy moth occurs from time to time in injurious numbers in certain localities. It is considered possible, however, to prevent any great injuries from the spread of this species. Notes are given on the distribution and injuries caused by the Hessian fly. An account is given of the various parts of the country visited by the entomologist in the investigation of injurious insects. This report contains notes on *Melolontha hippocastani*, *M. vulgaris*, *Tortrix viridana*, *Nematus ribesii*, gypsy moth, and *Hemerobious nervosus*. The last-named species is said to be one of the most important predaceous insects in Sweden. Notes are given on experiments in spraying with Paris green and kerosene emulsions. These operations are becoming more widely spread from year to year and are attended with better success. An account is given of certain household insects, including

Tinea pellionella, and *Tineola bisselliella*. Biological and economic notes are given on *Agrotis segetum*, *Hadena secalis*, *H. basilinea*, pea weevil, cabbage-root maggot, *Cassida nebulosa*, codling moth, *Cecidomyia pyricola*, *C. tritici*, and other species of less importance.

Report on injurious insects in Finland for the year 1900, E. REUTER (*Landbr. Styr. Meddel. [Helsingfors], 1901, No. 35, pp. 41*).—In this report especial attention is given to a discussion of the habits and life history of *Charæas graminis*. This insect proved especially injurious during 1900 and a circular letter of inquiry was sent to various parts of Finland for the purpose of obtaining a better idea of its distribution and the extent of its injuries. Notes are also given on a number of insects which caused the so-called silver top condition of grasses. A brief report is also made on *Sitones lineatus*, *Meligethes æneus*, cabbage weevil, cabbage butterfly, cabbage-root maggot, codling moth, *Argyresthia conjugella*, gypsy moth, and other miscellaneous insects.

Report of the committee on diseases of cane, A. KOEBELE (*Hawaiian Planters' Mo., 21 (1902), No. 1, pp. 20–24*).—Notes on the habits and life history of a species of leaf hopper and *Sphenophorus obscurus* as injurious to sugar cane.

The Hessian fly, H. GARMAN (*Kentucky Sta. Bul. 96, pp. 193–198*).—Experimental plats of wheat were planted at the station for the purpose of determining the length of time during which the female fly lays eggs. It was found that ordinarily the insect lives but a short time after depositing its eggs, but when the weather was not unusually severe some belated flies escaped the effects of early frosts and appeared later during warm days. The author's observations indicate that in order to secure complete protection against injury from this insect it is not safe to plant wheat earlier than October 3, and in the southern part of the State wheat should not be planted before the middle of October or perhaps the first of November. Brief descriptions are given of the insect in its various stages.

Two Noctuidæ injurious to cereals, S. LAMPA (*Ent. Tidskr., 22 (1901), No. 2–3, pp. 129–136, pl. 1*).—The author gives notes on the habits, life history, and means of combating *Hadena tritici* and *H. secalis*. Notes are given on the food plants of these species and extensive bibliographical references are made.

Colorado potato beetle in Europe, S. LAMPA (*Ent. Tidskr., 22 (1901), No. 2–3, pp. 170–174*).—Brief notes are given on the recent importation of the Colorado potato beetle into England, and attention is again called to the possibility of the spread of this insect in other parts of Europe. A number of weeds are found in all parts of continental Europe upon which the insect might feed.

Some orchard pests, J. M. STEDMAN (*Missouri State Bd. Agr. Mo. Bul., 1 (1902), No. 11, pp. 22–24*).—Brief notes on the habits, life history, and means of combating the plum curculio and cankerworm.

A monograph of the Coccidæ of the British Isles, R. NEWSTEAD (*London: Ray Society, 1901, vol. 1, pp. 220, pls. 39, figs. 20*).—In this volume the author gives a general account of the life history and habits, migration, distribution, acclimatization, and natural enemies of the Coccidæ. According to observations in England, the blue titmouse (*Parus cæruleus*) feeds extensively upon a number of species of scale insects. Other birds are also reported as more or less effective enemies of the Coccidæ. Notes are given on the parasitic and fungus enemies of Coccidæ, on methods of collecting and preserving these insects, and on the approved artificial remedial and preventive measures. The greater portion of the volume is occupied with a description of the various species of the subfamily Diaspinæ. The plates illustrating the volume are for the most part original and of excellent character.

San José scale investigations, III, V. H. LOWE and P. J. PARROTT (*New York State Sta. Bul. 202, pp. 167–214, pls. 2, fig. 1*).—*Spraying experiments with crude petroleum and other insecticides* (pp. 171–188).—The crude petroleum used in these experiments had a specific gravity of 44°; the emulsion was perfect and did not separate completely after being allowed to stand for more than 2 days. A winter treatment was given to plums, pears, and cherries. The trees were sprayed December 22–24, during an average temperature of 39° and accompanied with cloudy weather. The weather during the following week was also cloudy. In the same orchard a spring application was given April 18, at a temperature of 52°, with cloudy weather during the following week. Some of the trees were given both the winter and spring treatment, on December 24 and April 18. The winter treatment injured none of the plum trees when the 25 per cent emulsion was used, but all the trees were injured or killed by 40 per cent mixture. Old trees were more seriously affected than younger trees. Pears and cherries were uninjured. Plums were even more seriously injured by the spring treatment, but the pears and cherries were unaffected, even by the 60 per cent mixture. A combination of winter and spring treatment caused more damage to the trees than either single application. The spring treatment proved to be less injurious than the winter treatment, while both treatments together proved fatal with all mixtures above 25 per cent.

In experiments to determine the effect of crude petroleum upon hibernating scales a number of pear trees were sprayed October 23, with a temperature of 64°; the week following the application was clear. Other pear trees were treated in winter and spring. The trees were rather badly infested with the scale. In these experiments it was found that a 25 per cent emulsion could not be depended upon to kill dormant scales, while a 40 per cent mixture gave satisfactory results. No injury was observed on any of the trees which were sprayed once, although some were much weakened by the scale. Trees which were sprayed twice with a 60 per cent solution or with undiluted petroleum were killed or seriously damaged in every case.

Experiments were undertaken in spraying large apple trees to determine the efficiency of crude petroleum applications upon large trees. Applications were made on some of the trees in winter, and on others in the spring. The 25 per cent mixture had no effect on the scales and some live scales were found on trees sprayed with a 40 per cent mixture. This was probably due to the practical impossibility of completely covering large trees. Experiments on peach, pear, and apple trees which were given a winter treatment showed that the scale was not killed by 25 per cent mixture, while the 40 per cent mixture was effectual. Peach trees were somewhat injured by a 25 per cent mixture. From these experiments it is concluded that peach and plum trees are more sensitive to crude petroleum than apple, cherry, or pear trees, and that a 25 per cent mixture of crude petroleum can not be depended upon to kill hibernating scales.

A plum orchard was treated in the spring, partly with a resin wash and partly with so-called government whitewash. The trees were sprayed April 12, with an atmospheric temperature of 47°. Neither treatment had any effect on the scale.

Fumigation experiments with hydrocyanic-acid gas (pp. 188–210).—Experiments were conducted to determine the effect of the gas on healthy buds and the strength of gas required to destroy hibernating scales. Buds were fumigated in box fumigators and the amount of cyanid used varied from 0.18 to 0.3 gm. per cubic foot of space. Apple buds were not appreciably affected by the treatment. Cherry and pear buds suffered a slight injury from the gas. Peach buds were considerably injured when 0.3 gm. of cyanid per cubic foot was used. Plum buds were practically unaffected. In experiments to determine the effect of gas upon the scale, pear, peach, and plum trees were fumigated. In these experiments it was found that fumigation with gas at a strength less than 0.3 gm. of cyanid per cubic foot of space had no effect on scales when applied in the winter. In the spring the gas was much more effective, killing the scales when 0.18 gm. of cyanid per cubic foot of space was used. In the authors' opinion the principal advantage of fumigation over other treatment is in thoroughness, but that it is expensive if used upon large trees.

Notes are given on other insecticides, including whale-oil soap and crude petroleum combined; lime-sulphur-and-salt wash; and kerosene-lime emulsion. A simpler method for fastening the door of the tree fumigator, devised at the station, is described. Its chief advantage lies in the ease and quickness with which the door may be put in place. By this method the buttons previously used are replaced by stout straps which extend across the door to the margin of the fumigator.

Spraying and fumigating for San José scale, F. H. Hall, V. H. Lowe, and P. J. Parrott (*New York State Sta. Bul. 202, popular ed., pp. 6, figs. 2*).—A popular summary of the above bulletin.

Preliminary experiments in spraying to kill the San José scale insect in 1901, W. E. Britton (*Connecticut State Sta. Bul. 136, pp. 12, pl. 1*).—In experiments by the author twigs were examined before insecticides were applied for the purpose of determining the percentage of living scales. Another examination was made 6 weeks after spraying. The insecticides used in these experiments included common laundry soap, Babbitt's lye, kerosene, and crude oil. Applications were made on April 12, the kerosene being applied in a mechanical mixture containing from 15 to 20 per cent of the oil, and Babbitt's lye in the proportion of 1 lb. to 4 gal. of water. A pear tree drenched with crude oil showed less than 1 per cent of living scale insects after the application. The use of a 15 per cent mixture of kerosene was also fatal to most scales. Babbitt's lye was less effective than either the crude oil or kerosene. Various mixtures of crude oil with water caused such injuries to the foliage and fruit of peach trees as to prohibit its use on these trees when in leaf. Soap and water also injured the foliage nearly as badly as crude oil. The kerosene mixture did not injure the foliage. The crude oil was most effective of all in killing scales. In another experiment kerosene and crude oil in mixtures with water containing 10 to 15 per cent of the oils were used. Young scales were found crawling about on the trees the day after the application. A plum tree was sprayed with a 15 per cent mixture of kerosene until the insecticide dripped from the branches. The tree shed a few leaves but was not seriously damaged; only 3 of 308 scale insects remained alive. Currants sprayed on March 12 with a soap emulsion of kerosene containing 25 per cent kerosene were not injured and less than 1 per cent of the scale insects remained alive. The author concludes that it is safe to apply kerosene in a 15 per cent mixture with water to fruit trees and foliage and that the scale may be held in check to some extent by such treatment. It was found that crude oil and a 20 per cent mixture of kerosene destroyed the scales when applied to dormant trees late in the spring. The scale insects were not so effectively destroyed by the same treatment in June.

The principal scale insects of grapes, V. Mayet (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), No. 52, pp. 757–760, pl. 1*).—Descriptive biological and economic notes are given on *Dactylopius vitis* and *Lecanium cymbiforme*. According to the author's observations, the grapevines most frequently become infested with scale insects when they are in a weakened or unthrifty condition. Winter treatment is preferred to summer treatment. The main trunk of grapevines and branches may be painted with crude petroleum containing 5 per cent of naphthaline and 10 per cent of powdered lime. Another remedy recommended by the author is prepared in the following proportions: 1,000 gm. water, 300 gm. black soap dissolved while warm, 5 gm. heavy oil, 5 gm. naphthaline.

British vegetable galls, E. T. Connold (*London: Hutchinson & Co., 1901, pp. 312, pls. 130, figs. 27*).—In this volume the author describes and illustrates about two-thirds of the vegetable galls known in England and gives a list of the remainder, with a brief description of each. In the preliminary chapters the nature of vegetable galls is described, with notes on their sizes, shapes, colors, and on methods of collecting, mounting, and preserving them. One chapter is devoted to the mode of growth and various systems of classification of galls, and another to the collection and preservation of animal organisms which cause galls. The agents concerned in the production of galls are mites, nematodes, beetles, flies, plant lice, moths, wasps, and fungi. Galls may be formed on the roots, stem, branches, leaves, flowers, seed pods, and other organs of the plants. The discussion and description of each kind of gall are exhaustive and the original illustrations accompanying the text are of excellent character.

Spraying for second brood of codling moth, J. W. Lloyd (*Trans. Illinois Hort. Soc., n. ser., 35 (1901), pp. 451–459*).—It was observed that the second brood of the larva of the codling moth was entering late apples in the orchards of the experiment station to a considerable extent. On August 3, 5 trees were sprayed with Paris green at the rate of ¼ lb. to 50 gals. of water, and on August 10 a second application was made. Examinations of the fallen apples from unsprayed trees showed that 22.75 per cent of the larvæ had entered close to the stem, 33.48 per cent at the calyx, and 43.76 per cent at other points on the surface of the apple. Experiments in the field and in the laboratory indicated that young larvæ may be destroyed by spraying with Paris green, even after they have punctured the skin of the apple. An examination of the larvæ of codling moth in sprayed and unsprayed apples showed conclusively that the larvæ in unsprayed apples were in a more healthful and vigorous condition than those in sprayed apples.

Investigations concerning Lymantria monacha and its injuries in Södermanland during 1900, S. Bengtsson (*Ent. Tidskr., 22 (1901), No. 2–3, pp. 145–157*).—The author made a study of the habits of this species. Notes are given on the relative abundance of the 2 sexes. A large number of parasites were bred and are briefly described in the article.

Plum sawfly (Hoplocampa fulvicornis), J. Andersson (*Ent. Tidskr., 22 (1901), No. 1, pp. 57–60*).—Great damage is reported from the attacks of this insect. In some cases 90 per cent of the plums were injured. Various remedies are suggested, including picking off all injured fruit.

Imported willow and poplar curculio (Cryptorhynchus lapathi), F. M. Webster (*Extract from Jour. Columbus Hort. Soc., 16 (1901), No. 4, pp. 12, figs. 6*).—Brief notes are given on the distribution of this insect in the United States and on the injury caused by it in various States where it has become most numerous. A review of the European literature on this insect is given by A. H. Kirkland.

Notes on Australian Hemiptera, W. W. Froggatt (*Agr. Gaz. New South Wales, 12 (1901), No. 12, pp. 1592–1601, pl. 1*).—Brief biological and economic notes on a number of species of bugs which are injurious to cultivated crops in Australia.

Dangerous mosquitoes in Kentucky, H. Garman (*Kentucky Sta. Bul. 96, pp. 199–215, pl. 1*).—The author presents a general review of the results obtained by different authors in the study of the biology of mosquitoes. Among the species found in Kentucky, mention is made of *Anopholes punctipennis*, *A. maculipennis*, *Culex pungens*, *C. impiger*, *Psorophora ciliata*, and *Stegomyia fasciata*. The last-named species is the one which is commonly supposed to be connected with the transmission of yellow fever, and is stated by the author to be the most common species of mosquito in Kentucky. It was found to be breeding in barrels, buckets, and other utensils in which water was allowed to stand during the summer. With regard to the destruction of mosquitoes the author recommends the draining of ponds or covering them with a film of kerosene oil, and for protection against the bites of mosquitoes it is recommended that the exposed parts of the body be rubbed with naphthaline, oil of pennyroyal, or kerosene.

Carbon bisulphid as an insecticide, W. E. Hinds (*U. S. Dept. Agr., Farmers' Bul. 145, pp. 28*).—A general account is given of the nature, application, and effectiveness of carbon bisulphid for insecticide purposes. The discussion includes the following subjects: Liquid properties, vapor properties of carbon bisulphid, effects of inhalation of the vapor, diffusion of the vapor, insecticidal power, commercial uses. It is used in the treatment of phylloxera, root maggots, ants, white grubs, mole crickets, borers in trunks of trees, sucking insects on small plants, insects injurious to stored products, seed insects, clothes moths, other household insects, museum pests, and gophers. A brief account is also given of the effect of the vapor of carbon bisulphid on plants, on the growth of crops, on the germination of seed, on food stuffs and on fruits. An appendix to the bulletin, prepared by E. E. Ewell, discusses the amount of carbon bisulphid in a saturated atmosphere, the inflammability and explosiveness of carbon bisulphid vapor with air, and the ignition temperature of the vapor.

Experience with dust spray, A. A. HINKLEY (*Trans. Illinois Hort. Soc., n. ser., 35* (*1901*), *pp. 219, 220*).—The author has experimented for a number of years with insecticides in a dry form in the place of sprays. While the results are not always satisfactory it is believed that dry application may be, under certain circumstances, cheaper and more effective than liquid spray.

Insecticides and fungicides, J. K. HAYWOOD (*U. S. Dept. Agr., Farmers' Bul. 146, pp. 15*).—A report is made on the chemical composition and effectiveness of Paris green, London purple, Green Arsenoid, Pink Arsenoid, White Arsenoid, Paragrene, lead arsenate, Bug Death, Slug Shot, Black Death, Smith's Vermin Exterminator, P. D. Q., Instant Louse Killer, Lambert's Death to Lice, roach destroyers, Bordeaux mixture, Grape Dust, Veltha, and Fibro Ferro Feeder.

Report of the inspector of fumigation appliances, W. LOCKHEAD (*Toronto: L. K. Cameron, 1902, pp. 16, figs. 5*).—This is the third annual report by the author on fumigation, and is occupied with a discussion of the Canadian regulations for fumigation of nursery stock, methods of applying fumigation, necessary equipment for this work, and the results of observations made in different parts of Canada. Notes are given on fumigation in orchards, nurseries, greenhouses, flour mills, and granaries. With regard to the possible injury of nursery stock from fumigation with hydrocyanic-acid gas, the author believes that the most of such injury is due to exposure of the roots of young trees for too long a time. With careful attention to this point it is believed that the number of trees which fail to grow will be decidedly reduced.

Fumigation of imported plants, A. W. L. HEMMING (*Bul. Bot. Dept. Jamaica, n. ser., 8* (*1901*), *No. 11–12, pp. 184, 185*).—A copy is given of a proclamation announcing that hereafter plants, cuttings, buds, grafts, and packages or boxes in which such material is shipped shall be subject to a thorough process of fumigation with hydrocyanic-acid gas before being admitted into Jamaica.

FOODS—NUTRITION.

Experiments on the metabolism of matter and energy in the human body, 1898–1900, W. O. ATWATER and F. G. BENEDICT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 109, pp. 147*).—The details of 13 experiments with man are reported, in which the balance of income and outgo of nitrogen, carbon, and energy was determined. These were made with the aid of the respiration calorimeter. Experiments designed to test the accuracy of the apparatus were also made, in which heat was generated in the respiration chamber electrically or by the combustion of ethyl alcohol. In a number of experiments the subjects performed more or less severe muscular work, in others there was as little muscular activity as practicable. From these and earlier experiments (E. S. R., 11, p. 770) a number of general deductions were drawn which have to do with such topics as the food materials supplied and consumed, and the difference in demand of men at work and rest, the elimination of water, carbon dioxid, and energy under different conditions of work and rest. Especial interest attaches to the results which have to do with the measurements of energy. The following table shows the average percentages of energy given off from the body in the rest and work experiments:

Percentages of total energy given off from the body in different ways.

Heat.	In rest experiments.	In work experiments.
	Per cent.	*Per cent.*
From skin by radiation and conduction (and in exhaled air)	74.2	62.3
In urine and feces	1.4	.5
In water vaporized from lungs and skin	24.4	30.8
Heat equivalent of external muscular work done	....	6.4
Total	100.0	100.0

The following table compares the amounts of potential energy in the food materials actually oxidized in the body with the amounts of kinetic energy given off from the body, either as heat alone in the rest experiments, or as heat and external muscular work in the work experiments:

Comparison of income and outgo of energy in 19 experiments covering 65 experimental days—Amounts per day.

Subjects and kinds of experiments.	Number of experimental days.	Net income (potential energy of material oxidized in body).	Net outgo (kinetic energy given off from body.)	Difference (in terms of net income).	
REST EXPERIMENTS.					
Experiments with E. O.:					
Experiment in which the net outgo falls farthest below the net income (No. 5); average for the whole experiment	4	*Calories.* 2,482	*Calories.* 2,379	*Calories.* −103	*Per cent.* −4.1
Experiment in which the net outgo is farthest above the net income (No. 14); average for the whole experiment	4	2,131	2,193	+ 62	+2.9
Average for 9 experiments	33	2,288	2,278	− 10	− .4
Experiments with A. W. S.: Average for 1 experiment	3	2,304	2,279	− 25	−1.1
Experiments with J. F. S.: Average for 3 experiments	9	2,118	2,136	+ 18	+ .8
Experiments with E. O., A. W. S., and J. F. S.: Average for 13 experiments	45	2,255	2,250	− 5	− .2
WORK EXPERIMENTS.					
Experiments with E. O.: Average for 2 experiments	8	3,865	3,829	− 36	− .9
Experiments with J. F. S.: Average for 4 experiments	12	3,539	3,540	+ 1	0
Experiments with E. O. and J. F. S.: Average for 6 experiments	20	3,669	3,656	− 13	− .4
Rest and work experiments: Average for 19 experiments	65	2,690	2,682	− 8	− .3

The authors note that the experiments reported practically afford a demonstration of the action of the law of the conservation of energy in the living organism.

Results of experiments on the metabolism of matter and energy in the human body, W. O. Atwater, F. G. Benedict, et al (*Connecticut Storrs Sta. Rpt. 1900, pp. 96–129*).—Noted above from another publication.

Contribution to the subject of metabolism of matter and energy in man, A. Loewy and F. Müller (*Arch. Anat. u. Physiol., Physiol. Abt., 1901, pp. 299–322; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 6, p. 262*).—Experiments are reported of which one of the authors was the subject. During 4 days only ordinary laboratory work was performed. During the 6 remaining days of the experimental period the subject walked 20 to 22 kilogrammeters per day. The diet contained only a small quantity of protein, the amount being just sufficient for the days in which no work was performed. On the other days the amount of nitrogen-free material was increased. During the work period the nutrients were much more thoroughly assimilated than during the days in which the subject did not work. When no work was performed there was a loss of nitrogen. On the other days there was a gain in nitrogen and a loss of fat.

Principles of nutrition and nutritive value of food, W. O. ATWATER (*U. S. Dept. Agr., Farmer's Bul. 142, pp. 48, dgms. 2*).—The chemical composition and uses of food are discussed, as well as digestion, assimilation, excretion, dietary studies and standards, cooking of food, errors in food economy, and related topics. This bulletin is designed as a summary of available information on these topics with special reference to the results obtained in the Department of Agriculture investigations and the closely related work of the agricultural experiment stations.

Nutrition investigations among fruitarians and Chinese at the California Agricultural Experiment Station, 1899–1901, M. E. JAFFA (*U. S. Dept. Agr., Office of Experiment Stations Bul. 107, pp. 43, pl. 1*).—Dietary studies are reported with a family of so-called fruitarians who lived almost exclusively upon raw fruits and nuts, as well as similar studies of Chinese performing different amounts of muscular work. The digestibility of the fruitarian diet was also studied, as well as the income and outgo of nitrogen with one of the subjects. The following table shows the amounts of nutrients consumed per day by the fruitarians and the Chinese, as well as the cost of the diet:

Dietary studies of fruitarians and Chinese—Amounts consumed per person per day.

	Cost.	Protein.	Fat.	Carbohydrates.	Fuel value.
Fruitarians:	*Cents.*	*Grams.*	*Grams.*	*Grams.*	*Calories.*
Woman, 33 years old	23.7	33	59	150	1,300
Woman, 30 years old	17.2	25	57	99	1,040
Girl, 13 years old	19.0	26	52	157	1,235
Boy, 9 years old	19.9	27	56	152	1,255
Girl, 6 years old	17.0	24	58	134	1,190
Girl, 7 years old	27.5	40	72	134	1,385
Chinese:					
Dentist's family	16.4	115	113	289	2,705
Laundry association	21.0	135	76	566	3,580
Truck-farm laborers	19.7	144	95	640	4,100

In the case of the Chinese, the proportion of rice in the diet was especially studied, and the amount of this cereal eaten was compared with the amounts of wheat flour and other carbohydrate foods in ordinary dietaries. Concerning the Chinese dietaries, the following statements were made: "The Chinese studied, who are believed to be fairly representative of Chinese residents in California in similar employment, did not, as is often supposed, live almost entirely upon a vegetable diet. Indeed, they approached no nearer to such a diet than does the average American, who has no thought of doing without animal food. The diet was varied and the dietaries were well balanced, approaching quite closely to the commonly accepted dietary standards. Many of the foods eaten were unfamiliar to most Americans, but nevertheless can not be regarded as other than wholesome and nutritious.

"The Chinese dietary is commonly believed to be very inexpensive and limited in amount. As shown by these studies, it was quite cheap, but was neither scanty nor inferior.

"Rice on an average constituted between one-half and one-third of the total food consumed, and held much the same relation to the total food of the Chinese as do bread and other cereals, starches, etc., to the total food of the ordinary American family."

A diet with a small amount of protein, W. Caspari (*Arch. Anat. u. Physiol., Physiol. Abt., 1901, pp. 323–337; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 6, p. 264*).—In a 10-day metabolism experiment, of which he was himself the subject, the author endeavored to learn the protein minimum. When the daily diet furnished 13.26 gm. nitrogen it was possible to attain nitrogen equilibrium. This was not the case when the daily diet furnished 10.11 gm. nitrogen. From a comparison of his results with those obtained by other investigators, the author concludes that the minimum amount of protein required varies with different individuals, and may also vary with the same individual within rather wide limits.

The diet of prisoners, F. Hirschfeld (*Ztschr. Diätet. u. Phys. Ther., 4 (1901), pp. 37–53; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 6, p. 262*).—An investigation of the diet of a Berlin prison is reported.

Dietaries [at the New York State Reformatory], Z. R. Brockway (*New York State Reformatory, Elmira, Yearbook 1899, pp. 18–22*).—Brief statements are made concerning experimental diets furnished to some of the inmates of the New York State Reformatory. The total protein and energy supplied are recorded.

The therapeutic use of a vegetarian diet, T. Rumpf (*Ztschr. Diätet. u. Phys. Ther., 4 (1901), pp. 25–37; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 6, p. 265*).—The author found that a man long accustomed to an absolute vegetarian diet consumed daily 73 gm. protein, 28.6 gm. fat, and 698 gm. carbohydrates. The therapeutic uses of a vegetarian diet are spoken of. The author believes, however, that for persons in health a mixed diet is to be preferred.

Some new food products made from skim milk, J. König (*Fühling's Landw. Ztg., 51 (1902), No. 1, pp. 5–8*).—Several soluble and insoluble casein products which are made from skim milk are described, their composition given, and their manufacture and food value discussed.

Slimy bread, H. Svoboda (*Oesterr. Chem. Ztg., 4 (1901), No. 18, pp. 418, 419*).—A bacteriological study of slimy bread of local manufacture is reported.

Concerning the examination and valuation of egg pastes, M. Mansfeld (*Oesterr. Chem. Ztg., 4 (1901), No. 19, pp. 442, 443*).—Analytical data are reported.

Nutritive value and chemical composition of vegetables, A. Larbalétrier (*Jardin, 1901, May 5, p. 137; abs. in Jour. Soc. Nat. Hort. France, 4. ser., 2 (1901), May, pp. 458–460; Rev. Agr. Reunion, 7 (1901), No. 12, pp. 502–505*).—Analytical data are reported and discussed.

The bacteriology of vegetables grown on an infected soil, Wurz and Bourges (*Arch. Med. Exper. et Anat. Path., Paris, 1. ser., 13 (1901), p. 575; abs. in Public Health, 14 (1901), No. 4, pp. 250, 251*).—Experiments showed that vegetables grown in infected soils or watered with infected solutions transmitted pathogenic bacteria under the experimental conditions.

Concerning the amylolitic effect of saliva, P. Bielfeld (*Ztschr. Biol., 41 (1901), No. 3, pp. 360–367*).—Experiments are reported in detail which lead to the conclusion that within the experimental limits (1 to 10 cc. saliva or ptyalin solution) the quantity of ptyalin present is without effect upon the sugar produced. Further, the percentage amount of starch was without influence, provided the absolute quantity of starch remained the same in a given experiment. The larger the absolute quantity of starch in a given test, the greater the amount of sugar produced.

A contribution to the subject of the quantitative effect of pepsin, F. Krüger (*Ztschr. Biol., 41 (1901), No. 3, pp. 378–392*).—The author's experiments led to the following conclusions: The amount of cleavage products increases with the quantity of ferment present, though not proportionally. Provided the albumen present remains the same, the quantitative action of pepsin increases with diminished protein concentration, but not proportionally. The larger the absolute amount of albumen, the greater the amount of cleavage products which are produced. These deductions are compared with those noted above in experiments with ptyalin.

Further observations on the quantitative digestive power of pepsin, F. KRÜGER (*Ztschr. Biol., 41 (1901), No. 4, pp. 467–483*).—In the experiments reported, the effect of the amount of free hydrochloric acid present during the proteolytic action of pepsin was studied. According to the author, pepsin acts most powerfully when the digestive mixture contains from 0.18 to 0.4 free hydrochloric acid. The author's experiments are discussed in relation to the work of other observers.

On the preserving of fresh meat and on preserved meat from a hygienic and sanitary standpoint, W. ROHARDT (*Vrtljschr. Gerichtl. Med. u. Oeffentl. Sanitätsw., 3. ser., 21 (1901), pp. 321–355; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 6, p. 269*).—A general discussion of the subject.

A list of licenses granted by the dairy and food commissioner from January 1, 1901, to July 1, 1901, G. G. HUTCHISON (*Pennsylvania Dept. Agr. Bul. 86, pp. 421*).—In addition to a list of the licenses granted during the first 6 months of 1901 by the State dairy and food commissioner, the bulletin enumerates the food samples analyzed and the suits and legal proceedings instituted from January 1, 1900, to July 1, 1901.

"Of the 507 samples analyzed under the pure-food act 233 proved to be pure and 274 adulterated. Of the 18 samples of cheese 10 were full cream and 8 below standard. Of the 94 samples of milk 61 were pure and 33 adulterated. Of the 27 samples of condensed milk 19 were pure and 7 adulterated. Of the 66 samples of vinegar analyzed 41 were pure and 25 adulterated."

ANIMAL PRODUCTION.

Analyses of fodders and feeding stuffs, A. P. BRYANT (*Connecticut Storrs Sta. Rpt. 1900, pp. 82–95*).—In studying the effects of nitrogenous fertilizers upon the composition of feeding stuffs, analyses were made of a number of samples of cowpea fodder, corn stover, soy-bean seed, and white flint corn. A number of miscellaneous fodders and feeding stuffs were also analyzed, including corn fodder for silage, corn stover, oat straw, hay from mixed grasses, rowen, Hungarian grass hay, oat-and-pea hay, corn silage, Buffalo gluten feed, gluten meals, corn-and-cob meal, cotton-seed meal, wheat bran, wheat middlings, ground wheat, grain mixtures, and several proprietary and mixed feeds. In studying the effect of nitrogenous fertilizers, the total nitrogen and nitric-acid nitrogen were determined to learn whether the increase in protein, which has been observed to follow the use of nitrogenous fertilizers, was due to an increase of albuminoids or to nitrates taken up by the plants. The proportion of nitric nitrogen to total nitrogen in orchard grass in pot experiments ranged from 0.029 per cent to 0.041 per cent; in Hungarian grass (pot experiments), from 0.035 per cent to 0.048 per cent; in corn silage (plat experiments), from 0.010 to 0.018 per cent; in cowpea fodder (plat experiments), from 0.005 to 0.009 per cent; and in corn stover (plat experiments), from 0.009 to 0.01 per cent.

According to the author, "There was a larger proportion of nitrates present in the samples from the pot experiments than in those from the plat experiments; the comparison, however, is between different crops. It may be possible that there was less leeching of nitrogen from the soil in the pot experiments, but on this point these investigations furnish no evidence. While the first cutting of orchard grass in the pot experiments contained appreciable amounts of nitrates, the rowen from the same pots contained none. The corn seeds, as was to be expected, gave no tests for nitrates. No nitrates were found in the corn stover grown on the plats supplied with the mineral fertilizers without nitrogen."

Concentrated feed stuffs, J. B. LINDSEY (*Massachusetts Sta. Bul. 78, pp. 40, figs. 4*).—The more common commercial by-products used as concentrated feeds are described, and analyses made in accordance with the State feeding-stuff law are reported of cotton-seed meal, linseed meal, gluten meal, gluten feed, germ-oil meal, wheat middlings, mixed feeds, wheat bran, distillers' grains, malt sprouts, oil meal, bean meal, green-pea meal, cereal breakfast-food by-products, corn meal, hominy meal, oat feed, cob meal, Graham flour, rye meal, rye middlings, wheat-hay feed, a by-product obtained in the manufacture of baby food, Kafir corn, clover meal, poultry feeds made from grains, meat and bone meals, and meat scrap.

Average composition of feeding stuffs, W. FREAR (*Pennsylvania Dept. Agr. Bul. 87, pp. 41*).—Data showing the composition and digestible nutrients in feeding stuffs are reprinted from various sources. A method for computing the composition of mixed feeds is given.

Concentrated feeding stuffs and fertilizers licensed for sale in Wisconsin, 1902, F. W. WOLL (*Wisconsin Sta. Bul. 90, pp. 8*).—A list of 23 brands of feeding stuffs and 6 of fertilizers licensed for sale in Wisconsin during 1902, with the text of the Wisconsin feeding-stuff law and the fertilizer law.

Analyses of grasses and fodder plants, J. C. BRÜNNICH (*Queensland Agr. Jour., 9 (1901), No. 6, pp. 572–575*).—Proximate analyses are reported of hay and grass from alfalfa (*Medicago sativa*), prairie grass (*Bromus unioloides*), cocksfoot grass (*Dactylis glomerata*), and *Paspalum dilatatum*. The author also reports ash analyses of different sorts of hay.

Dried brewers' grains, T. DIETRICH (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 207–256, figs. 6*).—A summary of the available information on the production and feeding value of brewers' grains. A number of forms of apparatus for drying this material are described.

Dried distillery refuse, T. DIETRICH (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 257–262*).—The composition and feeding value of distillery refuse is discussed, a number of investigations on the subject being summarized.

Tang, P. R. SOLLIED (*Tidsskr. Norske Landbr., 1901, pp. 13–30; abs. in Centbl. Agr. Chem., 30 (1901), No. 6, pp. 375–377*).—The composition of a number of sorts of seaweeds used as feeding stuffs is given, together with results of artificial digestion experiments. According to the author, the fact should not be overlooked that seaweeds contain a considerable amount of pentosans, and on this account may be satisfactorily combined with materials rich in protein. The iodin which the plants contain is also regarded as of importance.

Silkworm excrement as a feeding stuff, G. E. RASETTI (*Staz. Sper. Agr. Ital., 34 (1901), No. 9, pp. 865–880, fig. 1*).—Analytical data are reported, showing that the material studied consisted largely of carbohydrates.

On the preservation of feeding cakes, R. W. TUINZING (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 153, 154*).—Experiments which are briefly reported led to the conclusion that the increase in water content observed when linseed cake is stored is due to the growth of mold.

Experiments on the utilization of the protein of gluten, O. KELLNER (*Landw. Vers. Stat., 56 (1901), No. 2–3, pp. 149–152*).—Experiment showed that considerable more ether extract could be obtained from gluten by digesting with pepsin and hydrochloric acid before extracting with ether than was the case by the ordinary method. On the basis of such experimental work the author calculates that the physiological nutritive value of 1 gm. of gluten protein is equal to 4.697 calories. The work is discussed in relation to the author's earlier investigations (E. S. R., 10, p. 669), the opinion being expressed that the new values do not modify the conclusions previously reached.

Methods of analyzing blood and the value of such data for studying proteid metabolism, G. ASCOLI (*Arch. Physiol. [Pflüger], 87 (1901), No. 1–2, pp. 103–115*).—Experiments are described and discussed.

Experiments on artificially lowering the protein metabolism of a sheep having fever, S. WEBER (*Arch. Exper. Path. u. Pharmakol., 47 (1901), pp. 19–47;*

abs. in Chem. Centbl., 1902, I, No. 3, p. 219).—Experimental data are reported and discussed.

The digestibility of glucose and its influence upon the utilization of protein, L. DUCLERT and R. SÉNÉQUIER (*Ann. Agron., 27 (1901), p. 209; abs. in Centbl. Agr. Chem., 31 (1902), No. 1, pp. 15, 16*).—Experiments in which rabbits were fed glucose in addition to meadow hay, showed that glucose was readily digested, provided the amount eaten did not exceed some 25 gm. per kilogram body weight. A test in which glucose was fed with alfalfa led to the conclusion that it did not effect the digestibility of protein. The rabbits fed alfalfa digested only 67 per cent of the total protein, those fed alfalfa and glucose digested 66 per cent.

The formation of sugar from fat, O. LOEWI (*Arch. Exper. Path. u. Pharmakol., 47 (1901), pp. 68–76; abs. in Chem. Centbl., 1902, I, No. 3, pp. 220, 221*).—Experiments with dogs fed phlorizine led the author to the conclusion that the protection of protein by fat was not brought about by preserving the entire protein molecule, but by the retention of the nitrogen radical of the protein, while the carbohydrate radical was used in other ways.

The behavior of xylan in the animal body, B. SLOWTZOFF (*Ztschr. Physiol. Chem., 34 (1901), No. 2, pp. 181–193*).—Experiments on the digestion of xylan were made with rabbits. It was found that from 33.17 to 82.91 per cent was digested. Of the resorbed xylan only a small portion (1.49 to 4.63 per cent of the total amount eaten) was recovered in the urine. The remainder was apparently utilized by the animal. It is uncertain, according to the author, whether zylan is a nutrient.

Steer feeding, D. O. NOURSE (*Virginia Sta. Bul. 121, pp. 15–19*).—A 15-week trial with 6 lots of 2 steers each, to test hay alone and with silage in comparison with corn stover, and to compare whole corn with corn meal, alone and with cotton-seed meal and bran, is summarized by the author as follows:

"A combination of foods, both grain and roughage, is best from every standpoint. Ground corn is better than whole corn after it has become hard. A mixture of corn meal and bran gave greatest gain and with least expense per pound. Cotton-seed meal was not, in these experiments, used with success, due at least in part, to the fact that in former years the steers had not become accustomed to it. Silage was a very economical addition to the roughage. Stover gave a bad showing when used without other roughage."

Conformation of beef and dairy cattle, A. M. SOULE (*U. S. Dept. Agr., Farmers' Bul. 143, pp. 44, figs. 44*).—With the object of pointing out the differences between good and inferior beef and dairy cattle, and the extent to which certain desirable qualities effect their value for beef and dairy purposes, the author discusses the conformation of cattle and stock judging, giving detailed information regarding the conformation of different parts of the body. Typical animals of various grades are described and the possibility of grading up common stock by crossing is discussed and explained.

The comparative value and the effect upon lamb crop of feeding various rations to ewes in winter, W. L. CARLYLE (*Wisconsin Sta. Rpt. 1901, pp. 16–24*).—Continuing earlier work (E. S. R., 13, p. 77), the comparative merits of different sorts of coarse fodder in combination with grain was tested with 4 lots of 12 ewes each. The grain ration of all the lots consisted of 0.5 lb. bran and oats 1:1 per head daily. Lot 1 was also fed corn fodder and corn stover, lot 2 corn silage and corn stover, lot 3 corn silage and blue-grass hay, and lot 4 sugar beets and blue-grass hay. The corn fodder contained 43 per cent ear corn. All the ewes weighed about 140 lbs. each at the beginning of the test. In 12 weeks the lots gained 140, 33, 156, and 175 lbs., respectively, the corresponding cost of food per head being 0.71, 0.7, 1.07, and 1.56 cts. The lots dropped respectively 18, 16, 19, and 21 lambs, the average weight at birth being 7.05, 8.82, 7.98, and 7.5 lbs.

According to the author, the corn fodder, corn stover, and corn silage rations were the cheapest and the ration containing roots and hay the most expensive, the cost of the ration in the latter case being approximately double that of the ration containing silage and fodder or stover and fodder. From this and a former test the conclusion is drawn that corn silage is one of the cheapest and most satisfactory feeds for breeding ewes in winter, and that a ration supplying coarse fodder entirely in the form of corn fodder is not entirely satisfactory for this purpose.

The food requirements of the pig for maintenance and gain, F. D. TAYLOR, reported by W. A. HENRY (*Wisconsin Sta. Rpt. 1901, pp. 67–72*).—The amount of feed required for maintenance and for gain was tested with 4 pigs, 2 being high-grade Berkshires and 2 razorback-Berkshire crosses, the investigation being similar to work previously reported (E. S. R., 12, p. 77). The rations selected consisted of a mixture of wheat bran, corn meal, and oil meal in varying proportions. These materials were analyzed. At the beginning of the trial the pigs weighed about 50 lbs. each. A grain mixture was fed sufficient for maintenance at this weight. The ration was then increased in such a way as to induce rapid gains until the pigs weighed 100 lbs. each. A period on a maintenance ration was then followed by a second period of gain, the pigs weighing at the close 150 lbs. It was found that on an average the pigs at 50 lbs. required 0.48 lb. shorts, 0.24 lb. corn meal, and 0.08 lb. oil meal daily for maintenance. At 100 lbs. they required 1.14 lbs. shorts, 0.57 lb. corn meal, and 0.19 lb. oil meal; and at 150 lbs. they required 1.2 lbs. shorts, 0.6 lb. corn meal, and 0.2 lb. oil meal. On an average the ration per hundred pounds live weight furnished 0.258 lb. protein, 0.069 lb. ether extract, 0.069 lb. nitrogen-free extract, 0.898 lb. crude fiber, and 0.052 lb. ash.

The author notes that per hundred pounds live weight the 150-lb. pig consumed least and the 100-lb. pig most. On an average the pigs required for maintenance corn meal, shorts, and oil meal, furnishing an amount of dry matter equivalent to 1.41 per cent of the live weight, or an amount of middlings furnishing dry matter equivalent to 1.37 per cent of the live weight. No differences were observed in the several periods between the razorbacks and grade Berkshires.

The food requirements during the periods of gain were also recorded, the results being expressed for average weights of 75 lbs., 125 lbs., and 175 lbs. At these weights the pigs required on an average 62.5 days, 58.8 days, and 54.5 days, respectively, to gain 50 lbs. The dry matter consumed per pound of gain was 3.19, 4.22, and 5.41 lbs. The dry matter consumed per hundred pounds of live weight daily at the 3 weights was 3.4, 2.9, and 3.06 lbs. The estimated dry matter in that portion of the daily food required for maintenance was 1.22 lbs., 1.76 lbs., and 1.80 lbs., respectively. It was calculated that the portion of the food required for maintenance at the different weights constituted 1.62, 1.4, and 1.08 per cent, respectively, of the live weight. The author notes that the food eaten for a given gain in weight increases materially with increased weight. The daily requirement for maintenance also increases, which would "tend to show that the 75-lb. pig would be the most profitably fed." But it also appeared that as the pigs increased in weight a smaller amount of food in proportion to body weight was required for maintenance, while the daily gain was larger. This, according to the author, would indicate that "the 175-lb. pig is fed at a greater profit than either the 75 or the 125 lb. pig."

The digestibility of the full ration was tested when the pigs weighed 125 lbs. and that of the maintenance ration when they weighed 150 lbs. each. On full feed the average coefficients of digestibility were dry matter 78.4, protein 73.9, fat 78.4, and nitrogen-free extract 89.2 per cent. On a maintenance ration the average coefficients were dry matter 54.6, protein 75.8, fat 82.5, and nitrogen-free extract 78.8 per cent.

Experiments in pig feeding, W. L. CARLYLE and T. F. MCCONNELL (*Wisconsin Sta. Rpt. 1901, pp. 25–58, figs. 17*).—Two tests similar in purpose to those previously carried on at the station are reported (E. S. R., 13, p. 78).

Effect of feeding various grain rations to growing and fattening hogs, W. L. Carlyle and T. F. McConnell (pp. 25–44, figs. 13).—Using 2 lots each made up of 3 pure-bred pigs and 2 razorback-Poland-China grades, the authors compared the relative merits of corn and rye 1 : 1 and peas and wheat shorts 1 : 2, all the grains being finely ground. The nutritive ratio of the first ration was 1 : 8.2 and of the second 1 : 4.1. The test covered 12 weeks. The average weight of the pigs at the beginning was 1.32 lbs. The average gain per pig per day in the 2 lots was 0.96 and 0.62 lb., respectively, the feed eaten per pound of gain being 5.52 and 7.62 lbs. The pigs were slaughtered and the results of a block test recorded, which included determinations of the strength of the bones and tendons in addition to the usual data. As pointed out by the authors, lot 1 ate more and gained more than lot 2. In other words, the ration with the wide nutritive ratio was the more profitable.

The results of a feeding trial to determine the comparative effect of feeding pigs rations of corn meal and of ground peas, *W. L. Carlyle* (pp. 44–58, figs. 4).—To further test the comparative value of ground peas and corn meal, these grains were each fed alone, using 2 lots each made up of 2 razorback pigs, 1 Yorkshire, and 2 razorback grades, weighing on an average some 48 lbs. each at the beginning of the trial. In 30 weeks the average daily gain per pig in lot 1 (fed peas) was 0.75 lb. In lot 2 (fed corn meal) it was 0.63 lb. The feed eaten per pound of gain was 4.52 and 4.91 lbs., respectively, the corresponding cost of a pound of gain being 6.78 and 4.34 cts. At the close of the test the pigs were slaughtered and a block test made. The nutritive ratio of the pea ration was 1 : 3.18 and of the corn ration 1 : 9.75. According to the author, the pigs fed peas, *i. e.*, the narrower ration, gave much better results than the lot fed corn. "The razorback-Poland-China cross-bred pigs ate the most grain, made the greatest average gain, had much the larger quantity of internal fat, and the greatest thickness of surface fat on outside of body."

From the 2 tests a number of general deductions were drawn which are in effect as follows: Feeding stuffs exercise a marked influence on the proportion of fat and lean meat in the carcass of growing pigs and may also materially affect the development of the various internal organs and the breaking strength of the bones and tendons. A ration of peas and shorts give a larger proportion of lean meat, firmer flesh, stronger bone and more blood than a ration of corn and rye. A ration of peas, when compared with a ration of corn, gave more marked results in these respects than did the ration of peas and shorts when compared with corn and rye. Rations of corn and corn and rye when fed to growing pigs tended to retard the development of their internal organs and to increase the proportion of fat meat. The thigh bones of pigs fed upon peas were on the average 26.9 per cent stronger than the thigh bones of pigs of the same age and breeding fed upon corn. "At the prevailing market prices for the grains in the rations fed, corn has proved to be a much cheaper feed for hogs than peas. Owing to the observed tendency to a lessened development of the internal organs and a reduction in the comparative strength of bones in corn-fed hogs, it is still an open question if, in the case of breeding stock, it would not be advisable to feed a much more expensive ration than corn and build up thereby a stronger vitality in the animal."

Whole corn compared with corn meal for fattening swine, W. A. HENRY (*Wisconsin Sta. Rpt. 1901, pp. 10–15*).—Continuing previous work (E. S. R., 13, p. 79), the comparative merits of whole and ground corn were tested with 2 lots, each containing 12 pure-bred and grade pigs, some of the latter showing razorback blood. Lot 1 was fed whole corn and wheat middlings 2 : 1; lot 2 corn meal and wheat middlings 2 : 1, mixed with water to a slop. At the beginning of the trial the average weight of the pigs of the 2 lots was 145 and 148 lbs. each. In the 12 weeks covered by the test the average gain per head was 74.4 and 86.5 lbs. respectively, the feed consumed per pound of gain being 5.88 and 5.53 lbs. The author notes that the pigs fed corn meal made larger gains and ate more than those fed whole corn. Taking into account the present trial and those made in former years, a saving has been effected by grinding the corn in 7 cases and in 2 cases there has been a loss. The greatest saving was 17.6 and the least 6 per cent. The greatest loss was 9 per cent and the least 2 per cent. According to the author, these figures do not take into account the cost of grinding, but are based entirely upon gains or losses in weight.

The feeding value of rape for swine, W. L. CARLYLE (*Wisconsin Sta. Rpt. 1901, pp. 59–67*).—Using 2 lots of 17 pigs each, the feeding value of rape was studied. Lot 1 was fed corn meal and shorts only *ad libitum*, while lot 2 was hurdled on rape and fed the same grain in addition. At the beginning of the trial all the pigs weighed on an average about 59 lbs. each. The average daily gain per pig without rape was 0.85 lb. and with rape 1.06 lbs. The grain eaten per pound of gain was 4.37 and 4.20 lbs., respectively. The corresponding cost of feed per pound of gain was 3.78 and 3.36 cts. From this and earlier tests at the station (E. S. R., 13, p. 80), a number of general conclusions are drawn, of which the more important follow: When properly grown, an acre of rape combined with corn and shorts has a feeding value for pigs 4 to 10 months old equivalent to 2,436 lbs. of the mixed grain and is worth $19.49 per acre. As a feed for growing pigs rape is superior to clover pasturage. Pigs are more thrifty, have better appetites, and make correspondingly greater gains when pastured on rape in conjunction with a grain ration than when fed on grain alone. "Rape is the most satisfactory and cheapest green feed for swine that we have fed. . . . Hogs should not be turned upon a rape pasture until the plants are at least 12 to 14 in. high and . . . they should be prevented from rooting while in the rape field. Rape is not a satisfactory feed when fed alone, when it is desired to have any live-weight gain made in hogs, though it has been found that they will just about maintain themselves without loss of weight on this feed alone.

Our saddle horses, A. BRUCE (*Agr. Gaz. New South Wales, 12 (1901), No. 12, pp. 1563–1588, pls. 2*).—The local horse-breeding industry is discussed and suggestions for improvement given.

Poultry experiments in 1900–1901, G. M. GOWELL (*Maine Sta. Bul. 79, pp. 9–40*).—A number of questions connected with poultry feeding were investigated.

Coops vs. house and yard (pp. 9–17).—Continuing previous work (E. S. R., 12, p. 585), 4 tests are reported on the comparative merits of feeding chickens in yards and in small coops, as has been recommended by French and English, and later by Canadian poultrymen. In the first test 20 Plymouth Rock chickens 95 days old were fed in small coops a porridge of corn meal and wheat middlings and meat meal (5:5:2) mixed with water for 28 days, gaining on an average a total of 1.34 lbs. A pound of gain required 8.92 lbs. of feed. Sixty-eight chickens of the same age, kept in a small house with a small yard and fed the same ration, made an average gain of 1.43 lbs., requiring 5.26 lbs. of feed per pound of gain. In the second test the experimental conditions were the same, except that the ration was mixed with skim milk instead of water, the amount of meat meal being correspondingly diminished. The chickens in coops gained on an average 1.68 lbs., requiring on an average 6.85 lbs. of feed per pound of gain. Similar values for chickens fed in coops were 1.713 and 4.03. These tests were repeated with chickens 160 days old at the beginning of the trial. On the ration mixed with water, the chickens fed in coops gained an average of 0.78 lb. each, requiring 9.74 lbs. per pound of gain, while those fed in yards gained on an average 0.45 lb., each requiring 16.87 lbs. of feed per pound of gain. On the same ration mixed with skim milk the average gain of the chickens fed in coops was 0.875 lb., the feed required per pound being 8.22. Similar values for the chickens fed in yards were 0.932 lb. and 7.63 lbs. According to the author, these results and those previously obtained show that close cooping is not necessary in order to secure the greatest gain in chicken fattening, and that the chickens made greater gains when given a little liberty than when kept in close confinement. The labor involved in caring for birds in small numbers in coops is greater than in caring for an equal number in a house and yard. The results are so pronounced that the author regards them as conclusive.

The fact is also pointed out that larger gains were made on the ration containing skim milk, and also that gains were more economically made by the young than the older chickens.

Experiments in incubation (pp. 18–25).—The effect of storing eggs in closed cases and in the open air, storing at different temperatures, and allowing them to remain for a time undisturbed, *i. e.*, "resting" the eggs before incubation, was tested, as well as the time required after mating to insure fertility, the duration of fertility, and the relative fertility of eggs of different shapes. The following table summarizes some of the results obtained:

Effect of storing eggs in different ways.

	Number of eggs incubated.	Number of chicks hatched.	Number of eggs infertile.	Number of eggs in which development stopped by the 12th day of incubation.	Number of eggs in which development stopped between 12th and 20th days of incubation.
Eggs stored in closed cases	81	30	11	36	5
Eggs stored in open air	79	19	9	41	9
Eggs stored at 70° F	66	23	4	20	19
Eggs stored at 50° F	62	18	4	18	22
Eggs rested before incubating	65	15	17	20	13
Eggs not rested before incubating	63	22	18	17	20

A test made with year-old Plymouth Rocks showed that eggs became fertile very soon after mating commenced. The cockerel was put in the pen with the hens in the evening and it is not probable that he mated with any hen until daylight the next morning, yet the eggs laid by 2 of the hens not more than 40 hours after mating yielded vigorous chicks.

To learn how long the fertility of eggs continues after mating has been discontinued the cockerel was removed from a pen of year-old Plymouth Rocks. The eggs laid by the 20 hens during the next 13 days were incubated. Eight eggs laid on the last day of the test yielded 3 good chicks. Of the 27 eggs laid during the first 3 days after the removal of the male, 10 yielded chicks. The 30 eggs laid on the last 3 days of the test yielded 7 chicks.

The results show diminished fertility, but it is evident that longer test periods are needed to determine the limits of its duration after mating. The work is to be continued.

Of 25 eggs of normal shape, 8 hatched and 9 were infertile. From the same number of very long eggs 9 chickens were hatched, 12 of the eggs proving infertile. From 25 short, roundish eggs 7 chickens were hatched, 8 eggs proving infertile. In the first case, 3 chickens died in the shell when well grown and 5 by the tenth day of incubation. Similar values for the long eggs were 2 and 2, and for the short, roundish 7 and 3.

Breeding for egg production (pp. 26–40).—The tests begun at the station several years ago on the possibility of breeding hens of superior egg-producing qualities (E. S. R., 12, p. 586) were continued. The results, which are reported in detail, led to the following conclusions:

"During the 3 years in which we have been selecting breeding stock by use of the trap nests we have found 30 hens that laid between 200 and 251 eggs each in a year. Twenty-six of them are now in our breeding pens and constitute—until other additions are made to them—the 'foundation stock' upon which our breeding operations are based. Males for our use have been raised from them during the last 2 years. The number of the foundation stock, now secured, makes practicable the avoidance of inbreeding, and this is to be strictly guarded against, as it is doubtful if the inbred hen has sufficient constitution to enable her to stand the demands of heavy egg production."

As the author notes, the tests have not continued long enough for final deductions.

Poultry raising on the farm, D. E. SALMON (*U. S. Dept. Agr., Farmers' Bul. 141, pp. 16, figs. 31*).—Breeds of poultry and poultry raising are discussed, especial attention being paid to poultry houses, coops, feeding troughs, drinking fountains, and related topics.

Experiments on feeding chickens when bacteria are excluded and on the value of the intestinal bacteria, SCHOTTELIUS (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 24, pp. 1165, 1166*).—In a paper presented at the seventy-third meeting of German Naturalists and Physicians at Hamburg, September, 1901, the author reported experiments with chickens hatched and fed in such a way that bacteria were excluded. The chickens ate readily and apparently digested their food normally, yet they did not gain in weight and died after about 20 days. Tests showed that the feces were free from bacteria. At the end of the same period, chickens fed normally weighed about 3 times as much as at the beginning. When the chickens fed under sterile conditions were inoculated with intestinal bacteria from normal chickens, they became strong and gained in weight.

DAIRY FARMING—DAIRYING.

A study of rations fed to milch cows in Connecticut, C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1900, pp. 130–157*).—This study began in 1892 and has been continued to the present time. The results for 1892 to 1897 were presented at length in a previous report of the station (E. S. R., 10, p. 681) and are here briefly summarized. Preliminary experiments undertaken during the winters of 1897–98 and 1898–99 to study the value of rations based upon milk yields have not been reported. In the experiments during the winter of 1899–1900, of which a detailed account is given, the effect of feeding according to the yield of butter fat was studied with 4 private herds of 8 to 18 cows each.

"Two tests were made with each herd, covering periods of 11 or 12 days. In the first test the entire herd was fed a ration which was essentially the same for each cow; while in the second test the ration was varied according to the yields of butter fat. Two grain mixtures were used in the second test. The first, together with the coarse fodder used, was called a basal ration, which was planned to contain not far from 2 lbs. of digestible protein daily. The actual amounts of digestible protein in the basal ration varied from 1.80 to 2.30 lbs. The second grain mixture was called a protein mixture. It was usually composed of the feeding stuffs which the farmer was using, combined in such proportions as to furnish approximately 0.3 of a pound of digestible protein for each pound of the mixture.

"The plan of feeding in the second test was to use the basal ration for all the cows in the test, and to add to this varying quantities of the protein mixture according to the yields of butter fat, as shown by the results of the first test. Those cows producing from 0.50 to 0.65 lb. of butter fat in the first test received the basal ration only; those producing from 0.66 to 0.80 lb. of butter fat received 1 lb. of the protein mixture in addition to the basal ration; those producing from 0.81 to 0.95 lb. of butter fat received 2 lbs. of the protein mixture in addition to the basal ration; while those producing 0.96 to 1.10 lbs. of butter fat received 3 lbs. of the protein mixture in addition to the basal ration."

The following table summarizes the results of each test:

Original and suggested rations fed to dairy cows.

	Average weight of cows.	Digestible protein.	Fuel value.	Nutritive ratio.	Total cost of ration.	Cost, less value of manure.	Daily yield of milk.	Daily yield of butter.	Total cost of 100 lbs. milk.	Total cost of 1 lb. butter.
Herd P:	*Lbs.*	*Lbs.*	*Calories.*		*Cents.*	*Cents.*	*Lbs.*	*Lbs.*		*Cents.*
First test.....	800	2.71	31,990	1:5.3	22.4	13.9	16.6	1.01	$1.35	22
Second test ..	800	2.92	30,950	1:4.7	20.4	11.1	16.2	1.03	1.26	20
Herd Q:										
First test.....	750	2.23	28,800	1:6.0	19.5	12.0	13.9	.88	1.40	22
Second test ..	750	2.37	27,250	1:5.2	19.4	11.3	16.3	.98	1.19	20
Herd R:										
First test.....	750	1.49	27,270	1:8.8	16.8	11.2	15.9	.84	1.06	20
Second test ..	750	2.36	27,400	1:5.2	18.4	10.6	16.8	.96	1.09	19
Herd S:										
First test.....	725	1.45	27,290	1:9.1	18.6	12.8	13.5	.78	1.38	24
Second test ..	725	1.98	26,460	1:6.2	17.2	11.2	16.7	1.03	1.03	17

"In 3 of the experiments the average cost of the ration used in the second test was less than that of the one used in the first test. The cost of producing 100 lbs. of milk was also less in the second test of the same 3 experiments, while the cost of producing 1 lb. of butter was less in all cases.

"The economy of feeding according to the yield of milk or of butter fat will depend much upon what yields are taken as a basis in feeding. In these experiments there was used about 2 lbs. of digestible protein for 0.50 to 0.65 lb. of butter fat, and the protein was increased by 0.3 lb. for an increase of 0.15 lb. in the yield of fat. In the cases of 3 herds this plan of feeding proved more profitable than the one of feeding a nearly uniform ration to all the cows.

"The experiments, as a whole, help to verify the earlier work of this station, and point out the economy of feeding a larger proportion of protein than most farmers are in the habit of feeding. Rations supplying from 1.80 to 2.60 lbs. of digestible protein per day, according to the yields of milk or of butter fat, have generally proven more profitable than those furnishing less protein."

Forage for dairy cows, T. L. Haecker (*Farm Students' Rev., 7 (1902), No. 5, pp. 74, 75*).—The improvement of cows by feeding is briefly discussed, and notes are given on several forage crops.

Oil cakes in the feeding of dairy cows, J. B. Martin (*Jour. Agricole [Paris], 13 (1902), No. 143, pp. 34–38*).—The relative value of different oil cakes for dairy cows is discussed, average analyses of several oil cakes are given, and 4 rations for dairy cows are suggested.

Records of station cows; feeding dairy cows, J. S. Moore (*Mississippi Sta. Bul. 70, pp. 19*).—Summarized records are given of the station herd of Jersey cows for the calendar years 1897–1901. The average yield of milk per cow for the 4 years varied from 4,043 to 5,149 lbs., and the average yield of butter fat from 210.4 to 278.6 lbs.

Experiments in comparing cotton-seed meal with wheat bran and cowpea hay with Johnson grass hay, and on the relative feeding value of different grains, have already been noted (E. S. R., 13, p. 586).

A test was made of the effect of feeding grain to cows on good pasture. Three cows were fed cotton-seed meal and wheat bran for 6 weeks, and 6 cows were fed the same amount during the same period and a reduced quantity during the 6 weeks following. The difference in yield was not sufficient to justify the feeding of grain.

Several rations for dairy cows are suggested and notes are given on the care of cows, rearing calves, and the influence of feed on the quality of milk and butter. The station herd was fed for periods of 2 weeks each rations containing, respectively, cotton-seed meal, cotton seed, and corn-and-cob meal. There was very little difference in the score of the butter from the 3 rations.

On the average composition of milk of pure-bred cows of different breeds, F. W. WOLL (*Wisconsin Sta. Rpt. 1901, pp. 85–97*).—Original analyses of 97 composite samples of milk of 82 pure-bred cows are reported. The average results by breeds are given in the following table:

Average composition of milk of pure-bred cows.

Breed.	Number of cows.	Number of analyses.	Solids.	Fat.	Casein and albumen.	Milk sugar.	Ash.	Solids-not-fat.	Fat in solids.
			Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Holstein	70	75	11.78	3.33	3.18	4.52*	0.75	8.45	28.3
Guernsey	2	12	14.46	5.39	3.45	4.83	.79	9.07	37.3
Shorthorn	2	2	12.60	3.52	3.53	4.63	.92	9.08	27.9
Red Polled	8	8	12.57	3.74	3.34	4.75	.74	8.83	29.7

The author has also compiled data from American and foreign sources on the composition of the milk of the principal American dairy breeds. The following table gives a summary of American data as regards fat content, and also the average daily yield of milk and fat:

Average fat content and daily yield of milk and fat of pure-bred cows.

Breed.	Fat content of milk.		Daily yield of milk and fat.		
	Number of cows.	Fat.	Number of cows.	Milk.	Fat.
		Per cent.		*Pounds.*	*Pounds.*
Jersey	164	5.13	153	24.5	1.26
Guernsey	67	4.87	53	28.9	1.41
Holstein-Friesian	502	3.30	493	48.9	1.61
Shorthorn	43	3.58	39	31.9	1.14
Ayrshire	33	3.85	18	27.7	1.07
Red Polled	15	3.84	15	26.6	1.02

Devon	28	4.64	25	11.8	.55
Polled Jersey	5	4.66	5	22.9	1.07
French Canadian	5	3.99	5	27.0	1.08

Annual milk and butter production of cows owned by patrons of the university creamery, E. H. FARRINGTON (*Wisconsin Sta. Rpt. 1901, pp. 98–128, figs. 14*).—Data obtained in farm tests of 6 dairy herds supplying milk to the university creamery, and reported in Bulletin 75 of the station (E. S. R., 11, p. 673), are reprinted with the results of additional work along this line.

The milk supply of the university creamery from April, 1894, to October, 1901, is shown in tabular form. During the 6 years from 1895 to 1900, inclusive, the average number of patrons varied from 50 to 67, and the annual amount of milk received from 1,890,400 to 2,437,840 lbs. The fat content of the milk from year to year varied between 4.08 and 4.20 per cent. It was highest in October and November, with no marked changes during other months. During the summer of 1901 milk was received from 95 herds, comprising in all 872 cows.

It was found difficult to secure the cooperation of patrons in the systematic and extended testing of the milk of individual cows, even where the station furnished all the necessary material for sampling and paid the patrons for the extra time involved. From August, 1897, to April, 1901, 217 cows on 13 farms were tested, the tests representing 135 complete and 98 partial lactation periods. Only 2 or 3 of the herds were tested for this entire period. Some of the data not previously published, showing extreme variations in the butter value of the cows on different farms, are given in the following table:

Range in value of annual products.

Patron.	Number of cows in herd.	Creamery value of cows.		
		Best.	Poorest.	Average.
Farm A, 1900	11	$82.23	$20.18	$39.20
Farm A, 1901	11	64.93	23.51	38.92
Farm D, 1900	6	51.28	28.40	44.42
Farm E, 1900	5	68.16	43.47	61.20
Farm E, 1901	4	70.72	59.47	62.11
Farm F, 1900	7	58.70	31.90	44.00
Farm G, 1900	14	72.21	39.32	56.57
Farm H, 1900	8	66.08	17.23	50.00
Farm H, 1901	8	62.71	46.65	56.00
Farm I, 1901	24	67.85	14.56	39.00
Farm J, 1901	7	51.14	37.58	46.00
Farm K, 1900	8	54.61	22.35	39.00
Farm K, 1901	8	46.81	36.69	42.00

Official tests of dairy cows, 1900–1901, F. W. WOLL and R. H. SHAW (*Wisconsin Sta. Rpt. 1901, pp 73–84*).—Detailed data are given of official 7-day tests of 120 Holstein and 4 Guernsey cows. In addition 1-day tests of 6 Guernsey cows are reported. Many of the cows were tested more than once. The results are not discussed, except briefly as regards variations in the fat content of the milk of the Holstein cows. Marked variations were found in the percentages of fat in milk from individual cows. "In most cows these differences can not be explained, as their causes are not yet understood."

Comparative skimming qualities of Holstein and Jersey milk, W. D. SAUNDERS (*Virginia Sta. Bul. 122, pp. 21–29*).—A comparison was made of mixed milk from a number of Holstein cows and from the same number of Jersey cows as regards skimming qualities. In a preliminary experiment 200 lbs. of milk from each breed was separated in each of 7 trials under like conditions. The average fat content of the Holstein milk was 3.77 per cent and of the skim milk 0.077 per cent. The average fat content of the Jersey milk was 5.65 per cent and of the skim milk 0.0385 per cent. In a second experiment extending over 4 months the cows of each breed were in corresponding stages of lactation and different separators were used. In each of 29 trials 100 lbs. of milk of each breed was separated. The average fat content of the Holstein milk was 3.45 per cent and of the skim milk 0.188 per cent. The average fat content of the Jersey milk was 5.71 per cent and of the skim milk 0.095 per cent.

The Trowbridge method of calibrating Babcock test bottles, E. H. FARRINGTON (*Wisconsin Sta. Rpt. 1901, pp. 129–131, fig. 1*).—A practical method of testing the graduation of milk test bottles proposed by O. A. Trowbridge, of Columbus, Wis., is described. The test bottle is filled with water to the zero mark and a piece of metal, standardized to displace 2 cc. of liquid is carefully lowered into the bottle by means of a fine wire to below the 10 per cent mark, to which the water should rise if the graduation is correct. Precautions in making the test, such as having the bottle clean and avoiding air bubbles, are mentioned.

The use and abuse of the Babcock test, C. H. ECKLES (*Dairy and Creamery, 4 (1902), No. 2, pp. 2, 3*).

The problem of a pure milk supply, H. D. CHAPIN (*Forum, 33 (1902), No. 3, pp. 293–296*).—A brief general discussion on this subject.

On the increased resistance of bacteria in milk pasteurized in contact with the air, H. L. RUSSELL and E. G. HASTINGS (*Wisconsin Sta. Rpt. 1901, pp. 185–194, figs. 2*).—In the report of the station for 1900 (E. S. R., 13, p. 83) it was shown, in confirmation of the work of Theobald Smith, that the tubercle bacillus is more resistant in milk when heated in an open than in a closed vessel. In the present report an account is given of experiments made with a micrococcus originally isolated from pasteurized milk, to determine if similar results could be obtained with other bacteria and to ascertain why the destruction of bacteria in milk is subject to such variation.

The thermal death point of the micrococcus with a 12-minute exposure in a sealed tube was found to be about 76° C. The results were practically uniform when bouillon, skim milk, whey, and milk were used as media. In milk heated in an open vessel the micrococcus resisted a temperature of 80°. Milk drawn from beneath the surface by a siphon was sterile, while numerous colonies developed on plate cultures made from the surface membrane. The surface membrane on milk heated at 80° was removed at the end of 10 minutes and showed the presence of bacteria. A second membrane formed, which was removed at the end of another period of 10 minutes and found to be sterile. The organism was not destroyed in the film when the milk was heated for 20 minutes at the same temperature.

The experiments show an increased resistance of the organism in the surface membrane. Two possible explanations of this phenomenon were advanced, (1) a diminished temperature of the surface membrane as compared with the remainder of the milk, and (2) protection afforded the bacteria by the membrane itself. The first was disproved by removing the membrane and immersing it in water at the same temperature. The second hypothesis is therefore considered the most probable explanation.

The ripening of cream, H. W. Conn and W. M. Esten (*Connecticut Storrs Sta. Rpt. 1900, pp. 13–33*).—This article has already been noted from another source (E. S. R., 13, p. 688).

Investigations on the sources of the acid organisms concerned in the souring of milk, R. H. Burr (*Connecticut Storrs Sta. Rpt. 1900, pp. 66–81*).—The bacteria mainly concerned in the souring of milk and cream in Connecticut are *Bacillus acidi lactici*, *B. acidi lactici II*, and *B. lactis aerogenes*, of which the first is by far the most important, comprising commonly 90 per cent of the organisms present in ripened cream. Three series of experiments were conducted by the author at the Connecticut Hospital for the Insane to determine the source of these organisms, especially that of *B. acidi lactici*.

In the first and second series of experiments made in 1900 and 1901, bacteriological studies were made of the milk as drawn directly from 70 cows kept under excellent dairy conditions. The results on the whole show that lactic acid bacteria are not present in freshly drawn milk, but are a secondary contamination from some external source. The acid organisms multiply rapidly, and soon check the growth of the liquefying and other bacteria present in fresh milk. All 3 species of lactic acid bacteria were found in the air and in the dust and dirt falling from the cows during milking. The *B. acidi lactici* was present in the air in the smallest numbers.

In the third series of experiments 2 cows reacting to tuberculin were slaughtered and a bacteriological study was made of their udders. In both cases the udders were apparently normal. None of the 3 species of bacteria was found. An organism producing an acid reaction in milk without curdling was found in both udders and is described. It is considered identical with the *Micrococcus acidi lactici* of Conn and the micrococcus described by Ward (E. S. R., 12, p. 184). This organism is not considered of any significance in the souring of milk.

Starters, G. L. McKay (*Iowa Agriculturist, 1 (1902), No. 3, pp. 5–7*).—A brief popular account of the use of pure cultures in the ripening of cream.

Water in butter—an important feature, G. S. Thomson (*Jour. Agr. and Ind. South Australia, 5 (1902), Nos. 6, pp. 544–549; 8, pp. 678, 679*).—The average water content of over 50 samples of South Australian butter analyzed by the author was 11.7 per cent. The butter trier was found unreliable as a practical guide for judging the amount of water in butter. A difference of 1.4 per cent in the water content of butter followed a difference of 4° F. in the temperature of the cream when churned.

Butter salted at the rate of 5 and of $2\frac{1}{2}$ lbs. of salt to 100 lbs. of butter contained, respectively, 10.5 and 12.7 per cent of water, and butter salted in brine at the rate of 3 and $5\frac{1}{2}$ lbs. of salt to 5 gals. of water contained, respectively, 13.4 and 14.6 per cent of water. Butter salted at the rate of 5, 7, and 10 per cent contained, respectively, 15.4, 17.9, and 18.8 per cent of water. Butter worked with 19 revolutions of worker per minute contained less water than butter worked with 45 revolutions per minute. The water content was not materially affected by the size of granules. There was an improvement in the flavor of butter kept in the refrigerator for 6 weeks.

Mottles in butter, J. Findelow (*Abs. in Dairy World, 10 (1902), No. 118, p. 192*).—It is stated that the author has shown by experiments that the following are some of the causes of mottles in butter: "Ripening the cream at too high a temperature, no matter how well it may be cooled afterwards; uneven distribution of salt; use of excessive cold water; insufficient washing; insufficient working; and uneven temperature throughout the mass of butter."

The microscopic examination of butter under polarized light, H. D. Richmond (*British Food Jour., 3 (1901), No. 36, p. 374*).—According to the author, margarin mixed with butter can in many cases be detected by examination under polarized light. Ordinary pure butter gives no bright appearance under polarized light, but under several conditions it may give the appearance of butter adulterated with small percentages of margarin.

The chemical changes in the ripening of cheese, W. F. Sutherst (*Sci. Amer. Sup., 53 (1902), No. 1373, p. 22007*).—The author discusses the rôle of bacteria, enzyms, and molds in the ripening of cheese, and gives analyses to show changes in composition. The total nitrogen in the fresh curd July 10 and in the cheese August 23 and October 16 was, respectively, 4.824, 4.916, and 5.021 per cent. The amount of casein and albumin decreased from 2.203 per cent August 23 to 1.850 per cent October 16, and the albumoses and peptones from 1.586 to 1.288. During the same time the amids increased from 1.120 to 1.848 per cent, and the ammonia from 0.007 to 0.025 per cent. The methods of analysis employed were those suggested by Stutzer (E. S. R., 8, p. 667).

Influence of cold-curing on the quality of cheese, S. M. Babcock, H. L. Russell, A. Vivian, and U. S. Baer (*Wisconsin Sta. Rpt. 1901, pp. 136–161, figs. 8*).—Four series of experiments made during a period of 4 years to study the effect of curing Cheddar cheese at lower temperatures than usual are reported. In the first series 2 cheeses were kept at a temperature below freezing (25 to 30° F.) for 14 and 17 months, respectively, and then analyzed. In the second series of experiments cheeses were made with 3, 6, and 9 oz. of rennet per 1,000 lbs. of milk and cured at temperatures of 15, 33, 40, 50, and 60° F. Analyses and scorings were made at frequent intervals. In the third series cheeses were made with 3 oz. of rennet per 1,000 lbs. of milk and cured at temperatures of 15, 40, and 60° F. Analyses and scorings at frequent intervals for 7 months are given. This series and the following are not yet completed. In the fourth series of experiments milk was obtained from different regions and a larger number of cheeses were made. The curing temperatures were 15, 40, 50, and 60° F. The results are discussed at some length and general conclusions are drawn.

The authors believe that lower temperatures than usual may be employed with perfect safety in the curing of cheese. "Not only have we found in our experiments that no bitter or other undesirable flavors have been produced, but that the quality of cheese cured under these conditions was on the whole better than that of those ripened at the more usual temperatures employed (60° F. and above). Good results have been obtained at all temperatures from 33 to 50° F., although more uniform results were obtained from 40 to 50° F. This indicates that the ordinary temperatures secured in cold-storage rooms are suitable for this purpose. The experiments made at temperatures below freezing show that the course of ripening is not normal and these can not be recommended for general practice, although the casein of cheese breaks down even under these low-temperature conditions."

The flavor of the cold-cured cheese was always mild. "In no case was there any of the sharp flavors that characterize old cheese ripened at the usual temperatures. This fact is very significant in indicating that the physical breaking down of the casein and the production of the peculiar flavors that characterize ripe Cheddar cheese are quite independent of each other, although under normal temperature conditions the 2 processes progress simultaneously."

The texture of cheese cured below freezing was often soggy and crumbly. The texture of cheese cured above freezing was almost without exception improved over that of cheese cured at the higher temperatures. The body of cold-cured cheese remained quite firm and the color even. "In all the cheese cured below 40° F. small, opaque, whitish specks were produced which were scarcely noticeable when the plug was cold but became apparent upon warming. An examination of cold-storage goods in various places revealed the fact that this was a common occurrence, and in the judgment of buyers was neglected as a factor in determining values, as these specks were generally inconspicuous and apparently had no effect on the flavor of the product. The nature of these bodies is yet under investigation."

Curing at lower temperatures than usual enhanced the keeping quality of the cheese and lessened the losses from shrinkage and mold.

"The system of cold-curing here proposed differs from simple cold storage of ripened cheese in that these low temperatures are employed from the beginning of the ripening period. In our experience the quality of such cheese, as measured by the standards of flavor, texture, and body, are materially improved, with the result that the value of the cheese per pound is somewhat increased, and particularly so when the lengthening of the commercial period of the cheese is taken into consideration. Not only is the value per pound improved, but the losses due to mold and shrinkage are diminished. . . .

"It should be kept in mind that the expense of this system of curing is somewhat greater than the old method, but the returns will undoubtedly more than balance the debit side."

The desirability of curing cheese by this method in central stations is briefly discussed.

Influence of sugar on the nature of the fermentations occurring in milk and cheese, S. M. Babcock, H. L. Russell, A. Vivian, and E. G. Hastings (*Wisconsin Sta. Rpt. 1901, pp. 162–176, figs. 2*).—The influence of environment on the production of flavor in cheese is discussed and several series of experiments are reported.

In milk from which the milk sugar had been removed by dialysis a putrefactive fermentation replaced the usual acid fermentation. Indol was invariably produced. In dialyzed milk to which glucose and sucrose were subsequently added no disagreeable odor developed. These experiments having shown that sugar prevents the putrefaction of proteid compounds in milk, the authors were led to study the effect of the removal of milk sugar upon the flavor of cheese.

Cheese was made from curds which had been thoroughly washed in order to remove the sugar, and cured along with cheese made from the same milk according to the usual Cheddar process. Analyses and scorings were made at frequent intervals. Cheese made from washed curds developed a putrid flavor, which became very marked. The cheese was also inferior in texture and body. During the first 2 months the total soluble nitrogen was greater in the Cheddar cheese as compared with the cheese from washed curds, but later this relation was reversed. Liquefying bacteria developed more rapidly than nonliquefying forms in cheese from washed curds.

"The more rapid peptonization of the casein in Cheddar cheese, as shown by the increased amounts of soluble proteids present, is undoubtedly attributable to the fact that this type of cheese contained a larger amount of digestive enzyms (galactase and pepsin), as the washing of the curd would to a considerable extent remove these ferments. But as the condition in the washed cheese permits the development of the digestive or liquefying bacteria, the soluble by-products formed as a result of the action of the enzyms which they secrete accumulate in the cheese and so increase the rate of digestion."

The effect of adding sugar to washed and also to normal curds was studied. Cheese from washed curds without the addition of sugar was adjudged worthless in a few months, while cheese from washed curds to which 2 to 3 lbs. of sugar per 1,000 lbs. of milk had been added developed no putrid flavor. The sugar series, however, did not equal the Cheddar controls. The conclusion is drawn that the addition of sugar to washed curds restored in part at least the conditions that prevailed in normal curds.

"When this conclusion is taken in connection with the results obtained when normal Cheddar and washed cheese were compared, it seems to indicate that the types of bacteria that may develop in a cheese are closely related to the presence and amount of sugar which the cheese contains; that the liquefying, digesting organisms are able to thrive better when the sugar is removed, and that under these conditions putrid flavors are produced that are entirely different from those normally occurring in typical Cheddar cheese. It is possible that the development of these liquefying forms and the appearance of the undesirable flavors noted are nothing more than mere coincidences, but when these two conditions are brought about through the removal of the sugar, and the normal conditions in large measure restored through the addition of sugar, it seems highly probable that the two phenomena are causally related.

"The whole series of experiments, not only with cheese but those made with dialyzed milk, seem to harmonize perfectly and indicate that the type of bacteria that develops in milk and cheese is largely controlled by the sugar content."

A pinhole organism in cheese curd, G. S. Thomson (*Jour. Agr. and Ind. South Australia, 5 (1902), No. 8, p. 682, pls. 3*).—An organism causing numerous small holes and a bitter flavor in cheese was isolated and studied. The appearance of milk inoculated with pure cultures of the organism and of curd and cheese from inoculated milk is shown.

Print cheese, E. H. Farrington (*Wisconsin Sta. Rpt. 1901, pp. 132–135, fig. 1*).—A method of making print cheese employed at the university is described. The usual method employed in making Cheddar cheese is followed except as regards pressing. The bottom of the rectangular mold used is a carved board which stamps a design and marks the cheese into prints. Cheeses made for cutting into 15 one-pound prints, each measuring $2\frac{1}{2}$ by $2\frac{1}{2}$ by $4\frac{1}{4}$ in., are illustrated. No difficulty was experienced in curing in the regular Cheddar cheese curing room.

Roquefort cheese, F. de Barrau (*Jour. Agr. Prat., n. ser., 3 (1902), Nos. 7, pp. 215–217; 9, pp. 294–296*).—An account of the Roquefort cheese industry.

Testing rennet, A. Rolet (*Laiterie, 12 (1902), No. 3, pp. 17–19*).—Directions are given for determining the quantity of rennet preparation to be added to milk in cheese making.

Statistics of oleomargarine, oleo oil, and filled cheese, 1900 and 1901, R. A. Pearson (*U. S. Senate, 57th Cong., 1st session, Doc. 168, pp. 22*).—Statistics relating to the production and distribution of oleomargarine, oleo oil, and filled cheese for the fiscal years 1900 and 1901. Statistics for previous years were published in the report of the Bureau of Animal Industry for 1899 (E. S. R., 13, p. 180).

Oleomargarine, J. H. Garber (*Twelfth Census United States, Census Bul. 138, pp. 16*).—Statistics of the manufacture of oleomargarine for the year ended May 31, 1900.

VETERINARY SCIENCE AND PRACTICE.

The relation of animal diseases to public health, D. D. Grout (*Sanitarian, 47 (1901), No. 383, pp. 310–324*).—The author discusses in a general way the danger from transmission of various animal diseases to man. Among the more important of such diseases mention may be made of glanders, rabies, anthrax, tuberculosis, milk sickness, smallpox, diphtheria, scarlet fever, and plague. Especial attention is devoted to a discussion of the problem of tuberculosis and the value of the tuberculin test in detecting the presence of incipient cases of this disease.

Insects as a living medium for cultivating infectious diseases of man and animals, C. von Holub (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 7, pp. 284–287*).—The author conducted experiments in cultivating the organisms of ulcus molle and syphilis in a large variety of living insects, including nearly all the orders of insects. It was found that the organisms grew rapidly and luxuriantly in the body cavity and various organs of all insects with which experiments were made. A rapid growth and development of the organisms took place, whether the insects were inoculated with the hypodermic needle or by being allowed to feed upon the organisms. It was found that by infecting an insect and then placing it in a cage with other insects of the same or different species, all the other insects ultimately became infected with the pathogenic organisms. The author calls attention to the great importance of these facts for the future development of the bacteriology of infectious diseases.

Influence of the body cavity on the hæmolytic power of serum from other animals, S. J. Meltzer (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 7, pp. 278–281*).—Numerous experiments in connection with this problem were carried out by the author. It was found that the serum of cattle operated vigorously in disintegrating the red blood corpuscles of rabbits. When the serum was previously kept for from 10 to 14 days at a temperature of living rooms, it was found that its hæmolytic property was entirely lost. Fresh normal serum of cattle maintained for 3 hours in the body cavity of a rabbit loses almost entirely its power of dissolving the red blood corpuscles of rabbits. During the experiment it was found that the serum of cattle when placed in the body cavity of a dead animal soon lost its hæmolytic property. It is concluded from these experiments that immune as well as normal sera lose their hæmolytic power by remaining for different lengths of time in the body cavity of another animal. It is believed that the disappearance of this property of the serum may be due to alexins.

Involution forms of bacteria on salt-agar, which resemble the plague bacillus, A. Rosenfeld (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 17, pp. 641–653*).—The author investigated these forms in a number of bacteria, including the bacillus of mouse typhus, of hog cholera, swine plague, ferret plague, chicken cholera, pseudo-tuberculosis, and the bacillus of Danysz. The various bacteria were cultivated for a considerable time on artificial nutrient media, at a temperature of 37° C. The usual formula was adopted for making a slightly alkaline agar medium, but instead of adding only 5 gm. of sodium chlorid to the liter of bouillon, from 20 to 50 gm. were used. The growth of different bacilli under these conditions showed great differences. In general there was a noticeable check to the development of bacteria in the presence of a large percentage of salt. The organisms of swine plague, pseudo-tuberculosis, and chicken cholera produced only a weak growth, even in the presence of slight quantities of salt, while the organisms of hog cholera, mouse typhus, and ferret typhus showed quite vigorous development in the medium containing 5 per cent of salt. In connection with the decrease in growth a modification of the form of individual elements was noted. In the organisms of hog cholera, ferret plague, and mouse typhus this phenomenon was first observed in media with a high salt content, and consisted simply in an enlargement of the rods and the formation of threads with considerable branching. In cultures of the bacillus of Danysz in media containing 5 per cent of salt, many swollen forms were observed, club-shaped, spindle-shaped, or even spherical. The various modifications of form which occurred under the influence of different percentages of salt in the nutrient media are described in detail. The author maintains, however, that these involution forms produced under the influence of salt should not be mistaken for the plague bacillus.

Injurious effects of sorghum on stock, T. E. COULSON (*Queensland Agr. Jour., 9 (1901), No. 1, p. 133*).—The author gives various instances of poisoning from eating sorghum in various stages. In one case 17 animals in one herd died from eating sorghum; in other instances cattle were allowed to feed upon sorghum in all its stages without suffering any harm. In most cases death resulted very quickly, even more quickly than from strychnin poisoning. An urgent request is made for a further investigation of this subject.

Report of the division of veterinary science, J. A. GILRUTH and C. J. REAKES (*New Zealand Dept. Agr. Rpt. 1901, pp. 186–268, pls. 9*).—Two outbreaks of anthrax occurred, and both were traceable to the use of "green bone" fertilizer. For some time shipments of this material have been accompanied by declarations that the bones were thoroughly sterilized, but these statements seemed to be of little value. Details are given of circumstances surrounding the 2 outbreaks of the disease.

Hog cholera occurred in 4 districts in outbreaks of greater or less severity. The majority of the outbreaks took place between July and December. Repeated outbreaks of the disease occurred on a certain farm, and after one appearance of the disease the hogs were all killed off, the buildings and food material burned, fences destroyed, and the land plowed. It is believed that by keeping hogs off this land for a period of 2 years the disease may be eradicated. The agglutination test in cases of hog cholera proved to be very reliable, according to the observations of the authors.

A case of verminous pleurisy combined with pneumonia was observed in a pig, but no further cases of the disease could be discovered. The worm which was apparently the cause of the disease was not identified, but is described as resembling trichinæ but being considerably smaller.

A considerable portion of the time of the veterinary staff was occupied with work in connection with tuberculosis. A large amount of inspection work was done, and the tuberculin test was applied on request from cattle owners. Detailed reports on the prevalence of tuberculosis and on the results of tuberculin tests are made by a number of the veterinary staff. The members of the staff are unanimous in their opinion as to the great value and reliable character of tuberculin when carefully and properly used. A large amount of tuberculous infection was observed in pigs which were fed on by-products of the dairy.

A number of cases of actinomycosis among cattle were observed, 2 cases being found in the udder of dairy cows.

Considerable attention was given to the study of cirrhosis of the liver, also known in horses as "Winton disease." Experiments showed that the disease could be successfully treated in horses by repeated doses of strychnin internally. The same disease was observed among a number of cattle. The authors were unsuccessful in attempts to isolate any pathogenic organism. It is believed that the primary seat of infection is not in the liver, and further search will be made for the specific organism in the alimentary tract or in some other organ.

Brief notes are given on epithelioma, especially as affecting the external eye membranes, œsophagus, and liver. An unusual number of cases are reported of hypertrophy of the thyroid glands in calves, lambs, and colts. This produced an appearance similar to that of goitre in human beings. Many calves were born with enlarged thyroids, and 150 lambs from a herd of 450 ewes were lost on account of this disease. The trouble appears to be associated with malnutrition and a condition of anemia in the parent animals. No outbreaks of the disease occurred among sheep which required especial investigation during the year. The number of deaths from malignant œdema after shearing or docking was much less, and this improvement is believed to be the result of better sanitary measures.

Notes are given on the various pathological material which was received for investigation at the laboratory of the veterinary division. A detailed report is given on the inspection of horses for unsoundness in selecting animals for military use, on inspection of dairies, veterinary inspection, and cruelty to animals.

An account is given of an investigation of a plague among rats occurring in Auckland. The appearance of the bacillus and the behavior on different media are described. A number of inoculation experiments were made in order to determine the virulence of the plague bacillus for rats and other experimental animals. These experiments indicate that little is to be feared from infection of rats and guinea pigs with the plague bacillus. In several instances artificially-infected rats were killed and eaten by other rats and the infection was not transmitted.

Brief notes are also given on a trip to Europe for the purpose of securing Shorthorn dairy cattle free from tuberculosis and improved stallions for service in the Colony.

Summary of results of experiments with tuberculous cows, C. S. Phelps (*Connecticut Storrs Sta. Rpt. 1900, pp. 175–187*).—The author summarizes results of experiments with 4 cows upon which several preliminary reports have already been made (E. S. R., 11, pp. 890, 891; 12, pp. 1086, 1087). At the tenth application of the tuberculin test, March 19 and 20, 1900, none of the cows reacted. Another test made on September 28 of the same year gave a reaction in 1 cow. Detailed notes are given on the progress of the disease in the different cows. In the early part of the fourth year 3 of the cows began to show signs of decline, but the fourth continued to give a good flow of milk and appeared to be in a vigorous state of health when killed in November, 1900. All of the cows were slaughtered and post-mortem examinations were made by Dr. N. S. Mayo. The disease was found to be generalized in 2 of the cows and somewhat restricted in the other 2.

In May, 1900, 3 calves from healthy cows were selected for further experiments on the infectiousness of milk of the tuberculous cows. The calves were placed in a small pasture and all possible precautions were taken to prevent transmission of the disease in any way except by the milk. The calves did not react to the tuberculin test on May 24 or on September 28, after having been fed over 4½ months on tuberculous milk. After the second test the calves were fed no more milk. One calf died on November 29 and was found on post-mortem examination to be tuberculous. The other calves were kept by themselves during the winter, and after having been tested with tuberculin in February, 1901, without reaction, were sent to pasture in May of that year.

As in previous reports on this subject, the author concludes that the danger of the spread of tuberculosis through the milk of infected animals is not so great as generally supposed. This is especially true during the earlier stages of the disease; after the tuberculosis has become generalized the danger is greater and all reasonable precautions are necessary to prevent the spread of the disease from such long-standing cases. It is recommended that all cows be tested with tuberculin and that those which react should be separated from the rest, and that the nonaffected animals should be subsequently tested at least once per year.

The extent to which tuberculin investigations among cattle in Sweden have been useful, L. G. L. Regner (*K. Landt. Akad. Handl. Tidskr., 40 (1901), No. 2, pp. 134–145*).—Since 1897 the Swedish Government has expended from $6,760 to $21,000 annually for the investigation and eradication of tuberculosis among cattle. The early investigations showed that about 30 per cent of the animals which were examined were tuberculous. Large herds showed a greater percentage of reacting animals. In 1897–98 the percentage of reacting animals in herds of from 2 to 15 was 25.5 per cent; in herds of from 16 to 30, 28.4 per cent; in herds of 31 to 60, 37 per cent; in herds of 61 to 100, 47.8 per cent; and in larger herds, 54.4 per cent. Of all the animals examined about 37 per cent were found free from tuberculosis. The isolation of nonreacting animals and feeding calves on pasteurized and boiled milk have given favorable results. During 1900 about 20,000 cattle were placed under special protection against the contagion of tuberculosis. The author ascribes great importance to annual disinfection of dairy barns and stables.—F. W. WOLL.

Congenital tuberculosis, V. VOIRIN (*Deut. Tierärztl. Wchnschr.*, *9* (*1901*), *Nos. 30, pp. 305–308; 31, pp. 315, 316*).—This paper was read before the general meeting of the Association of Veterinarians at Wiesbaden. The author gives a critical review of the literature relating to this subject and discusses the various possibilities of transmission of the disease to the fœtus before birth. It is considered that such transmission is possible in animals and man. Statistics, however, indicate that the percentage of congenital tuberculosis is exceedingly small. Of 370,000 calves slaughtered in Prussia only 73 were tuberculous.

Biochemical studies on the Bacillus tuberculosis, P. A. LEVENE (*Jour. Med. Research*, *6* (*1901*), *No. 1, pp. 135–144*).—The author investigated the chemical composition of *Bacillus tuberculosis* for the purpose of determining, so far as possible, the relationship between its composition and virulence. The pathogenic power of the bacillus in animal organisms appears to be due, according to the author, to its resistance toward destructive influences of the animal cells, rather than to any toxin which it secretes. Detailed notes are given on complete chemical analyses of samples of tubercle bacilli from different culture media. The different samples of tuberculinic acid which were obtained differ considerably in their composition, and it appears from these experiments that this acid is less stable than other nucleic acids.

On the value of tuberculin, C. J. POUND (*Queensland Agr. Jour.*, *8* (*1901*), *No. 6, pp. 476, 477*).—It is urged that the tuberculin test should be applied every 6 months, whether the animals appear to be healthy or not. Instances are cited in which a considerable portion of the herd has been found to be tuberculous within 3 months after the herd had successfully passed the tuberculin test. A thorough and repeated use of the tuberculin test is considered the most effective means for exterminating tuberculosis.

Anthrax, J. C. ROBERT (*Mississippi Sta. Bul. 72, pp. 12, fig. 1*).—The author gives a brief historical account of outbreaks of anthrax in Mississippi. The nature of the disease is discussed and notes given on the various domestic mammals and birds which are susceptible to infection by anthrax. It is believed that the rapid spread of anthrax in the recent outbreak in the State was due to inoculation of healthy animals by the bites of insects. An examination of the stomach contents of a fly which had sucked blood from infected animals demonstrated the presence of numerous anthrax bacilli. The symptoms of anthrax are briefly described. In controlling this disease little encouragement is received from any line of medical treatment. The main reliance must be placed on preventive measures. These should include a rigid quarantine, the destruction of carcasses of all animals which die of anthrax, the vaccination of animals which may have been exposed to the disease, and the thorough disinfection of premises where outbreaks have occurred. Animals may also be protected against such flies which may carry infection by smearing with offensive oily preparations.

Means of immunizing cattle against cattle plague, A. DUDUKANOV (*Arch. Vet. Nauk, St. Petersburg*, *31* (*1901*), *No. 10, pp. 897–900*).—In this paper a brief summary is given of the results obtained by the author in extended experiments with this disease. It was found that after vaccination the animal at once acquired a great resisting power against cattle plague. From artificially immunized animals blood may be drawn in large quantities, and frequently without greatly injuring the health of the animal or weakening the protective power of the serum obtained from such blood.

Blackleg, F. SIVORI (*Bol. Agr. y Ganadería*, *1* (*1901*), *No. 13, pp. 3–13, pl. 1*).—In various herds of cattle in Argentina outbreaks of blackleg occurred and the mortality in such herds varied from 2.5 to 6 per cent. The author made elaborate investigations for the purpose of definitely identifying the disease. An examination was made of the blood and various organs of affected animals and inoculation experiments were conducted on rabbits and guinea pigs, with the result that all tests proved conclusively that the disease was blackleg.

Texas fever, J. C. ROBERT (*Mississippi Sta. Bul. 69, pp. 15, figs. 4*).—During the past 2 years 65 northern cattle were vaccinated against Texas fever at the station; 18 of these were purchased by the station for experimental purposes, and of this number 16 passed through the period of inoculation fever and are at present carrying ticks and in good health. Of the other 47, 20 were vaccinated only once and 27 twice. Of the whole 47, 22 were kept free from ticks until after recovery from the inoculation fever, and none of these died; 25 were subjected to tick infestation before recovery from the fever, and 3 of these died. The nature of Texas fever is briefly described. A record is given of the various symptoms which appear in the inoculated animals. In one case the temperature reached 108° F. Notes are also given on the appearance of various organs as noted in post-mortem examinations. From the author's observations it is concluded that immunity to Texas fever is not transmitted to offspring, that nonimmune cattle of all ages are subject to the disease, and that southern cattle if prevented from becoming infested with ticks are equally as susceptible as northern. Blood inoculation is considered the most practical method of conferring immunity. Inoculated cattle should be kept entirely free from ticks until after recovery from inoculation fever. It is recommended that cattle ticks should not be entirely exterminated on farms south of the quarantine line for Texas fever. It is urged that a few ticks are necessary for the purpose of producing mild forms of the disease and thus immunizing southern cattle. Brief notes are given on the rations which should be fed during periods of fever, and on methods of vaccination.

Actinomycosis, F. SIVORI (*Bol. Agr. y Ganadería, 1 (1901), No. 1, pp. 21–25*).—The author gives a general account of this disease, including statistics on its prevalence in various countries. In parts of Argentina the disease prevailed in an epizootic form. Of 9,540 cattle which were examined 8 per cent were found infected with the disease. The different forms of actinomycosis are described according to their characteristic symptoms, and treatment with iodid of potash is recommended.

Operation for neomorphs of actinomycotic nature, C. DORN (*Berlin. Thierärztl. Wchnschr., 1901, No. 32, pp. 492–494*).—The author gives in detail the symptoms and operative procedure adopted in the surgical treatment of actinomycosis in various parts of the body. These operations were made on actinomycotic tumors in the cheek, reproductive organs, nasal passages, eyelids, and bones.

Pleuro-pneumonia (*Agr. Jour. Cape Good Hope, 19 (1901), No. 3, pp. 195, 196*).—This disease having become prevalent among cattle in the Transvaal and the Orange River Colony, a proclamation was issued by the government to prevent the importation of cattle from these countries into noninfected regions.

Milk fever, P. BRIDGE (*Farm and Home, 20 (1901), No. 1000, p. 100*).—The term milk fever is considered inappropriate for this disease, on account of the fact that the temperature of affected cows is usually normal, or even subnormal. Preference is given to the term postpartum paralysis. While it is generally recognized that cows which have once had milk fever are very susceptible to the disease at all future times of calving, yet it is argued that such animals may be legally declared sound.

Milk fever, J. C. ROBERT (*Mississippi Sta. Bul. 71, pp. 6, fig. 1*).—A brief account of the cause, symptoms, and treatment of this disease. The author recommends the use of Schmidt's treatment.

Parturient paresis: Schmidt's treatment, W. R. FRENCH (*Amer. Vet. Rev., 25 (1901), No. 5, pp. 356–358*).—Notes are given on the symptoms, treatment, and results, in 6 cases of this disease, 5 of which recovered under treatment with iodid of potash. In all these cases antiseptic precautions were observed and hourly massage of the udder was rigidly enforced.

The eradication of sheep scab, MATTHEISEN (*Deut. Tierärztl. Wchnschr., 9 (1901),* *No. 34, pp. 345, 346*).—Statistics are presented showing the prevalence of sheep scab in different districts and in different herds. The following regulations have been adopted for the control of this disease in 1902: All sheep are to be inspected between January 1 and April 1 in order to determine whether or not they are infected; the inspection must be made without previous announcement; scabby sheep are to be treated as soon as possible after shearing, according to the method of Fröhner. Sheep are first to be treated for a period of 3 or 4 days on the scabby spots with a mixture of 1 part English creolin, 1 part alcohol, and 8 parts green soap. They are then to be washed, and then dipped for 2 minutes in the 2½ per cent aqueous solution of creolin, after which the scabby spots are to be brushed for about 3 minutes and the sheep to be again dipped in the solution. The treatment is to be repeated in 1 week.

Treatment of sheep scab, FRÖHNER (*Deut. Tierärztl. Wchnschr., 9 (1901), No. 38, pp. 385–387*).—The results obtained by treatment of this disease according to Fröhner's method are discussed in a critical manner. It is believed that the failures from the use of this method are due to the creolin. Of 3,866 sheep treated for scab by this method in 1900, 3,500 were later slaughtered on account of the development of scab which appeared to be unchecked by the treatment. It is believed that the treatment would be much more effective if applied before shearing, since the solution would be thus held longer by the wool and the scab mite would be subjected to a longer exposure to the insecticide.

Heartwater in sheep and goats (*Agr. Jour. Cape Good Hope, 19 (1901), No. 5, pp. 302–314, figs. 2*).—Experiments made by the Colonial Veterinary Department indicated that the disease known as heartwater was not communicated by ordinary sources of infection. It was suspected that some species of tick was concerned in the transmission of the disease from animal to animal. The entomological department made experiments along this line and demonstrated conclusively that the bont tick (*Amblyomma hebræum*) was an agent in the transmission of the disease.

Further experiments were made in the artificial communication of the disease by means of ticks. It was shown that even a limited infestation by young bont ticks which fed during their larval stages on the diseased animals will produce the disease in a severe form in susceptible animals. An excessive infestation by other ticks which have been allowed to feed on diseased animals does not produce the disease in susceptible animals.

Inoculation against swine erysipelas, KÜHNAU (*Milch Ztg., 30 (1901), No. 24, pp. 372–375*).—The nature and cause of this disease are discussed in a general way. The author describes the usual symptoms of swine erysipelas and gives an account of experiments which have thus far been conducted in perfecting a protective serum for inoculation and in devising a convenient and practical method for making the inoculation.

Lymphangitis saccharomycotica equorum, A. DEDYULIN (*Arch. Vet. Nauk, St. Petersburg, 31 (1901), No. 9, pp. 814–822*).—This disease is known under a number of names, including African glanders, trembling lymphangitis, epizootic lymphangitis, and curable farcy. The symptoms and pathological changes produced by this disease are described in detail. In experiments with remedies for treatment of the disease the author obtained different results, according to the susceptibility of the affected horses and according to the virulence of the infection. In some cases all forms of treatment were unsatisfactory, while in others fairly satisfactory results were obtained by a combination of internal and external remedies. The colloidal silver preparations were given in intravenous injections in doses varying according to the nature of the diet. For external application upon ulcerated areas, caustic potash, iodin with glycerin, corrosive sublimate, naphthaline, and iodoform gave fairly good results.

Observations on skin diseases which have appeared in cavalry horses in the region of the loins and under the saddle since the introduction of the new army saddle, KALKOFF (*Ztschr. Veterinärk., 13 (1901), No. 4, pp. 149–172,* *figs. 5*).—Detailed notes are given on the structure of the saddle recently introduced in army service and on the parts of the horse with which the saddle comes in contact during movement. A number of skin diseases have been produced in a considerable proportion of horses by rubbing of the saddle and the evidence for considering the saddle as the cause of these diseases is critically discussed. One of the more important forms of skin diseases which is produced in this manner is eczema. It is believed that the most effective means for preventing the development of these diseases lies in further improvement of the form of saddle so as to reduce so far as possible friction during the movement of the horse.

The most common irregularities of the teeth of the horse, I, C. McCulloch (*Virginia Sta. Bul. 119, pp. 157–169, figs. 13*).—Brief notes on the irregularities in the number of the teeth, form and union of the incisors, form of the central enamel, in the length and width of the jaws, and from the effects of cribbing and excessive or insufficient wear. A brief account is also given of fraudulent modification of the appearance of the teeth.

The most common irregularities of the teeth of the horse, II, C. McCulloch (*Virginia Sta. Bul. 120, pp. 11, figs. 10*).—Descriptive notes on irregularities of the molar teeth of the horse which are due to excess or lack of wear, or to the employment of fraudulent means in changing their appearance.

Canine rabies: Its distribution and eradication, J. Ehrhardt (*Die Hundswut: Ihre Verbreitung und Bekämpfung. Aarau: Emil Wirz, 1900, pp. 87, charts 7*).—The author gives a statistical account of the presence of rabies in Germany, Hungary, Austria, Belgium, France, England, Italy, Roumania, Bulgaria, Servia, and Switzerland. Especial attention is given to the unusually extensive outbreak of the disease in Switzerland, and to the various means which were adopted for checking the progress of rabies in that country.

Clinical pathology of rabies in dogs, W. Lellmann (*Berlin. Thierärztl. Wchnschr., 1901, No. 31, pp. 465, 466*).—In 3 dogs the circumstances surrounding their infection were well known. The point of infection was in the neighborhood of the central nervous system. Paralysis of the lower jaw was manifested early in the progress of the disease, and the symptoms of so-called dumb rabies were pronounced. The development of the dumb or rabid form of the disease, in the author's opinion, does not depend so much on the place at which infection occurred, but upon the virulence and quantity of the infectious material, upon the susceptibility of the nervous system to rabies, the nearness of the point of infection to the medulla oblongata, and upon the temperament of the animals which are infected.

A new method for rabies inoculations and for removing the spinal cord, T. Oshida (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 25, pp. 988–991*).—The author describes in detail his method of inoculating rabbits with rabies virus through the optical foramen. When carefully carried out this operation is considered safer than any other which has yet been devised. Injury to the optic nerve does not usually occur and the operation has the great advantage of being simple and convenient. If the virus is injected into the eyeball or orbital cavity the animal does not develop rabies, and if the virus is injected too deeply into the brain the animal dies from cerebral hemorrhage. These dangers may be avoided by careful manipulation so that the rabies virus is deposited just under the dura mater.

In removing the spinal column of rabbits the author disinfects the surrounding tissue, makes two sections of the spinal column in the cervical and lumbar regions, and then introduces a rod with sterilized absorbent cotton on the end. By pressing upon this rod the spinal cord is easily forced out from the other end of the canal.

Transmission of malignant jaundice of the dog by a species of tick, C. P. Lounsbury (*Agr. Jour. Cape Good Hope, 19 (1901), No. 11, pp. 714–724*).—In cooperation with the colonial veterinary surgeon, Doctor Hutcheon, the author undertook a number of experiments for the purpose of determining the possible connection of ticks with the disease of dogs commonly known as malignant jaundice, and sometimes less properly called distemper and dog plague. At first experiments were made with the ticks in the younger stages, and no infection took place. Later experiments with adult ticks showed that the blood parasites which cause the disease are readily transmitted by adult ticks. The common dog tick of the Cape region, and the one with which experiments were made, is *Hæmaphysalis leachi.* It appears that infection can pass from the mother ticks into the eggs, and that the blood parasite requires some time for reaching a stage in which infection of the dog can take place. It appears, therefore, that the ticks are not merely transmitting agents but true secondary hosts for the blood parasites.

A previously undescribed chicken epizootic, A. Krausz (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 25, pp. 980–982*).—An epizootic outbreak occurred in a large hennery where fowls have recently been imported from Italy. The disease attacked chiefly the young fowls, and affected birds quickly lost their appetite, remaining standing in one place, and appeared sleepy. Underneath the lids an œdematous swelling appeared, and in many cases the eyelids were stuck together. Death occurred in a majority of cases 10 to 15 minutes after the chief symptoms appeared. Post-mortem examinations showed that the veins were filled with blood and all vital organs were congested. The liver was somewhat enlarged. Bacteriological investigations showed the presence of an organism which was identified as *Staphylococcus pyogenes albus.* Inoculation and feeding experiments with this organism gave negative results, but no young chickens were to be had for such experiments. Isolation of diseased birds and disinfection of their quarters were completely effective in checking the progress of the disease.

Note on the veterinary service for the year 1900 (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 3, pp. 149–152*).—Statistics are given on the distribution and prevalence of glanders, rabies, sheep pox, foot-and-mouth disease, anthrax, pleuro-pneumonia, tuberculosis, and cattle plague. A brief account is also given of a number of animals slaughtered in the abattoirs, the number of cattle and sheep imported, and the activity of the vaccine institute for the year.

Veterinary pharmacy and toxicology, A. F. Delaud and O. Stourbe (*Pharmacie et toxocologie vétérinaires. Paris: J. B. Baillière & Sons, 1900, pp. 496*).—In this volume the authors present a discussion of veterinary medicines; the preparation and administration of drugs; weights, measurements, and doses of drugs; determination of the density of liquids; the principal forms of medicines; and the classification of drugs used in veterinary practice. In the second part of the volume the subject of toxicology as applied to domesticated animals is treated.

The stock-owner's adviser, C. K. Rhodes (*Richmond, Va.: B. F. Johnson Publishing Co., 1901, pp. 574, figs. 140*).—In this volume the author discusses the history, habits, breeding, hygiene, dietetics, anatomy, and treatment for various diseases of horses, cattle, sheep, swine, and dogs. The diseases of the horse receive the most extended treatment. These diseases are discussed under the following chapters: Inflammation, fractures of bones, diseases of bones, diseases of joints, lameness, sprains and strains, diseases of the feet, wounds, injuries to the mouth, tumors, eye diseases, hernia, diseases of the head and neck, of the skin, of the veins and arteries, lymphatics, diseases of the reproductive organs, diet during disease, symptoms of diseases, contagious diseases, diseases of the respiratory organs, of the alimentary canal, of the nervous system, liver, spleen and pancreas, kidneys, heart, diaphragm, parasitic diseases. The purpose of the volume is to furnish the ordinary stockman in simple language a description of symptoms and treatment for the diseases which are ordinarily met with in domesticated animals.

Insurance of slaughterhouse animals, Siedamgrotzky (*Deut. Thierärztl. Wchnschr., 9 (1901), No. 16, pp. 157–160*).—The author outlines the proposed plan by which animals about to be slaughtered are insured. The chief features are concerned with the matter of indemnity paid by the government for animals suffering from contagious diseases.

AGRICULTURAL ENGINEERING.

Drainage of southern Indiana, J. F. NEWSOM (*Jour. Geol., 10 (1902), No. 2, pp. 166–181, pl. 1*).—This article discusses the drainage of that portion of southern Indiana which "lies south of a line running from Indianapolis east to the Ohio State line, and from Indianapolis southwestward along the course of the West White River to the mouth of that stream." The drainage of this area is dependent upon geological structure, and is not controlled primarily by glacial drift. The drainage, except in the eastern part of the area, is toward the southwest, following the dip of the strata.

Report on irrigation investigations for 1900, E. MEAD (*U. S. Dept. Agr., Office of Experiment Stations Bul. 104, pp. 334, pls. 25, figs. 29*).—This is an account of investigations on the methods of conserving, distributing, and using water in irrigation made in 1900 under the supervision of the expert in charge of irrigation investigations of this Office. It includes a review of the principal results of the investigations, by E. Mead; a discussion of methods and results, by C. T. Johnston; and reports by special agents and observers as follows: Irrigation along Pecos River and its tributaries, by W. M. Reed; Irrigation in the Salt River Valley, by W. H. Code; Irrigation at the Arizona Experiment Station farm, by A. J. McClatchie; Duty of water under Gage Canal, Riverside, Cal., 1900, by W. Irving; Irrigation investigations in Nevada, by J. M. Wilson; Water administration in Utah, and Duty of water on Big Cottonwood Creek, 1900, by R. C. Gemmell; Irrigation under canals from Logan River, by G. L. Swendsen; Irrigation under the Great Eastern Canal, Platte County, Nebr., by O. V. P. Stout; The use of water for irrigation at Wheatland, Wyo., by C. T. Johnston; Duty of water on the Laramie Plains, 1899, by W. H. Fairfield; Duty of water in Idaho, by D. W. Ross; Use of water in irrigation in the Yakima Valley, by O. L. Waller; Irrigation investigations in Montana, 1900, by S. Fortier; Progress report on silt measurements, by J. C. Nagle. The investigations made during 1900 followed the same general lines as those of the preceding year (E. S. R., 12, p. 895), although better equipment and increased skill and experience of those in charge have permitted their extension in several important directions. Special attention has been given to a study of the duty of water and the conditions which influence it, since information on this point is necessary as a basis for planning irrigation works and to assist in framing contracts for supplying water, which will be in accord with the necessities of users and enable those charged with the division of streams to properly perform their duties.

"An examination of the reports of the different experts and special agents shows close agreements between the average rainfall and average duty of water in 1899 and 1900. These averages are based on measurements made in 10 States and Territories, at stations which are scattered over a region which embraces about one-third of the United States.

	Feet.
In 1899 the average rainfall for the irrigation period was	0.44
In 1900 the average rainfall for the same period was	.45
The average depth of water applied to crops in 1899 was	4.35
The average depth of water applied in 1900 was	4.13"

One of the more important new lines of investigation reported on is the determination of the volume and fertilizing qualities of the silt carried by the rivers of the West and Southwest. This has an important bearing on the question of the duration of storage works, and the results reported show that the construction of reservoirs should always be preceded by a careful investigation of this subject. Examinations of samples of water from the principal rivers of Texas and the results of studies of the silting up of the Austin and Pecos reservoirs are reported with suggestions as to methods of dealing with the silt problem.

Irrigation in the United States, E. MEAD (*U. S. Dept. Agr., Office of Experiment Stations Bul. 105, pp. 47, pls. 12, fig. 1*).—The testimony of the expert in charge of irrigation investigations of this Department before the United States Industrial Commission June 11 and 12, 1901. This testimony "presents a review of the irrigation situation in the United States, including not only the arid region of the West, but also the humid sections of the South and East. The testimony also deals briefly, but in some detail, with the practical aspects of extending public aid to irrigation, either through the State or national governments."

Irrigation practice among fruit growers on the Pacific Coast, E. J. WICKSON (*U. S. Dept. Agr., Office of Experiment Stations Bul. 108, pp. 54, pls. 10, figs. 7*).—This bulletin, prepared under the direction of Prof. Elwood Mead, expert in charge of irrigation investigations of this Office, presents the results of a special investigation into the conditions, extent, and methods of irrigation as practiced among fruit growers on the Pacific Coast.

Irrigation possibilities of the Lower Colorado River, J. B. LIPPINCOTT (*Forestry and Irrig., 8 (1902), No. 4, pp. 153–159, figs. 4*).

A complete irrigation system, A. P. DAVIS (*Twentieth Century Farmer, 1902, No. 69, pp. 1, 2*).—An argument in favor of irrigation development under national control.

Earthen reservoirs, A. P. DAVIS (*Forestry and Irrig., 8 (1902), No. 3, pp. 121–123*).—Brief directions for the construction of such reservoirs.

Hydrography (*Twenty-first Ann. Rpt. U. S. Geol. Survey, 1899–1900, pt. 4, pp. 768+XI, pls. 156, figs. 329*).—This includes a report by F. H. Newell of progress of stream measurements for the calendar year 1899 similar to those of previous years (E. S. R., 12, p. 797), a preliminary description of the geology and water resources of the southern half of the Black Hills and adjoining regions in South Dakota and Wyoming, by N. H. Darton; and a paper on The High Plains and their utilization, by W. D. Johnson. "The first paper discusses the results of measurements of the flow of various streams in different parts of the United States, the data being presented in diagrammatic form as well as by statistical tables. The arrangement adopted for this progress report is a geographic one, beginning in the extreme northeastern part of the United States and ending in the extreme southwestern." The second paper deals more particularly with the artesian water supply of the region studied and "the results obtained have interest and value not only to the citizens in the vicinity of the Black Hills, but to a still larger class who, in all parts of the country, are seeking an underground supply of water." The article also treats of the topography, geology, soils, mineral resources, climate, and timber of the region. The third paper gives "the result of field work begun in 1896 in western Kansas and extending over portions of Nebraska, Colorado, Oklahoma, and Texas." The article discusses the general characteristics, origin, and structure of the High Plains, the deficiencies of climate, the necessity for irrigation, and the impossibility of general irrigation on account of the insufficiency of the water supply.

Relative velocity in streams, D. T. SMITH (*Nature [London], 65 (1901), No. 1678, p. 174*).—The author claims "that friction against the bed increasing progressively from the middle to the margin divides every stream longitudinally into two halves, which roll spirally toward each other. This spiral being determined by the friction, its helix rises with the speed, or the increased friction depending on the speed, which in turn depends on the slope of the channel. It follows that beyond a certain speed the stream loses all the momentum gained by its fall in beating with the two outward moving undercurrents against the channel walls. In this way the stream attains its kinetic equilibrium."

Public water supplies (*Ohio State Bd. Health Rpt. 1899, pp. 88–206, 451–732, charts 57*).—Reports on the water supplies for various towns in Ohio and on the measurement of the flow of the rivers of Ohio and their value as sources of public water supply.

The evolution of reaping machines, M. F. MILLER (*U. S. Dept. Agr., Office of Experiment Stations Bul. 103, pp. 43, pls. 9, fig. 1*).—This article summarizes the history of the various stages in the development of reaping machines. It has not been attempted to refer to all inventions in connection with reaping machines, but as a rule only those are considered which have marked some important advance in the development of the perfected modern machine. A partial bibliography of the subject is given.

The test station and information bureau for agricultural machines of the Bavarian Academy of Weihenstephan, 1896–1901, H. PUCHNER (*Vrtljschr. Bayer. Landw. Rath., 7 (1902), No. 1, pp. 44–55*).—A brief account is given of the work done by this institution during the period named.

Eighth annual report of the commissioner of public roads for the year ending October 31, 1901 (*New Jersey State Com. Pub. Roads Rpt. 1901, pp. 197, pls. 34, map 1*).

Roads and national welfare, J. P. O'REILLY (*Nature [London], 65 (1902), No. 1680, p. 222*).—A brief discussion of this topic.

Roads; their construction and maintenance, A. GREENWELL and J. V. ELSDEN (*London: Whittaker & Co., 1901, pp. VII+280*).

Refrigerating machines; their construction and use, R. STETEFELD (*Die Eis- und Kälteerzeugungs-Maschinen. Ihr Bau und ihre Verwendung in der Praxis. Stuttgart: Max Waag, 1901, pp. 488, pls. 35, figs. 313*).

MISCELLANEOUS.

Fourteenth Annual Report of Alabama Station, 1901 (*Alabama College Sta. Rpt. 1901, pp. 321–344*).—This includes the organization list of the station, a financial statement for the fiscal year ended June 30, 1901, a report of the director on the work and publications of the station during the year, and brief departmental reports.

Thirteenth Annual Report of Connecticut Storrs Station, 1900 (*Connecticut Storrs Sta. Rpt. 1900, pp. 194; sup., pp. 12*).—This includes the organization list of the station, a financial statement for the fiscal year ended June 30, 1900, a report of the director on the different lines of station work during the year, and miscellaneous articles noted elsewhere. A supplement to the report contains a list of the publications of the station since its organization.

Nineteenth Annual Report of New York State Station, 1900 (*New York State Sta. Rpt. 1900, pp. 494*).—This contains the organization list of the station, a financial statement for the year ended September 30, 1900, a list of periodicals received by the station, a meteorological record noted elsewhere, and reprints of Bulletins 174–195 of the station on the following subjects: Fumigation of nursery stock (E. S. R., 12, p. 273); a parasite of carnation rust (E. S. R., 12, p. 358); inspection of concentrated commercial feeding stuffs during 1900 (E. S. R., 12, p. 877); report of analyses of commercial fertilizers for the spring and fall of 1900 (E. S. R., 12, p. 1026); inspection of Babcock milk-test bottles (E. S. R., 12, p. 1083); an anthracnose and a stem rot of the cultivated snapdragon (E. S. R., 12, p. 1055); miscellaneous notes on injurious insects (E. S. R., 13, p. 65); a fumigator for small orchard trees (E. S. R., 13, p. 71); experiments on the sulphur-lime treatment for onion smut (E. S. R., 13, p. 58); notes on some dairy troubles (E. S. R., 13, p. 85); the influence of the temperature of curing upon the commercial quality of cheese (E. S. R., 13, p. 86); the New York apple-tree canker (E. S. R., 13, p. 59); the sterile fungus Rhizoctonia as a cause of plant diseases in America (E. S. R., 13, p. 55); commercial fertilizers for potatoes (E. S. R., 13, p. 41); spraying for asparagus rust (E. S. R., 13, p. 147); a little-known asparagus pest (*Agromyza simplex*) (E. S. R., 13, p. 159); report of analyses of Paris green and other insecticides in 1900 (E. S. R., 13, p. 108); a fruit disease survey of western New York in 1900 (E. S. R., 13, p. 148);

the substitution of soda for potash in plant growth (E. S. R., 13, p. 121); San José scale investigations, I (E. S. R., 13, p. 369); San José scale investigations, II (E. S. R., 13, p. 370); and director's report for 1900 (E. S. R., 13, 396).

Annual Report of South Carolina Station, 1901 (*South Carolina Sta. Rpt. 1901, pp. 21*).—This includes the organization list of the station; reports of the agriculturist, assistant agriculturist, State chemist, botanist, veterinarian, and horticulturist; and a financial statement for the fiscal year ended June 30, 1901. The report of the State chemist contains a summary of fertilizer analyses made during the year.

Fourteenth Annual Report of Tennessee Station, 1901 (*Tennessee Sta. Rpt. 1901, pp. 16*).—This includes the organization list of the station, a brief report of the president of the University of Tennessee relating to the work of the station, departmental reports reviewing the different lines of work and stating briefly some of the results obtained during the year, a list of available station publications, and a financial statement for the fiscal year ended June 30, 1901. Some results of soil analysis and of cooperative fertilizer experiments are given in the report of the chemist. The report of the horticulturist is noted elsewhere.

Annual Report of Virginia Station, 1901 (*Virginia Sta. Rpt. 1901, pp. 14*).—This contains the organization list of the station, a financial statement for the fiscal year ended June 30, 1901, and brief reports of the director and heads of departments.

Eighteenth Annual Report of Wisconsin Station, 1901 (*Wisconsin Sta. Rpt. 1901, pp. 352*).—This contains the organization list, a report of the director on the work and publications of the station, miscellaneous articles abstracted elsewhere, lists of exchanges and acknowledgments, analyses of fertilizers reprinted from Bulletin 86 of the Station (E. S. R., 13, p. 236), text of the Wisconsin fertilizer law and the feeding-stuffs law, and a financial statement for the fiscal year ended June 30, 1901.

Eleventh Annual Report of Wyoming Station, 1901 (*Wyoming Sta. Rpt. 1901, pp. 30*).—This includes the organization list of the station; a report of the director containing notes on the work and equipment of the station and abstracts of Bulletins 46–94 of the station issued during the year; a financial statement for the fiscal year ended June 30, 1901; and departmental reports outlining work in progress during the year.

Finances—meteorology—index (*Maine Sta. Bul. 78, pp. 177–200+8*).—This contains a list of acknowledgements, meteorological observations noted elsewhere, a financial statement for the fiscal year ended June 30, 1901, an index to the annual report for 1901 (Bulletins 70–78), the organization list of the station, brief notes on the aim and work of the station by the director, and reprints of newspaper bulletins published in 1901, as follows; The Colorado potato beetle, feeding-stuffs inspection law, and the chinch bug.

Bulletins of Alabama Station (*Index to Vol. IX, Buls. 113–117, and Ann. Rpt. 1901, pp. 447–464*).

Experiment Station Work, XIX (*U. S. Dept. Agr., Farmers' Bul. 144, pp. 32, figs. 9*).—This number contains articles on the following subjects: Maintenance of soil fertility, Thomas slag, rotation of crops, gardening under glass, winter irrigation of deciduous orchards, improvement of American grapes, condimental and medicinal cattle and poultry foods, feeding rice meal to pigs, dressing and packing poultry for shipment, the curing of cheese, and an improved cow stall.

Crop Reporter (*U. S. Dept. Agr., Division of Statistics Crop Reporter, 3 (1902), Nos. 10–12, pp. 8 each*).—Crop conditions on April 1, 1902, are given and various articles of a statistical nature are included in these numbers, among which are the following: The cotton trade and industry of Japan, the production of cork, principal crops of Russia, the United States coffee trade with South America, crops and live stock in Manitoba, principal crops of Ireland and changes in crop areas since 1855, proposed efforts to extend maize culture in Russia, the banana trade, imports of beef into the United Kingdom, hop crop of Germany, the Department's cotton statistics, the world's flax crop, the horse trade of the United States with foreign countries, the world's corn crop, production of honey and wax in 1899, production and exports of Argentina, and the horse trade of Canada with foreign countries.

Domestic animals in the United States (*Twelfth Census United States, Census Bul. 156, pp. 22*).—This bulletin gives the statistics of domestic animals on farms and ranges, by States and Territories, on June 1, 1900. Statistics of the domestic animals not located on farms or ranges were published in Census Bulletin 17. The aggregate number of domestic animals in the United States is given as follows: Neat cattle 69,438,758, horses 21,216,888, mules 3,445,029, asses and burros 111,450, sheep 61,837,112, swine 64,694,222, goats 1,949,605.

Report of the enological station of Haro, Spain (*Mem. An. Estac. Enol. Haro, 1901, July, pp. 24*).

The Babcock medal presentation, W. A. Henry (*Wisconsin Sta. Rpt. 1901, pp. 6–9*).—A brief account is given of the presentation to Dr. S. M. Babcock of the medal voted by the Wisconsin legislature in 1899 (E. S. R., 12, p. 999). Brief extracts are given from the addresses of Governor Robert M. La Follette, Ogden H. Fethers, and Ex-Governor W. D. Hoard.

NOTES.

Alabama College.—C. C. Thach, M. A., for about 15 years professor of English in the college, has been elected to the presidency, made vacant by the death of William LeRoy Broun.

California University and Station.—Leroy Anderson, in charge of dairy husbandry, has been elected principal of the new California Polytechnic School which has been located at San Luis Obispo. The last legislature appropriated $50,000 for the establishment of such a school, and a tract of about 280 acres of land for a farm and campus has been bought. One or more buildings will be erected during the coming summer. For the present attention will be confined to agricultural instruction on a practical scale, but later it is expected to broaden the scope of the school to include various trades.

Delaware Station.—The governing board at a recent meeting adopted a resolution calling for the appointment of a committee to investigate the method of managing the station by the council, with a view to a possible change. The station council is at present an administrative body, composed of the staff of the station and the committee on agriculture from the board of trustees.

Purdue University and Station.—C. S. Plumb, professor of animal husbandry and dairying in the university and directer of the station, has resigned to accept the chair of animal husbandry in the Ohio State University.

Kentucky Station.—C. W. Mathews, horticulturist, has withdrawn from the station and will hereafter devote his time exclusively to college work.

Louisiana University.—Congress, by a recent act, has ceded to the university the tract of land embracing approximately 150 acres, together with the buildings, which it has occupied subject to the needs of the United States for military purposes. The tract was originally a military fort, and some years ago was turned over to the State for the use of the university until such time as it might be needed for purposes of defense. Mr. John Hill, a prominent sugar planter near Baton Rouge, has given $32,000 to the university for the erection of a fireproof library building as a memorial to his son. The State legislature at its recent session appropriated $47,000 for the erection of a dormitory and a building for the mechanic arts department, and $8,500 for furnishing the library building mentioned above. The usual appropriation of $15,000 for the experiment stations was made, and the appropriation for the State geological survey, which is under the charge of the director of the stations, was increased to $2,500 a year for 2 years.

Massachusetts College and Station.—S. T. Maynard has resigned his position as professor of horticulture in the college and horticulturist of the station.

Michigan College and Station.—At a recent meeting of the board, C. D. Smith was relieved from the superintendency of the farmers' institutes and made agriculturist of the station, in addition to his duties as director. L. R. Taft was made superintendent of institutes and also State inspector of orchards and nurseries in place of D. W. Trine, resigned. Professor Taft is succeeded as head of the horticultural department in the college by U. P. Hedrick, who also becomes superintendent of the grounds. Philip W. Ayres, of New Hampshire, was elected professor of forestry. The board also adopted plans for the new mechanical building, which will contain rooms for the departments of electrical engineering and physics and for civil engineering, and appropriated $5,000 for the equipment of the new bacteriological laboratory.

Montana Station.—R. W. Fisher has been appointed assistant horticulturist of the station.

Oklahoma Station.—A. G. Ford, B. S., who was assistant in chemistry in this station from 1898 to 1900, has been appointed associate chemist. A. B. McReynolds, assistant in chemistry, has severed his connection with the station. An assistant in soils and crops has been provided for, but the position has not yet been filled.

Pennsylvania College and Station.—John A. Woodward and Chas. W. Stone have been reelected members of the board of trustees, and Chas. M. Schwab and M. E. Conard have been elected trustees *vice* Amos H. Mylin and Samuel R. Downing Chas. A. Browne, jr., has been promoted to the rank of first assistant chemist of the station and instructor in agricultural chemistry in the college, and T. I. Mairs, assistant superintendent of the correspondence courses, has also been appointed instructor in animal industry in the college. At the recent commencement gifts to the college were announced as follows: By Andrew Carnegie, $100,000 for a library building; by Mr. and Mrs. Chas. M. Schwab, $60,000 for an assembly hall, and by Jas. Gilbert White, class of '82, $10,000 for a graduate fellowship and $10,000 additional for three undergraduate scholarships. Thorne M. Carpenter, assistant chemist, and W. T. Carter, fellow in agricultural chemistry, are no longer connected with the station.

Texas College and Station.—J. H. Connell, director and agriculturist, has resigned to accept the position of assistant manager of *The Texas Farm and Ranch*, and will enter upon his new duties during the latter part of July. This, with the previous resignations, will make an entire change in the agricultural and horticultural departments in the college and station, except in the case of the assistant agriculturist in the station. F. W. Mally, State entomologist, failed of reelection at the June meeting of the governing board.

Utah College and Station.—James A. Wright, horticulturist, has resigned to accept a position as agricultural editor in connection with *The Salt Lake Tribune*.

West Virginia University and Station.—A. D. Hopkins, entomologist, has resigned to accept the position of forest entomologist in this Department. K. C. Davis, horticulturist, has resigned to accept the position of principal of the Dunn County Agricultural School, in Wisconsin.

Association of American Agricultural Colleges and Experiment Stations.—The announcement has been issued of the sixteenth annual convention of the association, to be held at Atlanta, Ga., October 7, 1902. "Atlanta and Athens have been selected on invitation of the city, the chamber of commerce, the citizens, and the State University. Arrangements have been made for holding one session at Athens and a meeting of station workers at Experiment. After adjournment, excursions will be offered at liberal rates to Lookout Mountain, Tenn., and Asheville, N. C., the latter at the invitation of Mr. George Vanderbilt. Concessions, it is expected, will be obtained from the railroads and the hotels. Full details of all necessary matters will be sent out by the secretary well in advance of the date of the meeting. The general programme and programmes for the sections will be duly issued, together with circulars of information respecting hotel rates and places of meeting."

Briarcliff School.—The School of Practical Agriculture at Briarcliff Manor, N. Y., has outgrown its present quarters on the farm of Mr. W. W. Law, and it has been decided by the trustees to seek a new location, where there will be greater opportunity for growth. A tract of 415 acres near Poughkeepsie, N. Y., has been secured for a permanent site, and the erection of the necessary buildings will proceed as rapidly as funds are available. It is hoped to transfer the school from Briarcliff Manor some time next spring. For the immediate needs of the school a fund of $200,000 is being raised by subscription. Additional subscriptions have been asked for, and it is hoped eventually to swell the fund to $1,000,000. Speaking of the school, Director George T. Powell says: "At Poughkeepsie, to an extent greater than has been possible at Briarcliff, the students will handle farm machinery and tools, prepare the soil, apply fertilizers, sow the seed, plant orchards, make gardens and greenhouses, propagate flowers, control insects, treat the diseases of plants and animals, and perform every practical detail necessary to be understood on a big or a little farm. It should be said that our aim is chiefly to make the school a practical institution in every respect. Our students have come from different sections of the country, and mostly from the cities, and our experience has been that the actual physical labor of farming incident to our course of instruction in field work does not in any way detract from the attractiveness of study, even in the cases of young women students, of whom we have not a few."

School of Aviculture in France.—A short account of the poultry farm school at Gambais, near Houdan, France, is given in a current number of the *Journal of the Board of Agriculture* of Great Britain. This school was founded by decree of the Minister of Agriculture in 1888, on a farm where the present directors had successfully carried on artificial incubation for some years previously. It is in the midst of a district where poultry farming is extensively followed. The practical appliances used at the school are more or less the invention of the original founders, who have introduced many improvements in existing machinery. The course, which is very practical, covers 3 months, and three courses are given from February to October. Pupils of either sex over 15 years of age are received alternately. A certain amount of elementary education is presupposed. The fees for the three months' course, including tuition, board, and lodging, are about $70. On leaving the school, pupils who have shown capacity to act as instructors in aviculture receive a certificate of competency, which, it is said, enables them without difficulty to obtain employment in this line of industry. Some 500 pupils have passed through the school since its foundation in 1888.

Personal Mention.—We note from *Science* that Douglas A. Gilchrist, professor of agriculture and director of the agricultural department at Reading College, has been appointed professor of agriculture at the Durham College of Science, Newcastle, in succession to Prof. T. H. Middleton, who was recently elected to the chair of agriculture in the University of Cambridge.

According to *Gardeners' Chronicle*, A. Millardet, professor of botany in the University of Bordeaux, France, has retired from active duty. Mr. Millardet's name is associated with the discovery of Bordeaux mixture, one of the widest known and most satisfactory of fungicides.

Dr. E. Zacharias, formerly director of the Botanic Gardens at Hamburg, has become director of the Hamburg Botanical Institute. This includes the Botanic Gardens, Economic Botanical Museum and Laboratory, and the Section of Seed Control and Plant Pathology.

Prof. Dr. Augusto Napoleone Berlese has been elected professor of phytopathology in the Royal High School for Agriculture in Milan, Italy.

Dr. J. B. de Toni, lately at Camerino, has become professor of botany and director of the Botanic Gardens at the University of Sassari, Italy.

Dr. Alessandro Trotter, late assistant in the Botanical Institute of the University of Padua, has been chosen professor of natural history and phytopathology in the School for Grape Culture and Enology at Avellino, Italy.

Dr. A. Fischer, professor of botany in Leipzig, has been called to the position of professor of botany and director of the Botanic Gardens at the University of Basel, Switzerland.

Dr. Treub, director of the Botanical Institute and Gardens at Buitenzorg, Java, is away on leave until March, 1903.

Miscellaneous.—A bill authorizing the transfer of supervision of national forest reserves, now under the jurisdiction of the General Land Office of the Interior

Department, to the Department of Agriculture, was defeated in the House of Representatives June 10, considerable objection developing on the score of additional expense and divided authority in administration.

In the consideration by the House of Representatives of the bill for the irrigation of arid lands, the agricultural colleges were brought forward quite prominently and in a way to show that they have many champions. The bill, as is known, dedicates to the construction of irrigation works the funds arising from the sale of public lands in the arid States, which is the principal source from which the Morrill fund is derived. A clause in the bill provides that in case the receipts from the sale of public lands not embraced by the irrigation bill are insufficient for the purposes of the second Morrill act, the deficiency shall be made up from any moneys in the Treasury not otherwise appropriated. An amendment to this clause, offered by Mr. Grosvenor, was to the effect that no part of the proceeds from the sales of public lands required to carry into full effect the provisions of the act of August 30, 1890 (the second Morrill act), should be set apart or diverted to the irrigation fund; in other words, that the colleges should be first provided for. The advocates of this amendment claimed that the second Morrill act practically mortgaged a portion of the proceeds from public lands; that the wisdom of this action was agreed to at the time the act was passed, and that the clause in the irrigation bill as it stood would place the colleges, in case of a deficiency, which was almost certain, at the mercy of Congress. The amendment was discussed at much length, and the point was made that the bill would take away the main support of the colleges, and would thus make them a direct burden upon the other resources of the Treasury. The position of the experiment stations in this regard was also pointed out, as well as the effect which the passage of the bill might have upon the pending bill to provide schools of mines in connection with the land-grant colleges. The opponents to the amendment claimed that as the bill stood it made the necessary provision for meeting the emergency, and that special legislation would not be necessary in order to provide the funds. It was quite evident that the friends of the irrigation bill realized how seriously Mr. Grosvenor's amendment would affect its operation, by withholding so large an amount from its working fund. The amendment was defeated and the irrigation bill, which has now become a law, carries the provision mentioned above for maintaining the appropriation under the second Morrill act.

The Board of Agriculture of Great Britain has given notice that the Colorado potato beetle has again made its appearance at Tilbury. It requests farmers and gardeners to examine their potato plants and to send to the board any insects suspected to be the potato beetle for investigation. The board has issued a leaflet with colored illustrations of the beetle, which it is sending out free of charge upon application.

The Department of Agriculture of Victoria has recently begun the publication of a journal similar to the monthly publications of a number of the Australian colonies. In it will be reported the results of the investigations and studies carried on by the officials of the Department of Agriculture, together with other matters of interest to those engaged in agricultural pursuits. The first number contains over 100 pages on subjects relating to horticulture and fruit growing, cereals, tobacco industry, economic entomology, live stock, dairying, and veterinary science. The articles are popular in character, and the initial number presents an attractive appearance. It should prove not only a useful source of information to the farmers of Victoria, but a means of following up what is being done in experimental and educational branches in that country.

The following note regarding an international agreement for the protection of birds useful to agriculture, concluded at Paris on March 19, is taken from *Science:* The parties to the agreement are Belgium, France, Greece, Lichtenstein, Luxemburg, Monaco, Austria-Hungary, Portugal, Sweden, Switzerland, and Spain. The agreement contains 16 clauses, of which the first states that birds useful to agriculture, especially insect eaters and birds enumerated in the lists attached to the agreement, are to enjoy an unconditional protection, and that the destruction of these birds, their nests, eggs, and broods is to be forbidden. Certain nocturnal birds of prey, as well as woodpeckers, bee-eaters, swallows, and several birds of the sparrow species, appear as useful birds, while ravens, magpies, jays, and others are branded as mischievous. Some exceptions protect sporting and other rights. Italy, a country in which the capture of northward-bound birds is a regular trade, does not appear amongst the signatories. According to statistics recently given in the Reichstag, no less than seven hundredweight of migratory birds were put on the Verona market at one time. The agreement will shortly be submitted to the Reichstag.

At the last session of the South Australian House of Assembly a resolution was adopted affirming the desirability of making experiments with cereals, manures, etc., under the auspices of the Department of Agriculture. In view of the present condition of the finances, the Minister of Agriculture has decided that for this season the work will be confined to experiments with fertilizers and with rust-resistant wheats. The experiments with fertilizers will be cooperative, and will be carried on at nine different places, there being, as a rule, 10 plats of 2½ to 3 acres each at the different places. About 20 rust-resistant wheats have been selected for trial in different localities. These experiments are likewise cooperative, the farmers all being members of the agricultural bureau and entering into an agreement to sell one-half of the crop of each variety to the department at 6d. above the local market price, "the object being to afford the neighboring farmers an opportunity of securing seeds of desirable wheats at a reasonable price." The Minister of Agriculture anticipates, another season, undertaking experiments in the fertilizing of vineyards, orchards, and pastures, as there is believed to be good opportunity for useful work in each of these directions.

EXPERIMENT STATION RECORD.

Vol. XIII. No. 11.

The biological activities of the soil, and their relations to soil fertility and to the availability of soil constituents, have not yet received the attention which their importance warrants. The study of maintenance of fertility and crop production has been confined too generally to supplying the necessary commercial fertilizers to meet the temporary demands. This field has been experimented upon quite thoroughly, and the limitations of fertilizer experiments are quite keenly felt by some who have followed that line for a series of years.

Little progress has as yet been made in studying availability or the conditions which influence or control it. It is now recognized as being associated with the biological activities taking place within the soil, and these in turn as influenced by a variety of conditions such as temperature, moisture, the atmosphere of the soil, etc. The process of nitrification, for example, may be changed to denitrification by unfavorable conditions of temperature and moisture, resulting in the dissipation of the nitrogen which has been made available by the first process. But the effect which different methods of tillage and soil management have upon the available plant food in the soil is only known to a very limited degree; for we have only slight knowledge of the character of the changes which are taking place and of the influences which favor or retard the desirable processes.

A plea for investigation along this line, in addition to fertilizer experiments, was made in a recent paper by W. Farrer before the Australasian Association for the Advancement of Science.[1] In this paper Mr. Farrer points out that the transformation of potential plant foods into available and assimilable forms is accomplished by the chemical, physical, and biological activities which are constantly occurring in the soil, and expresses the opinion that available materials may be produced in increased quantitities by increasing and stimulating these activities. He advocates making "such improvements in

[1] The absolute dependence of agricultural progress upon experiments, and suggestions in regard to some directions in which experimental work should be done for the agriculture of Australia. Reprinted in Agr. Gaz. New South Wales, 13 (1902), pp. 206–214.

our methods of tilling and managing the soil as will enable us to increase, and, if possible, give direction to the activities of the chemical and biological (bacterial) forces which are incessantly at work in it, and cause them to change potential plant foods into available forms in greater abundance than they do by means of our present methods." He reasons that "as the soil is known to be in general well supplied with potential plant foods—sometimes within 8 inches of the surface with enough for some hundreds of crops—it would be a far more philosophical course to make it our aim to learn how to make the greatest possible use of these potential plant foods than to devote our energies almost exclusively, as until lately we have been doing in our field experiments, to the study of hand feeding our crops with manures." He does not contend that we shall be able to dispense altogether with manures and fertilizers, but believes that "the potential plant foods which are already in the soil can be made to contribute far more largely, and that they should be made to contribute as much as possible to the nourishment of our crops; and that eventually, under ordinary conditions and for ordinary (as distinguished from intensive) farming, it will only be found necessary to hand feed crops with such plant foods as the soil is naturally or may become by cropping insufficiently provided with, or particular crops require in special abundance."

This proposition is not a novel one, but comparatively little experimental work has yet proceeded from it as a basis. The importance of the biological agencies at work in the soil has probably only been hinted at. The desirability of a better knowledge of them as a means of progress was forcibly pointed out by Professor Conn in his recent book on Agricultural Bacteriology. Professor Conn says:

"The whole problem of the soil fertility is inextricably woven with bacterial fermentation. From the origin of the soil, through its use by plants and the subsequent destruction to their original condition of the products formed, we find nearly every step accompanied by bacterial action. The continued fertility of the soil is thus associated with bacterial life. In the future the problem of the proper treatment of soil for the use of agriculture will be, in a very large degree, a problem of the proper control of bacteria. Agriculturists must learn to stimulate the bacterial actions which are advantageous and check those which are disadvantageous, if they would insure the continuance of soil fertility."

Referring to the possibility of influencing chemical changes in the soil, Mr. Farrer ventures the suggestion that "it may be we shall learn how, either by particular methods of treatment, or by the addition of certain substances, to give direction to, as well as increase, the chemical activity amongst the constituents of the soil. If we could learn, for instance, how to make soluble some of the insoluble silica in the soil, we might promote the formation of zeolitic substances, which are valuable for reasons of the same character as are the double humates." A number of American investigators, notably Hilgard and Snyder, are working in this direction, and have shown the important relation which the zeolitic substances and humates bear to soil fertility.

As Mr. Farrer remarks, the great need is for methods of investigation. "We must make the best use we can of our knowledge of principles for planning our experiments, and, when they fail, for finding out the causes of our failures, which we must go on eliminating until we have succeeded." The difficulties of the work should inspire rather than deter the investigator, and the possibilities for the exercise of originality and for securing results of the highest importance should attract a considerable number of investigators to take up the work systematically.

To a certain extent we are in a transition stage as regards soil and fertilizer investigations. We long since abandoned the theory of returning to the soil all of the fertilizing ingredients which the crop takes from it. We are relying upon the soil to furnish a certain amount of these substances in available form year by year, and are searching for a means of determining approximately how much of these available substances may be expected from a given soil, as a basis for the intelligent application of fertilizers. We know that the soil is of most complicated constitution; that its composition is constantly changing, mainly in the vegetable matter, as are also its physical conditions, particularly temperature and moisture, and that in consequence chemical changes of a complicated and obscure character are continually taking place in the fertile soil, through which small quantities of assimilable plant food are released from unavailable forms.

Considering these facts in connection with what is already known of the life of the soil, it would seem that studies of these biological and chemical agencies, and the conditions of culture and soil management favorable to their action or control, should at least form a prominent part in the study of problems of soil fertility.

The successful opening of the Graduate School of Agriculture at Columbus, Ohio, on July 7 is encouraging and inspiring to those who have been instrumental in arranging for it, and to the instructors who take part in it as well. The national character of the school was shown by the presence at the inaugural exercises of the Secretary of Agriculture, the president of the Association of American Agricultural Colleges and Experiment Stations, and a member of the executive committee of that association who has long been associated with agricultural education, as well as by the attendance of students from 25 different States, representing every section of the country.

There has been comparatively little effort in our agricultural colleges in the direction of providing courses of post-graduate instruction in the different branches of agriculture. The need for such advanced study for men who are to become instructors in the agricultural colleges, investigators in the experiment stations, and leaders in other fields of agricultural endeavor is being felt. This is a healthful sign, for it indicates that we are making progress. The establishment of a graduate school of agriculture, even though it covers only one month, is a significant step, for it marks a distinct epoch in the development of agricultural education.

The school is unique, for, so far as known, no such summer school of agriculture, embracing in its corps of instructors so many of the leading agricultural teachers and investigators, has ever been held by any country before. The opportunity to meet these specialists and gain something of their points of view is in itself an unusual one, which should prove of great advantage to the students; and the number and character of the latter will insure the instructors an inspiring audience.

An important result of the school will be to show some of the lines along which agriculture may profitably be specialized, and to open up to the younger college graduates the opportunities which are afforded for advanced study. It will serve also to bring out the strength of the workers in their respective lines, and to enforce the desirability of making provision for university instruction in agriculture. As the dean of the school said in his opening address: "In an unusual measure we believe this school will furnish inspiration and up-to-date knowledge to workers in our agricultural institutions gathered out of many States and Territories; but beyond this we believe that in its ultimate results the school will greatly aid in the formation of public opinion in favor of the more thorough and rational organization of agricultural education and research."

The early literature of agriculture, except for the writings of a comparatively few authors, is very little known, even in the most general way. With a view to encouraging greater familiarity with the earlier writers and preparing the way for a study of their works, Dr. Max Güntz has issued a Handbook of Agricultural Literature, in three parts. The first part appeared in 1897 and the third or final part has just been issued. In his preface Dr. Güntz expresses the belief that this early agricultural literature is a relatively neglected subject, even among specialists, but that it is of value in tracing the history of agriculture and the development of our theories, and might well form a part of the training of men who are taking advanced study in that branch.

The work represents a vast amount of search through the literature of different periods as found in a number of large libraries, and, so far as known, is the first attempt to bring these writings together in a systematic manner. The arrangement is by periods. Beginning with the Greek and Roman writers, the author follows the development of the literature which was epoch making or especially noteworthy for the times, down through the centuries, frequently noting briefly the conditions of agriculture which were prevalent at the different periods.

The work does not consist merely of bibliographical lists, but is more descriptive in character. In most cases some account is given of the books cited and the ground covered by them, and there are frequently brief biographic notes on the writers. Portraits of some 38 of these writers are given. Particular phases of the subject are discussed in several general articles. The evolution of different classes of books, as the "husbandman literature," agricultural handbooks, agricultural calendars, etc., is traced, and later the development of periodical literature.

For the recent literature the book is far more complete for Germany than for any other country; and the list of periodicals for the United States displays a lack of familiarity with our literature and sources of publication which is lamentable in a book of this character.

Such a work should possess considerable value as a basis for historical study, and in itself it makes it possible for the reader to get a general survey of the early writers on agriculture and their works.

1302—No. 11—02——2

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Report of the professor of chemistry, R. Harcourt (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 35–42*).—Analyses are here reported of soap, sorghum silage, several grains used as poultry foods, and of drippings from washed and unwashed curds made to determine the loss of casein due to washing. The loss before salting was greater in the case of washed curd, but after salting was greater in the case of curd which had not been washed. The total loss of casein was increased by washing. Work with sugar beets is noted elsewhere.

Miscellaneous chemical analyses, A. D. Selby and J. W. Ames (*Ohio Sta. Bul. 127, pp. 175–218*).—Analyses of various materials made by the chemical department during the years 1892–1901 are reported. These include corn and corn products, clover and timothy hay, wheat and wheat products, strawberries, blackberries, raspberries, currants, gooseberries, cherries, grapes, lead arsenate, Paris green, crude petroleum, dried blood, nitrate of soda, sulphate of ammonia, boneblack, phosphatic slag, acid phosphate, phosphate rock, muriate of potash, tankage, mixed fertilizers, corncob ashes, wood and coal ashes, jadoo fiber, liquid manure, limestones, and mineral waters. Some of the analyses have previously been reported (E. S. R., 11, pp. 142, 1046). Data concerning the average composition of many of the materials are collated from publications of other stations.

Treatise on agricultural chemistry (*Ann. Agron., 27 (1901), No. 12, pp. 594, 595; Rev. Sci., 4. ser., 17 (1902), No. 2, pp. 51–53*).—Notes on the second edition of Dehérain's well-known *Traite de Chimie Agricole*, which was presented to the French Academy December 9, 1901.

A plan for cooperating in the study of available plant food, C. C. Moore (*U. S. Dept. Agr., Bureau of Chemistry Circ. 9, pp. 8, figs. 3*).—A plan for the cooperative study of the soil of four fiftieth-acre plats bearing, respectively, oats, spring barley, spring rye, and spring wheat. The methods of sampling and analysis are described in detail. The proposed method of determining available phosphoric acid and potash given in this circular has already been noted (E. S. R., 13, p. 927).

On the determination of citrate-insoluble phosphoric acid, C. D. Harris (*Jour. Amer. Chem. Soc., 24 (1902), No. 1, pp. 25–27*).—An improved method of filtering the citrate solution is described as follows: Place in the bottom of a carbon filter "a tightly fitting perforated porcelain disk, to which is attached a small wire that extends down beyond the small end of the carbon filter. A rubber stopper is then fitted tightly in a pressure bottle and the carbon filter passed through it. A layer of asbestos is placed on the disk in the carbon filter and by the aid of pressure this gave entire satisfaction. By this method it took only from 30 to 40 minutes to filter and wash the residue." To save time in precipitation the author recommends the following procedure: "Just before adding the molybdic solution, to precipitate the phosphoric acid, neutralize the excess of acid with ammonia, and then add 10 or

12 gm. of ammonium nitrate; then the molybdic solution can be added immediately, for the ammonium nitrate cools the solution down to where it is safe to precipitate and no waiting to cool is necessary as is the case if ammonium nitrate is added before the excess of acid is neutralized."

The determination of calcium, strontium, and barium as oxalate, C. A. Peters (*Ztschr. Anorgan. Chem., 29 (1901), No. 1, pp. 145–155*).—Methods in which these substances are determined by titration of the oxalates with permanganate solution are described in detail and a number of determinations are reported. From these the conclusion is drawn that calcium may be accurately determined by titration of the oxalate with permanganate solution if hydrochloric acid (with the addition of a manganous salt) is used as a solvent. Practically complete precipitation of strontium by ammonium oxalate may be obtained in solutions containing one-fifth by volume of 85 per cent alcohol. Almost complete precipitation may be obtained in water solutions if the dilution does not exceed 250 cc. The strontium oxalate may be accurately titrated with permanganate solution either when sulphuric acid or hydrochloric acid (with the addition of manganese oxalate) is used as the solvent. Barium may be practically completely precipitated by means of ammonium oxalate in solutions containing one-third by volume of 85 per cent alcohol. The oxalate may be accurately titrated with permanganate solution when dissolved in hydrochloric acid with the addition of manganous salt. The strontium and barium oxalates may be converted into carbonate by ignition and weighed as such.

On the determination of sulphur in soils, T. Pfeiffer and R. Riecke (*Mitt. Landw. Inst. Univ. Breslau, 1 (1901), No. 5, pp. 47–51*).—The presence of large amounts of iron was found to interfere with the accurate determination of sulphuric acid by the ordinary method of removing iron with ammonia and precipitating sulphuric acid with barium chlorid in acid solution. The tests of different methods reported indicate that accurate results can be obtained only by fusion of the soil with potassium hydroxid and oxidizing substances.

Determination of nitrogen, F. Jean (*Ann. Chim. Analyt., 6 (1901), p. 441; abs. in Chem. Centbl., 1902, I, No. 5, p. 333*).—A distilling apparatus, especially a device for preventing solutions from being carried over into the condenser, is described. For decomposition of the mercury compounds the author uses sodium hypophosphite instead of sodium sulphid.

Analysis of water, H. Potell (*Bol. Agr. São Paulo, 2. ser., 1901, No. 10, pp. 635–649*).—This article discusses methods of analysis.

The evolution of the oxygen absorption test in water analysis, J. B. Weems (*pp. 8*).—This is a paper read before the Iowa Engineering Society at its thirteenth annual meeting at Davenport, January 16–19, 1901. A brief review of the history of this test is given, with a list of references to literature.

A delicate method for the detection of formaldehyde, C. Arnold and C. Mentzel (*Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 8, pp. 353–356*).—To 5 cc. of an alcoholic extract of the material under examination are added 0.03 gm. of phenylhydrazin chlorid and 4 drops of a solution of ferric chlorid. Upon the addition of 10 to 12 drops of concentrated sulphuric acid, with cooling of the solution, a red color appears.

The quantitative estimation of formaldehyde, L. Vanino and E. Seitter (*Ztschr. Analyt. Chem., 40 (1901), No. 9, pp. 587–589*).—The estimation of formaldehyde by the proposed method is made by the use of potassium permanganate, as often previously employed, and the use of strong sulphuric acid and hydrogen peroxid.

In carrying out the method 35 cc. of two-tenths normal potassium permanganate solution is placed in a glass stoppered flask of about 250 cc. capacity. There is added a previously mixed and cooled solution of 30 gm. of concentrated sulphuric acid and 50 gm. of water. There is then added slowly, with constant shaking, 5 cc. of about

1 per cent formalin solution, which is made by diluting 10 cc. of commercial formalin with 400 cc. of water. The flask is then stoppered and set aside for 10 minutes, with occasional shaking. The excess of potassium permanganate is then eliminated by the addition of one-tenth normal hydrogen peroxid solution.

With the author's work, 1 cc. of potassium permanganate solution determined iodometrically contained 0.0072601 gm. $KMnO_4$=0.001723 gm. H.COH; 21.175 cc. hydrogen peroxid equal 10 cc. potassium permanganate solution.

Progress in the analysis of butter, margarin, cooking fats, and oils, A. Hasterlik (*Oesterr. Chem. Ztg., 5 (1902), No. 7, pp. 148–152*).—A review of recent literature.

Note on the Reichert value of butter and other fats, E. Reychler (*Bul. Soc. Chim. Paris, 3. ser., 25 (1901), pp. 142–144; abs. in Analyst, 26 (1901), No. 300, pp. 71, 72*).—The author suggests an extension of the Reichert-Meissl method so as to obtain the amount of volatile insoluble acids. Instead of filtering, he adds 50 cc. alcohol, and, if necessary, a little ether to the distillate, and titrates the solution in the usual way. The ratio thus obtained between the total volatile acids and the soluble volatile acids varies with different fats, the difference being especially marked between butter and cocoanut oil. A table of results is shown.

Determination of cocoanut oil in butter, F. Ranwez (*Rev. Internat. Falsif., 14 (1901), No. 4, pp. 89–94; abs. in Chem. Centbl., 1901, II, No. 14, pp. 835, 836*).—A compilation and test of methods. That of Vandam is recommended. In this the amount of fatty acid soluble in alcohol of 60° strength is determined and the results expressed in cubic centimeters of deci-normal alkali.

The anatomy of the fruit of the cocoanut, A. L. Winton (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 208–225, figs. 11*).—The morphology and macroscopic structure of the cocoanut are described, and the histological characters of its different parts figured and discussed. Means are suggested for the detection of powdered cocoanut shells in ground spices. Of 147 samples of black pepper examined 21 contained ground cocoanut shells; of 37 samples of cloves 7 were similarly adulterated, and of 24 samples of allspice 6 contained cocoanut-shell powder. Radical differences in the composition between cocoanut shells and the spices to which they are added are shown by the analyses of the different materials.

Detection and approximate estimation of minute quantities of arsenic in beer, brewing materials, food stuffs, and fuels (*Jour. Soc. Chem. Ind., 21 (1902), No. 2, pp. 94–96, fig. 1*).—This is a report of the joint committee of the Society of Chemical Industry and of the Society of Public Analysts recommending and describing the Marsh-Berzelius method.

Methods for the analysis of insecticides and fungicides, J. K. Haywood (*U. S. Dept. Agr., Bureau of Chemistry Circ. 10, pp. 8*).—Methods are given for the analysis of Paris green, London purple, copper carbonate, potassium cyanid, soap, soda lye, tobacco and tobacco extracts, and formalin.

Experiments on the separation by means of metallic salts of the albuminoids produced by digestion, Z. Černy (*Arch. Physiol. [Pflüger], 87 (1901), No. 10–12, pp. 614–633*).—Laboratory work is described in detail.

The analysis of some new tanning materials, F. A. Blockey (*Jour. Soc. Chem. Ind., 21 (1902), No. 3, pp. 158–162*).

A method of gas analysis, A. Samojiloff and A. Iudin (*Physiologiste Russe, 2 (1901), No. 31–35, pp. 171–184, fig. 1*).—The method described is especially recommended for determining carbon dioxid and oxygen in respired air.

The sampling and preparation of shoddy, wool dust, and similar materials for analysis, L. Meggitt (*Jour. Soc. Chem. Ind., 21 (1902), No. 2, pp. 105, 106*).—Directions are given for the preparation of samples for the determination of nitrogen.

The pentosans, G. Bertrand (*Bul. Assoc. Chim. Sucr. et Distill., 18 (1901), No. 12, pp. 1019–1025*).—A historical and descriptive article on the pentosans.

The action of ammonium chlorid on various silicates, F. W. Clark and G. Steiger (*Ztschr. Anorgan. Chem., 29 (1902), No. 3, pp. 338–352*).

A new viscometer, L. Meggitt (*Jour. Soc. Chem. Ind., 21 (1902), No. 2, p. 106, fig. 1*).

BOTANY.

A university text-book of botany, D. H. Campbell (*New York: The Macmillan Co., 1902, pp. XV+579, pls. 15, figs. 493*).—This recent contribution to American botanical literature is, as its name suggests, a text-book for use in colleges and universities and is in no way intended as a laboratory guide, nor to supplant any of the numerous botanies for secondary schools. The author has presented in a very compact form an outline of the essentials of botany, and the work is intended more as a reference text-book than otherwise. As far as possible the illustrative material has been drawn from our native flora, and this feature will doubtless commend itself to American students. After a general introduction the author considers the plant body, describing its parts, structure, and function. A similar chapter is devoted to the plant cell, after which the classification of plants is treated in several chapters. In this the several orders are described, beginning with the lowest and ending with the highest, the sequence of orders following in the main that of Engler and Prantl in their Die natürlichen Pflanzenfamilien. The physiology of the plant is discussed at considerable length, the method of treatment being based largely on that of Pfeffer's recent work, but the results obtained by other recent investigators have been quite extensively incorporated. Chapters are devoted to the relation of plants to their environment and to their geological and geographical distribution. Short lists of works that are believed to be of most value for the student are appended to the various sections, and the illustrations are for the most part new, many having been drawn expressly for this work.

The movements of plants, F. Darwin (*Nature [London], 65 (1901), No. 1672, pp. 40–44, figs. 6*).—This article is a lecture delivered by the author before the British Association for the Advancement of Science, in which an attempt is made to explain the different movements in plants and their physiological causes. The author appears to consider that gravity in some of its modifications is the principal stimulus to plant movement.

Injuries to plants by London fog and engine smoke, G. Henslow (*Jour. Roy. Hort. Soc. [London], 26 (1901), Nos. 2–3, pp. 310–313*).—This is a lecture delivered to the students at the gardens of the Royal Horticultural Society, in which the injurious effects of fog and smoke are shown. A similar paper by the author has been noted (E. S. R., 12, p. 826), in which the percentage of sulphurous acid occurring in the atmosphere was given. These figures are erroneous, according to the present paper. The average amount of sulphurous acid in dull weather should have been 6 mg. per 100 cu. ft. of air. The amount in a light fog was 8.16 mg., while in a thick yellow fog it amounted to 20.4 mg., instead of percents as given in the previous article.

Influence of mineral salts on the production of tubercles on pea roots, E. Marchal (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 24, pp. 1032, 1033*).—By means of peas grown in water cultures, the author has investigated the effect of different salts of potassium, sodium, calcium, ammonium, and magnesium upon root tubercle development. The different salts were used in strengths ranging from 0.5 to 5 gm. per liter of its culture medium. The results showed that the alkaline nitrates in the proportion of 1:10,000 checked the production of root tubercles on peas grown in water cultures. The ammonium salts exercised a similar action when used in strengths of 1:2,000. Potassium salts tended to retard symbiosis when used in strengths of 1:200, and sodium salts, 1:300, acted similarly. On the other hand, calcium and magnesium salts greatly favored the production of root tubercles. Phosphoric acid, although quite variable, depending on the base used, in the main exercised a stimulating effect. The action of the nitrates seems to be the production of an osmotic state which is prejudicial to the entrance of the organism causing root tubercles.

The formation of bacteroids in artificial media, A. Stutzer (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 25, pp. 897–912*).—Studies are reported on the bacteroids of peas, alsike clover, red clover, crimson clover, horse beans, vetches, garden beans, lupines, serradella, and soy beans. The organisms as influenced by growth in a number of artificial media are described.

The assimilation of free elementary nitrogen, E. Jacobitz (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 22, pp. 784–794; 23, pp. 833–844; 24, pp. 876–890*).—A critical review is given of some of the more important literature relating to the assimilation of atmospheric nitrogen, and a bibliography of 113 publications is included.

The nitrogenous constituents of green leaves, E. Winterstein (*Ber. Deut. Bot. Gesell., 19 (1901), No. 5, pp. 326–330*).

Investigations on the fixation of carbon by leaves and the diffusion of carbon dioxid, H. T. Brown (*Ann. Agron., 27 (1901), No. 9, pp. 428–439*).—This is a translation by E. Demoussy of a presidential address delivered before the British Association for the Advancement of Science (E. S. R., 11, p. 1015).

The presence of a glucosid formed during the germination of beech seed, P. Tailleur (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 20, pp. 1235–1237*).—During the process of germination of beech seed a glucosid is formed which is said to disappear with the first season's growth. It is localized in the hypocotyl and is present to a slight extent in the upper part of the root, but is not found in the cotyledons nor does it occur in the stems or leaves. This glucosid acted upon by the diastase of the seed in the presence of water gives rise to methyl-salicylic ether and glucose, which is assimilated by the plant. This ether is identical with that produced by wintergreen and which has also been found produced under the same conditions as described above in the roots of Polygola and Spiræa, in the petioles and leaves of certain species of Azalea, in the bark of black birch, and other plants.

A physiological balance, A. Petermann (*Bul. Inst. Chim. et Bact. Gembloux, 1901, No. 70, pp. 22, 23, pl. 1*).—A form of balance is described which was devised by Gregaire and Hendrick, by the use of which a constant state of humidity may be secured throughout the growing period of a plant.

The genera of Gastromycetes, C. G. Lloyd (*Cincinnati: Author, 1902, pp. 24, pls. 10*).—The author presents a general classification of the genera of Gastromycetes. An introduction is given in which the various parts of the fungi are described and the life history is traced. A brief historical sketch is given of the group, followed by the classification in which about 22 genera are recognized.

Monilia sitophila, an economic fungus of Java, F. A. F. C. Went (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 15, pp. 544–550; 16, pp. 591–598, pl. 1; Proc. Sec. Sci. Koninkl. Akad. Wetensch. Amsterdam, 3 (1901), pp. 489–502*).—A description is given of "ontjom," a small cake said to be quite common in West Java. It is made from peanuts and is of an orange color, due to the conidia of the fungus *M. sitophila*. The fungus seems to exert a very active influence through enzyms secreted by it upon the material of which the cake is made. The morphology of the fungus is described at length and the various changes induced by it are traced. A study was made on the influence of nutrition on the secretion of enzyms by this fungus. The fungus thrives well on such media as peanuts, bread, carrots, milk, broth, potatoes, etc. The growth on the various media shows that albuminous substances and peptone can serve as sources of carbon and nitrogen. For the production of the enzym which characterizes the fungus the author found that certain substances favored its development. The enzym, to which the name maltoglucase is given, is exclusively secreted when the fungus has access to certain carbohydrates. The best for this purpose is raffinose, followed by dextrin, maltose, galactose, glycogen, cane sugar, etc., in the order named.

Monilia sitophila and its appearance as the first vegetation on the ash fields left by volcanic eruptions, A. G. VORDERMAN (*Teysmannia, 12 (1901), No. 6, pp. 274–279*).—The author notes the occurrence of this fungus abundantly on the branches and trunks of trees in a district where everything had been killed by a rain of hot ashes after a volcanic eruption.—H. M. PIETERS.

The useful plants of French Guiana, M. GRESHOFF (*Bul. Kolonial Mus. Haarlem, 1901, No. 25, pp. 23–45*).—Brief economic notes are given upon a collection of nearly 200 useful plants of French Guiana which were prepared for the Paris Exposition of 1900.

FERMENTATION—BACTERIOLOGY.

A contribution to the knowledge of bacterial diseases of plants, C. J. J. VAN HALL (*Inaug. Diss., Univ. Amsterdam, 1902, pp. 198*).—In the first part of this work the author summarizes our knowledge relative to plant diseases that are known to be caused by bacterial attacks, and briefly considers a large number of others which are considered as probably of bacterial origin, but of which the evidence is not wholly conclusive. Among the diseases which have been demonstrated as of bacterial origin are the brown rot of crucifers, brown rot of potatoes, cucurbit wilt, Wakker's hyacinth disease, sweet-corn wilt, pear blight, lilac blight, olive tuberculosis, bean bacterial blight, carrot rot, ruta-baga and turnip rot, a new disease of iris, and the rot of hyacinths due to *Bacillus hyacinthi septicus*. Among those which are suspected as being due to attacks of bacteria are a rotting of potatoes, mulberry-tree blight, corn blight, timothy blight, a sugar-beet disease, celery bacteriosis, cotton-boll blight, fruit rot of tomatoes, sorghum blight, onion slime rot, grape gummosis, grape bacteriosis, "maladie d'Oleron" of grapes, a form of potato scab, bacteriosis of lupines, sugar-cane gummosis, canker of ash trees, etc. The evidence of the bacterial origin of the carnation bacteriosis, the mosaic disease of tobacco, and the "sereh" disease of sugar cane is not considered as sufficient to permit of their being classed as bacterial diseases.

In the second part of the dissertation an account is given of the author's investigations on some new diseases. These included studies of *Bacillus subtilis* and *B. vulgatus* as parasites which cause the rotting of parts of many plants; descriptions of a new disease of the German and Florentine iris, due to attacks of *Pseudomonas iridis*, n. sp.; a rotting of potato stems by *Bacillus atrosepticus;* and a disease of lilacs caused by *Pseudomonas syringæ*, n. sp. The symptoms of these different diseases are fully described, and the results of isolation, culture, and inoculation experiments are given. The new species of bacteria are described in detail, and their behavior toward a large number of media is indicated.

On different forms of hereditary variation of microbes, M. W. BEIJERINCK (*Proc. Sec. Sci. Koninkl. Akad. Wetensch. Amsterdam, 3 (1901), pp. 352–365*).—An account is given of observations made upon many bacteria when grown in various cultures. In comparing the results obtained with bacteria and similar organisms the rules found applicable to higher organisms do not apply. In the first place, there is a want of sexuality, the variations being comparable with bud variations of the higher plants; and in the second place, the organisms are unicellular, which, in the author's opinion, tends to render more apparent the phenomena of variation. A discussion is given of different forms of variation and the conclusion drawn that hereditary variability is a function of growth, in particular of slackened or weakened growth, and that variability attacks only one characteristic at a time. The forms of hereditary variability are grouped in 3 classes: In those in which variation is caused by degeneration all the individuals gradually losing their vegetative power, so that species may cease to exist. By transformation, individuals may lose a specific characteristic and acquire another. By hereditary variability or variation, the normal form throws off some individuals which possess characteristics strongly differing from those of the normal form, while the normal form continues to propagate quite unchanged. The author believes that many of the so-called new species are only variants of others and are not new species. Especially is this true among bacteria where the want of crossing strongly favors the continuation of variants once produced. If these variants become isolated the discoverer is liable to recognize them as new species, but their affinities can be determined only after prolonged investigation.

Symbiosis and symbiotic fermentation, J. R. GREEN (*Proc. Roy. Inst. Great Britain, 16 (1900), II, No. 94, pp. 261-273*).—In a paper read before the Royal Institution, the author discusses symbiosis at considerable length, describing many of the best known forms. Among those mentioned are the symbiosis between phanerogams, the symbiosis of lichens, the symbiosis existing between the Leguminosæ and the bacteria of the root tubercles, and the symbiosis in kephir, ginger beer, and that reported from Madagascar in which sugar cane is attacked by organisms which consist of yeast and bacteria associated in the same way as are the organisms of the ginger-beer plant.

The disinfectant properties of washing powders, C. F. DOANE (*Maryland Sta. Bul. 79, pp. 51-64*).—A report is given of the value of a number of washing powders, sal soda, baking soda, and caustic soda as disinfectant agents for the cleansing and purifying of culinary and dairy implements and vessels. The washing powders were found to have a decided value for destroying bacteria, as also did the sal soda. Baking soda had little or no effect on the germs present in the cultures tested. Dilute caustic soda was also without effect. A test was made to determine whether the free alkali in the washing powders is entirely responsible for their antiseptic properties, the results indicating that such is not the case.

The effect of physical agents on bacterial life, A. MACFADYEN (*Proc. Roy. Inst. Great Britain, 16 (1900), II, No. 94, pp. 448-457*).—An abstract is presented of a paper in which the effect of various physical agents on bacterial life is described. Among those mentioned are gases, electricity, mechanical agitation, etc.

Studies of the efficiency of water filters in removing different species of bacteria, S. DE M. GAGE (*Massachusetts State Bd. Health Rpt. 1900, pp 527-535*).—A report is made on the relative efficiency of continuous and intermittent filters for the removal of bacteria from river water. The filters were constructed, and the waters tested were supplied with a number of species of organisms, and the filtrate examined. The intermittent filter showed somewhat greater distribution of species and a slightly poorer efficiency than the continuous filter. The efficiency of the continuous filter in removing bacteria in every instance but one was about 99 per cent. Both kinds of filters were most efficient in the removal of the more common and widely distributed species of bacteria.

Notes are also given on the significance of *Bacillus coli* in filtered water. This organism is found in the effluents of filters more commonly than *B. typhi*, the waters being examined for that organism at the same time. The experiments indicate that *B. coli* is more hardy than the other species, and *B. typhi* could not serve as a test organism as well as the previous species.

Studies of media for the quantitative estimation of bacteria in water and sewage, S. DE M. GAGE and E. B. PHELPS (*Reprint from Proc. Amer. Pub. Health Assoc. 1901, pp. 8*).—A report is given of the comparative value of a number of different media for the estimation of bacteria in waters and sewage. The tendency at present is toward a medium which will permit of the shortening of the period of incubation necessary to give an opinion on the purity of water. Of the dozen or more media tested, that known as Nahrstoff-agar has advantages over all the other media for quantitative work. In all the tests with this medium, the counts of bacteria more nearly approximate the actual bacterial content of the water than is the case with any other medium known to the authors. This medium is said to be a pure albumose made from egg albumen, and, although somewhat complex in composition, is less liable to vary than the usual materials used. This is considered a distinct advantage, as it enables bacteriologists to prepare a medium of uniform composition, making the results obtained at different laboratories comparable.

Bacteria and sewage, F. Clowes (*Proc. Roy. Inst. Great Britain, 16 (1900), II, No. 94, pp. 317–324, figs. 9*).—A discussion is given of the relation between sewage and bacteria, and the purification of sewage by the action of numerous organisms.

Bacteria and the disintegration of cement, R. G. Smith (*Proc. Linn. Soc. New South Wales, 26 (1901), pt. 1, pp. 107–117*).—A number of authors having reported the disintegration of cement linings of waterworks and reservoirs by the action of bacteria led the author to investigate the subject in connection with the Sydney water supply. The cement above water line was hard, while below the water it was soft and easily broken away. An examination of the sediment showed the presence of a considerable number of bacteria; among them were specimens of *Vibrio denitrificans* and *Micrococcus radiatus*. Cultures were made of these organisms and they were grown upon cement blocks without any disintegration being observed. As a result of these observations the author believes there is considerable room for doubting the action of micro-organisms on cement, but thinks that the action is purely chemical, brought about by the decomposing and solvent action of the water.

On the nature of certain oxidizing ferments, J. H. Kastle and A. S. Loevenhart (*Amer. Chem. Jour., 26 (1901), No. 6, pp. 539–566*).—A report is given of extended studies on the oxidizing ferment found in the common potato. As a result of their investigations the authors claim that oxygen is absolutely essential to the production of the guaiacum-bluing ferment of the potato. This so-called oxidizing ferment, they believe, is an organic peroxid and not a true soluble ferment. It is believed that the oxidizable substances are oxidized to the peroxid condition by molecular oxygen, and that the peroxids thus formed give up part of their oxygen to other less oxidizable substances present in the cell; in other words, that the process of rendering oxygen active by the living cell is probably brought about in essentially the same way as that accomplished by phosphorus, benzaldehyde, and other oxygen carriers—that is, as one phase of autooxidation.

Oxidizing enzyms, C. R. Newton (*Indian Gard. and Plant., 9 (1901), No. 22; abs. in Jour. Soc. Chem. Ind., 21 (1902), No. 3, p. 182*).

Note on the production of casease by a streptothrix parasite, E. Bodin and C. Lenormand (*Ann. Inst. Pasteur, 15 (1901), No. 4, pp. 279–288*).—The authors describe a fungus of the form Oospore of Microsporum that when grown in a milk culture produces an enzym that is able to coagulate the casein like rennet and another enzym that possesses the power to dissolve the coagulated casein like the casease of Duclaux.

ZOOLOGY.

Destroying gophers and prairie dogs, D. E. Lantz (*Kansas State Bd. Agr. Quart. Rpt. 1902, Mar. 31, pp. 325–330, pl. 1, fig. 1*).—*Geomys bursarius* is generally distributed in the eastern part of Kansas, while *G. lutescens* is found chiefly in the western parts of the State. The adoption of the bounty system in destroying these pests is considered ineffective. The use of carbon bisulphid and traps in the burrows, and scattering poisoned baits are recommended for destroying these animals. The prairie dog is especially common in the western part of the State, where it is estimated that

2,000,000 acres of land are infested. Fumigation with carbon bisulphid and the use of baits poisoned with strychnin are recommended.

A coli bacillus affecting the hamster, B. GALLI-VALERIO (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 7, pp. 273-276, figs. 2*).—An infectious disease was observed among hamsters which had been imported from Alsace in 1900. The disease caused the death of a large proportion of infected animals within a few days. Animals which died of the disease showed an enlargement of the liver, which was affected by a complete fatty degeneration. Microscopic examination of the liver, spleen, and blood revealed the presence of large numbers of bacilli which belonged to the coli group. Detailed notes are given on the culture experiments conducted with these organisms. Inoculation experiments with rabbits, guinea pigs, and chickens gave negative results. Positive results, however, were obtained from experiments on mice.

Studies on the bacillus pathogenic for rats, B. ISSATSCHENKO (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 1, pp. 26-28*).—The author made numerous experiments on the bacillus, which was found to cause fatal infection in mice and rats but which did not affect domesticated animals; cats, dogs, chickens, and pigeons were not infected by eating food containing pure cultures of the bacillus. Feoktistoff carried out similar experiments on horses, cattle, hogs, sheep, dogs, cats, and domestic poultry, with similar results. None of the animals became infected or showed any evidence of disease. In feeding experiments with the bacillus it was found that rats and mice almost without exception became infected with a fatal disease. The death rate was greatest 15 days after infection. Only 2.7 per cent of the rats and mice upon which experiments were made resisted infection.

The value of the bacillus of Danysz in destroying rats, G. MARKL (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 5, Orig., pp. 202-204*).—Numerous experiments were made for the purpose of comparing the effect of this bacillus with that of the bacillus of mouse typhus. It was found that the serum of a rabbit which had been inoculated subcutaneously with a sterilized culture of the Danysz bacillus agglutinated the culture of this organism when added in the proportion of 1 to 50, or 1 to 100 parts, while it had no such effect on the culture of the bacillus of mouse typhus. It is believed that the use of the Danysz bacillus in destroying rats offers only slight advantages over chemical poisons.

Comparative studies on the bacillus of Danysz, and a new organism pathogenic to rats, M. GRIMM (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 7, Orig., pp. 286-293*).—The behavior of these 2 organisms on various nutrient media, and their pathogenic properties and resisting power to different chemical and physical agents, are compared. The new organism described by the author proved to be very pathogenic for rats, but experiments indicated that it was also pathogenic to some extent for the larger domesticated animals. Its use, therefore, in combating rats on farms or in the neighborhood of cities must be somewhat limited.

The biology of the trypanosoma of rats, JÜRGENS (*Arch. Hyg., 42 (1902), No. 3, pp. 265-288*).—The material with which the author made his experiments was obtained from 2 wild gray rats which were thoroughly infested with trypanosoma. It was found possible to transmit the parasites to white rats, in all of the 47 tests which were made. A small quantity of blood was taken from the caudal vessels of the infected rats, mixed with an equal quantity of normal salt solution, and injected into the peritoneal cavity of the experimental animals. The demonstration of the parasites in the blood of the inoculated animals was possible after 3 or 4 days. The incubation period, during which it was not possible to find the parasites, varied somewhat according to the amount of material which was used for inoculation purposes. The incubation period is also much affected by the developmental stage of the parasites. If the blood which is used for inoculation contains larval parasites, the period of incubation is only 1 or 2 days.

Annotated list of the birds of Oregon, A. R. WOODCOCK (*Oregon Sta. Bul. 68,* *pp. 118, pl. 1*).—In this bulletin the author has prepared a list of all birds known to nest or to be found as migrants in the State of Oregon. The number of species thus slited is about 325. Brief notes are also given on the nesting and feeding habits of various species. A copy of the bird laws of Oregon is appended to the bulletin.

The birds of Ontario in relation to agriculture, C. W. NASH (*Toronto: L. K. Cameron, 1901, pp. 79, figs. 32*).—In this pamphlet notes are given on the feeding habits of hawks, owls, shrikes, crows, blackbirds, orioles, meadow larks, woodpeckers, nuthatches, titmice, thrushes, robins, catbirds, wrens, warblers, flycatchers, swallows, sparrows, and a few game birds. In general it is argued that birds, by their extensive destruction of insects, render a service to agriculture which far more than counterbalances the damage caused by eating fruits and grains.

The relation of birds to horticulture, W. R. LAZENBY (*Proc. Columbus Hort. Soc., 16* (*1901*), *No. 1, pp. 62–64*).—It is believed by the author that the unusual prevalence of certain species of injurious insects may be partly due to the reckless destruction of birds.

Bird notes, M. W. DOHERTY (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 31–34*).—Brief notes are given on the prevalence and feeding habits of orioles and sparrows, as well as upon the migratory movements of birds as observed for the season of 1901.

The feeding habits of Corvus cornix, G. STAES (*Tijdschr. Plantenziekten, 7* (*1901*), *No. 1, pp. 1–9*).—In this article the results are given of a series of investigations on the feeding habits of this species of crow. Of the 150 stomachs which were examined, 39 were empty, 85 contained plant substances almost exclusively, 5 were filled with the remains of animal food, and 8 contained mixed food. A considerable variety of insects were found which had been eaten by the crow, some of the species being injurious and some beneficial. The crow had also fed upon corn, cereal grains, potatoes, and other farm crops.

The value of Fringilla cœlebs for agriculture and horticulture and general remarks on the protection of birds, J. RITZEMA BOS (*Tijdschr. Plantenziekten, 7* (*1901*), *No. 5–6, pp. 165–176*).—This species of bird, while feeding largely upon seeds, is also known to eat a considerable variety of insects in various stages, and is therefore considered distinctly beneficial to agriculture. Notes are also given on the desirability of protecting all common birds which are known to have beneficial feeding habits.

Legislation for the protection of birds other than game birds, T. S. PALMER (*U. S. Dept. Agr., Division of Biological Survey Bul. 12, rev. ed., pp. 143, pls. 4, figs. 7*).—A revised and enlarged form of this bulletin, including copies of legislation enacted since the publication of the first edition of the bulletin (E. S. R., 12, pp. 616, 617).

Directory of State officials and organizations concerned with the protection of birds and game, 1902, T. S. PALMER (*U. S. Dept. Agr., Division of Biological Survey Circ. 35, pp. 10*).—A list of State officials concerned with the protection of birds and game, as well as officials connected with national organizations, State organizations, and Audubon societies, for this purpose.

METEOROLOGY.

Storms accompanied by snow at different stations in Italy (*Nature* [*London*], *65* (*1902*), *No. 1686, p. 372*).—"In connection with the campaign against hailstorms, Prof. V. Monti publishes in the *Bulletin of the Italian Meteorological Office* some statistics of the number of storms accompanied by snow at different stations, as recorded for the period 1881–1887, inclusive. The phenomenon of snow during thunderstorms is shown to be very rare in Italy, and in about one-fourth of the storms in which snow fell it was also accompanied by hail. When account is taken of the time of year, as well as of the altitude of the station, it is found that in the majority of cases snowy thunderstorms occurred when snowy weather was the normal condition of affairs. There are but few records of snow falling out of season as a result of the sudden cold produced by thunderstorms. These statistics, so far as they go, are interesting as affecting the theory that by bombarding a thunderstorm the hail is transformed into snow. If snow frequently falls after a storm-cloud has been bombarded, and rarely under other circumstances, the theory in question obtains support. But, as Professor Monti points out, we have not at present sufficiently complete statistics to enable any very definite conclusions to be drawn."

Meteorological summary for 1900, C. A. Patton (*Ohio Sta. Bul. 128, pp. 219–231*).—This summary includes notes on the weather and tabulated daily and monthly records of observations at the station at Wooster, Ohio, on temperature, precipitation, cloudiness, direction of the wind, etc., and for comparison, similar data for previous years and for other parts of the State. The following is a summary of results:

Summary of meteorological observations in Ohio.

	For the experiment station.		For the State.	
	1900.	Average for 13 years.	1900.	Average for 18 years.
Temperature (°F.):				
Mean	50.7	49.2	52.2	50.8
Highest	(July 4) 95	(Aug. 8, 1891) 99	(July 4, Aug. 6, and Aug. 10) 103	(July 4, 1897) 113
Lowest	(Feb. 27) 10	(Feb. 10, 1899) 21	(Jan. 29, Feb. 27) −20	(Feb. 10, 1899) −39
Mean daily range	20.6	20.6	....	....
Greatest daily range	(May 6) 43	(Oct. 6, 1895) 55	(Feb. 9) 57	(Sept. 28, 1897) 67
Clear days	149	123	....	....
Cloudy days	118	119	....	....
Days rain fell	132	126	107	127
Rainfall (in.):				
Greatest monthly	(Aug.) 5.97	(July, 1896) 8.05	....	....
Least monthly	(Dec.) .99	(Sept., 1897) .29	....	....
Mean yearly	....	....	32.87	37.78
Prevailing direction of wind	SW	S.-SW	SW	SW.

Meteorological observations, H. H. Hume and A. W. Blair (*Florida Sta. Rpt. 1901, pp. 96, 97*).—A tabular summary of daily observations on maximum and minimum temperature, atmospheric pressure, and rainfall for the 6 months ended June 30, 1901.

Meteorological summary for the year 1901, D. Valet (*Chron. Agr. Canton Vaud, 15 (1902), No. 9, pp. 267–271*).—A summary of observations at Lausanne and other places in Switzerland on temperature of the air and soil, precipitation, sunshine, etc.

The moon and thunderstorms, A. B. MacDowall (*Nature [London], 65 (1902), No. 1686, p. 367, fig. 1*).—Diagrams are given which show the distribution of thunderstorms about the different quarters of the moon as shown by data recorded at Greenwich. The results are compared with those reported by Hann. "All agree in showing a larger percentage [of thunderstorms] about new moon than about full moon and in the two earlier phases than in the two later."

The mode of action of cannon used for protection against hail, G. Gastine and V. Vermorel (*Grêle, 2 (1901), Nos. 3, pp. 12–18; 4, pp. 13–16*).

Hailstorms and cannonading, F. Houdaille (*Les orages à grêle et le tir des canons. Paris: Félix Alcan, 1901, vol. 1, pp. ——, figs. 63; rev. in Ann. École Nat. Agr. Montpellier, n. ser., 1 (1901), No. 1, p. 98*).

Climatological atlas of the Russian Empire, RYKATCHEW (*Atlas climatologique de l'Empire de Russie. St. Petersburg, 1900; rev. in Nature* [*London*], *65* (*1902*), *No. 1694, pp. 554, 555*).

Destruction by lightning in Ontario, 1901, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 2–6*).—A summary of statistics collected by the agricultural college relating to loss of life and destruction of buildings and stock during the year, with a brief discussion of means of protection of barns from lightning.

SOILS.

Lands of the Colorado Delta in the Salton Basin, California, F. J. SNOW, E. W. HILGARD, and G. W. SHAW (*California Sta. Bul. 140, pp. 51, pl. 1, figs. 5*).—This is an account of a study of the soils and agricultural conditions and possibilities of that portion of the delta of the Colorado River which slopes toward the north into the Salton Basin or Sink. The area "is to a considerable extent covered with alluvial deposits originally derived from the Colorado River; as is clearly indicated by their nature, as well as by the fact that at times of exceptional high water (such as occurred in 1890) the river overflows into the basin through 2 channels, named respectively the Salton and New rivers. The alluvial deposits of the river finally cut off the upper end of the Gulf [of California] so that now a large area of alluvial country, or delta, extends between the Salton Basin and the present head of the Gulf. As to the thickness of these delta deposits, the only evidence as yet available is from a boring at Imperial made to determine the feasibility of obtaining artesian water in this region. This boring was carried to the depth of 685 (?) ft. without penetrating anything different from the various materials found at or near the surface, and without finding water. It is thus apparent that the Gulf was originally of very considerable depth." Within this area occur two extreme typical classes of soil, namely, a very hard compact clay and a silt or loam soil. The latter occupies about one-fourth of the entire area studied. Between these two extremes occur many transition grades. "The silt soil contains about 60 per cent of silt of medium to coarse grade, which imparts the distinctive character to the soil. It also carries from 10 to 15 per cent of very fine silt, which in some respects might act similarly to clay in respect to capillary power. The soil characterized as clay carries about 30 per cent of clay proper, and over 60 per cent of very fine silt; making over 90 per cent of extremely fine matter, which, when compacted (as much of it is), makes a material almost impervious to water."

Experiments made in long glass tubes showed that "the silt soil became wet to the depth of 3 ft. within 18 hours, while in the case of the clay soil it required 165 days for the water to reach the same depth; a rate entirely prohibitive of successfully handling this soil under its highly saline conditions."

In tests of the capillary rise of water in the soils it was found that in the case of the silt soils the water rose 2 in. in 7 minutes, 4 in. in 18 minutes, 7 in. in 1 hour, and 10 in. in 1 hour and 43 minutes, "while it took the clay 11 hours and 17 minutes to draw the water to a like height, or approximately 10 times as long. This rate, however, diminishes somewhat more rapidly in the silt as the water column ascends, than it does in the clay. The water-holding power is greater by 30 per cent in the case of the clay than in the silt, which might be expected on account of the difference in the nature of the 2 soils."

The chemical analyses of the soils reported show that as a rule their intrinsic fertility is high. The percentage of potash is large, "there being nearly four times as much as the average for soils of humid regions," and the supply of phosphoric acid and humus is good. The percentage of lime is high and it is present largely in the form of carbonate. The proportion of soluble matter is much larger in the clay soil than in the silt or loam soil. The percentage of alkali in the soils is very variable, but generally high. This alkali is of the "white" type, that is, that in which the relatively innocuous sulphates predominate. "Carbonate of soda is quite subordinate, because of the presence of gypsum throughout the materials. Common salt is rather abundant near the surface, but only in small supply below the first 3 ft., until a depth of 20 ft. is reached. Nitrates appear to be present throughout, to an extent varying from 1,000 to 1,800 lbs. per acre (0.025 to 0.044 per cent) in 4 ft. depth; increasing from the surface downward, contrary to the usual rule." While it appears that the clay soils are more heavily impregnated with alkali than the silt or loam soils it would seem that the clayey, plastic, and impervious character of the former is a more serious obstacle to their utilization for agricultural purposes than the alkali salts.

Analyses of water of the Colorado River, Blue and Cameron lakes, and of a well at Cameron Lake, with reference to their use in irrigation, are reported. The results show that the composition of the Colorado River water is quite variable at different periods of the same season and in different seasons and that while it "could be used with impunity upon the silts, it would but increase the extremely undesirable saline conditions of the clay soils of the region." Methods of irrigating alkali lands so that evaporation from the surface is reduced to a minimum are discussed and the need of a thorough system of drainage is explained. The climatic conditions and the plant growth of the region are described and a list of crops adapted to alkali soils with their limits of tolerance for alkali is given.

Willis and Huntsville tobacco soils, H. H. Harrington and P. S. Tilson (*Texas Sta. Bul. 61, pp. 14, pls. 2*).—Chemical and mechanical analyses of 18 samples of soil from Willis and 6 from Huntsville are reported, with analyses of 6 samples of Connecticut Valley tobacco soils and a discussion of the adaptability of the Texas soils to the growth of filler and wrapper tobacco. Recommendations are given regarding the fertilizers required, based upon analyses of the ash of 4 samples each of the tobacco leaf grown in the 2 localities. Determinations of nicotin showed that the percentage in the Willis and Huntsville tobaccos varied from 1.75 in the wrapper to 2.5 in the filler. The conclusion was reached that the soils of Willis are admirably adapted to the growth of high-grade filler or wrapper, the growth of filler perhaps being more likely to be profitable under present conditions than the growth of wrapper tobacco. "Yet with greater outlay of capital, and especially with the introduction of shade growth, and with the application of irrigation, a most satisfactory wrapper can be grown."

The soil and the agricultural conditions of Prussia, A. Meitzen and F. Grossmann (*Der Boden und die landwirthschaftlichen Verhältnisse des Preussichen Staates. Berlin: Paul Parey, 1901, vol. 6, pp. XVIII+656+526*).—The sixth annual report on the comprehensive survey of the soil and agricultural conditions of Prussia, published under the auspices of the Minister of Agriculture, Domains, and Forests. It deals with the history of the people and the economic phases of their agriculture.

Chemical exploration of Belgium soils, A. Petermann (*Bul. Inst. Chim. et Bact. Gembloux, 1901, No. 71, pp. 36*).—Mechanical and chemical analyses of 15 samples by the author's well-known methods, are reported.

Analyses of soils, Paarl and Worcester Divisions, C. F. Juritz (*Agr. Jour. Cape Good Hope, 20 (1902), No 6, pp. 351–363*).—This is a report on work in continuation of the soil survey of the province (E. S. R., 13, p. 119), and includes results of analyses of 44 samples of soils. The average amounts of fertilizing constituents in these soils were, for the Paarl Division, lime 0.03 per cent, potash 0.041, phosphoric acid 0.044, nitrogen 0.1; for the Worcester Division, lime 0.136 per cent, potash 0.022, nitrogen 0.124. These results show that the Paarl soils are "rather poor in lime, potash, and phosphoric acid, while the average amount of nitrogen they contain is about normal." The Worcester soils, on the other hand, contain "as a rule a fair amount of lime, potash, and phosphoric acid, and also a good quantity of nitrogen."

The subsoil, L. DUMAS (*L'Ing. Agr. Gembloux, 12 (1902), No. 6, pp. 255–261*).—This article attempts to show that in spite of the predominating influence attributed to it by scientific and practical men, the surface soil is probably of less importance in plant growth than the subsoil for the following reasons: (1) The roots of plants descend as rapidly as possible into the subsoil, in many cases to a considerable depth, the surface soil (0.1 to 0.35 meter) serving the requirements of the plant only during germination and the early stages of growth; (2) the plant draws its water supply largely from that layer of the soil, which has a higher retentive power for water than the surface soil and so holds a reserve for times of need; and (3) the plant only partially uses the food supply of the surface soil and draws its nourishment during the greater part of its period of growth from the supply of plant food in the subsoil. To this latter fact may be ascribed in part the capricious action of commercial fertilizers. Under ordinary systems of farming the tendency is to enrich the surface soil at the expense of the subsoil. Nature seeks to restore the equilibrium by promoting in various ways the descent of the fertilizing constituents into the subsoil. Improvement of the subsoil by thorough drainage, the occasional growth of deep rooting plants such as the legumes, etc., is advised. The practice of a system which returns a liberal amount of organic manure to the soil, as opposed to the exclusive use of commercial fertilizers, is also recommended.

Humus, F. SESTINI (*Studi e Ricerche Ist. Lab. Chim. Agr. Univ. Pisa, 1900–1901, No. 17, pp. 11*).—A discussion of the formation, properties, and functions of humus.

Humus as a preservative against frost, W. R. FISHER (*Nature [London], 65 (1901), No. 1677, p. 152*).—Illustrations of the fact stated by Wollny that spring and autumn frosts are dangerous on peaty soils only when the surface of the latter is dry are reported.

Experiments on black pocosin soils and methods of treating them (*Bul. North Carolina State Bd. Agr., 23 (1902), No 1, pp. 37, 38*).—These soils, which occur in considerable areas in the eastern part of North Carolina, contain large amounts of organic matter and are quite productive when first cleared, but after a few years' cultivation become absolutely unproductive. The use of lime, potash salts, and acid phosphate has been found beneficial.

The improvement of peaty soils and marsh lands, R. ROGER (*Jour. Agr. Prat., n. ser., 3 (1902), No. 7, pp. 217–220*).

The decomposition of organic matter in cultivated soils, H. LAGATU (*Ann. École Nat. Agr. Montpellier, n. ser., 1 (1901), No. 1, pp. 65–94*).—This is a critical review of the literature of this subject, dealing especially with investigations relating to the combustion of organic carbon and nitrogen in the soil.

Studies in nitrification, J. G. LIPMAN (*Jour. Amer. Chem. Soc., 24 (1902), No. 2, pp. 171–186*).—Observations on the progress of nitrification in 3-lb. lots of soil in 6-in. flower pots and 100-gm. samples in 750-cc. Erlenmeyer flasks, are reported. The soils used were (1) a calcareous sand, (2) a loam soil, and (3) an artificial greenhouse soil rich in organic matter. "For the determination of organic and of total nitrogen, the Kjeldahl and the Kjeldahl modified methods were used. The Ulsch and the phenolsulphonic acid methods were used for the determination of nitrates. Of the different methods proposed for the determination of nitrites in the presence of nitrates, the method first proposed by Griess and known as the sulphanilic acid and naphthylamin method was selected because of its convenience and delicacy. Ammonia was determined by distillation with soda or magnesia, and titration against standard acid or by nesslerizing. For qualitative tests there were also used metaphenylenediamin for nitrites, and brucin and diphenylamin for nitrates."

The Griess method for nitrites and the phenolsulphonic acid method for nitrates as used in these experiments are discussed. The precautions found to be necessary to insure accuracy with the latter are stated.

The pots were placed in porcelain saucers and the water content of the soil was maintained at about 25 per cent of the water capacity of the soils by addition from below. At the end of the period the nitrites and nitrates in the soil were obtained for determination as follows: "One hundred grams of soil were shaken in a 2-liter bottle, provided with a stopper, with 1 liter of distilled water. After shaking for 5 minutes the liquid holding the nitrites and nitrates in solution was filtered, about a gram of freshly precipitated and washed aluminum cream added to the filtrate and the latter shaken. It was then filtered again, 100 cc., representing one-tenth of the nitrates held in solution, carefully measured off for the determination of nitrates, and 100 cc. for the determination of nitrites." The influence of varying amounts of common salt and of sulphur, and of stirring the soil, on the nitrification of ammonium sulphate was studied in the pot experiments. In the experiments in flasks the influence of varying amounts of water and of sodium chlorid, ferrous sulphate, calcium carbonate and sulphate, and large quantities of organic matter was studied. The results obtained with the pots were inconclusive. In the experiments in flasks it was found that with amounts of water varying from 8 to 12 cc. per 100 gm. soil there was little difference in the rate of nitrification. "There was a distinct diminution in the amount of nitrates produced as the amount of salt was increased, still the differences were not very great, and from this experiment we must conclude that quantities of salt up to 0.1 per cent, or 3,500 lbs. to the acre, while they retard nitrification, do not stop it entirely."

Ferrous sulphate in amounts varying from 10 to 100 mg. per 100 gm. of soil apparently had little effect. "Where equivalent amounts of gypsum were used the nitrification was, on the whole, fairly uniform, and slighter than in the flasks where calcium carbonate was used. . . . It appears that more nitrate was formed where 1 per cent of organic matter was present than where only 0.5 per cent was present."

The life of the soil, C. Bauverd (*Jour. Soc. Agr. Suisse Romande, 43 (1902), No. 1, pp. 17–20*).—A brief review of an article by Chuard on this subject.

On the emission and absorbtion of heat and their importance in relation to the temperature of the earth's surface, N. Ekholm (*Meteor. Ztschr. [Vienna], 19 (1902), No. 1, pp. 1–26, fig. 1*).

The adaptation of seeds to soil, S. Castex (*Bul. Agr. Algérie et Tunisie, 8 (1902), No. 5, pp. 121–124*).—A brief discussion of the influence of the chemical properties of the soil on the seed and its offspring.

FERTILIZERS.

Contribution on the treatment of barnyard manure with absorbents to prevent the loss of nitrogen in form of ammonia compounds, H. D. Haskins (*Massachusetts Sta. Bul. 81, pp. 17, 18*).—Experiments to determine the relative absorbtive power for ammonia of magnesium sulphate (kieserite), potassium-magnesium sulphate, kainit, potassium sulphate, and calcium sulphate are referred to. Although the results, "in all probability, do not represent the actual nitrogen absorption power of the chemicals as used in ordinary farm practice," they show that calcium sulphate (gypsum) possesses the lowest absorptive capacity for ammonia of any of the materials tested, the results with magnesium sulphate being highest in this respect.

Permanence of manure, T. Jamieson (*Proc. Agr. Research Assoc. [Aberdeenshire], 1901, pp. 26–42, dgms. 5*).—A summary of 17 years' experiments undertaken for the purpose of securing "precise and reliable information upon the relative permanence of different forms of manure" to be used in determining the compensation for unexhausted manure under the "Agricultural Holdings Act." The fertilizers used were various forms of bone, superphosphate, coprolite, and sodium and potassium nitrates. The results showed that by the fifth year the fertilizers had become practically exhausted, that the complete fertilizers gave the highest results throughout, that the effect of the phosphates depended very largely upon their fineness and was greatly increased by the addition of nitrogen and potash. The most lasting effect was observed in case of coarse and slowly decomposing bone, followed by steamed bone meal with nitrate of potash and dissolved bone. "Generally the results show that the manures that stood somewhat low in the first turnip crop (in consequence of rough division) stand relatively higher in the grass—bones now standing above all the other manures; coprolite standing above superphosphate; and nitrates, which stood lowest in the turnips, now exerting their effect in the fourth year, the grass crop being one that is responsive to nitrogen."

Deep culture and the turning under of green manures and barnyard manure, WODARG (*Deut. Landw. Presse, 29 (1902), No. 15, p. 122*).—A plea for a thorough study of this subject.

Deep culture and turning under green crops and barnyard manure (*Deut. Landw. Presse, 29 (1902), No. 22, pp. 185, 186*).—A general discussion of this subject.

Green manuring with lupines and the use of nitrogenous fertilizers, C. SCHREIBER (*Rev. Gén. Agron. [Louvain], 10 (1901), No. 11, pp. 481–488, fig. 1*).—The author concludes from the results of experiments that the nitrification of lupines as green manure proceeds too slowly to dispense with the addition of an active nitrogenous fertilizer. In this connection nitrate of soda was found preferable to sulphate of ammonia. The renovation of the soil by means of green manuring with lupines and a supplementary application of commercial fertilizers is considered economical.

Bokhara clover as a nitrogen collector, BANNERT (*Deut. Landw. Presse, 29 (1902), No. 22, p. 184*).—A brief note.

Compost formulas (*Bul. North Carolina State Bd. Agr., 23 (1902), No. 3, pp. 31–34*).—Formulas and instructions are given for the preparation of composts of barnyard manure, cotton seed, and cotton-seed meal with acid phosphate and kainit. The injurious action of lime in composts is briefly referred to.

Fertilizers and the fertilization of the soil, A. LARBALÉTRIER (*Les engrais et la fertilisation du sol. Paris: J. B. Baillière & Son, 1901, pp. 332, figs. 74*).

Contribution to the study of the feeding of plants with phosphorus, T. SCHLOESING (*Compt. Rend. Acad. Sci. Paris, 134 (1902), No. 1, pp. 53–55, figs. 2*).—Previous investigations along this line are referred to and determinations of phosphoric acid soluble in distilled and recently boiled water in 2 soils, one very rich in soluble phosphoric acid, the other very poor, are reported. Small lots of soil (40 to 100 gm.) were repeatedly (10 to 11 times) shaken up with relatively large amounts of water (1,750 to 1,850 cc.), the solutions clarified with a small amount of calcium nitrate (100 mg. per liter), and phosphoric acid determined by the molybdic method. Parallel tests were made on each soil, cultivated and uncultivated, and kept uniformly moist. The phosphoric acid in each water extract is shown in tables and diagrams. The total soluble phosphoric acid was 150.2 mg. per kilogram in the uncultivated soil rich in this constituent and 122.1 mg. in the same soil after growth of a crop (corn), a difference of 28.1 mg.; 14.33 mg. in the uncultivated soil poor in soluble phosphoric acid and 8.8 mg. in the cropped soil, a difference of 5.53 mg. For the 36 kg. of soil used for each experiment with corn the difference was in the first case 1,012 mg., in the second 199 mg. Analyses of the corn plants showed that they took up in the first case 1,115 mg. of phosphoric acid, in the second 451 mg.

The utility of alkaline phosphatic manures, J. HUGHES (*Sci. Amer. Sup., 53 (1902), No. 1375, pp. 22034–22036*).—Noted from another source (E. S. R., 13, p. 234).

Increasing the calcium phosphate content of phosphorite, K. J. LISSENKO (*Zap. Imp. Russ. Techn. Obschtsch., 35 (1901), p. 825; abs. in Chem. Ztg., 26 (1902), No. 18, Repert., p. 62*).—By a process of grinding and sifting a large proportion of the sand in phosphorites may be removed and the content of pure calcium phosphate correspondingly increased. The product thus obtained is better adapted to the manufacture of superphosphates than the crude material.

Some observations on ammonium-magnesium phosphate, E. SELLIER (*Rev. Gén. Chim. Appl.*, *5* (*1902*), *p. 77; abs. in Chem. Ztg.*, *26* (*1902*), *No. 22*, *Repert.*, *p. 73*).—The author found in the course of experiments that ammonium-magnesium phosphate is not completely decomposed by magnesia at boiling temperature.

On the use of sulphate of ammonia, W. HASSELMAN (*Meded. Proefstat. Suikerriet West Java*, *1902*, *No. 55*, *pp. 7*).—A brief discussion of the absorptive power of the soil for ammonium sulphate, and its effect on capillary rise of water, nitrification, and the calcium carbonate of the soil.

The action of potash on plant life, H. WILFARTH and G. WIMMER (*Arb. Deut. Landw. Gesell.*, *1902*, *No. 68*, *pp. 106*, *figs. 14*).—This is a detailed account of pot experiments with potatoes, tobacco, buckwheat, mustard, chicory, oats, and sugar beets. The method used was essentially that of Hellriegel, modified to secure better aeration and to prevent loss of fertilizing matter in drainage. The soil used was a sand-peat mixture very poor in potash. The results obtained show that potash is absolutely essential to plants, and is needed throughout the period of growth. The yields increased in proportion to the amount of potash applied until the maximum, determined by the size of the pot or the water supply, was reached. Beyond this point the effect of an increased application of potash was shown, not in an increase of yield, but in an increase of potash content of the plant. The greater the amount of potash available in the soil, the greater the amount taken up by the plant, especially by the leaves and straw, the potash content of the seeds, roots, and tubers remaining remarkably constant with variations in the supply of potash, and increasing only when a large excess of potash was applied. It was shown that the potash was very completely taken up by the plant, whether needed for growth or not. Even when potash was applied in excess far beyond the point of increasing the yield it was largely (90 to 95 per cent) taken up by the plant. Potash appeared to be especially necessary for such plants as potatoes, sugar beets, etc., which produce organs which store up reserves of starch, sugar, and fat. Small potatoes poor in starch and small sugar beets poor in sugar were produced when there was a deficiency of potash. A deficiency of potash also retarded the development of grain in case of cereals and buckwheat. In the case of such crops many of the seeds were imperfectly developed or abortive. Plants suffering from potash hunger have a generally sickly appearance as distinguished from their appearance when suffering from lack of phosphoric acid or nitrogen. In the latter cases the plants are small but normal in all parts. Plants insufficiently supplied with potash, especially potatoes and beets, appeared to be very susceptible to rot. Potash deficiency has a characteristic effect on the leaves of plants, especially as regards coloring. The spaces between the leaf veins show first characteristic brownish stripes, followed later by white spots, causing a peculiar crinkling, and finally the leaves dry up, with a more or less brown color. No such appearance was noted in case of deficiency of phosphoric acid or nitrogen.

The experiments on the possibility of substituting soda for potash were not entirely conclusive and are being continued, but they indicated that while soda is taken up to a considerable extent by plants, and exerts some influence, it can not perform the functions of potash in plant growth.

The results of experiments with kainit and 40 per cent potash salt, BACHMANN (*Fühling's Landw. Ztg.*, *51* (*1902*), *No. 4*, *pp. 147–155*).—With rye the results as a rule favored the 40 per cent salt, both on limed and unlimed soil; with oats and barley they were not conclusive.

Potash fertilizers on soils rich in potash, L. GRANDEAU (*Jour. Agr. Prat.*, *n. ser.*, *3* (*1902*), *No. 10*, *pp. 309–311*).—Experiments by Maercker are briefly reviewed, which afford a striking illustration of the fact that the need of the application of potassic fertilizers is determined by the assimilable and not by the total potash present. In the author's opinion complete information as to the soil potash can be obtained only by 4 distinct determinations, (1) the total potash, including that combined as silicates, (2) potash soluble in weak mineral acids, (3) potash soluble in citric acid (1 gm. per liter), and (4) potash soluble in water.

Why and when may one dispense with potash fertilizing? A. Felber (*Deut. Landw. Presse, 29 (1902), No. 20, pp. 164, 165, figs. 4*).—Experiments with oats to test this point are reported. Stable manure was applied alone and in combination with potash salts and nitrogenous and phosphatic fertilizers. The results show that the potash salts in some cases gave profitable returns on soils well supplied with potash and receiving liberal applications of manure. This is attributed to the fact that the potash compounds of the soil and of manure are not readily assimilable by plants. In the author's opinion the need of soils for potash can be determined only by carefully planned and conducted experiments. It is also claimed that potash salts may be safely used in combination with any kind of fertilizer or manure.

Potash salts as a top-dressing, A. Felber (*Deut. Landw. Presse, 29 (1902), No. 28, pp. 237, 238, fig. 1*).

The use of potash as a protection against injury from frost, Vibrans (*Deut. Landw. Presse, 29 (1902), No. 18, p. 148*).—Referring to Baumann's observations that plants fertilized with potash salts were injured to a less extent by frost than those not so treated, the author suggests that this may be a result entirely of physical action in the soil influencing the temperature, and not due to concentration of the carbohydrates in the plant, as suggested by Baumann. He cites in support of this view the old practice of applying kainit to the soil, in anticipation of frost, to protect beets.

Potash as a protection against frost, Baumann (*Deut. Landw. Presse, 29 (1902), No. 23, p. 197*).—In reply to above suggestion of Vibrans the author points out that the beneficial action of potash salts in protecting from frost was observed after these salts had been taken up by the plants from the soil.

The value of liming for marsh soils, E. Möller (*Deut. Landw. Presse, 29 (1902), No. 30, p. 254*).

Fertilizer inspection, C. D. Woods and J. M. Bartlett (*Maine Sta. Bul. 81, pp. 65–80*).—This bulletin contains analyses of 150 brands of fertilizers (manufacturers' samples) licensed before March 1, 1902, with a summary of the chief provisions of the State fertilizer law.

Analysis of commercial fertilizers sold in Maryland, H. B. McDonnell et al. (*Maryland Agr. Col. Quart., 1902, No. 15, pp. 51*).—A report of the results of inspection of fertilizers, September, 1901, to January, 1902, inclusive.

Fertilizer inspection in Massachusetts, C. A. Goessmann (*Massachusetts Sta. Bul. 81, pp. 20*).—This bulletin includes analyses of fertilizers sent to the station for examination, of licensed fertilizers collected by the agent of the station during 1901, and of Paris green; instructions regarding sampling of fertilizers and to manufacturers, etc.; a discussion of trade values of fertilizing ingredients; and a brief account of experiments with manure preservatives (see p. 1028). The fertilizing materials examined included wood ashes, limekiln ashes, cotton-seed meal, bone, fish, tankage, Thomas slag, jadoo fiber, dried and pulverized rockweed, mill waste, sheep fertilizer, milk casein, besides mixed fertilizers and soils.

Fertilizer inspection in North Carolina, B. W. Kilgore (*Bul. North Carolina Bd. Agr., 23 (1902), No. 3, pp. 3–26*).—The names and guaranteed composition of fertilizers registered for 1902, and analyses and valuations of 78 samples of fertilizers examined during the spring of 1902, with the usual explanations regarding freight rates, valuation, etc.

Analyses of commercial fertilizers, J. Hamilton and W. Frear (*Pennsylvania Dept. Agr. Bul. 89, pp. 195*).—This bulletin contains the text of the fertilizer law of Pennsylvania, notes on valuation, a discussion of the composition of raw materials and the cost of fertilizer constituents, and tabulated analyses and valuations of 761 samples of fertilizing materials examined during 1901. The average composition of the fertilizers examined during 1901 is given and their selling price and valuation are compared with similar data for fertilizers examined during previous years.

On the rational use of sulphite solutions from fiber factories in the preparation of fertilizers, T. Knösel (*Chem. Ztg., 26 (1902), No. 21, p. 229*).—This is a brief account of a patented process in which sulphite solution evaporated to 25° Baumé is mixed with an equal amount of Thomas slag, thereby largely increasing the percentage of citrate-soluble phosphoric acid in this material.

Formation of oceanic salt deposits, particularly of the Stassfurt beds. XXIV. Gypsum and anhydrite. 3. Natural anhydrite and its formation at 25°, J. H. van't Hoff and F. Weigert (*Sitzber. Kgl. Preuss. Akad. Wiss. Berlin, 1901, XLVIII, pp. 1140–1148; abs. in Jour. Chem. Soc. [London], 82 (1902), No. 472, II, p. 137*).

FIELD CROPS.

Report of the experimentalist, C. A. Zavitz (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 82–111*).—The work here reported consists largely of variety and culture tests and is in continuation of experiments conducted for some years (E. S. R., 13, p. 338). Brief comments on other work by the experimentalist are also given.

Seed grain selections with oats, barley, peas, and spring and winter wheat have been in progress from 5 to 8 years, and the average yields of straw and grain and the weight of grain per measured bushel in each case are in favor of large, plump seed as compared with medium-sized or small seed. Shrunken seed of barley and spring and winter wheat and broken seed of barley produced small yields. Split seed of peas and winter wheat yielded only 10 and 8 bu. of grain per acre, respectively.

Of 228 varieties of oats tested during the past 14 years, White Siberian, Oderbrucker, Vick American Banner, and Bavarian were among the very best general-purpose varieties. Joanette Black is reported as a large yielder, with exceedingly short straw. It stools abundantly and for this reason very thin sowing is recommended on rich soils. Daubeney and Alaska have proved to be very early varieties. Seed oats obtained from varieties sent from the college to the Missouri station 4 years ago were compared with seed from the same varieties grown continuously at the college. The Missouri seed produced the largest yield of grain per acre and the Ontario seed the heaviest grain per measured bushel. Continuous seed selection of Joanette oats for 9 years resulted in 1901 in a yield of 44.4 bu. for large, plump seed, 28.5 bu. for light-weighing and light-colored seed, and 37 bu. per acre for hulled seed. The grain from large, plump seed weighed 5 lbs. more per measured bushel than that produced from light seed.

Among the 6-rowed varieties of barley grown for a number of years, Mansbury gave decidedly the best results. The average results for the past 13 years show that this variety yielded about 9 bu. per acre more than the common 6-rowed barley of Ontario. Oderbrucker, Scotch Improved, and Imperial Six-Rowed are also classed among the best. The best 2-rowed barley yielded an average of about 13 or 14 bu. of grain less per acre than the best 6-rowed variety. New Zealand Chevalier and French Chevalier were among the very best 2-rowed varieties. The hulless barleys gave much smaller yields of grain than Mansbury. Of the varieties tested for several years Guy Mayle, Purple, and Black Hulless produced the most grain.

A mixture of barley and oats in 9 different proportions was tested for 2 successive years. The mixture of 1 bu. of oats and 1½ bu. of barley per acre gave the best yield of grain in 1900 and the second best in 1901, but the average yield for the year was in favor of this proportion. It was found that in the yield of straw 1½ bu. of oats and 1 bu. of barley made the best record.

In several years' experiments with spring wheat, excluding the macaroni varieties, Red Fife, Herison Bearded, Wellman Fife, and Red Fern gave the best average results. Wild Goose, a macaroni wheat, gave decidedly the largest yield of grain of all the varieties grown. Medeah, Bart Tremenia, Sorentina, and Algiers, the other macaroni wheats grown in these experiments, also gave better yields than any of the finer varieties of spring wheat.

The winter-wheat varieties grown for 6 years were Dawson Golden Chaff, Imperial Amber, Egyptian Amber, Early Genesee Giant, Michigan Amber, Turkey Red, and Treadwell, the average yields being 54.1, 51.5, 50.1, 49.7, 49.3, 40.6, and 39.1 bu. per acre, respectively. Buda Pesth, which has been grown for only 4 years, has an average yield of 49.6 bu. It was noticed that among 100 varieties of winter wheat Imperial Amber, Egyptian Amber, Early Genesee Giant, and Michigan Amber were almost free from injury by the Hessian fly. Turkey Red, grown in Ontario for 8 years, was little affected by the fly, but the same variety obtained from Kansas in 1900 was considerably injured. Bisseli, Geneva, Turkey Red, Emporium, Amherst Isle, Imperial Amber, Reliable, Arnold Hybrid, Red May, and McPherson were most rust resistant, and American Bronze, Helena, Silver Star, Early Genesee Giant, Early Red Clawson, and Red Velvet Chaff, the least rust resistant. The best average yields for several years from seeding on different dates were obtained from the grain sown on or before September 9. Drilling and broadcasting have given practically equal results for 7 years. This season an experiment was begun with drilling one-half of the seed one way and drilling the other half crosswise. The cross drilling gave slightly better results than the common method. The results for 6 years show that cutting wheat after it has become very ripe gives the highest weight per measured bushel and the largest yield of grain and straw.

In the average results for several years Mammoth winter rye gave the largest yield of grain per acre, surpassing the common rye by 5 bu. in 1898, 1½ bu. in 1900, and 14 bu. in 1901. The 4 varieties of spring rye, Dakota Mammoth, Prolific Spring, Common, and Colorado Giant, yielded 38.3, 33.3, 32.6, and 15.6 bu., respectively, in 1901, and 41.8, 37.6, 35, and 25 bu. per acre, respectively, on an average for 4 years.

The average results of 3 varieties of buckwheat grown for 6 years show that Japanese yielded 20.3, Silver Hull 16, and Common Grey 13.8 bu. of grain per acre. In the production of straw these varieties stood in the same order.

The largest average yields per acre of peas grown for 7 years were obtained from White Wonder, New Zealand Field, Early Britain, Egyptian Mummy, New Zealand Brown, and Tall White Marrowfat. No varieties proof against the pea weevil have as yet been found. Grass peas, for a period of 7 years, have given an average yield of 25.7 bu. of grain and 2.2 tons of straw per acre. The average results for 7 years with the Egyptian or Chick pea (*Cicer arietinum*) show that 35.6 bu. of grain and 1 ton of straw were obtained per acre. The growing season in Ontario has been found too short for maturing cowpeas.

Of 29 varieties of field beans grown for 5 successive years, Day Improved Leafless, White Wonder, Medium or Navy, Burlingame Medium, Pearce Improved Tree, Schofield, Snowflake, and Boston Pea bean produced the largest average yields, which ranged from 22.3 bu. for Day Improved Leafless to 20.8 bu. for Boston Pea bean. Among 5 varieties of soy beans Early Yellow has given much the best results during a period of about 10 years, and in 1901 produced 25.3 bu. of grain per acre.

Common and hairy vetches were grown for seed in 1900 and 1901, but the results were not satisfactory from spring sowing. All fall sowing of hairy vetch produced over 8 bu. of seed per acre, which is considered a profitable yield, since the seed costs from $5 to $7 per bushel. For the production of green fodder the vetches have given promising yields.

Experiments have been in progress for 5 years with Manitoba, Common, and Russian flax, and the results have been fairly uniform for all varieties.

In testing the seed-producing capacity of different millets, it was found that the average yield for 4 years of California millet was 40.4 bu. and of Hungarian 36.4 bu.

of seed per acre. Japanese Panicle and Common millet produced smaller yields of seed.

In 1900 and 1901 the ears of the earlier varieties of dent, flint, and sweet corn were shelled to ascertain the yields of grain. Of 28 varieties treated in this way the following produced an average of over 60 bu. of shelled corn per acre: Hathaway Yellow Dent, Great Western, North Star Yellow Dent, King Phillip, Genesee Valley, Keil Early Dent, Pride of Canada, Salzer South Dakota, and Angel of Midnight.

In an experiment conducted for 2 successive years to determine the seed production of different varieties of sugar cane the Fodder cane produced the largest yield of seed, 20.8 bu. in 1900 and 24.2 bu. in 1901, followed by Early Minnesota Sugar Cane with a yield of 19.9 bu. in 1900 and 15.7 bu. in 1901. Among the varieties of broom corn Early Japanese produced the largest yield of seed, 30.8 bu., Improved Evergreen being second, with 29.5 bu. per acre. The Dwarf variety of broom corn averaged only 5.3 bu. Brown Durra produced the largest yield of seed among a number of other sorghums. The yields of 16 different sorghums grown for green fodder are given in a table.

The average production of sunflower seed for 4 years was 64.8 bu. by the Mammoth Russian sunflower, 62.7 by the White Beauty, and 55 bu. per acre by Black Giant.

In 1901, 103 varieties of potatoes were under test. They were planted May 23, in rows 26.4 in. apart, the sets placed 1 ft. apart in the row, and only one piece planted in a place. The seed was planted 4 in. deep, and level cultivation was given. The largest yields this season were produced by the Sunlit Star, American Wonder, Daisy, Pearl of Savoy, and Rural Blush. From the average results for a series or years it is concluded that Empire State, Pearl of Savoy, American Wonder, Dempsey Seedling, and Rural New Yorker No. 2 are among the best general-purpose varieties. For very early use, Stray Beauty, Howe Premium, and Early Ohio are recommended. The work in the selection of seed potatoes has shown in its results that large potatoes or large pieces produced greater yields than small potatoes or small pieces. Large potatoes cut into pieces of about 2 oz. in weight gave very satisfactory results. Planting one set in a place was found most profitable. The results of other tests indicated that potatoes should be planted immediately after the tubers are cut into sets. Remedies for the potato beetle are given.

Of several hundred varieties of roots tested for at least 5 years in succession, the following have given the best yields: *Long Red mangels*—Evans Improved Mammoth Sawlog, Simmers Improved Mammoth Long Red, and Steele-Briggs Long Red Selected, *Intermediate mangels*—Carter Champion Yellow; *Globe mangels*—Carter Warden Yellow; *swedes*—Hartley Bronze Top, Kangaroo, and Sutton Magnum Bonum; *fall turnips*—Cow Horn, and Jersey Navet; *carrots*—Mammoth Intermediate Smooth, Improved Short White, and Improved Half Long White. Large, plump seed of these different root crops, according to results for several years, has given best yields as compared with medium-sized and small seed. It was found that the seed of root crops should be sown quite close to the surface, and especially in the case of mangels and sugar beets. Taking the average of all the tests with the different roots, sowing on the level produced from 4 to 5 bu. per acre more than sowing on ridge land. On an average, early thinning gave $1\frac{3}{4}$ tons of roots per acre more than later thinning. Twenty-five varieties of sugar beets for feeding purposes were tested this season, and the yields are shown in a table. The results of the chemical analyses have been noted elsewhere.

Of fodder corn 138 varieties, including flint, dent, and sweet corn, were grown. Mammoth Cuban and Mastodon Dent have given promising results in southern Ontario, and Wisconsin Earliest White Dent has produced the largest yield of ears per acre among 67 varieties grown for 5 years in succession. Salzer North Dakota, Compton Early, and King Philip, 3 flint varieties, and North Star Yellow Dent have also given good results. Planting corn 2 in. deep gave the best average yields of total crop per acre for 3 years.

Among the different mixtures of peas and oats grown for green fodder, 2 bu. of Siberian oats and 1 bu. of Prussian Blue peas gave very satisfactory results. The average results for 5 years for the different mixtures under test were as follows: *Early varieties*—Daubeney oats and Chancellor peas, 5.9 tons; *medium early varieties*—Siberian oats and Prussian Blue peas, 6.9 tons; and *late varieties*—Mammoth Cluster oats and Prince Albert peas, 6.1 tons of green crop per acre. On an average the early varieties were cut 70 days, the medium early varieties 77 days, and the late varieties 84 days after seeding took place.

Early White Vienna kohl-rabi gave the largest yield per acre in 1901, and also in the average of 5 years.

The results for 7 years show that Dwarf Essex rape produced an average of 22.4 tons and Victoria 20.6 tons of green forage per acre. From the results of experiments carried on for 5 years, it was found that large rape seed yielded 70.4, medium-sized seed 15, and small seed 12.4 tons of green fodder per acre. The average results of sowing rape on level and ridge land are somewhat in favor of ridging. Subsoiling immediately before sowing produced no advantage. The results from planting rape seed at different depths have varied in different years, but in general were in favor of shallow planting.

The results with a number of leguminous crops and grasses grown for green fodders, hay, and pasture are reported.

Field crops, G. E. Day (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp 63, 64*).—The culture of different field crops at the college in 1901 is briefly noted.

Plant food trials, H. E. Stockbridge (*Florida Sta. Rpt. 1901, pp. 22–35, fig. 1*).—Fertilizer tests with sweet potatoes, sugar cane, Irish potatoes, corn, cotton, and cassava are reported. Each crop received a series of fertilizer applications, including a standard application and multiples and fractional parts of the same. The check plats received no fertilizers.

Sweet potatoes.—The experiment with sweet potatoes demonstrated that the normal application consisting of 200 lbs. acid phosphate, 204 lbs. cotton-seed meal, 66 lbs. nitrate of soda, and 80 lbs. sulphate of potash per acre was the most profitable formula.

Sugar cane.—The standard formula for sugar cane consisted of 50 lbs. each of acid phosphate and muriate of potash and 400 lbs. of cotton-seed meal per acre. Increasing this application had no material effect on the crop. Diminishing the proportion of phosphoric acid and of nitrogen reduced the nitrogen content of the cane and diminishing the proportion of potash reduced the yield.

Potatoes.—In connection with the tests on Irish potatoes, a study was made of cotton-seed meal, castor pomace, and nitrate of soda as sources of nitrogen. Cotton-seed meal and castor pomace gave practically the same result, but the nitrate increased the yield over these 2 forms by 30 per cent. The standard application for potatoes consisted of 500 lbs. acid phosphate, 250 lbs. cotton-seed meal, 125 lbs. nitrate of soda, and 200 lbs. sulphate of potash per acre. This application proved very effective on soil exhausted by tobacco culture and this result is considered a demonstration of the value of crop rotation. Cowpeas preceding the potatoes increased the yield 40 per cent. Where only one-half of the normal application of phosphoric acid was applied a larger yield of potatoes was obtained than where the full normal application was used. A reduction of the normal application of potash to one-half diminished the yield 40 per cent, representing a financial loss of $5.50 per acre.

Corn.—In the tests with corn an application of 200 lbs. acid phosphate, 125 lbs. cotton-seed meal, 75 lbs. nitrate of soda, and 100 lbs. muriate of potash was used as the standard. This application increased by one-half gave an increase in yield of 18 bu. per acre, but the result was the same when the application was diminished by one-half. This increase was the largest in the series of tests and the use of one-half the normal application was the most profitable.

Cotton.—The normal application in the experiments with cotton consisted of 187.5 lbs. acid phosphate, 137.5 lbs. cotton-seed meal, and 25 lbs. muriate of potash per acre. An application in which the phosphoric acid had been reduced one-half from the normal gave the most profitable results in the series. Diminishing the proportion of nitrogen and potash was found unprofitable.

Cassava.—The results here showed that a reduction of the normal application consisting of 125 lbs. acid phosphate, 150 lbs. cotton-seed meal, and 75 lbs. muriate of potash per acre decreased the yield considerably as compared with the normal application and the same increased by one-half or doubled. In this test the check plat receiving no fertilizers produced a larger yield than any of the plats which had received a smaller quantity of fertilizer than the normal application. The normal formula gave a yield of 539 lbs. of roots per acre, $1\frac{1}{2}$ times the normal, 742 lbs., and double the normal, 785 lbs.

Report of the agricultural work for 1900, J. R. BOVELL and J. P. D'ALBUQUERQUE (*Imp. Dept. Agr. West Indies Rpt. 1900, pp. 178*).—The work reported consisted of experiments with sugar cane and several leguminous crops. Cooperative fertilizer experiments with sugar cane were conducted on a number of plantations and in reporting the results the mechanical and chemical analysis of the soil and the rainfall for the particular locality are given. Experiments with seedling and other varieties of canes are described, and a list of selected varieties is given, together with their general characters, yield, and composition. The experiments with leguminous plants consisted mainly of variety tests of cowpeas. All results are tabulated in detail. In addition to the analyses of the different varieties of cowpeas, the analyses of Bengal bean, velvet bean, horse bean, woolly pyrol, monkey pea, *Dolichos formosus*, *D. cultratus*, *Phaseolus semierectus*, *P. helvolus*, and *Cyanopsis* sp. are reported.

Field experiments, F. B. GUTHRIE (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 894–902*).—This report presents the results of experiments with different fertilizers applied in different combinations and quantities. The experiments were conducted with wheat at the Wagga and Bathurst experimental farms in 1900.

Experiments at Bathurst Experimental Farm, A. A. DUNNICLIFF (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 1005–1009*).—Brief notes on experimental work with cereal and forage crops in 1900.

Cereals, legumes, grasses, and saltbushes at Coolabah Farm in 1900, R. W. PEACOCK (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 1028–1031*).

Report on the experimental plats at the Hawkesbury Agricultural College, G. L. SUTTON (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 964–973*).—This report enumerates the varieties of cereals, legumes, sorghums, millets, and other forage plants grown experimentally during the season of 1900. The results with numerous species of grasses growing on permanent plats are briefly noted.

General experiments at Wagga Experimental Farm, G. M. McKEOWN (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 994–1002*).—Brief notes on culture, fertilizer, and variety tests with cereal and forage crops in 1900.

Field crops at Wollongbar Experimental Farm in 1900 (*Agr. Gaz. New South Wales, 12 (1901), No. 8, pp. 1012–1017*).—Short notes on culture and variety tests with cereal, hay, and root crops.

Guide to experiments at Manor Farm, Garforth, 1901 (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Pamphlet 15, 1901, pp. 17, pls. 2, map 1*).—This bulletin is a brief tabular statement of experiments with fertilizers and barnyard manure on grass, oats, potatoes, and swedes. The varieties of the different crops under test are enumerated.

Investigations on the cereal crops of Roumania, V. CARNU-MUNTEAUNU and C. ROMAN (*Recherches sur les céréales Roumaines. Bucharest, 1900, pp. 227*).—This publication, issued by the experiment station at Bucharest, discusses wheat, corn, and barley culture in Roumania, and reports in tabular form the chemical analyses of the various crops for different sections of the country.

An experiment on the improvement of cereals, E. Gavillet (*Chron. Agr. Canton Vaud, 14 (1901), No. 20, pp. 498–502*).—This article reports the results of variety tests with oats, and calls attention to the very promising results obtained with a number of foreign varieties, including American Banner and Improved American.

The seeding of grain, J. Speir (*Jour. Bd. Agr. [London], 8 (1901), No. 4, pp. 438–446*).—This article discusses tillering, size of seeds, quantity, germination, and change of seed, quality of the land, date of sowing, broadcasting, and drilling, and the losses which occur in seeding.

Manures for a four-year rotation, D. A. Gilchrist (*Jour. Bd. Agr. [London], 8 (1901), No. 3, pp. 324–327*).—An account is given of a four-year rotation and the use of fertilizers in connection with it. The fertilizers were applied at the beginning of the rotation. The best financial results for the entire rotation were obtained from an application of 2 cwt. of nitrate of soda, and 6 cwt. of basic slag per acre.

Experiments with potash fertilizers, Clausen (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), No. 48, pp. 736–739, fig. 1*).—In these experiments oats, beets, and horse beans were grown in pots containing a heavy marsh soil. Potash was supplied to each crop in the form of kainit, 40 per cent potash salt, and sulphate of potash. The use of kainit gave the largest increase in the yield of oats, and the application of potash in general increased the production of grain as compared with that of straw. The different forms of potash increased the yield of beets from 12 to 22 per cent. Beets were found to be the most sensitive to impurities contained in the potash fertilizers. The results with horse beans were vitiated to some extent.

Catch and cover crops, J. Gould (*Rural New Yorker, 60 (1901), No. 2699, p. 691*).—An article discussing the culture of oats and Canada peas and of rape as catch and cover crops.

Fertilizer experiments on irrigated meadows, B. Tacke (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 46, pp. 263, 264*).—A description of the work and the results obtained are given, and a grass-seed mixture for this class ot meadows recommended. It is the intention to continue the experiments for a series of years before drawing definite conclusions.

Manuring of meadow hay, R. S. Seton (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Pamphlet 14, 1900, pp. 12*).—The results of the cooperative fertilizer tests on meadows conducted in 1900 showed that the most profitable proportions of commercial fertilizers were 1½ cwt. ot nitrate of soda, 2 cwt. superphosphate, and 3 cwt. of kainit per acre. The annual or biennial use of barnyard manure for this purpose was also found profitable.

Rotation of crops as a means of destroying weeds on meadows, Ulrich (*Sächs. Landw. Ztschr., 49 (1901), No. 45, pp. 1072, 1073*).—A brief account is given of the ways in which a rotation may be arranged with a view to destroying weeds on meadows.

Cultivation by the use of deep-rooting plants, R. H. Elliot (*Jour. Bd. Agr. [London], 8 (1901), No. 3, pp. 313–323*).—This article discusses the value derived from the culture of deep-rooting plants, and dwells upon the necessity of conserving humus and restoring it to the soil.

Seed corn and some varieties for Illinois, A. D. Shamel (*Breeders' Gaz., 40 (1901), No. 21, pp. 882–884, figs. 7*).—This article discusses the growing of seed corn and enumerates the varieties of corn bred in Illinois. The occurrence of barren stalks is also briefly considered.

Corn crop tables of Standard Cattle Co., Ames, Nebr. (*Ames, Nebr.: Standard Cattle Co., 1900, pp. 16*).—These tables show the yields of corn, the estimated amounts of stover, and the cost of producing the crop on the lands of the company for the years 1893–1899, inclusive.

Cotton culture, R. J. REDDING (*Georgia Sta. Bul. 56, pp. 121–154*).—These experiments are continued from previous years (E. S. R., 13, p. 40). In 1901, 26 varieties were tested. Peterkin, Wise, Schley, Pullnot, Culpepper, and Jones, given in the order of their value of total products, headed the list in profitable returns. Omitting Culpepper and Jones, they ranked in the same order in the production of lint cotton per acre. Mascot, the earliest variety, produced a total crop valued at $42.11 per acre and ranked thirteenth as to profitableness. The highest value of total crop in these experiments was $44.13 per acre. Sims Long Staple, the only variety of upland long staple type grown in these tests, ranked twenty-fifth in the value of lint and seed produced. This season, unlike the results of the 7 previous years, the best half of the number of varieties had the smallest bolls and also the smallest seeds, still "it seems fair to conclude from the 8 years' record that large bolls, large seed, and a high percentage yield of lint are closely related with the greatest value of total product of lint and seed, and that these are all desirable qualities."

Varietal notes and directions for selecting a variety and selecting seeds in the field are given.

This season's results of the composite seed test were equally significant with those obtained in previous years.

Taking into consideration the results of distance experiments for this and the 2 previous seasons, the author concludes that on soils varying in productive capacity of from 1 to $1\frac{1}{2}$ bales per acre the best results will be obtained when the plants are placed 12 in. apart in rows 4 ft. wide.

As in 1900, the results of the comparison between thorough and ordinary preparation of the soil were inconclusive. The yield of plats which had received a preparatory plowing, subsoiling, and harrowing was a little smaller than the yield of the plats not given this extra preparation.

A potash test on a certain soil showed that with 362 lbs. of 14 per cent acid phosphate, 139 lbs. of cotton-seed meal, and 38 lbs. of nitrate of soda per acre, at least 31.20 lbs. of muriate of potash would be required to produce a maximum yield of seed cotton. A nitrogen test with cotton-seed meal and nitrate of soda indicated that on the soil on which the test was made no nitrogen, or at most a very little, is required when 355 lbs. of 15 per cent acid phosphate and 28 lbs. of 50 per cent muriate of potash are applied per acre. The author believes that the soils of middle Georgia can be brought into such condition by a regular rotation of corn and cowpeas, small grain and cowpeas, and cotton that they will not require nitrogenous fertilizers.

The weather conditions for a series of seasons are shown in the bulletin, and brief notes on cotton culture, together with fertilizer formulas for the crop, are given in an appendix.

Experiment on cotton at the society's experimental farms at Mit-el-Diba and Ghizeh, G. P. FOADEN (*Jour. Khedir. Agr. Soc. and School Agr., 3 (1901), No. 6, pp. 248–261, figs. 2*).—Fertilizer and rotation experiments with cotton are reported. The results indicated that suitable applications of commercial fertilizers give profitable results. Superphosphate increased the yield satisfactorily and hastened maturity, while nitrate of soda also increased the yield, but greatly delayed ripening, and produced a crop somewhat inferior in quality. A mixture of superphosphate and nitrogen gave the best results. The author recommends the use of 3 or 4 cwt. of superphosphate and from $1\frac{1}{4}$ to $1\frac{1}{2}$ cwt. of either nitrate of soda or sulphate of ammonia per acre. Potash alone did not give profitable returns. In rich soil where cotton was grown immediately after berseem the application of manures had very little effect. Cotton grown after crops requiring irrigation during the summer did not give very good yields. The use of suitable mixtures of manures was found to hasten the maturity of the cotton crop.

Cotton cultivation in India, G. P. FOADEN (*Jour. Khedir. Agr. Soc. and School Agr., 3 (1901), No. 5, pp. 220, 221*).—Statistics on the crop of 1900–1901.

The cost of cotton cultivation, G. P. FOADEN (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 5, pp. 217–219*).—A brief consideration of the outlay involved in growing cotton in Egypt, Queensland, and America.

The exhaustive effects of the cotton crop, G. P. FOADEN (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 5, pp. 205–209*).—This article gives the quantities of plant food withdrawn from the soil by the cotton plant and compares them with amounts removed by the most common field crops.

Cowpea culture, J. F. DUGGAR (*Alabama College Sta. Bul. 118, pp. 40, figs. 2*).—Various experiments with cowpeas conducted at the station during the last 6 years are described and the results reported and discussed. Directions for the culture of the cowpea for seed and for hay are given.

Cowpeas were planted in April, June, and July, and from the results obtained it is concluded that usually nothing is gained by planting before May. For the production of seed, planting in June was most satisfactory. New Era cowpeas planted April 26 matured 2 crops before frost.

Tests in subsoiling and liming did not show an increase in yield.

In one test broadcast sowing gave a larger yield of hay than drilling and cultivating, but the author does not consider broadcasting as certain a method in unfavorable seasons.

Among the large number of varieties tested New Era and Black and Red Ripper produced the most seed. Wonderful and Clay produced the largest average yield of hay for 3 years. The number of seeds per bushel varied from 94,634 with Taylor to over 236,000 with New Era and Small Black. The number of pounds of dry unhulled peas required to shell a bushel ranged from 78 lbs. with the Brown-eye Crowder to 90 lbs. with Wonderful.

On the station soil fertilizer produced very slight gains. For poor sandy or loamy soils the use of acid phosphate with or without potash is recommended. The results of 3 tests showed a superiority of acid phosphate over crude phosphate.

Analyses were made of the different parts of the cowpea plant, and the results are given in tabular form. With some varieties from 51 to 75 per cent of the whole plant by weight was obtained in the hay, and of this quantity the leaves averaged 30 per cent. The leaves were found to be at least twice as rich in protein as the other parts of the plant. It is stated that cowpea hay resembles wheat bran in composition, and that the seeds are much richer in nitrogen than either wheat bran or corn.

As compared with velvet beans, cowpeas have an advantage in curing and in palatability, but a disadvantage in being subject to attacks of nematode worms and several fungus diseases. At the station, cowpeas have also given a higher average yield than velvet beans, soy beans, and beggarweed. By sowing sorghum with cowpeas the yield of hay was increased, but it did not facilitate curing.

"Cows pastured on cornstalks and drilled cowpeas between the corn rows afforded butter and increased live weight worth, in 1900, \$4.47 per acre grazed over. The next year the returns in butter alone from cowpeas drilled between the corn rows was \$5.28 per acre."

Winter forage crops for the South, C. R. BALL (*U. S. Dept. Agr., Farmers' Bul. 147, pp. 36, figs. 24*).—This bulletin discusses the past and present winter forage conditions of the South, and briefly reviews the forage resources of the region for the winter months. A list of forage crops, including grasses, leguminous plants, and rape, is recommended as furnishing forage during the winter. Each species is described and directions for its culture are given.

Grasses (*New Zealand Dept. Agr. Rpt. 1901, pp. 159–163*).—The kinds of grasses on trial at the Momohaki Experiment Station, New Zealand, with brief notes on their value, are given in a table.

Grass seeding (*Rural New Yorker, 60 (1901), No. 2688, p. 530*).—A report on an experimental seeding of grass by the Clark method.

Grass seeded without grain (*Rural New Yorker, 60 (1901), Nos. 2688, p. 531; 2689, pp. 545, 546*).—A description of the Clark system of grass culture.

Manila hemp culture in Manila, H. AUSTIN (*New Zealand Dept. Agr. Rpt. 1901, pp. 294–300*).—This is a report presenting information on the hemp industry in the Philippine Islands. The culture and preparation of the plant is discussed and statistics on the industry from 1890 to 1900, inclusive, are presented.

New Zealand hemp (Phormium tenax) (*New Zealand Dept. Agr. Rpt. 1901, pp. 289–294*).—Report of the commissioner appointed to examine the machines and processes submitted in competition for the bonuses offered for the encouragement of the New Zealand hemp industry.

Investigations upon the growth of hops, 1895–1901, A. D. HALL (*Jour. Bd. Agr.* [*London*], *8 (1901), No. 4, pp. 459–469*).—Growing hops upon string and wire gave better results than the use of poles, and cutting away the vine at picking time produced a weakening effect which was noticeable for 2 seasons. The Butcher, umbrella, and Worcester systems of stringing are described. The results of a 5-year test of the different systems did not show a definite advantage in favor of any one system. Stripping the plant of the lower leaves to facilitate spraying caused no loss in the years of vigorous growth, but in the seasons when the development of the plants was slow they did not recover from the check which they had received from the removal of these leaves. In a cultivation test the discontinuance of all cultivation beyond the destruction of weeds for 7 successive years resulted in no particular reduction of the crop, though perhaps in a slight inferiority in the quality. Deep cultivation at the time the hops began to form induced earlier ripening.

Several chapters on the lupine, O. SCHELLENBERGER (*Fühling's Landw. Ztg., 50 (1901), Nos. 12, pp. 423–431; 13, pp. 463–471; 14, pp. 489–494*).—This article discusses the culture of lupines, their use for soil improvement, and their value for feeding purposes. In considering the culture the author speaks of the different varieties, the sensitiveness of the plant to the lime content of the soil, the kind of seed to be used, the effects of inoculation of the soil, and the diseases to which lupines are subject. The discussion of lupines for soil improvement consists of concise presentations of the observations made by prominent agriculturists and investigators. The consideration of lupines as fodder is devoted mainly to the subject of the harmful alkaloids of the plant and the methods of removing them. Of the different kinds the blue lupine is considered of greatest economical value. This species has the best developed root system, and a low alkaloid content, in addition to being one of the best nitrogen gatherers and seed producers. It is also least sensitive to lime and frost.

A new variety of lupine, A. SEMPOLOVSKI (*Deut. Landw. Presse, 28 (1901), No. 99, p. 821*).—A brief note describing the development of a red lupine from a sport of the blue lupine. The new variety has been fixed, and has certain advantages over the mother variety. The results of chemical analyses of the 2 varieties are given.

Salt for mangels (*Agr. Jour. Cape Good Hope, 19 (1901), No. 9, pp. 590–691*).—A brief article on fertilizing the soil for mangels and the use of salt in that connection.

Culture of oats in 1900, P. P. DEHÉRAIN and C. DUPONT (*Ann. Agron., 27 (1901), No. 11, pp. 551, 552*).—Of 3 varieties grown at Grignon, Ligowo gave the best yield of grain. This is a yellow variety, and for this reason it is not a favorable sort for the Paris market.

A new Paspalum (*Queensland Agr. Jour., 9 (1901), No. 5, p. 463*).—Under this title a brief note on *P. virgatum* is given. The species is compared with *P. dilatatum.*

Paspalum dilatatum (*Agr. Ledger, 1901, No. 1 (Agr. ser., No. 33), pp. 9*).—A description of results obtained in India.

Paspalum dilatatum (*Queensland Agr. Jour., 9 (1901), No. 6, pp. 532–534*).—Notes on the value of this grass for Australia.

Early potatoes by the "boxing" system (*Farmers' Gaz., 60 (1901), No. 42,* *p. 761*).—A description of growing early potatoes by means of starting the sprouts by a special method.

Desirable extra-early potato, C. W. FORD (*Amer. Agr., 61 (1901), No. 12, p. 52*).—History and description of the Irish Cobbler potato.

The potato, L. ROUBAL (*L'Ing. Agr. Gembloux, 12 (1901), No. 5, pp. 190–210*).—This article discusses a wide range of subjects related to the culture of potatoes and their uses.

Fertilizer and variety tests with potatoes (*New Zealand Dept. Agr. Rpt. 1901, pp. 164–166*).—The tabulated results show that superphosphate, steamed bone dust, and Thomas slag invariably gave the best results, while kainit diminished the yield. The different varieties tested are briefly described.

The influence of manuring on the chemical composition of potatoes, W. F. SUTHERST (*Chem. News, 84 (1901), No. 2192, pp. 258, 259*).—The chemical composition of potatoes grown on unmanured soil is compared with the composition of tubers grown on soil which received 20 tons of barnyard manure or an application of 5 cwt. of superphosphate, 2 cwt. of muriate of potash, and 2 cwt. of sulphate of ammonia per acre. On account of insufficient data no definite conclusions are drawn.

Rice culture in Japan, F. MAIN (*Jour. Agr. Prat., n. ser., 2 (1901), No. 50, pp. 761–763*).—A general article on the rice industry of Japan.

Culture experiments with Petkus rye in Sweden, S. RHODIN (*Deut. Landw. Presse, 28 (1901), Nos. 101, pp. 836, 837; 102, pp. 851, 852*).—These experiments were carried on for 6 years. The results show that this variety of rye is very resistant to unfavorable winter weather. The average weight of the rye for the entire period was 71 kg. per hectoliter, and the average proportion of grain to straw was as 55:100. Cooperative tests showed that it was the best variety for many sections, but that in some localities the requirements of soil and climate for its successful culture could not be fulfilled.

The use of commercial fertilizers for rye in East Germany, GERLACH (*Deut. Landw. Presse, 28 (1901), Nos. 74, pp. 623, 624; 75, pp. 629, 630; 76, pp. 641, 642*).—This article presents observations and results of experiments on growing rye with commercial fertilizers in the eastern provinces of Germany.

A cross between spelt and wheat, P. H. STOLL (*Deut. Landw. Presse, 28 (1901), No. 101, p. 840, fig. 1*).—A brief statement on the method of producing this cross, with a description of its characters and qualities.

Sugar beets, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 38–42*).—Cooperative culture tests with sugar beets were made, and the results are here recorded by districts. Brief directions for the culture of sugar beets are also given. Tests were made by 25 farmers in each of 15 different districts, and the results for this entire series show an average sugar content of 15.61 per cent and a purity of 87.49 per cent. The average yield of beets per acre was 17 tons and 495 lbs.

Sugar beets for feeding purposes, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, p. 37*).—Twenty-five varieties of sugar beets for feeding purposes were grown and the average weight of the beets, with the percentage of sugar they contained and the coefficient of purity for each sample, is reported in a table without further comment.

The sugar beet, L. MALPEAUX (*La betterave à sucre. Paris: Masson & Co., pp. 206, figs. 26*).—A general and popular treatise on the culture of the sugar beet. A list of 32 reference works is given.

Sugar-beet culture in Egypt (*Deut. Zuckerind., 26 (1901), No. 28, pp. 1322–1325*).—This article discusses the possibility of sugar-beet culture in Egypt, and reports briefly the results of several cultural tests.

Beet crop tables of the Standard Cattle Co., Ames, Nebr. (*Standard Beet Sugar Co., pp. 16*).—General instructions for sugar-beet culture are given and the results of growing sugar beets on the fields of the company, including the cost for the years 1893–1898, inclusive, are tabulated.

Influence of manure upon sugar beets, W. H. JORDAN and G. W. CHURCHILL (*New York State Sta. Bul. 205, pp. 251–264*).—Experiments were conducted for the purpose of comparing the composition of sugar beets grown with commercial fertilizers and those grown with stable manure applied in the spring before planting. From 20 to 40 tons of stable manure and in most cases 1,000 lbs. of commercial fertilizers were applied per acre. No manure whatever was used on the check plats. These experiments were conducted for 4 consecutive years, and during that time at least 6 varieties of seed were grown. The results for the different years are given in tables and discussed. The beets obtained were all of high quality, the average being somewhat better with the stable manure than with no manure or with commercial fertilizers. Stable manure did not induce an excessive growth of leaves as compared with commercial fertilizers.

Sugar cane, G. J. B. BLEKKINK (*Orgaan Ver. Oudleer. Rijks Landbouwschool, 13 (1901), No. 160, pp. 226, 227*).—A discussion of methods practiced in sugar-cane culture in Java.

Sugar cane as a halophilous plant (*Jour. Agr. Trop., 1 (1901), No. 5, pp. 145, 146*).—This article points out the fact that sugar cane can thrive on soils impregnated with salt.

The sugar industry of Roumania (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 49, Sup. 39, pp. 189, 190*).—Statistics.

The culture of sulla in Southern Spain, DE SAN-BERNARDO (*Jour. Agr. Prat., n. ser., 2 (1901), No. 50, pp. 752–754*).—The culture of sulla is discussed and results of experiments are reported. A plat inoculated with soil from a field on which sulla had matured produced 45 times as much green fodder per hectare as a plat uninoculated.

Results of experiments on swede growing, R. S. SETON (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Pamphlet 16, 1900, pp. 16*).—A report on the results of cooperative fertilizer and variety tests with swedes in 1900.

Tobacco business in France, J. C. COVERT (*U. S. Consular Rpts., 67 (1901), No. 255, pp. 502–505*).—This article embodies statistics on the amount of tobacco sold annually and gives a description of the organization and management of the State tobacco factory at Lyons.

Fertilizer and variety tests with turnips and mangels (*New Zealand Dept. Agr. Rpt. 1901, pp. 166–171*).—The results of these tests are given in tables.

Velvet bean, H. K. MILLER (*Florida Sta. Bul. 60, pp. 448–468, pls. 4*).—This bulletin contains a report on investigations with the velvet bean and a popular description of its culture, together with its uses as a soil renovator, fertilizer, cover crop, and ornamental. It was shown by analysis that the dried root of the plant contained 1.41 per cent of nitrogen, and by calculating the weight of the dried root to the basis of an acre, it was found that 690 lbs. of dried root would be produced. These figures show an increase of 9.7 lbs. of nitrogen per acre obtained from the root alone. The quantity of nitrogen removed in the hay from an acre is estimated at 131.5 lbs., so that if the hay were plowed under, 141.2 lbs. of nitrogen per acre would be added to the soil.

Analyses of the vines at different stages of maturity are recorded in tables. From the time the bloom appears until before the seeds begin to form is considered the proper time for cutting the velvet bean for hay. From further analyses it was found that a ton of beans in the pod contains 54.8 lbs. of nitrogen, 31.8 lbs. of potash, and 13.8 lbs. of phosphoric acid, representing a fertilizing value of over $10. Feeding experiments are noted elsewhere.

Field experiments with wheat, J. F. HICKMAN (*Ohio Sta. Bul. 129, pp. 27*).—The work reported in this bulletin consisted of variety tests and of cultural investigations. The average results for the 9 years indicate that Mealy and Early Ripe wheats are 2 of the best yielders on upland soils of average fertility. Red Russian, Poole, and Gypsy were close competitors for first place. Valley is recommended as the best variety for rich, strong, or low lands such as creek or river bottoms. Nigger, Egyptian, Currell Prolific, Mediterranean, New Monarch, and Improved Poole proved to be high yielding varieties, while Jones Square Head, Jones, Winter Fife, Royal Australian (Clawson), Early White Leader, New Longberry, and Martin Amber were some of the less promising sorts in these tests. The Mealy wheat, grown at the Station for 11 years in succession, gave relatively the highest average yield in the comparative tests. Observations seem to indicate that this variety has a tendency to shrivel when grown on low or otherwise rich land, but the results of the last year show that under like conditions it does not shrivel worse than the other varieties. The results of the year show that a larger proportion of white wheats than of red wheats were shrivelled.

Under normal conditions seeding at the rate of 8 to 10 pecks per acre gave a superior quality with higher yields as compared with thinner seeding. Eight or nine pecks of seed per acre are recommended for the thinner and less fertile soils of the State and 5 or 6 pecks for the rich, alluvial, or very strong upland soils. Comparatively late seeding gave the best results, but the author warns against deferring seeding too long in order not to interfere with a good, strong, fall growth. From the results of using different grades of seed it is concluded that either the quality of the seed does not influence the crop materially or that the variation in the quality of the seed was not sufficiently marked.

The California wheat industry, N. A. COBB (*Agr. Gaz. New South Wales, 12 (1901), No. 11, pp. 1317–1348, figs. 43; Dept. Agr. New South Wales, Misc. Pub. 519, pp. 32, figs. 43*).—This article presents personal observations in the wheat-growing regions of California. The author describes the most important varieties grown, pointing out their adaptation to the conditions of soil and climate, and discusses at some length the methods of harvesting grain and the machines employed for that purpose.

Wheat culture on the experiment field at Grignon in 1900 and 1901, P. P. DEHÉRAIN and C. DUPONT (*Ann. Agron., 27 (1901), No. 11, pp. 534–551*).—This report compares the results of 3 varieties of wheat, Japhet, Bordeaux, and Noe, spring sown in 1900, and 2 varieties, Japhet and Scholley, fall sown in 1901. Of these varieties, Japhet gave the best yields. The weather conditions which prevailed during the season, and the treatment of the soil with reference to rotation and fertilization, are shown in tables. Sowing wheat the latter part of October gave better results than sowing about 2 weeks later. In these tests wheat grown after potatoes gave larger yields than wheat grown after beets. It was found that vetch was not a favorable crop to precede wheat.

Variety tests of wheat (*New Zealand Dept. Agr. Rpt. 1901, pp. 158, 159*).—The results with 10 varieties of wheat are tabulated. Marshall Chaff produced the best yield.

Australian methods of testing and improving wheat (*Agr. Ledger, 1901, No. 2 (Agr. ser., No. 34), pp. 11–31*).—These methods are discussed and their applicability to India with special reference to the prevention of rust is considered.

The harvest of wheat, rye, and mixed grain (*Semaine Agr., 21 (1901), No. 1063, pp. 305, 306*).—Estimates on the production of wheat, rye, and mixed grain in France for 1901, and a discussion of the commercial relation between the millers and bakers of the country.

The cost of producing wheat, rye, and potatoes (*Sächs. Landw. Ztschr., 49 (1901), No. 49, p. 1154*).—A brief note on the cost of producing these crops in Germany.

The cost of producing our most important field crops, W. H. HOWARD (*Die Produktionskosten unserer wichtigsten Feldfrüchte. Berlin: Paul Parey, 1901*).

Colonial plants, H. JUMELLE (*Les cultures coloniales. Paris: J. B. Baillière & Son, 1901, vols. 1, pp. 360, figs. 101; 2, pp. 430, figs. 103*).—The author has brought together for the use of French colonists the divers methods employed in the culture of tropical and subtropical plants. Volume I treats of food plants and Volume II of industrial and medicinal plants.

HORTICULTURE.

Report of the professor of horticulture, H. L. Hutt (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 67–73*).—This is a brief outline of the course of agricultural instruction observed in the college, with an account of some experimental work in testing strawberries, raspberries, blackberries, currants, gooseberries, and tomatoes. Of the strawberries grown, Stone Early has been one of the most uniform in productiveness from season to season. Among the leading early varieties are Sadie, Wesley, Anna Kennedy, and Van Deman; and among the best mid-season varieties Clyde, Irene, Warfield, Tennessee Prolific, and Williams. Of the raspberries grown, Columbian and Shaffer, of the purple varieties, head the list for productiveness, while Marlboro, Cuthbert, and Loudon rank among the best red varieties. Of the black raspberries, Older, Eureka, Gault, and Smith Giant are considered best. In a test with gooseberries the least productive of the American varieties gave nearly double the yield of the most productive English variety. Pearl was the best American variety grown. In tests of tomatoes for from 1 to 4 years, Atlantic Prize, Earliest of All, Mayflower, Express, Plentiful, and Dominion Day are given as a few of the most valuable varieties.

Report of the horticulturist, H. H. Hume (*Florida Sta. Rpt. 1901, pp. 76–86, pls. 2*).—This is a brief outline of the work of the horticulturist during the year, including descriptive notes on 30 varieties of pecans, in addition to those noted in Bulletin 54 of the station (E. S. R., 12, p. 751). Forty-five varieties of strawberries have been grown at the station. The best of these are stated as follows: McKinley, Lady Thompson, Murray Extra Early, Brandywine, Cloud, Michel Early, Johnson Early, and Improved Newman. Lady Thompson was practicatly free from disease and Michel Early was also comparatively free.

American horticultural manual, I, J. L. Budd and N. E. Hansen (*New York: John Wiley & Sons, 1902, pp. 417, figs. 106*).—This manual is intended to meet the needs of students, amateurs, and beginners in horticulture. It discusses the leading principles and practices connected with the propagation, culture, and improvement of fruits, nuts, ornamental trees, shrubs, and some of the more common garden plants in the United States and Canada. The plan of the work provides that Part II, which is not yet published, shall treat of systematic pomology. In the discussion of orchard fruits, subtropical fruits like the orange, lemon, pomelo, olive, fig, date palm, pineapple, etc., are included. A chapter is devoted to the history, development, and culture of American grapes. Chapters are also devoted to raspberries and blackberries; strawberries; currants and gooseberries; promising wild fruits; nut trees; ornamental shade, lawn, and park trees; ornamental shrubs and vines; perennials and bulbs; vegetable and small fruit garden; and irrigation. The large number of subjects included has necessitated a rather brief treatment of each.

Problems of heredity as a subject for horticultural investigation, W. Bateson (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1900*), *No. 1–2, pp. 54–61*).—Largely a review of the work of Mendel and de Vries.

The mechanism of hybridization and the production of races, A. Gautier (*Rev. Vit., 16* (*1901*), *Nos. 413, pp. 529–534; 414, pp. 557–564; 415, pp. 585–590*).—A general review of this subject with particular reference to vines.

The rôle of artificial pollination in horticulture, Foussat (*Jour. Soc. Nat. Hort. France, 4. ser., 2* (*1901*), *July, pp. 703–715*).—The improvements in plants in form, color, size, hardiness, etc., brought about by artificial cross pollination, are discussed.

The book of the greenhouse, J. C. Tallack (*London and New York: John Lane, 1901, pp. 103, pls. 10, figs, 6*).

Greenhouse construction, B. C. Ravenscroft (*London: L. Upcott Gill*).

Fuel material and boilers for greenhouse heating, O. Peschke (*Möller's Deut Gart. Ztg., 16 (1901), No. 47, pp. 562–565*).—Some data on the fuel value of coke, stone coal, and peat are given, together with a discussion of boilers for heating greenhouses.

The manuring of market-garden crops, B. Dyer (*London: Vinton & Co., Ltd' 1898, pp. 64*).—The author has brought together the results of a large number of experiments in fertilizing all the more usual garden crops, including cabbage, onions, lettuce, Brussels sprouts, cauliflowers, broccoli, asparagus, rhubarb, Jerusalem artichokes, strawberries, Globe artichokes, carrots, parsnips, spinach, beets, celery, and potatoes. The experiments, on the whole, bring out the fact that market gardeners frequently pay too large prices and use too large amounts of barnyard manure in their gardening operations. For some crops it was found that commercial fertilizers used alone were most economical, but that on the whole the best method of manuring was to combine the use of a moderate quantity of barnyard manure with the liberal use of commercial fertilizers.

The artichoke, J. Mathiaud (*Rev. Hort. et Vit., 33 (1901), No. 11, pp. 210–216*).—A paper on varieties, methods of culture, including care over winter, and the diseases and insects affecting.

Forcing beans, R. Priebe (*Möller's Deut. Gart. Ztg., 16 (1901), No. 47, pp. 567–570*).—Directions are given for forcing beans in the greenhouse. Seed 3 years old is preferred in this work.

Cauliflower, H. H. Hume (*Florida Sta. Bul. 59, pp. 425–439, pls. 2, fig. 1*).—Full directions are given for the culture, fertilizing, and marketing of cauliflower in Florida, with an account of the chief insects affecting and methods for their control. Work at the station has shown that the cauliflower can be profitably grown in Florida. Varieties of the forcing type, like Extra Dwarf Erfurt, Early Snowball, and Dry Weather, are considered most desirable. The seed used should be the best. Seeding the first week in August was found the earliest date at which a good stand of plants could be secured. About 6 months are required between the time the seed is sown to the maturity of the crop. At transplanting time the leaves should be cut back from one-half to one-third. In the station work, sufficient well-rotted stable manure is used to cover the ground 1 to 1½ in. deep. This is supplemented by a fertilizer mixture made up of 250 lbs. nitrate of soda, 400 lbs. cotton-seed meal, 600 lbs. acid phosphate, and 400 lbs. high grade sulphate of potash. The stable manure and half the commercial fertilizers are applied broadcast 2 to 3 weeks before planting and thoroughly worked into the soil. The remainder of the fertilizers are applied 1½ to 2 months after the plants are set by scattering it around them and lightly raking in. If the soil is sufficiently rich in vegetable matter the barnyard manure is omitted and more commercial fertilizers added.

Celery culture, W. R. Beattie (*U. S. Dept. Agr., Farmers' Bul. 148, pp. 32, figs. 7*).—Popular discussion of the growing of celery, including notes on diseases and insects affecting, profits in the business, varieties, and marketing.

Celery growing in Orange County, C. F. Heil (*Pacific Rural Press, 62 (1901), No. 16, pp. 244, 245*).—A paper on this subject dealing with cultural methods and cost of growing. The cost of growing an acre of celery in Orange County, California, placing the rent of land at $30 per acre, is given as $75. From an acre 1,000 to 1,500 dozen bunches are obtained, for which buyers pay from 10 to 18 cts. per dozen.

Whitloof chicory and the formation of second-growth leaves, E. Carpiaux (*Bul. Agr. [Brussels], 17 (1901), No. 5, pp. 564–568*).—The author has studied the chemical transformation that takes place in plants which produce a secondary growth at the expense of the reserve material of the root. Chicory was the subject chosen, and analyses are given of chicory roots before and after having produced a second growth of leaves. The results are stated as follows: The inulin, which is the principal reserve material of chicory roots, decreases notably in the production of second-growth leaves. The nitrogenous material, both albuminoid and nonalbuminoid, undergoes no appreciable modification during the growth of the secondary leaves. These are transported from the mother root to the growing product, but there is no transformation of amid bodies into albuminoids. In the production of the foliage only a small portion of the phosphoric-acid content in the mother root is used, but a considerable portion of the potash.

Pollination of cucumbers, O. Schmeiss (*Möller's Deut. Gart. Ztg., 16 (1901), No. 20, p. 242*).—Contrary to the author's usual practice, the hand pollination of cucumber blossoms in the forcing house was not found necessary, good fruits being secured without it.

A guide to the cultivation, harvesting, and marketing of the ginseng plant (*New York: Crowell & Kirkpatrick Co., 1902, pp. 52, figs. 9*).—This is largely a compilation of different works on ginseng cultivation. Besides the cultivation, harvesting, and marketing of ginseng, it contains some notes on the history, botany, and uses of the plant. A list of buyers and growers of ginseng is appended.

Stable manure and nitrogenous chemical fertilizers for forcing lettuce, S. A. Beach and H. Hasselbring (*New York State Sta. Bul. 208, pp. 307–342, pls. 10*).—The results of earlier work by the station in forcing lettuce with different combinations of fertilizers and on different soils have been previously noted (E. S. R., 10, p. 957). In the present account the results of work in forcing lettuce from 1898 to 1901 are recorded. The experiments were carried out in the forcing house, using boxes 15 by 15 by 8 in. inside. Four lettuce plants were grown in each box. Both a medium clay loam and a rather light sandy loam were used, and the experiments with the different fertilizers were made in duplicate with these 2 soils. An excess of phosphoric acid and potash over the requirements of the plants was used in the soil of each box. The problems studied were the comparative values for lettuce forcing of the nitrogenous fertilizers—dried blood, nitrate of soda, dried blood and nitrate of soda combined, and sulphate of ammonia. These fertilizers were used alone in the different boxes and combined with well-rotted horse manure. The first year the stable manure in the different boxes constituted 5, 10, 15, and 20 per cent by weight of the soil used, and the following years these same percentages in bulk were used. In other boxes without commercial fertilizers, stable manure constituted 33⅓ per cent of the soil. Grand Rapids and Rawson Hothouse varieties of lettuce were used. The results secured are reported in a series of tables and discussions, showing the weight of the crop secured with each fertilizer on the different soils and with th different amounts of stable manure.

When the commercial fertilizers were used alone considerably better results were secured than when no fertilizers were used, but they did not force the crop rapidly enough to maturity to be profitable. The nitrate of soda generally gave better results on the clay loam than the other commercial fertilizers, but on the sandy loam it was not as beneficial as dried blood. The addition of lime to the nitrate of soda increased the yield on the sandy loam, but decreased the crop on the clay loam. The results with the other fertilizers when used without manure were variable in the different years, but drie blood generally gave the best results on the sandy soil.

When manure was added to the commercial fertilizers much better yields were secured than without it, and these yields were proportionately much better with the 5 and 10 per cent applications than with the 15 and 20 per cent applications. Of the various commercial fertilizers used with the 5 and 10 per cent applications of stable manure, the yields with dried blood in 16 out of 20 tests were better than the yields with nitrate of soda, and better in 7 out of 10 tests than with sulphate of ammonia. In 11 tests the yields were better than with a combination of dried blood and nitrate of soda, while in 9 tests the reverse was true. The general conclusions are drawn that much better lettuce crops may be forced by the addition of stable manure to commercial fertilizers than without it, but that it is not good economy to make repeated heavy applications of the manure to the same soil.

Compacting the soil made up of 33⅓ per cent of manure resulted in better yields than when the soil was not thus treated. Throughout the experiments the clay loam proved a better forcing soil than the sandy loam.

Abstracts are given of the work done in forcing lettuce by other experiment stations.

Fertilizers for forcing lettuce, F. H. HALL, S. A. BEACH, and H. HASSELBRING (*New York State Sta. Bul. 208, popular ed., pp. 8, pls. 2*).—A popular summary of the above bulletin.

Melons, A. PETTIGREW (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1900*), *No. 1-2, pp. 118-127, figs. 4*).—The muskmelon is considered and directions given for its culture under glass.

Commercial fertilizers for onions, W. H. JORDAN and F. A. SIRRINE (*New York State Sta. Bul. 206, pp. 265-274*).—It was believed that onion growers in the second judicial department of New York were using excessive amounts of commercial fertilizers for their onion crop each year. Experiments were therefore begun in 1897 to test this belief. A complete commercial fertilizer mixture, analyzing 4 per cent nitrogen, 8 per cent phosphoric acid, and 10 per cent potash, which is popular with onion growers of that section, was used; and 500, 1,000, 1,500, and 2,000 lbs. per acre, respectively, applied to different plats for 4 years in succession on one field and for one year on another. The soil upon which the experiment was conducted was especially suitable for onions, being black, peaty, and friable, with a water table about 2 ft. below. The average cost of the fertilizers used and the yield of onions per acre for the 4 years are shown in the following table:

Cost of fertilizers and average yield of onions per acre.

Amount of fertilizer.	Cost of fertilizers.	Average yield.	Increase from use of fertilizers.	Cost of increase per barrel.	Profits from use of fertilizers.
		Barrels. [a]	*Barrels.*	*Cents.*	
No fertilizer		85.3			
500 lbs	$5.47	118.4	33.1	16.6	$35.84
1,000 lbs	10.94	125.2	39.9	27.4	38.87
1,500 lbs	16.41	132.0	46.7	35.1	41.90
2,000 lbs	21.87	134.4	49.1	44.5	39.44

[a] Barrel = 150 lbs.

The table shows that the profits from using the fertilizers were greatest with the first 500 lbs. applied. In the opinion of the authors, considering the variations of market price of onions from year to year and the vicissitudes in growing, the use of more than 500 lbs. of fertilizers on the soils in question was attended by danger of financial loss.

In the duplicate of the experiment, carried out for a single season, there was no increase whatever from the use of fertilizers, the soil on which the experiment was conducted being well enough supplied with these elements from the manuring of preceding years. It is believed that this unnecessary use of manures on soils already rich in plant food illustrates a common mistake of farmers engaged in intensive operations. In this test 13 per cent of the yield, when no fertilizer was applied, was small pickle onions, 3 per cent when 500 lbs. was applied, 1.9 per cent when 1,000 lbs. was applied, 3.1 per cent when 1,500 lbs. was applied, and 4.3 per cent when 2,000 lbs. was applied.

Fertilizer problems, F. H. HALL, W. H. JORDAN, G. W. CHURCHILL, and F. A. SIRRINE (*New York State Sta. Buls. 205, 206, popular ed., pp. 8*).—This is a popular summary of Bulletins 205 (see p. 1042) and 206 of the station, noted above.

Plantain cultivation in the Assam Valley, B. C. Basu (*Indian Agr., 26 (1901), No. 11, pp. 342-345*).—This article gives the characteristics of many cultivated varieties of plantain, methods of culture and manuring in the Assam Valley, diseases and insects affecting, yield and prices, use as food, fodder, and alkali, and methods of preparation. The value of the plant from the standpoints of fiber, medicine, etc., is also discussed.

Tomato culture, R. H. Price (*Texas Farm and Ranch, 20 (1901), No. 49, pp. 10, 11*).—Tomato culture in Texas is dealt with. Dwarf Champion and Acme are the only varieties recommended. A hotbed is necessary for growing an early crop, and plants are put out from May 10 to 15. It is recommended to train the vine to one long stem and tie to stakes.

Culture of truffles, E. Zacharawicz (*Rev. Vit., 16 (1901), Nos. 411, pp. 485-488; 412, pp. 518-520*).—Methods observed in France in planting, fertilizing, cultivating, and harvesting truffles are described.

Lessons in commercial fruit growing, E. S. Goff (*Madison, Wisconsin: University Cooperative Association, 1902, pp. 221, figs. 48*).—This is intended as a beginners' text-book for use in the class room. The text is stated concisely with the expectation that it will be amplified by the instructor. Orchard and small fruits, nuts, grapes, and citrus fruits are considered in the work, and these are discussed topically from the standpoint of cultural range, propagation, planting, and care of the trees; the insects and diseases affecting them; and the harvesting, storage, and marketing of the fruit. Brief summaries follow the different sections and chapters, and suggestions are given for laboratory work. The final chapter is devoted to the business management of the fruit plantation. The work will be found a convenient guide to those giving instruction along these lines.

Fruits and shrubs, S. B. Green (*Minnesota Sta. Bul. 72, pp. 321-332, 338, 339, figs. 4*).—At the Coteau farm, which is located in southwestern Minnesota, in the region of scant rainfall, wild plums, apples, raspberries, blackberries, strawberries, buffalo berries, sand cherries, high-bush cranberries, currants, gooseberries, June berries, and mulberries have been successfully grown only by the aid of forest protection. Without it, indifferent results or failure have resulted. A list is given of a number of the more important shrubs and vines that succeed best at the station. The best hedge plants for division lines and for ornamental purposes are the common English buckthorn and buffalo berry. For high-hedge purposes box elder is considered one of the best. The wild plum is considered a desirable fruit for locations having conditions similar to those at the station. Apples should be grown in rather closely planted small orchards, surrounded by windbreaks, or else in alternate rows with box elder. The most hardy varieties thus far tried are Hibernal, Patten Greening, Duchess, Peterson Charlamoff. Among the crabs, Minnesota, Martha, Pride of Minneapolis, Transcendent, Virginia, and Sweet Russet are the best tried. Raspberries and strawberries should be heavily mulched with straw. Over strawberries the mulch should be at least 6 in. thick after it has settled down. This treatment will frequently prevent the formation of "nubbins."

Fertilizing orchard trees, A. Wagner (*Wiener Illus. Gart. Ztg., 26 (1901), No. 10, pp. 345-352*).—The author discusses the use of various manures and artificial fertilizers for orchard trees, and gives suggestions for fertilizing them in accordance with the number of square meters over which the roots of the tree extend. This is determined by adding from 1 to 3 meters to the diameter of the crown of the tree. The area in square meters of the circle thus formed is easily calculated. The amount of fertilizer to apply to each square meter is given for a number of fertilizers as follows: (1) Liquid manure (with phosphoric acid or superphosphate), 5 liters in spring and summer; (2) liquid night soil (with wood ashes or a potash salt), 3 to 4 liters in spring and summer; (3) compost, 10 kg. in fall, winter, or spring; (4) stable manure, 4½ kg. in fall, winter, or spring.

When artificial manures are used the following amounts may be applied: (5) Thomas slag (containing 15 per cent citric acid soluble phosphoric acid), 40 to 60 gm. in fall, winter, or early spring; chlorid of calcium, 20 to 30 gm. in fall, winter, or early spring; nitrate of soda, 20 to 50 gm., one-half applied with the phosphate fertilizer and the other half in the spring; (6) superphosphate (containing 15 per cent water-soluble phosphoric acid), 30 to 50 gm. in winter or spring; chlorid of potash 20 to 30 gm. in winter or early spring, and nitrate of soda 20 to 50 gm., one-half to be applied with the potash and phosphate and the other half in the spring. The chlorid of potash in mixtures 5 and 6 above may be replaced by the cheaper 40 per cent potash salt, and in such case 25 to 35 gm. should be used.

Fertilizer experiments with orchard trees, flowers, and vegetables, C. H. Claassen (*Verslag Proefnem. Tuinbouw Zuid-Holland, 1898, pp. 56*).—The results are given of fertilizer experiments carried on with orchard fruits, rhododendrons, and hyacinths. Both barnyard manure and commercial fertilizers were used. Some data are also given on the results of variety tests with cucumbers and melons, and of a culture test with grapes.

Manures and fruit trees (*Bul. Soc. Cent. Forst. Belg., 8 (1901), No. 1, pp. 41–44*).—A discussion is given of the principals of fertilizing fruit trees, with specific recommendations based on the work of A. Wagner (see p. 1048).

The book of the apple, H. H. Thomas (*London and New York: John Lane, 1902, pp. 112, pls. 9, figs. 8*).—This is the sixth volume of the series of Handbooks of Practical Gardening, edited by H. Roberts. It deals primarily with apple culture in England, including descriptions of dessert and cooking varieties of apples most prominent there, and includes chapters by the editor on the history and cookery of apples and on the preparation of cider. English methods of apple culture are so different from those observed in this country that the book will be found of but little practical use to American orchardists.

Bananas (*Shamba [Zanzibar], 1901, Nov. 6, Sup. pp. 3*).—The varieties of bananas grown in Zanzibar for different purposes and their cultivation are here considered in some detail.

The Chinese cling group of peaches, G. H. Powell (*Delaware Sta. Bul. 54, pp. 32, figs. 9*).—The general characteristics, history, and classification of the Chinese cling group of peaches are given, together with historical and descriptive notes of 65 varieties. Synonyms of these varieties are also given. In this work the author has endeavored to revise the nomenclature of the group and simplify the names. The name "Chinese cling group" is believed to be more exact than "Northern Chinese race," by which the group is quite generally known, and is therefore proposed for it. The varieties of this group most largely grown are stated to be Greensboro, Carman, Thurber, Georgia, and Elberta.

Variations in olives during ripening, C. E. Zay (*Staz. Sper. Agr. Ital., 34 (1901), No. 11–12, pp. 1080–1085*).—Analytical data, including ash constituents, are reported.

The fig, R. H. Price and E. A. White (*Texas Sta. Bul. 62, pp. 17–29, pls. 12*).—A brief discussion is given of fig culture in Texas, including details for propagation, fertilizing, planting, and pruning. Various kinds of figs are classified and descriptive notes given of 20 varieties. The correct nomenclature of the different varieties has been made a special feature of the bulletin. The variety quite generally known as the Magnolia fig has been found to be identical with Brunswick, Clare, and Barnisotte. Figs are not extensively grown in Texas, and their more general use is advocated. The following varieties, mentioned in the order of their productiveness, have been successful on the station ground: Brown Turkey, Black Marseilles, White Marseilles, Brunswick, Violet de Bordeaux, Early Violet, Pitaleuse, Brown Marseilles, Negro Largo, Grosse Verte, and Angélique.

Notes on plantations of caprifig trees, G. EISEN (*Pacific Rural Press, 62 (1901), No. 24, p. 272*).—In order to secure with certainty 3 crops per season of caprifigs, the author advises the planting of several different kinds of caprifigs. The caprifig trees should also be grown in at least 2 different plantations as a guard against injury from frost and to insure a crop of caprifigs when they are wanted. One of the plantations should be on low ground out of danger of severe frost. Caprifig trees should be planted close together and at various places about the fig orchard. The trees require no pruning, but should be headed low and encouraged to sucker freely in order that there may be plenty of shade for the wasps. Caprifigs should be grown on their own roots and not grafted as standards on other fig stock, nor is it advisable to graft them on the limbs of Smyrna fig trees.

Caprification in Algiers, TRABUT (*Rev. Vit., 16 (1901), Nos. 412, pp. 501–504, figs. 3; 413, pp. 537–543, figs. 10*).—A popular discussion of fig caprification in Algiers, and a description of the Blastophaga and of its method of fertilizing figs.

On the culture of dwarf fruit trees, G. LIND (*K. Landt. Akad. Handl. Tidskr., 39 (1900), No. 5–6, pp. 369–372*).

Cacao: A treatise on the cultivation and curing of cacao, J. H. HART (*Trinidad: The "Mirror" Office, Port-of-Spain, 1900, pp. 117, figs. 9*).—This book is based on the author's 25 years' experience in the botanical department of the West Indian service. It deals in a popular manner with the culture of cacao, its preparation for market, botany and nomenclature, diseases affecting, chemistry of cacao, manufacture of chocolate, export, etc.

Coffee trees, É. DE WILDEMAN (*Les caféiers. Brussels: Veuve Monnom, 1901, pp. 43*).—A general classification is given of the species of the genus Coffea, with the usual botanical descriptive notes.

Coffee cultivation, J. T. PALACHE (*Jour. Jamaica Agr. Soc., 5 (1901), No. 9, pp. 347–356*).—Directions are given for growing coffee in Jamaica.

Coffee culture in São Paulo, A. G. DA SILVA TELLES (*O café eo estado de S. Paulo. São Paulo: "Diario Oficial," 1900, pp. 60*).

Report on coffee, with special reference to the Costa Rican product, J. B. CALVO (*U. S. Dept. State, Bureau of American Republics, 1901, pp. 15*).

The Butin Schaap method of coffee grafting, A. PREYER (*Tropenpflanzer, 5 (1901), No. 5, pp. 220–224, figs. 2*) and A. ZIMMERMANN (*Meded. 'S Lands Plantentuin, 1901, No. 49, pp. 54, figs. 32*).—The method followed by Mr. Butin Schaap in the grafting of coffee trees is described and some notes added as to its practical application. The method is essentially as follows: The scions are cut out early in the morning and transported in closed baskets to the place of using. Here each scion is cut arrow shape below the first node, and placed in a simple split 3 cm. long, either in the terminal or second bud of the stock. The side leaves are removed, except 2 of the smaller uppermost ones of the scion. The graft is tied in place with woolen yarn, but is neither waxed nor smeared over with other material. Both scion and wound are then covered over with a glass beaker. This preserves a constantly moist atmosphere about the scion and prevents its drying out. As soon as the scion and stock have grown together both the glass and yarn are removed.

Grafting coffee trees is of primary importance in districts where nematodes are abundant. These severely affect Arabian coffee varieties, but Liberian tree roots are seldom attacked. The Liberian trees are, therefore, used as stock for Arabian and other better sorts of coffee. Another advantage is the increased yields obtained from the Liberian trees when grafted with the Arabian, Maragogipe, or other improved varieties, while the quality of the Arabian coffee, etc., does not seem to be in any manner injuriously affected by growing on Liberian stock. It is suggested that this may point the way to the improvement of nonremunerative coffee plantations.

The best trees for stocks are those not less than 3 years old, and the graft is made on the central stem. Older trees that have grown too high may be cut off about 3 feet from the ground, and the strongest shoot that comes from the stump be used to graft on, the other shoots being removed. It is advised that the scion used should be taken from healthy, vigorous 6-year-old trees.

Some revelations about the cultivation, the commerce, and the use of coffee, J. C. ALVES DE LIMA (*Syracuse, N. Y.: Mason Press, 1901, pp. 16, pl. 1, map 1*).—Statistics of coffee production in Brazil and of the importation of coffee into the United States. A map is included showing the chief coffee zones of Brazil.

On the composition of some common berries, J. A. HUMMEL (*Farm Students' Rev., 6 (1901), No. 8, p. 119*). The author reports the composition of several varieties of currants, gooseberries, black and red raspberries, and strawberries.

Strawberry packages, J. M. BUISSON (*Rev. Hort. [Paris], 73 (1901), No. 20, pp. 470–472, figs. 9*).—The various packages used for marketing strawberries in the Paris market are described and illustrated.

Preparation of dried raisins, TRABUT (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 2, pp. 493–497, figs. 4*).—Sultana raisins are prepared in Algiers by first dipping them for about 2 seconds in a boiling lye solution made up of 500 gm. of caustic potash and 30 liters of water. After dipping, the grapes are spread out on trays and left in the sun 1 or 2 days. The trays are then piled up one on the other where the raisins dry without further care.

Hazelnut culture, L. SCHENZ (*Möller's Deut. Gart. Ztg., 16 (1901), No. 12, pp. 135, 136*).—Brief notes on methods of hazelnut culture, with description of 37 varieties.

Hazelnut culture, L. SCHILDKNECHT (*Möller's Deut. Gart. Ztg., 16 (1901), No. 14, p. 162*).—Soil, methods of culture, and cost and profits in hazelnut culture near Leipzig are noted. Generally the business has not proved very profitable.

Vanilla: Its culture, preparation, and commerce, H. LECOMTE and C. CHALOT (*La vanillier; sa culture, préparation, et commerce de la vanille. Paris: C. Naud, 1902, pp. 228, figs. 28*).—This is a popular account of the culture of the vanilla tree, and of the preparation of the vanilla of commerce. The book opens with a botanical account of the plant, followed by botanical descriptions of the different species of vanilla and an account of the climatic and soil conditions necessary for its growth. Directions are given for setting out a vanilla plantation, the care necessary to give it, and the means of combating insect and fungus pests. Methods of planting are discussed, together with harvesting, packing, the chemistry of the plant, commercial preparation of vanilla extract, adulterations of vanilla, and the production of vanilla in different countries. A bibliography of 58 papers on the subject is appended.

Vanilla; culture in Mexico, R. LOPEZ Y PARRA (*La vainilla; su cultivo y beneficio en la Républica Mexicana y en el extranjero. Mexico: Imprenta "El monograma," 1900, pp. 69*).

Rubber culture in Venezuela, L. MORISSE (*Sci. Amer. Sup., 52 (1901), No. 1355, pp. 21724, 21725*).—The methods of the Indians in gathering rubber in the Venezuelan rubber forests are set forth, and an account given of the extent of the forests and of some experiments in pricking rubber trees and gathering the product. During 15 days the author states he pricked 912 trees daily, securing 80 kg. of coagulated milk per day, from which 50 kg. of fine and dry caoutchouc were secured, worth 7 francs per kilogram.

Gums and gum resins from Senegal and Soudan, J. VUILLET (*Agr. Prat. Pays Chaud, 1 (1901), No. 3, pp. 327–341*).—An account is given of the production and commerce of gums and gum resins in Senegal and Soudan, with descriptions of the principal species of Acacia from which these gums are obtained, and of several other gum trees.

History of the chrysanthemum, G. E. MCCLURE (*Gardening, 10 (1901), No. 223, pp. 99–101*).—A paper on this subject, read before the St. Louis Florists' Club, November 9, 1901.

Relative to the grafting of Clianthus dampieri, S. MOTTET (*Rev. Hort.* [*Paris*], *73* (*1901*), *No. 11, pp. 256, 257, fig. 1*).—Notes on successful grafts made between *C. dampieri* and other species of the genus.

Propagation and culture of choice dracænas, A. FREY (*Amer. Gard.*, *22* (*1901*), *No. 365, p. 860*).—Methods of propagation by cuttings, roots, and stems are considered, as well as methods of topping and the treatment to be given the young plants. Seven varieties are briefly described.

Lilies, R. W. WALLACE (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1900*), *No. 1–2, pp. 98–113, figs. 23*).—Some notes on the nature of lilies, their botanical classification, and cultural requirements.

Cultivation of the narcissus in gardens, S. E. BOURNE (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1900*), *No. 1–2, pp. 39–53, fig. 1*).—An extended account is given of the garden culture of narcissus, including a discussion of situations and soils, planting, manuring, replanting, insect and fungus pests, etc.; and a list is given of the best sorts for outdoor culture. Some directions are also given for the cultivation of narcissus in cold frames and greenhouses.

The golden poppy, E. E. SMITH (*San Francisco: San Francisco News Company*, *1902, pp. 232, pls. 2, figs. 65*).—This book contains the botanical history of California's State flower—the golden poppy, or Eschscholtzia, and allied genera. The history of the flower, references to it in literature, its use in graphic and decorative art, economic uses, culture, and poetry and interesting items relating to it have been pleasingly brought together. A bibliography of *E. californica* is included.

Rose analysis, 1895–1901 (*Jour. Hort.*, *53* (*1901*), *No. 2770, pp. 391–395*).—The relative position of varieties of roses exhibited on the prize stands at the English National Rose Society's exhibition, for a number of years, is shown in a series of analytical tables.

Grafting of flower buds on Syringa vulgaris (*Bol. Roy. Soc. Tosc. Ort.*, *26* (*1901*), *No. 4, p. 109; abs. in Jour. Roy. Hort. Soc.* [*London*], *26* (*1901*), *No. 1, p. 220*).—A method for obtaining forced lilac flowers is briefly described. It consists in grafting lilac shoots, grown in the open and bearing flower buds, into the ends of branches of plants in the greenhouse which have already flowered. The shoots should be 15 to 20 cm. in length and the graft inserted between the wood and cortex of the stock. The buds begin development in 10 to 12 days, and in about 20 days the flowers appear.

Forcing violets, J. RUDOLPH (*Rev. Hort.* [*Paris*], *73* (*1901*), *No. 20, pp. 476, 477*).—Notes on methods of forcing under glass, in the open, and in pots.

Report on essence-producing plants in Algeria, R. SCHILLING (*Bul. Dir. Agr. et Com.*, *6* (*1901*), *No. 21, pp. 359–374*).—The geranium is the principal plant dealt with. Methods of planting, harvesting, and distilling the crop, filtering, packing, and shipping the product are reported upon in detail. Other essence-producing plants noted are *Eucalyptus globulus*, bitter orange, *Acacia farnesiana*, and thyme, the commercial importance of each being noted.

Gardens for school children, G. H. KNIGHT (*Pearson's Mag.*, *12* (*1901*), *No. 69, pp. 348–353, figs. 8*).—A brief account and illustrations are given of several school gardens in foreign countries and at Dayton, Ohio. The estimated cost of establishing a school garden for 200 children is placed at $1,500.

American gardens, G. LOWELL (*Boston: Bates & Guild Co.*, *1902, pp. 32, pls. 112, dgms. 48*).—This is a quarto publication consisting of 20 pages of introductory matter relative to the history of gardening, and 112 full-page plates illustrating 58 American gardens in different parts of the country. These illustrations are taken from the better American gardens and intended to set forth the art of gardening as it has been developed in America.

Illustrated encyclopedia of garden culture, T. RÜMPLER (*Illustriertes Gartenbau-Lexikon. Berlin: Paul Parey, 1902, pp. 936, figs. 1002*).—This work has lately undergone an extensive revision under the direction and cooperation of some of the best gardeners of Germany. It is arranged alphabetically with reference to plants cultivated in the greenhouse and garden, and to miscellaneous horticultural subjects.

FORESTRY.

The forest garden, S. B. Green (*Minnesota Sta. Bul. 72, pp. 303–321, figs. 10*).—A report is given of forest investigations begun at Coteau farm, the object being to determine the hardiness of trees, the kinds adapted to different plantings, and the rate of growth of the different trees. This region is situated in a high prairie, and is representative of a considerable area of the southwestern part of the State. The trees were planted in rows 8 to 10 ft. apart and 2 ft. apart in the row. The soil was cultivated to keep down the grass and weeds and to preserve a soil mulch. It was found that after establishing a windbreak it is comparatively easy to grow trees on the land under investigation, if reasonable attention is paid to keeping the soil cultivated about the plants. It was also found possible to produce a shelter belt and also a fuel supply at the same time. For this purpose the author recommends the use of the common white willow of that section. This will produce annually from 3 to 5 cords of firewood per acre. The nursery stock used in this experiment was nearly all grown within the State, and consisted of 48 varieties of trees, the hardiness of which is reported upon in detail.

The effect of ice storms on trees, H. H. Chapman (*Forestry and Irrig., 8 (1902), No. 3, p. 130*).—An account is given of the effect of a severe storm, accompanied by rain and ice, on trees on Staten Island. The trees were elm, beech, tulip, poplar, and black oak; and many had sound limbs broken that were 4 in. or more in diameter. White oak alone seemed to resist serious damage by the greater strength of its branches. To calculate the force which causes such destruction, a number of twigs were cut transversely and diagrams made of the thickness of twig and ice incrustation. Calculating from the relative area in cross section, it was found that twigs ⅛ in. thick were carrying from 30 to 40 times their weight of ice, and those ¼ in. thick about 20 times their weight. While the exact calculation would be rather difficult, it seems safe to say that branches 1 in. thick were called upon to support a weight more than 10 times as great as usual, and possibly considerably more. In addition to this heavy weight, the trees were subjected to high winds, multiplying the effect of the heavy burden. In many cases all the limbs of trees were broken and the crown reduced fully 90 per cent.

Colorado forest fires in 1901, H. Michelsen (*Forestry and Irrig., 8 (1902), No. 3, pp. 111–116*).—There were 140 forest fires in the forest reservations of the State during the year; the area burned amounted to 1,690 acres; and the timber destroyed was valued at $5,375. Outside the reserves, 100 square miles of timber land were burned over. The loss by counties is given, and the possible effect of the destruction of the forest cover on evaporation is commented upon.

The planting of exotic trees in southern Florida, J. Gifford (*Forestry and Irrig., 8 (1902), No. 3, pp. 116–121, figs. 4*).—Attention is called to the value of a number of exotic trees for planting in southern Florida. Among the trees suggested for such planting are mentioned the kukui nut (*Aleurites moluccana*), various species of eucalyptus, cajeput (*Melaleuca leucodendron*), camphor trees, and cork oak.

Tree planting in Maryland, A. Neilson (*Forestry and Irrig., 8 (1902), No. 2, pp. 72–75, figs. 4*).—An account is given of the carefully kept record of the tree planting that has been conducted for 80 years at Priestford Farm, Harford County, Maryland. Beginning in 1822 the farm had no timber of any consequence. At the present date it contains a wood lot of 40 acres and, in addition, has about 3,000 locust trees of various ages. All fencing material needed in the past 60 years has been produced on the farm, and a large amount of posts and other material has been sold in the meantime. In the spring of 1822 there were planted a considerable number of yellow poplars, red oaks, white ash, maples, hemlocks, and catalpas; all but the catalpas coming from nearby woods. At the present time the maples average 33 in. in diameter, the poplars 48 in., hemlocks 36 in., white ash 38 in., catalpas 30 in., and red oaks 24 in. In the same year there were planted 4,000 chestnuts from which trees were grown, and at the present time there are 70 standing in the wood lot, 40 of them of the original planting, the remainder being second and third growth from stumps. The original trees average 30 in. in diameter, while the others average 15 in. in diameter. In 1826 a lane half a mile long was planted with yellow locust seed. The trees were allowed to grow for about 30 years before any cutting was done. In 1875 posts to the value of $500 were sold. In 1901 sales were made to the amount of about $800, and prior to 1875 no record was kept of any of the cuttings. Additional notes are given of different plantings from 1826 to 1898.

Forestry in Massachusetts, W. H. MANNING (*Forestry and Irrig., 8 (1902), No. 2, pp. 80–83, figs. 2*).—Attention is called to the fact that the first settlers of Massachusetts did not find an impenetrable tangle of forests covering the State, but there were extensive openings where by fire and other means the forests had been destroyed. After the settlement of the country the woods were cut so rapidly that a scarcity of timber began as early as 1760. About 1792 the Massachusetts Society for Promoting Agriculture offered prizes for the most expeditious way of clearing lands in areas of not less than 20 acres. At the same time they conducted investigations to ascertain whether the growth of timber kept pace with the cutting. It was found that cutting so greatly exceeded the natural growth that a serious scarcity of firewood was threatened, and this led to a reversal of the former policy, and prizes were offered for forest plantations. The early plantations were made of hard wood principally, such as oaks and hickories, followed later by the white pine, and at a still later period with larches, Scotch pine, and Norway spruce. It was soon found that the foreign trees possessed no advantages over the native ones. During this time but little attention was given to the development of the existing forest growth. The attempts at reforestation are briefly traced and suggestions given for planting. At the present time the mixed forest growth has little or no value except for cord wood, and it is estimated that the production of cord wood amounts to about 1 cord per year per acre up to 30 or 40 years. In general the annual growth near towns increases in assessed value about $1 per acre up to the time of cutting. According to the author, the State census shows that farmers and other owners of wood lots throughout the State have secured a return of 5 per cent on the value of their wood lots.

Maple plantations in Vermont, G. H. MYERS (*Forestry and Irrig., 8 (1902), No. 3, pp. 123–126, figs. 3*).—An account is given of plantings of maple trees in Vermont which were the result of the offering of prizes for the best plantations. A number of small plantations were made, 7 of which still remain, and were examined by the writer during the past summer. These plantations vary from ½ to 15 acres. The methods of planting and present condition are described. In general, the artificial plantations are reported in poor condition, and attention is called to the possible results of thinning the volunteer or natural growth as means for the production of sugar orchards.

Forests of Alaska, B. E. FERNOW (*Forestry and Irrig., 8 (1902), No. 2, pp. 66–70, figs. 2*).—The author describes the forests of Alaska, calling particular attention to their availability and uses. While conceding that the forests are of considerable extent, he doubts their value for the best quality of lumber, at least under the present conditions.

Forestry in connection with the sand dunes of Queensland, A. J. BOYD (*Queensland Agr. Jour., 10 (1902), No. 2, pp. 123–125, pls. 2, figs. 2*).—A description is given of a number of sand dunes occurring along the shores of various parts of

Queensland. These dunes are rapidly encroaching upon the land in certain places, and attention is called to the desirability of checking them by forest and other planting. It is stated that marram grass and Ipomœa grow abundantly along the coast, and wherever these plants occur in thick growth the sand is fixed. After the dune has been checked a protection is afforded for forest operations, and it is recommended that plantings should be made of the cluster pine (*Pinus pinaster*) and the cypress pine, both of which seem particularly adapted to the purpose.

SEEDS—WEEDS.

Germination of clover and grass seeds (*Jour. Bd. Agr. [London], 8 (1902), No. 4, pp. 510–512*).—A report is given of a series of experiments conducted at the Vienna Seed Testing Station in which the loss in germinating power of clover and grass seed which had been stored for some years is shown. A number of varieties of clover and grass seed were tested for 5 consecutive years. The germination for the different tests is given, together with the average loss in germinative ability during the 4 years elapsing between the first and last test. Red clover lost in this time 17.5 per cent of its germinative ability, alsike 79.4, white clover 32.4, alfalfa 23, tall oat grass 51.1, perennial rye 50.9, meadow fescue 40.5, timothy 9.4, orchard grass 7.3, redtop 44.8, and sheep fescue 70 per cent. The suggestion is made that if clover and grass seeds are to be kept for any length of time, care should be taken that only seed showing a high percentage of germination is selected, and it should be protected from moisture and kept at an even cool temperature.

Germination of the seeds of some common cultivated plants after prolonged immersion in liquid air, A. D. SELBY (*Bul. Torrey Bot. Club, 28 (1901), No. 12, pp. 675–679*).—Seeds of the castor bean, yellow lupine, maize, flax, wheat, rye, cucumber, sensitive plant, serradella, and a few others, were submitted to prolonged immersion in liquid air, after which they were placed to germinate between moist filter paper. Similar lots of seed were also planted in a greenhouse and the germinations in the two conditions are reported. The seeds were divided into 2 lots, one of which was suddenly brought into the liquid air, a portion of which remained 6 hours and the remainder 12 hours. In the second series of experiments, the introduction into the temperature of the liquid air was gradual. These seed remained 24 and 48 hours, respectively, after which they were germinated. With the exception of the seed of the maize, no apparent change occurred as a result of the low temperature to which they were subjected. The kernels of maize cracked badly, showing that the hardened endosperm could not withstand the stress imposed. There was apparently no unfavorable effect on the germination of the seed that could be traced to the immersion. With sunflower, wheat, and rye the prolonged subjection of these seed to the temperature of −190° C. for 48 hours seemed to increase the promptness of the germination to some extent.

Valvular torsion as a means of seed dispersal in Ricinus, E. M. WILCOX (*Abs. in Science, n. ser., 15 (1902), No. 377, p. 456*).—In order to secure accurate data regarding the efficiency of valvular torsion for seed dispersal in the castor bean, the ground about a plant in the open field was divided into quadrants and the surface frequently cultivated, so that seeds could not be blown about by the winds after falling. The distances to which the seeds were thrown were measured from the base of the plant and are shown in tabular form. The plant was 104 cm. in height and the inflorescence, at maturity, was 36 cm. in length. The greatest distance to which any seed was thrown was 325 cm. (about $10\frac{2}{3}$ ft.)

Report on mustard spraying, M. W. DOHERTY (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 26–29*).—During the past season the author conducted some demonstration experiments for the eradication of wild mustard by spraying with solutions of copper sulphate. Fields of oats, wheat, and barley, which were infested with this weed, were sprayed during the early summer and the results of the applications are given. The strength of solution used was 10 lbs. of copper sulphate to 40 or 45 gal. of water, this amount of the herbicide being applied to each acre. After having sprayed over the fields, the owners were requested to give their opinion as to the results, and the letters received are given in the report. In all cases where the application was made while the mustard was young the weed was completely destroyed; where it had sent up flower stalks and was in a hardened condition less successful results were obtained. In some instances it was thought that the second spraying could have been applied with good results. The author believes that at an expense of about 80 cts. per acre it is practicable to eradicate this weed from cereal fields, and if persisted in for a number of years no further trouble need be apprehended.

Report on the spraying of charlock and wild radish, J. R. CAMPBELL (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Garforth Expts., 1899, Pamphlet 4, pp. 12, figs. 3*).—A report is given of a number of experiments conducted with different strengths of iron sulphate and copper sulphate solutions for the destruction of charlock and wild radish. The efficiency of different machines for application is shown, and the influence of weather is indicated. The applications were made in fields of oats, barley, and spring wheat, some of which had been seeded to clover and grasses. No permanent injury was noted to any of the crops, and when applied early enough the charlock was destroyed where the solution used contained not less than 2 per cent copper sulphate or 10 per cent iron sulphate. The effect of these sprays on other plants was tested, and it was found that when sprayed with a 12 per cent solution of iron sulphate, peas and beans were somewhat damaged; carrots, parsnips, onions, and leek but slightly injured; lettuce, radish, and cress suffered considerably; mustard was completely killed; beets slightly damaged; while grass, cereals, and clover were practically uninjured. The action of the sprays on charlock is commented upon and the hypothesis advanced that the result is due to the presence in the cruciferous plants of substances which react chemically with the iron or copper salts to the injury of the plants. Summarizing his experiments, which included the spraying of 144 acres of infested grain crops, the author claims that the operation was completely successful only when plants were taken in their youngest stages. Bright, dry, calm weather is a necessary factor to success, and solutions should be applied at the rate of not less than 40 gal. per acre.

One hundred Yorkshire weeds, W. G. SMITH (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Garforth Expts., 1899, Pamphlet 12, pp. 9*).—A list is given of 100 weeds which are considered more or less troublesome. The common and botanical names are given and the duration of the plants and soils frequented are indicated.

DISEASES OF PLANTS.

Notes on some plant diseases, H. H. HUME (*Florida Sta. Rpt. 1901, pp. 86–96, figs. 3*).—Descriptive notes are given of some diseases of cantaloupe, the lettuce drop, and strawberry leaf spot. The cantaloupe diseases described are the Macrosporium blight, caused by *Macrosporium cucumerium*, and a Sclerotium disease. The Macrosporium attacks both the leaves and the vines, producing on the leaves yellowish spots which increase in size until the larger ones may attain a diameter of half an inch. The spots are well defined and after some time become more or less confluent, forming large, irregular, brownish areas on the leaves. The fruiting period of vines affected by this disease is materially shortened and the quality and flavor of fruit produced is decidedly inferior. Spraying with Bordeaux mixture, it is believed, will be efficient in protecting the plants from this disease, and experiments are to be carried out during the coming season.

The Sclerotium disease, which is due to an undescribed species, has been very prevalent, the fungus attacking the fruit and vines. Upright-growing parts of plants are not affected, the disease seeming to attack those portions in contact with the ground. Upon the fruit the attack is very noticeable, the first sign of the presence of the disease being a slight rotting on the underside of the melon, followed by the formation of a white fringe of fungus mycelium surrounding the whole fruit. This disease is difficult to control, but it is thought destroying affected plants and spraying the vines and ground with Bordeaux mixture will give relief.

The lettuce drop has proved quite destructive in some localities. The immediate cause seems to be the fungus *Sclerotinia libertiana*. The fungus is both an active and a facultative parasite and spreads with great rapidity. Owing to the lateness of its appearance, no experiments were conducted for its control, but subirrigation, removal of the diseased plants, and spraying are suggested as possible remedies.

The strawberry blight (*Sphærella fragariæ*) exists on the strawberry plants throughout the year, so that there is no necessity for the production of winter spores. For the protection of the plants thorough and repeated sprayings with fungicides are recommended. Marked differences are reported in the susceptibilty of different varieties, and a brief list is given of varieties which appear nearly free from disease and those which are badly affected.

Notes on some plant diseases, W. LOCHHEAD (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 20–25, figs. 6*).—The life histories of grain rusts and the black rot of grapes are given, and suggestions offered for their prevention so far as practical means are known.

The more important fungus diseases of cultivated plants and means for their prevention, E. HOTTER (*Die wichtigsten Pilzkrankheiten der landwirthschaftlichen Culturgewächse und ihre Bekämpfung. Gratz, 1900, pp. 60, figs. 48*).—After discussing plant diseases in general and their distribution and amount of injury caused by them, a description is given of the structure and development of fungi, their life history, relation between the fungus and host plant, etc. The fungus diseases are then taken up and briefly described, being grouped together according to their relationships. Suggestions are given for the prevention of these diseases and a chapter is devoted to a discussion of the value of Bordeaux mixture as a fungicide.

Some Helminthosporium species and the diseases produced by them on barley and oats, K. P. RAVN (*Ugeskr. Landm., 46 (1901), No. 18, pp. 192–194*).

A "foot" disease of cereals, G. DELACROIX (*Extr. from Bul. Soc. Mycol. France, 17 (1901), No. 2, pp. 9, figs. 2*).—A description is given of the fungus *Ophiobolus graminis* which is parasitic upon various cereals, attacking them in the lower internodes and causing the stems to fall over in a way similar to that produced by the attacks of the Hessian fly. Mangin has concluded that this disease was primarily due to *Leptosphæria herpotrichoides* and that the Ophiobolus is of secondary importance (E. S. R., 10, p. 650). The author gives an account of a number of experiments in which wheat was grown in pots that were infested with spores and the stubble of wheat plants attacked by both fungi. In comparing the results obtained by his cultures he found that both fungi produce the same condition and that the density of planting influences to a great degree the gravity of the disease. When sown thickly the foot disease is of much greater importance in causing the plants to lodge. Notes are given in conclusion on the germination of the spores of *Ophiobolus graminis*, and its perethecial stage is described.

The downy mildew of grasses, V. PEGLION (*Staz. Sper. Agr. Ital., 34 (1901), No. 5–6, pp. 506–532, pls. 3*).—An extended study is given of *Sclerospora graminicola*, a fungus nearly allied to Peronospora. The fungus was for a number of years only known as occurring upon species of Setaria, but the list of host plants as given by the author includes wheat, oats, *Avena fatua*, couch grass, canary grass, perennial rye grass, and reed grass; and it probably occurs on redtop, creeping soft grass, reed canary grass, and sea meadow grass. The effect produced by the fungus upon its various host plants is shown and the technical characteristics of the fungus are described at length. The conditions for the appearance and spread of the disease are mentioned, and rotation of crops is recommended as one of the most efficient methods of combating it.

A new disease of potatoes in France, G. DELACROIX (*Extr. from Jour. Agr. [Paris], 1901, Sept. 7, pp. 7*).—An account is given of the appearance of a bacterial disease of potatoes in France which is attributed to *Bacillus solanacearum*. The characteristics of the disease are described at some length. There seems to be a decided difference in varieties as to susceptibility to this disease. Early varieties, such as Quarantaine and Red Saucisse, are very subject to the disease, while Richter Imperator is less so, and others apparently not at all liable. Although this disease was first reported in the United States it is not definitely known to be of American origin. In addition to this bacterial disease, the mycelia of a number of fungi are frequently observed in the stems of affected plants. The fungi noted are a form of Fusarium, *Rhizoctonia solani*, a species of Vermicularia, and a dark brown mycelium which appears to be that of *Torula convoluta*. For protection against these fungi, the author recommends rotation of crops, careful attention to fertilizers, and preliminary treatment of the seed tubers with a solution of formaldehyde.

Investigations respecting defective growth and premature decay of the sugar cane occasioned by root disease, Z. KAMERLING (*Rpt. West Java Sugar Expt. Sta. "Kagok," Pekalongan, Java, 1900, pp. 18-21; reprint from Internat. Sugar Jour., 3 (1901), Aug.*).—The early observations on root diseases of cane are briefly reported. In 1894 Wakker showed that in some cases the disease was caused by *Marasmus sacchari*, and proposed to call the disease the "dongkellan disease," from the Malay word referring to the woody lower extremity of the cane. Kobus later arrived at the conclusion that there was more than one cause of disease which resulted in a desiccation of the stems and leaves through the cutting off of the water supply. The author believes that, aside from a few doubtful cases, two distinct kinds of root disease exist in Java which occasion extensive damage to sugar cane. One of these seems to be confined to a particular variety of cane known as Louziers; the other is commonly known as root disease. This latter disease has spread considerably within the last few years, and constitutes a great danger to the sugar industry. The effect of the root disease, as shown upon the plant, is described at some length. At the beginning the root system is sound and the plant develops in a normal manner, but after a period varying from 2 to 8 months the disease appears on the lowermost roots. After the root system is attacked the demand of the leaves for water can not be supplied and the wilting becomes manifest. If at this period the plant is earthed up it may revive on account of the formation of sound roots in the fresh earth, but this effect is only temporary as the disease attacks consecutively the roots issuing from the higher nodes of the cane. The plant accommodates itself to a certain extent to the insufficient water supply by diminishing its leaf surface. The lower leaves begin to dry and roll up, so that instead of 13 or 14 vigorous leaves but 10 or 11 will be observed on the stock, and later perhaps only 3 or 4 remain. This root disease is so peculiar in its mode of appearance and the way in which it attaches itself to certain soils as to be quite characteristic, and it is believed that soil studies must be made in connection with it. It has been observed that the disease is most troublesome on old estates where the land has been under cane for many years. It seems probable that not only the available food supply must be taken into consideration, but the physical condition of the soil as well in studying this disease.

A review of the diseases and injuries of Deli tobacco, F. W. T. HUNGER (*Meded. 'S Lands Plantentuin, 1901, No. 47, pp. 53*).—Compiled notes are given of a number of the more common diseases to which Sumatra tobacco is subject. The appearance of the disease, means of spreading, and, where known, the causes and methods of combating are described. The diseases are grouped under the headings constitutional diseases, such as fasciation and abnormal growth; fungus diseases; diseases and injuries due to unfavorable atmospheric conditions; diseases attending the curing of tobacco; and unclassified diseases, such as the mosaic disease, etc.

A rust on cultivated lettuce, H. A. BALLOU (*Amer. Gard., 22 (1901), No. 366, p. 874*).—Notes the occurrence of *Puccinia prenanthis* upon cultivated lettuce. When observed it was in the æcidial stage, and while common upon the wild lettuce it apparently has not been reported as occurring upon the cultivated species. The occurrence of the fungus upon this host plant is attributed to the fact that the lettuce was grown on low, moist land, and the season being cold and wet made the host unusually susceptible.

Apple rots in Illinois, G. P. CLINTON (*Illinois Sta. Bul. 69, pp. 189–224, pls. 10*).—A review is given of the different fruit rots which have been observed on the apple in the State of Illinois. Among those mentioned are the fruit burn, which is caused by the scalding or sunburning of the apples, the brown rot, soft rot, fruit blotch due to a *Phyllosticta* sp., the black rot, and a number of miscellaneous decays that are sometimes noticed. The fruit blotch is believed to be caused by an undescribed fungus that somewhat resembles *Phyllosticta limitata*, but is distinct from that as well as related species.

The principal portion of the bulletin is occupied with a discussion of bitter rot. This is probably of widest distribution and occasions the most injury of any of the apple diseases. Spraying has been tried with more or less success for its prevention, and experiments are still being prosecuted along this line, and the results will be reported later. The appearance of the affected fruit and conditions affecting the development are described. So far the bitter rot is reported in Illinois as occurring only on the apple, although elsewhere it is known to attack the pear, peach, quince, and grape. The manner of infection and life history of the fungus are described at some length.

The summer stage, which is the one commonly known as *Glœosporium fructigenum*, was investigated at considerable length by means of artificial cultures and artificial infections. It was found that the bitter-rot fungus would develop on a variety of fruits if spores were introduced under the epidermis by means of a needle. In this way it was found possible to infect apples, pears, peaches, grapes, tomatoes, etc. The details of the artificial inoculations are given. While studying this stage the author discovered the permanent form of the fungus, which he calls the Gnomoniopsis stage. While occurring with considerable abundance in his culture media, this was observed but twice on apples, one of which was on an apple that had been inoculated with Glœosporium spores and kept for a considerable time in a moist chamber. Infection experiments were carried on in which the mature form of the fungus was developed from the Glœosporium stage and the Glœosporium stage from the mature form, thus completing the life cycle of the fungus. In following the precedent generally established for the naming of fungi—that they be named from their mature or permanent stage rather than from the summer stage—the author proposes the name be changed to *Gnomoniopsis fructigena*, a technical description of which is given.

A new species of Botrytis parasitic upon the Japanese persimmon, U. BRIZI (*Staz. Sper. Agr. Ital., 34 (1901), No. 8, pp. 767–773*).—A description is given of *Botrytis diospiri*, n. sp., and the injury it causes upon its host plant is described. The fungus attacks the fruit when approaching the period of ripening, causing its abnormal growth and preventing perfect maturity. Spraying with a 2 per cent solution of Bordeaux mixture is recommended as a preventive treatment.

Studies on the cause of grape-leaf perforations, U. BRIZI (*Staz. Sper. Agr. Ital., 34 (1901), No. 8, pp. 774–788*).—A disease of grape leaves, in which ragged perforations were made in the leaves, made its appearance rather suddenly in central Italy. Investigations by the author showed it was due to attacks of *Glœosporium ampelophagum* which was frequently associated with the common grape anthracnose.

A root mold of coffee, A. ZIMMERMANN (*Teysmannia, 12 (1901), No. 6, pp. 305–309, figs. 3*).—A root disease of coffee that had lately killed a number of trees was studied and found to be caused by a fungus which though not in fruit was very characteristic in its habit. The fungus, which the author calls the black root mold of Java coffee, penetrates the cells of the inner bark and of the medullary rays, and ramifies into the cells near the medullary rays. The hyphæ are black when old, but the young tips are almost colorless and are covered with granules of lime. The fungus uses up the starch in the cells and eventually causes the leaves to turn yellow and fall. The death of the tree follows in time.—H. M. PIETERS.

The "blorok" disease of Coffea arabica, A. ZIMMERMANN (*Teysmannia, 12 (1901), No. 7–8, pp. 419–429, figs. 4*).—A disease of the leaves of the coffee tree known by the name of blorok disease has attracted much attention. The diseased leaves are characterized by a pale spotting or rather clouded effect, the upper surface of the diseased area losing the normal green color. In this area the cells of the epidermis are shrunken and yellow, and the neighboring cells are also yellowed. A similar condition prevails on the lower surface. The diseased trees do not die at once, but are sickly for a time and eventually succumb. No parasites were found in the diseased cells, and the cause of the trouble has not yet been determined. It is thought that bacteria may be responsible for the disease.—H. M. PIETERS.

Parasites of vanilla, E. BORSAGE (*Rev. Agr. Réunion, 7 (1901), No. 4, pp. 142–149*).—Notes on attacks of various insects and fungi upon vanilla. The principal injury seems due to attacks of *Calospora vanillæ*. The different stages of the life history of the fungus and the effect produced upon the host plant are described. One striking effect is shown in the ash analysis of the stems and leaves, in which the potash and phosphoric acid are greatly reduced and the lime increased in the diseased plants.

Growing China asters, R. E. SMITH (*Massachusetts Sta. Bul. 79, pp. 26, figs. 19*).—After briefly describing the methods of cultivation of asters, the author considers in detail some of the diseases and injuries to which the garden asters are subject. One of the most common and destructive diseases is that known as wilt or stem rot. This first appears soon after the plants are set out in the bed, and is generally prevalent throughout the season. If affected plants be examined they will be found to be badly rotted just at the surface of the ground, only the hard inner woody portions remaining. This, however, is the final stage of the disease, and it may be noticed on careful examination earlier in the season when the normal color of the plants becomes affected, and usually more on one side than on the other. The disease is due to a species of Fusarium, as yet not definitely determined, and it appears that it is contracted in the seed bed as a result of crowding and too much moisture. There appears to be no evidence that it is contracted after the plants are set in the field. To avoid it the seedlings must be grown in favorable conditions, those grown out of doors or in cold frames being preferred to greenhouse-grown plants. Conditions somewhat similar to the wilt or stem rot are caused by attacks of white grub and root lice. In the case of attacks of the white grub the plant wilts at once, and by pulling it up the nature of the trouble may be discovered. The wilting and stunted growth due to root lice is less easily distinguished. The affected plants fail to grow, have a wilted, unhealthy appearance, and often remain in the bed all summer without apparently increasing in size. If pulled up, the roots will be found covered with masses of a bluish-colored root louse in all stages of development. As the life history of this pest does not seem to be fully understood, the recommendation is made that new and uninfested soil should be used in both seed and permanent beds as a preventive measure.

A second serious disease is that known as the yellow disease or blight. It is a disease of very obscure origin, which produces a bright yellow spindling growth of plants. The affected parts do not die or wilt, but do not develop properly. The effects produced by this disease are summarized. The roots appear to be well developed and normal, and while no structural changes are observed in the stems, branches, or leaves, these organs are of a pale yellow color and quite deficient in chlorophyll. There are certain modifications produced in the flower that are also mentioned. A number of causes are discussed, such as nematode worms, root lice, fungi, bacteria, varieties, effect of transplanting, heredity, property of soil, etc., from which it has been determined that none of these can be definitely ascribed as the cause of the disease. It seems that it is due to an obscure derangement of the vital functions of the plant. Brief notes are given on the aster rust, and attacks of beetles, grasshoppers, etc.

Leptosphæria vagabunda and Pleospora negundinis, C. A. J. A. Oudemans (*Proc. Sec. Sci. Koninkl. Akad. Wetensch. Amsterdam, 3 (1901), pp. 141–151, pl. 1*).—Descriptions are given of these fungi which cause diseases of trees, the first species occurring on linden and the second on Negundo. The Leptosphæria causes small oval black spots 0.5 to 1.5 cm. long on the surface of the young branches. The infection takes place through the lenticels, and as the dead tissue is cut off by a cork layer it is comparatively harmless. Associated with it was found a new species of Phoma, to which the name *P. tiliæ* is given. It is believed to be a form in the life cycle of the fungus. Experiments are reported in which a number of black spots were cut from the bark, crushed, and thoroughly macerated with distilled water, after which the mass was filtered through a Chamberland-Pasteur filter, and young shoots of healthy trees were treated with the filtrate by inoculation and by immersion. The branches changed to a reddish-brown color within a few days, while others treated in a similar manner with distilled water remained green. The disease of Negundo seems to be confined to nursery stock under 3 years old, and causes much injury. Diseased branches show discolored areas somewhat resembling those described above as occurring on the linden. In this case the infection is apparently through wounds, often at the base of the leaves. An enzym is associated with this fungus as in the former case, and is believed to be the principal cause of the injury. In both diseases the mycelia are the sources of injury, and from both of them the enzym has been separated. The mycelial filaments of the Tilia disease are colorless, devoid of partitions, and very thin and delicate; while those occurring in the disease of Negundos were brownish in color, septate, and occurred in considerable masses. The enzym of the Tilia disease acts locally; that of the Negundo may give rise to infections at considerable distance from the point of inoculation.

A disease of birch trees, R. Paulson (*Essex Nat., 11 (1900), p. 273, figs. 8; abs. in Jour. Roy. Hort. Soc.* [*London*], *26 (1901), No. 1, p. 206*).—This disease, which is reported in Epping forest and elsewhere, completely destroys many of the trees. The disease is attributed to the fungus *Melanconis hillistoma*. Hitherto this fungus has been considered to be a saprophyte, attacking only dead tissues, but the conclusion is arrived at that it occurs on the living branches, causing their death; however, as a rule, its perfect form is only found on dead branches. The course of the disease is said to be rapid.

Pestalozzia hartigii in Ariège (*Rev. Eaux et Forêts, 40 (1901), No. 17, pp. 537–539*).—The occurrence of this fungus upon young beech seedlings is reported, and it is thought to be the first record of its occurrence in France. The fungus attacked the young trees in the nursery, causing a reddish-brown discoloration at the collar of the plant. The most serious injury was done in nurseries situated at an elevation of about 1,350 meters. It is reported to have destroyed at least 30 per cent of seedlings in some localities.

The leaf-cast disease of pine, E. Ebermayer (*Allg. Forst u. Jagd Ztg., 67 (1901), Sept., pp. 309–314*).—A review is given of the various theories relative to the cause of leaf casting of pine trees, particular attention being given to the theories of excessive evaporation, frost injury, and attacks of the fungus *Lophodermium pinastri.*

Continued studies on the formation of the witches' broom rust (Puccinia arrhenatheri) on the barberry, J. Eriksson (*K. Landt. Akad. Handl. Tidskr., 39* (*1900*), *No. 5-6, pp. 346-360*).

On the organization of an international system of phytopathological experimentation, J. Eriksson (*K. Landt. Akad. Handl. Tidskr., 39* (*1900*), *No. 5-6, pp. 361-368*).

ENTOMOLOGY.

Report of the entomologist, H. A. Gossard (*Florida Sta. Rpt. 1901, pp. 58-75*).—The author continued the work of the inspection of nurseries, and reports that the nurseries within the State are carefully and effectively fumigated. The cottony cushion scale is no longer a serious enemy, having been largely destroyed by the Australian lady bug. The peach scale has also been checked by the attacks of the lady bugs. Notes are given on the habits and life history of a number of other scale insects and mealy bugs. San José scale is now reported from 25 different localities in the State. Injury to pecans is reported from *Acrobasis caryæ* and *Mineola juglandis*. The white fly was unusually abundant during the year, but its numbers were much reduced by fungus diseases, especially the red and brown fungus. One orange grove, which has been infested for at least 10 years with this insect, seems not to have suffered severely. Good results are reported from the use of resin wash in combating this insect, and the author also recommends spraying during the winter with a 10 or 15 per cent mixture of kerosene in water. Fumigation experiments were made with the assistance of C. W. Woodworth. Several patterns of tents were used for covering trees in the orchards. Details are given of the management of these tents and the time required for fumigating trees. It was found that a greater volume of gas was obtained when the sulphuric acid and water were mixed and used immediately than when the mixture was allowed to become cool. No serious injury was done to the foliage, whether fumigation was done at night, in cloudy weather, or in bright sunshine. The white fly was nearly exterminated by fumigation. It was also observed that lady bugs were not all destroyed during the process of fumigation, although many of them were stupefied, but later recovered from the effects of the gas. Brief notes are also presented on a number of miscellaneous insects.

First report of the government entomologist, 1899-1900, C. Fuller (*Rpt. Govt. Ent., Dept. Agr. Natal, 1899-1900, pp. 154, pls. 25, figs. 33*).—This constitutes the report of the author as government entomologist for Natal, and contains, in addition, a general discussion of insects and a special consideration of numerous notes on various plant diseases, weeds, etc. The plant diseases which receive most attention are oat rust, "corn blight," barley blight, potato blight, and potato scab, as well as a number of fungus diseases of fruit trees and small fruits. A study was made of the biology of *Striga coccinea*. This weed was found to fix itself upon the roots of corn, from which it absorbed a portion of its nourishment.

General directions are given for spraying orchard and garden crops, and for making a choice of spraying machinery and of insecticides. Formulas are given for the preparation of the most important insecticides. Directions are also presented for the application of hydrocyanic-acid gas in orchard fumigation.

A popular classification of insects is given, and of the important insects which receive special consideration the following may be mentioned: *Colias electra*, injuring alfalfa; *Sesamia fusca*, attacking corn; codling moth; wattle bagworms; a species of Animula which is more or less injurious to *Acacia mollissima; Egybolia vaillantina*, injurious to peaches; *Ophiuza lienardi*, attacking various species of fruit trees; cutworms; diamond-back moth; grain moth (*Gelechia solanella*); blister beetle; grain weevil; *Monochamus leuconotus*, injurious to coffee; a fruit fly belonging to the genus Ceratitis, and closely related to the species which is injurious in Cape Colony; horse botfly, jigger flea; locusts (especially *Acridium purpuriferum*); cockroaches; white ants; bedbugs; spittle insects; woolly aphis; cabbage aphis; a large number of species of scale insects; onion thrips; and ticks of various species. Each species is described and notes are given of its habits and life history, together with recommendations of the best methods for combating it.

Entomological notes and inspection report for 1901, S. A. Forbes (*Trans. Illinois Hort. Soc., n. ser., 35 (1901), pp. 142–154*).—Injury from cankerworm is reported as having shown rapid increase during the past few years. For controlling this insect in orchards, spraying with Paris green or arsenicals is recommended. For the protection of large shade trees the use of bands impassable by the female is urged; for this purpose a band of heavy wrapping paper smeared with a thick layer of printers' ink or tar, and thinned with oil to prevent drying out too soon, is recommended. Some injury to young apples from green fruit worms is reported. These insects are difficult to destroy, but are usually prevented from doing serious harm when the orchard is sprayed early in the spring. The apple flea weevil (*Orchestes pallicornis*) is reported as burrowing in the leaves in its larval condition. The beetles feed on the under surface of the leaves, eating round holes in them. The details of its life history are not known. The pear-leaf blister mite has been unusually abundant in Illinois nurseries and it is urged that all affected stock should be treated with kerosene or fumigated with hydrocyanic-acid gas before sending out. Brief notes are given on general nursery inspection and insecticide work of the State inspector and his assistants.

Annual report of the zoologist, C. Warburton (*Jour. Roy. Agr. Soc. England, 62 (1901), pp. 257–271, figs. 4*).—Especial attention is devoted to a study of the life history of the black currant gall mite (*Phytoptus ribis*). The usual remedies which have been recommended for this mite are considered unsatisfactory. In observing the habits of this pest it was noted that the mite frequently stands upon its tail end for 5 minutes or longer at a time; occasionally they spring into the air from such position and are carried off by the wind to a considerable distance. While standing in the upright position they take every opportunity to fasten themselves upon insects which may visit the currant bushes. They may thus be transported to much greater distances than they could crawl. Large numbers of them perish from year to year. A few, however, succeed in penetrating the new buds, in which situation they are found about the first of June. Buds infested with mites survive the winter. The buds may be so slightly affected that they develop in the spring, or may perish, in which case the mites leave the buds and distribute themselves by crawling. It is believed that the mites which are seen crawling about in early spring are all doomed to perish, and it is therefore not recommended that any insecticide treatment be given at that time. The period at which spraying is considered effective is about the last week in June. Brief biological and economic notes are given on *Apion apricans*, *Oscinis frit*, *Plutella cruciferarum*, carrot fly, and a number of forest and fruit tree insects, including *Cryphalus tiliæ*, *Xiphydria dromedarius*, *Oribata orbicularis*, and *Andricus glandium*.

An account of the condition and work of the laboratory of agricultural entomology at the Royal High School of Agriculture in Portici from its foundation to 1901, A. Berlese (*Relazione sullo stato e sulla attività del laboratorio di entomologia agraria presso la R. Scuola Superiore di Agricoltura in Portici. Rome: G. Bertero & Co., 1902, pp. 101, figs. 5*).—The author gives an account of the collections of insects and books belonging to the institution. The apparatus and equipment of the laboratory are described. A bibliography of the entomological publications from the laboratory from its foundation to 1901 is given. The insects which required special investigation by the staff of the laboratory are briefly mentioned. Among the important ones are *Caloptenus italicus*, *Porthesia chrysorrhœa*, *Dactylopius citri*.

Injurious insects, W. LOCHHEAD (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 18–20, fig. 1*).—Brief notes are given on formulas for the preparation of Paris green, hellebore, insect powder, whale-oil soap, kerosene emulsion, and a combination of Paris green and Bordeaux mixture. The insects which were especially injurious during the season 1901 were Hessian fly, apple-tree borers, plant lice, San José scale and other species of scale insects, as well as potato-stalk borer, rose chafer, asparagus beetle, and tussock moth. It is reported that the tussock moth is at present a less serious enemy of the shade trees than it was 3 or 4 years ago.

Third report of the State entomologist and pathologist on the San José scale, and the administration of the crop-pest laws of Virginia, W. B. ALWOOD (*Richmond, Va.: C. W. Saunders, 1901, pp. 58, pls. 10, figs. 4, map 1*).—Brief notes are given on the history of the San José scale in Virginia. Copies are given of the various acts of the State legislature which have been passed regarding this insect and also of the rules and requirements for the government of the State entomologist and pathologist in enforcing the law. According to the most recent act of the State legislature the Board of Crop Pest Commissioners are authorized to inspect orchards and other premises, and are specifically charged with nursery inspection and the inspection of nursery stock shipped into the State from outside sources. The author discusses the problems connected with the inspection of imported nursery stock. It is urged that certificates of inspection should not be accepted unless they are issued from offices with which entomologists of known standing are connected. The author gives a statement of the requirements in the ordinary form of certificate of inspection in Virginia. The question of the constitutionality of inspection laws is discussed and it is argued that State inspectors should not be asked to accept certificates without reference to the qualifications of the person who signs them.

The San José scale is gradually becoming more widely distributed throughout the State. Wherever there is a city or large village in an infested county, the town property is usually found to be the center of greatest infestation. In general the local spread of the San José scale is still slight; in some instances, however, it has been of a serious nature. A list of States is given to which infested nursery stock has been traced, and the dissemination of the scale by State nurseries and outside nurseries is presented in a tabular form. The author discusses the general condition with regard to infestation by the San José scale in different States. The insect pests and plant diseases which are dealt with according to the Virginia inspection laws are San José scale, woolly aphis, peach yellows, black knot of plum and cherry, pear blight and twig blight of apple, and crown gall. A brief description is given of each one of these pests and the most effective remedies are suggested in each case. Especial attention is given to remedial measures against San José scale and the results of experiments extending over several years are summarized. It is concluded that kerosene furnishes the most reliable remedy against the scale for use on hardy fruit trees and other plants, in winter or summer. There is some danger in careless use of kerosene on peach trees and other stone fruits. Soap washes, when strong enough to be effective, are found to be more dangerous for summer work than kerosene and much more expensive. Directions are given for the preparation and application of kerosene sprays. It is urged that where only a few young trees or plants are found infested in a given locality, these plants should be destroyed, since in this way the scale may be destroyed for the particular locality. The author does not believe that the San José scale can be exterminated, but the methods in present use are sufficient to hold it in check. A list of the host plants of the San José scale are given and a detailed financial statement is appended to the report.

Treatment for San José scale in orchards. I, Orchard fumigation, F. A. SIRRINE (*New York State Sta. Bul. 209, pp. 341–372, pls. 10*).—During the winter of 1900–1901 a number of apple and peach trees which had been fumigated during the previous winter were again treated. Tests were also made in other orchards consisting of a mixture of apple, cherry, peach, pear, plum, chestnut, and walnut. Apple trees which were treated at the rate of from 15 to 25 gm. cyanid of potash per 100 cubic feet, on different days from March 23 to April 13, received no injury. Peach treas which were fumigated at the rate of 15 gm. per 100 cubic feet were not injured, while a number of trees exposed to the gas generated from 20 gm. per 100 cubic feet were slightly injured and the grass around the base of the trees was killed. The experiments demonstrated that it is unsafe to allow peach trees to be exposed to the action of hydrocyanic-acid gas for a period of 12 hours, whatever weight of cyanid of potash per cubic foot was used. Vigorous trees, including peach, may be treated with 2½ oz. of cyanid per 100 cubic feet for not more than 30 minutes, while the trees are dormant. Peach trees which are not vigorous may be injured by such treatment, but the injury is not usually permanent. Peach trees in the orchard may be treated from 30 to 60 minutes with 1¾ oz. cyanid per cubic foot, even after the buds begin to open. Walnut, chestnut, plums, and cherries will endure the same treatment as peach.

With regard to the effect of the gas on scale insects the experiments showed that fumigation may be depended upon to exterminate the San José scale on orchard trees of medium size. Experiments were made to determine the best proportions in which to mix the cyanid, sulphuric acid, and water. It was found that a slight excess of acid and from 2 to 4 times the usual quantity of water gave rapid and uniform action and satisfactory results. The smaller the pieces of cyanid the more rapid is the chemical action, and where the cyanid is broken too finely the chemicals may be thrown out of the vessel in which they are contained by the violence of the reaction.

It was found that in fumigating trees when the earth was moist about 50 per cent of the gas was absorbed by the soil. It is recommended that double the amount of cyanid generally used for nursery stock should be used in orchard work.

The author gives a detailed description in connection with drawings and figures of a hexagonal box fumigator designed for use in orchards. The chief advantages of this fumigator are that it allows a rapid and accurate estimate of the cubic contents, it may be placed around a tree without being elevated over it, it contains a minimum amount of waste space, it can be stored in a comparatively small space, and it does not break off or rub the buds. The cost of fumigation varies so exceedingly, according to the style of fumigator used and other conditions, that it can not be stated except with qualifications. When 1 oz. of cyanid is used for every 100 cubic feet of space the cost is about 12½ cts. per tree when fumigated with tents, and 18 cts. when treated with a box fumigator.

The Aphididæ of North America, W. D. Hunter (*Iowa Sta. Bul. 60, pp. 61–138*).—In this bulletin the author has compiled a list of titles of the literature on North American plant lice. A list of titles of general articles is given, followed by a catalogue of the family Aphididæ, arranged in a systematized manner with reference to literature under each species. A host index of the North American species of Aphididæ is also presented, and the bulletin is furnished with an index to the species of plant lice which are discussed. The total number of genera recognized in the bulletin is 32, and of species 325.

Familiar butterflies and moths, W. F. Kirby (*London, Paris, New York, and Melbourne: Cassell & Co., Limited, 1901, pp. 144, pls. 18, figs. 4*).—In this volume the author gives a general description of the appearance, life history, and habits of a number of common lepidoptera, including various families of butterflies and moths. Brief directions are given for the collection of butterflies and moths, together with notes on the occurrence of these insects in different seasons of the year. A number of species considered are of economic importance, and their food plants are mentioned. The plates illustrating the work are in color and well executed.

The codling moth and late spraying in Oregon, A. B. Cordley (*Oregon Sta. Bul. 69, pp. 121–160, pls. 4.*)—The author gives an account of a trip through certain parts of Oregon for the purpose of determining the extent of infestation of apple orchards by the codling moth. With regard to the question of the number of broods, it is believed that there are only 2. The various statements which have been made to the effect that 3 or 4 broods occur are not based on breeding records, but simply on the fact that larvæ and eggs may be found throughout a long season and that the different stages of the insect may be passed through in a comparatively short time under favorable conditions. The insect is described in its different stages and an account is given of its life history. At Corvallis there appears to be no relation between the time at which the apple trees bloom and the dates on which the moths emerge. Egg laying is delayed to a later date than that usually given in the Eastern States. The first eggs were observed out of doors on June 21 and deposition of eggs did not become general until June 28; the petals had fallen by April 28, or 2 months previous. Observations during the years 1898 to 1900 showed that while the blossoms fell at dates ranging from April 28 to May 10, the egg laying did not begin before the middle of June and did not become general before about June 25. In southern and eastern Oregon the egg laying may take place earlier.

A compilation of the records of the evening temperature in the neighborhood of Corvallis disclosed the fact that the temperature rarely reaches 60° in the evening during the month of May. Observations indicate that the codling moths rarely deposit eggs when the evening temperature falls much below 60° F. The eggs were found by the author in orchards at all times from the latter part of June until October 1, or later. They were found more commonly upon the fruit than upon the leaves. The length of the larval period was found to vary from 16 to 24 days. In breeding cages the moths of the first brood appeared on August 3, from larvæ which had pupated on July 21, and the moths of the second brood emerged on May 29 of the following year from eggs which had hatched September 12.

Notes are given on the various natural enemies of the codling moth, including fungus diseases, parasitic and predaceous insects, and birds. While large numbers of the larvæ of the codling moth are destroyed by fungus disease, it is not believed that this fungus could be successfully used in an artificial way in controlling the pest. The most important help in the destruction of the codling moth is rendered by birds of various species.

The greatest loss from the codling moth in the Willamette Valley and other parts of Oregon occurs after August 1. Spraying experiments were conducted for the purpose of determining the relative efficiency of early and late applications. Four applications were made with Bordeaux mixture to which 1 lb. of Paris green was added for each 200 gal. The applications were made on May 13, June 11, June 25, and August 11. One or more of the applications were omitted from some of the trees in order to determine which application was most important. These experiments showed that up to July 20 only 2 per cent of the apples were infested, whether they had been sprayed or not. The first application seemed to be valueless, and the second and third nearly so, while the fourth was apparently the only effective one. Similar experiments were repeated for 1900, the applications being made May 7 to 14, June 22 to 27, July 26 to 28, and August 31 to September 1. In these experiments the least satisfactory results were obtained with Ben Davis, of which about 30 per cent were wormy; Newtown pippins standing near them in the same orchard were almost absolutely free from codling moth, while the Baldwins were infested to the extent of about 1 or 2 per cent. Trees that were given the last 3 applications showed less than 5 per cent infestation, while those that were sprayed 4 times were infested to the extent of 3 per cent. It is believed that in order to prevent injury from codling moth as far as possible the fruit should be kept covered with a film of poison from the time when the earliest eggs are deposited until the middle of September. The author believes that the expense of banding is hardly necessary where spraying has been carefully done.

In an appendix to the bulletin E. L. Smith and J. D. Olwell give the results of insecticide work in their orchards. For a part of this practical work arsenite of soda was used, while on other trees a mixture of Paris green and London purple was applied. Both of these orchardists have found it possible to prevent to a large extent the injury of the codling moth and therefore believe that spraying for this purpose is profitable. It is stated that much of their success has depended upon spraying during the first or second week in September.

The periodical cicada in 1902, W. D. Hunter (*U. S. Dept. Agr., Division of Entomology Circ. 44, n. ser., pp. 4, figs. 2*).—The circular calls attention to the fact that brood No. X was due to appear during May in 17 or more States as well as in the District of Columbia. The usual recommendation is made not to trim fruit trees too closely during the spring; and a request is made for voluntary reports from various localities in which the cicada appears.

Insect enemies of forests and forest products, A. D. Hopkins (*Forester, 7 (1901), No. 10, pp. 250–254, figs. 5*).—Popular notes on insects injurious to forest trees and lumber, with special reference to the species which attack coniferous trees. Attention is called to the desirability of further experiments for devising practical plans for combating the attacks of forest insects.

Insects injurious to elm trees, E. P. Felt (*New York State Fisheries, Game and Forest Com. Rpt. 1899, pp. 351–379, pls. 3, figs. 7*).—Notes are given on various mechanical and chemical methods for destroying insects. An account is given of the life history, habits, and means of combating elm-leaf beetle, bagworm, fall webworm, antiopa butterfly, elm borer, and elm bark-louse.

The protection of fruit trees against animal enemies, O. Taschenberg (*Schutz der Obstbaume gegen feindliche Tiere. Stuttgart: E. Ulmer, 1901, pp. 341, figs. 75*).—This volume constitutes one part of the author's treatise on insect and fungus enemies of fruit trees. In the introduction a general account is given of the anatomy and classification of insects, and of the various physical, mechanical, and chemical means which have been adopted for destroying insect pests upon fruit trees. Especial attention is given to those insecticide methods which are best suited for preventing injuries from insects to the roots, trunk, buds, flowers, leaves, and fruits of various fruit trees. The more common injurious insects are mentioned and economic and biological notes are given on each species thus discussed.

Lantern traps and the destruction of injurious insects, V. Vermorel (*Les pièges lumineux et la destruction des insectes nuisibles. Montpellier: Coulet & Son, 1 02, pp. 64, figs. 31*).—The author gives a general historical account of the various uses to which the lantern traps have been put in collecting and destroying insects. A large number of different styles of traps are described and illustrated. A bibliography of the subject is given and a list of economic plants is presented in connection with the most important injurious insects which affect each plant. Experiments have shown that a large variety of insects may be captured in this manner, but lantern traps are especially effective in attracting butterflies and moths. A calendar is presented showing the most important injurious insects which appear during different periods of the year and which may be caught by means of lantern traps.

Fumigation methods, W. G. Johnson (*New York: Orange Judd Co., 1902, pp. 313, figs. 83*).—In this volume the author gives a general account of the use of hydrocyanic-acid gas and carbon bisulphid in fumigating various kinds of orchard trees, nursery stock, and other plants, under various conditions. The volume includes a history of the discovery of the value of this gas for insecticide purposes, the method of generating the gas, physiological effects on plants, effects on animal life, the apparatus suitable for use in orchards, cost of the application, equipment for fumigating nursery stock, construction of ventilators and floors, methods of fumigating in greenhouses and cold frames, application in mills, elevators, and other buildings, fumigation of grains and other seeds, the diffusion of gas in the air, the recent work with hydrocyanic-acid gas, and the economic value of fumigation. Abstracts are given of the laws regulating nursery and orchard inspection and fumigation in the United States, Canada, and other countries. The chapter devoted to a discussion of carbon bisulphid contains an account of the use of this chemical in fumigating seeds, fruits, plants, mills, and other buildings; in the destruction of insect pests in clothes, and in killing prairie dogs, rats, mice, and other injurious animals.

Report of analyses of Paris green and other insecticides in 1901, L. L. VAN SLYKE and W. H. ANDREWS (*New York State Sta. Bul. 204, pp. 243–250*).—The authors analyzed 40 samples of Paris green and found that the amount of arsenic varied from 56.13 to 62.87 per cent. So far as the total arsenic content is concerned the Paris green examined was of high quality, the percentage of arsenic being greater than that required by law. The amount of free arsenious oxid found in these samples varied from 0.88 to 2.64 per cent, the average being 1.28 per cent. This quantity of free arsenic is considerably below the danger limit, and the Paris green sold in the New York markets is therefore considered effective and safe. The amount of copper in the samples examined varied from 26.53 per cent to 31.14 per cent. Analyses were also made of English Bug Compound, Laurel Green, London purple, and Paris-green Bordeaux mixture.

Fungicides, insecticides, and spraying calendar, G. E. STONE, H. T. FERNALD, and S. T. MAYNARD (*Massachusetts Sta. Bul. 80, pp. 15*).—Brief directions for preparing and applying the common fungicides and insecticides, and their combinations, together with a spraying calendar.

A new fungus disease for Rutherglen bug (*Agr. Gaz. New South Wales, 12 (1901), No. 12, p. 1629*).—The department of agriculture of the Colony has imported samples of *Sporotrichum globuliferum*, and it is hoped that this fungus may be of some service in checking the ravages of *Nysius vinitor*.

Insects injurious to stored grain, J. M. STEDMAN (*Missouri State Bd. Agr. Rpt. 1900, pp. 102–107*).—Brief notes on pea weevil, species of bean weevil, *Calandra granaria*, *C. oryzæ*, *Silvanus surinamensis*, *S. cassiæ*, and the Angoumois grain moth.

Systematic catalogue of the galls of animal origin of Europe and the Mediterranean basin, G. DARBOUX and C. HOUARD (*Catalogue systématique des zoocécidies de l'Europe et du Bassin Méditerranéen. Paris: Laboratoire d'Évolution des Êtres Organisés, 1901, pp. 544, figs. 863*).—The authors classify the various gall formations, which are found on plants and which are due to animals, in a system which is based on the part of the plant which is affected. In general, plant galls may be classified into those which affect the apex of growth and those which affect the lateral surfaces of growing parts. Each general class may then be divided according to the actual structure which is attacked. Galls which affect the tip of growing parts may be arranged into classes according as the fruit, inflorescence, flower, bud, or apex of twigs are affected, while the other general classes of galls may be subdivided into those which affect the root, stem, or twig and leaf. The species of animals which cause the various plant growths belong to the following families: Eryophyidæ, Cynipidæ, Tenthredinidæ, Cecidomyidæ, Aphididæ, and Psyllidæ.

The mosquitoes of Paris, their injuries, and means of eradication, R. BLANCHARD (*Arch. Parasit., 5 (1901), No. 4, pp. 615–635*).—The only species of mosquito which the author has been able to find in Paris is *Culex pipiens*. According to the testimony of other authors, however, *Anopheles maculipennis* has been also found in the city. The author gives brief notes on diseases with which mosquitoes are supposed to be connected as carriers of infection, and on the habits and life history of these insects. In combating mosquitoes a discussion is given on the efficiency of the method of adding pyrethrum flowers to water in which mosquito larvæ are found. In destroying adult mosquitoes the use of various substances for fumigation is discussed. These substances include essence of terebinth, iodoform, chloroform, ether, flowers of pyrethrum, and a mixture of these flowers and the root of valerian (sold under the name "zanzolina"). The draining of stagnant pools and the application of kerosene to the surface of water in which mosquito larvæ are found are discussed.

Mosquito brigades and how to organize them, R. Ross (*New York: Longmans, Green & Co., 1902, pp. 100*).—A general account is given of the habits and life history of different species of mosquitoes, with special reference to the locations in which the larvæ are found. The author outlines in detail a system of organized effort for the destruction of mosquitoes in and near towns. The scheme embraces the collection and removal of tin cans, broken bottles, and other receptacles in which water might be collected and mosquito larvæ might occur. Especial attention is to be given to the drainage of pools and small ponds of stagnant water in which mosquitoes are known to breed. It is urged that in towns where mosquitoes occur in large numbers organized effort should be put forth to combat them according to approved methods. A superintendent, who should preferably be a medical or sanitary officer, is to be assisted by a number of workmen, and the men are to visit all premises in the town at regular intervals for the purpose of preventing the extensive breeding of mosquitoes. It is not hoped that these efforts will be successful in exterminating mosquitoes, even in a limited area, but it is believed that their numbers may be greatly reduced. The author reviews the more important literature on the subject and gives bibliographical references to the chief works on mosquitoes.

Insects beneficial to horticulturists, J. S. Hine (*Proc. Columbus Hort. Soc., 16 (1901), No. 1, pp. 26–29*).—Brief notes on the relationship of predaceous and parasitic insects to horticulture.

Report of the lecture on apiculture, H. R. Rowsome (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 125, 126*).—It was found that by placing queens in an inverted glass carboy and then introducing drones the desired cross could easily be secured. Much difficulty has been experienced heretofore in controlling the fertilization of queens. Brief notes are also given on the economy in the utilization of partially filled sections in feeding them back to the swarms.

Bee culture, G. W. Williams (*Missouri State Bd. Agr. Rpt. 1900, pp. 71–81*).—Brief notes on the various processes connected with raising bees, including the general system of management, wintering, and bee pasture The author claims to have obtained profitable returns from the cultivation of certain bee plants exclusively for honey These plants included Simpson's honey plant, cure-all, and fig wort.

A simple fixed frame and an improved bottom board, H. R. Stephens (*Queensland Agr. Jour., 9 (1901), No. 6, p. 556*).—Brief descriptive notes on 2 cheap and convenient devices for use in beehives.

Annual report of the Royal Sericultural Station at Padua (*Ann. R. Staz. Bacol. Padova, 29 (1900), pp. 131, pl. 1*).—This report contains a number of articles relating to sericulture, among which the following may be mentioned: The work of the Royal Sericultural Station for the year 1900, E. Verson (pp. 5–11); The organization of markets for silkworm cocoons in Italy, E. Verson (pp. 15–40 and 97–104); Armature of the prolegs of the silkworm larvæ, E. Verson (pp. 41–65); A disease of spinners and rearers of the silkworm, E. Quajat (pp. 66–76); Rapid and gradual incubation, E. Quajat (pp. 77–84); Influence of the time of washing the eggs upon hatching in the spring, and upon accidental hatching in autumn, E. Quajat (pp. 85–89); Creolin in the silk industry, E. Verson (pp. 90–96). It was found that the vapor of creolin uniformly exercises a poisonous influence on the eggs of the silkworm. The mortality in the eggs may vary from 4 to 100 per cent, according to the length of time during which they are exposed to creolin. A bibliography of literature relating to sericulture which appeared in 1900 and 1901 is appended to the report.

FOODS—NUTRITION.

Report of the department committee appointed to inquire into the use of preservatives and coloring matters in the preservation and coloring of food (*London: Eyre & Spottiswoode, 1901, pp. XXXVI+497, figs. 23*).—This volume contains the detailed report of the British official committee on food preservatives appointed in 1899, together with minutes of evidence and appendices reporting a number of special investigations, experiments, and discussions or summaries. A number of these have to do with such topics as the law and practice in certain foreign countries and the British colonies as to preservatives and coloring matter in food; the use of preservatives in dairy and vegetable products, the use of preservatives and coloring matter in foods, drinks, and drugs; analyses of milk and other products with a view to detecting preservatives and coloring matters; analyses of commercial preservatives; physiological experiments, and related topics. Regarding the use of preservatives and copper salts, the recommendations of the committee (which consisted of Herbert Maxwell, T. E. Thorpe, H. Timbrell Bulstrode, and F. W. Tunnicliffe) were as follows:

"That the use of formaldehyde or formalin, or preparations thereof, in foods or drinks be absolutely prohibited, and that salicylic acid be not used in a greater proportion than 1 grain per pint in liquid food and 1 grain per pound in solid food. Its presence in all cases to be declared.

"That the use of any preservative or coloring matter whatever in milk offered for sale in the United Kingdom be constituted an offense under the Sale of Food and Drugs Acts.

"That the only preservative which it shall be lawful to use in cream be boric acid or mixtures of boric acid and borax, and in amount not exceeding 0.25 per cent expressed as boric acid. The amount of such preservative to be notified by a label upon the vessel.

"That the only preservative permitted to be used in butter and margarine be boric acid or mixtures of boric acid and borax, to be used in proportions not exceeding 0.5 per cent expressed as boric acid.

"That in the case of all dietetic preparations intended for the use of invalids or infants chemical preservatives of all kinds be prohibited.

"That the use of copper salts in the so-called greening of preserved foods be prohibited."

F. W. Tunnicliffe presented a minority report which was not averse to the reasonable use of copper salts for greening vegetables.

Experiments upon the effect of boracic acid and formaldehyde upon the live weight, growth, and food assimilation of young sucking pigs, A. D. Hall, H. S. Hammond, and F. W. Tunnicliffe (pp. 306–311, figs. 4).—Digestion and nitrogen metabolism experiments, in which boracic acid and formaldehyde were added to the rations of pigs, are reported. The authors' general conclusions follow:

"The experiments conducted with boracic acid showed a negative result attending the administration of this substance, and a combinative examination of the feces of a boracised and normal pig showed no sensible difference in the amounts of fat, nitrogen, and fiber digested in the 2 cases. Formalin gave similar results; the administration of formalin did not materially alter the rate of growth.

"Our experiments would show that the digestion of young, rapidly growing pigs, as reflected in their general health and increase in live weight, is not sensibly affected by the regular administration over a long period, of doses of boracic acid and formalin in much larger proportions than they are usually employed for the preservation of food."

Report upon certain experiments made upon the extent to which the copper ingested with artificially coppered peas is absorbed and retained by the human body, F. W. Tunnicliffe (p. 312).—Experiments with man on the effect of copper are reported, in which the amounts eaten and excreted in the urine and feces were determined. The general conclusions follow:

"From our research, we regard the conclusion justified that copper, when ingested in the form in which it occurs in carefully preserved peas, is for the most part voided directly with the feces, and differs, in so far as concerns its absorption and retention by the human body, from the ordinary salts of copper."

Report on the influence of formic aldehyde upon the metabolism of children, F. W. Tunnicliffe and Otto Rosenheim (pp. 313–336, figs. 10).—Abstracted from another publication (E. S. R., 13, p. 774).

Report on the influence of boric acid and borax upon the general metabolism of children, F. W. Tunnicliffe and Otto Rosenheim (pp. 337–354, figs. 9).—The literature of the subject is reviewed and experiments on the effect of borax and boric acid reported, in which the metabolism of nitrogen and phosphorus and the assimilation of fat were the special features studied. The conclusions which were drawn follow:

"[As regards boric acid] small doses up to 1 gm. per diem, continued for some time, exert, in healthy or delicate children, no influence upon proteid metabolism. The assimilation of the proteid food was improved in one healthy child (B). The phosphorus metabolism was unaffected in all cases. The assimilation of phosphorus was in all cases improved. The assimilation of fat was not affected. The body weight increased in all cases. The quantity of dry feces was not affected. Their nitrogen and phosphorus percentage was slightly decreased. No inhibitory effect upon intestinal putrefaction could be demonstrated.

"[As regards borax] continued doses of 1.5 gm. have no influence in healthy or delicate children upon proteid metabolism. The proteid assimilation was unaffected in healthy children, slightly depressed in the delicate child. The phosphorus metabolism was not affected in healthy or delicate children. The assimilation of phosphorus was improved in all cases, the improvement being least marked in the case of the delicate child. The fat assimilation was improved in the case of one healthy child, and unaffected in the case of the others. The body weight was increased in all cases; the increase was most marked in the case of the delicate child. The weight of dry feces and their nitrogen phosphorus percentage remained unaltered. Borax tended rather to increase intestinal putrefaction.

"[When given together] both boric acid and borax were quickly eliminated, no cumulative action being therefore probable. Neither boric acid nor borax in any way affected the general health and well-being of the children."

Digestibility of proteins, A. Jolles (*Monatsh. Chem., 22 (1901), pp. 991–995; abs. in Jour. Soc. Chem. Ind., 21 (1902), No. 2, p. 132*).—The author has shown in earlier investigations that there are differences in the constitution of proteids, and that the constitution influences the portion of nitrogen which is converted into urea on oxidation. Experiments with man were undertaken to learn the comparative nutritive value of casein and fibrin, the former yielding about 73 per cent of its nitrogen as urea and the latter about 45 per cent. In the casein period 16.7 per cent of the total nitrogen of the food was absorbed, and in the fibrin period 34.3 per cent. According to the author, therefore, the physiological nutritive value of the proteids as regards nitrogen depends on the amount of the urea forming groups. The hexone bases were apparently less completely utilized than the nitrogenous bases, since they could be detected quantitatively in the feces.

Sixth report on food products, E. H. Jenkins (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 95–102*).—The State laws regulating the sale of foods are quoted, and details of the work of the station in carrying out the provisions of the law are given. During the year, 1,686 samples were examined.

Milk and cream, A. L. Winton, I. F. Harris, and M. Silverman (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 102–118*).—Of samples of milk analyzed during the year, 8.5 per cent were found to be adulterated, the greater part by skimming or watering.

Added preservatives, either formaldehyde or borax, were found in 9 samples. One sample of cream was found to contain formaldehyde.

Coffee, A. L. WINTON (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 119–122*).—Seven samples of coffee beans and 50 of coffee were examined, 5 of these (all ground coffee) were found to be adulterated.

Jellies, jams, and preserves, A. L. WINTON, A. W. OGDEN, and C. LANGLEY (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 122–134*).—Jellies and similar products and their process of manufacture are briefly described. Analyses of 66 samples are reported. Nineteen per cent of the samples were found to be pure, 51 per cent adulterated, and 30 per cent marked compound.

Tomato catsup, chili sauce, and other sauces, A. L. WINTON and A. W. OGDEN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 135–144*).—During the year 106 samples were examined; 21 contained no added preservative, and 20 no artificial coloring matter.

Crême de menthe, crême de violette, crême de rose, and other cordials, A. L. WINTON, A. W. OGDEN, and C. LANGLEY (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 144–148*).—Of the 28 samples of cordials examined, all but 6 contained added coloring matter, 3 contained added vegetable dyes, and the others chemical colors.

Vanilla extract, A. L. WINTON and M. SILVERMAN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 149–162*).—Of the 62 samples examined, 15 were found to be unadulterated.

"Vanilla crystals," A. L. WINTON and M. SILVERMAN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 162–163*).—According to the authors, a flavoring material called "vanilla crystals" consisted of sugar with the addition of a small amount of vanillin and coumarin.

Lemon extract, A. L. WINTON and A. W. OGDEN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 163–174*).—Fifty-one of the 66 samples examined were found to be below the standard; 4 samples were marked compound.

Orange extract, A. L. WINTON and A. W. OGDEN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 175, 176*).—Analyses of a number of samples are reported.

Miscellaneous flavoring extracts, A. L. WINTON (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 177, 178*).—A number of fruit flavoring extracts were examined.

"Frostlene," A. W. OGDEN (*Connecticut State Sta. Rpt. 1901, pt. 2, p. 179*).—Three samples of this material for making icing, etc., were examined.

The use of coal-tar dyes in foods, A. L. WINTON (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 179–182*).—A general discussion of the subject.

The adulteration of tea with tea fruit, A. L. WINTON (*Connecticut State Sta. Rpt. 1901, pt. 2, p. 183, fig. 1*).—Tea fruit was identified as an adulterant of tea.

"Puregg," A. L. WINTON and A. W. OGDEN (*Connecticut State Sta. Rpt. 1901, pt. 2, p. 184*).—Judging by an examination this material consisted of desiccated eggs, with a small amount of coal-tar dye and salicylic acid.

Fungicide, A. L. WINTON and M. SILVERMAN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 184, 185*).—This material, which is recommended for preserving cider and sweet wines, contained, according to the authors, a large amount of sodium benzoate.

"Hyper-samphire," A. L. WINTON and M. SILVERMAN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 185, 186*).—From an analysis of this material, which is sold for preserving eggs, "it appears that over two-thirds of the mixture consists of common salt, the remainder being free salicylic acid, sodium salicylate, and small amounts of sulphites, bisulphites, and sulphates. One and one-third ounces of a mixture of 3 parts of salicylic acid and 1 part of sodium bisulphate, costing not more than 15 cts., would have about the same value as 4 ozs. of hyper-samphire for use in the preserving solution described."

Spices, A. L. WINTON and M. SILVERMAN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 186–193*).—Details of the examination of 216 samples of bulk spices are reported, of which 29 per cent were found to be adulterated.

Cream of tartar, A. W. OGDEN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 194, 195*).—The examination of 41 samples of cream of tartar is reported.

Macaroni, spaghetti, vermicelli, and noodles, A. L. WINTON and A. W. OGDEN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 196–202*).—The authors examined 83 samples of Italian pastes and noodles. The proximate composition is reported, as well as data regarding the presence of added coloring matter, etc.

Miscellaneous examinations, A. L. WINTON, A. W. OGDEN, and M. SILVERMAN (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 202–204*).—Konut, said to be a cocoanut product; cooking oil, consisting largely or entirely of cotton-seed oil, and a number of samples of butter, flour, baking powder, spices, etc., sent by private individuals were examined.

Microscopic investigation of fruits, A. L. WINTON (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 225, 226*).—Brief statements are made concerning the microscopic investigations which the author has undertaken with fruits.

Food products examined for the dairy commissioner in the twelve months ending July 31, 1901 (*Connecticut State Sta. Rpt. 1901, pt. 2, pp. 205–207*).—Brief statements are made concerning the examination of a number of samples of butter, molasses, and vinegar.

Meats and meat products at the Paris Exposition of 1900, H. E. ALVORD (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 223–234*).—A descriptive article.

Food grains of India, A. H. CHURCH (*London: Chapman & Hall, 1886, pp. XI+180, pls. 35; Sup. 1901, pp. VIII+23*).—The major portion of this volume consists of a reprint of the first edition, containing a botanical description and chemical analysis of a large number of cereals, legumes, etc., used as food in India. The supplement contains similar data for grains examined since the first edition was published, including among other materials Polish millet (*Paspalum sanguinale*); black Burmese rice (*Oryza sativa*); bamboo seed (*Bambusa tulda*); buckwheat of the higher Himalaya (*Fagopyrum tataricum* var. *himalaica*); and gorgon fruit (*Euryale ferox*).

Grain foods in Manchuria, H. B. MILLER (*U. S. Consular Rpts., 68 (1901), No. 255, pp. 541–543*).—Brief notes are given on the use of tall millet, wheat, imported flour, beans, maize, and vermicelli by the Chinese in Manchuria.

Further notice on milling qualities of different varieties of wheat, E. H. GURNEY and G. NORRIS (*Agr. Gaz. New South Wales, 12 (1901), No. 2, pp. 1402–1425*).—Continuing previous work (E. S. R., 11, p. 242), the authors give in tabular form details of the milling properties of 98 samples of wheat.

Recent experiments with sweet potatoes (*West Indian Bul., 2 (1900), No. 4, pp. 293–302*).—Tests on drying and grinding sweet potatoes are reported, as well as an analysis of the resulting sweet-potato flour.

Peas, beans, vetches, and their milling products, A. KOEHLER (*Landw. Vers. Stat., 55 (1901), No. 6, pp. 401–434, pls. 2*).—An extended summary of investigations on this subject.

New or little known oil-bearing seeds of the French colonies, E. HECKEL (*Les graines grasses nouvelles ou peu connues des colonies françaises. Paris: A. Challamel, 1902, pp. IV+187, figs. 32*).—Oil-bearing seeds are described and discussed, and in many cases analytical data are reported.

Olive oil: Its source, production, character, and uses, F. BOEHM (*London: F. Boehm, 1901*).—The subject is treated as follows: (1) Botanical origin, habitat, and character of the plant; (2) method of preparing the oil; (3) geographical distribution of the trees; (4) production and export of various countries; (5) chemical and physical characters of the oils; (6) pests which attack the orchards; and (7) uses.

Concerning the composition of sweet raisin wine, A. SCHNEEGANS (*Arch. Pharm., 239 (1901), No. 8, pp. 589–591*).—The composition of 3 sorts of raisin wine is reported. Two samples were made from Zante currants and the third from raisins from Asia Minor.

Food and drugs, C. J. HIGGINSON (*London: Effingham Wilson; rev. in Analyst, 27 (1902), Apr., p. 136*).—A second edition, revised and enlarged, of this volume which, according to the sub-title, is designed as a manual for solicitors, public analysts, inspectors, etc., and contains a consolidation of the various food acts of Great Britain.

Handbook of hygiene, T. WEYL (*Handbuch der Hygiene. Jena: Gustav Fischer, 1901, Sup. 1, pp. 74+36+85, figs. 6, dgms. 17*).—This volume contains 3 papers, viz, Notes on school hygiene and that of the profession of teaching, by L. Burgerstein; The hygiene of labor in an atmosphere of compressed air, by P. Silberstern; and The hygiene of the alcohol question, by A. Delbrück.

Handbook of public health, laboratory work, and food inspection, O. W. ANDREWS (*London: Baillière, Tindall & Cox; Portsmouth: Charpentier & Co., 1901, pp. 292, figs. 74*).—This volume is divided into 3 parts. The first considers the inspection of meat, fish, and poultry intended for human food; the second the inspection of water, air, and milk, and other food stuffs, as well as alcoholic beverages. In the third part meteorology and the influence of various atmospheric phenomena on health and disease are treated of.

Hygiene of the stomach, a practical dietetic guide, E. MONIN (*L'hygiène de l'estomac; guide pratique de l'alimentation. Paris: Octave Doin, pp. XV+432*).—The principal animal and vegetable foods are discussed, as well as condiments, beverages, diet, and related topics. A new edition.

Report on dieting of pauper lunatics in asylums and lunatic wards of poorhouses in Scotland, J. C. DUNLOP (*Glasgow: James Hedderwick & Sons, 1902, pp. 98*).—A number of dietary studies are reported and discussed, and suggestions for improvement are offered

ANIMAL PRODUCTION.

The excretion of phosphoric acid by carnivora and herbivora, W. BERGMANN (*Arch. Exper. Path. u. Pharmakol., 47 (1901), pp. 77–81; abs. in Chem. Centbl., 1902, I, No. 3, pp. 219, 220*).—The author calls attention to the fact that dogs ordinarily excrete phosphoric acid in the urine, but when calcium carbonate is fed they excrete the phosphorus in the feces. The author shows that if sodium phosphate is injected subcutaneously it is eliminated through the kidneys, even if calcium carbonate is supplied in the food. The diminished amount of the phosphoric acid in the urine when the diet contains an abundance of calcium carbonate is regarded as due to the fact that it is not absorbed, and not to the excretion of absorbed phosphoric acid through the intestine. In experiments with herbivora (sheep) the phosphoric acid subcutaneously injected was excreted in the feces. Glycerin phosphoric acid when subcutaneously injected was excreted by a dog in the urine and by a sheep in the feces as inorganic phosphoric acid.

Note on the cleavage of sugar from protein, J. WOHLGEMUTH (*Berlin. Klin. Wchnschr., 37 (1900), pp. 745–749; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 6, p. 250*).—A number of experiments are reported.

The effect of sugar on the organism, P. ALBERTONI (*Centbl. Physiol., 15 (1901), pp. 457–459; Chem. Centbl., 1902, I, No. 1, p. 59*).—Experiments with a dog showed that grape sugar increased the action of the heart. Data are recorded concerning the resorption of grape sugar in the intestines.

Effect of sodium nitrate on the metabolism of dogs, E. ROST (*Arb. K. Gesundheitsamte, 18 (1901), pp. 78–99; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), No. 3, pp. 121, 122*).—The effects of large, medium, and small doses of saltpeter were studied. Neither small nor large doses affected the general condition, appetite, or body weight. Small doses did not affect metabolism or the secretion of urine. Larger doses increased the secretion of urine and diminished the metabolism of nitrogen.

Velvet bean as forage and food, H. K. Miller (*Florida Sta. Bul. 60, pp. 457–462, 465, 466*).—In a digestion experiment with 2 steers the average coefficients of digestibility of green velvet-bean vines were as follows: Dry matter, 69.3; protein, 73.3; fat, 81.3; crude fiber, 59.6; and nitrogen-free extract, 82.4 per cent. The average coefficients of digestibility of velvet-bean hay of poor quality were as follows: Dry matter, 74.2; protein, 68.8; fat, 78.7; crude fiber, 78; nitrogen-free extract, 75.7; and ash, 20.4 per cent. The nutritive ratios of the digested portion in the 2 tests with green velvet-bean vines were 1:5.3 and 1:5.7. Similar values for the 2 tests with velvet-bean hay were 1:12 and 1:11.4. Using the same coefficients of digestion obtained with the poor hay, it is calculated that the nutritive ratio of good velvet-bean hay cut when the pods were well formed would have a nutritive ratio of 1:6. The details of the experiment are recorded in both cases.

Relative to the food value of the beans, it is stated that in many cases stock seem reluctant to eat the material at first, but do so greedily upon becoming accustomed to it. The following table shows the composition of the beans and of the beans and pods:

Composition of velvet beans.

	Bean and pod.	Shelled bean.
	Per cent.	*Per cent.*
Water	12.28	11.46
Protein	17.13	22.69
Fats	4.61	6.60
Crude fiber	14.25	7.56
Nitrogen-free extract	47.72	48.53
Ash	4.01	3.16

Furze, whin, or gorse (*Jour. Agr. and Ind. South Australia, 5 (1901), No. 4, pp. 320, 321*).—Notes on the feeding value and methods of feeding gorse.

Feeding stuff inspection, C. D. Woods and J. M. Bartlett (*Maine Sta. Bul. 80, pp. 41–64*).—In compliance with the provisions of the State Feeding Stuff law, analyses have been made of a number of samples of cotton-seed meal, gluten meal of different brands, gluten feed, germ-oil meal, linseed meal of different brands, flaxseed meal, calf meal, animal meal, beef scrap and similar poultry feeds, commercial breakfast food by-products, and mixed feeds, bran, middlings, and red dog flour. The results obtained are discussed, especial attention being given to condimental feeds and similar products.

Pressing forage, M. Ringelmann (*Ann. Inst. Nat. Agron., 24 (1897–1900), No. 16, pp. 203–216*).—Experiments are reported on the mechanical work required to compress alfalfa hay and straw of different sorts, as well as considerable data on related topics.

American breeds of beef cattle, with remarks on pedigrees, G. M. Rommel (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 34, p. 34, pls. 23*).—After a brief historical review of the subject of cattle raising in America, the author discusses the characteristics of the principal breeds and such related topics as pedigrees and herd-books. A list of the breeders' associations in the United States is included.

Steer feeding, G. E. Day (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 56–58*).—Two tests with steers are reported. In the first the comparative value of corn silage and roots are studied. For 147 days, 6 steers averaging some 1,110 lbs. each, gained 1,464 lbs. on a ration of silage, hay, and meal. Six similar animals during the same period gained 1,407 lbs. on a ration of roots (turnips and mangel-wurzels), hay, and meal. The dry matter eaten per pound of gain in the 2 cases was 12.62 and 13.95 lbs., respectively. Both silage and roots were fed in the proportion of 4 lbs. to 1 of hay. The same grain ration was fed to both lots. According to the author, "The cost of producing a ton of silage was considerably less than that of a ton of mangels; and since silage contains, according to our estimates, twice as much dry matter as roots, the cost of producing a ton of dry matter was very much lower in the case of the corn crop.

"Making every allowance for errors, for variations in conditions, and for the uncertainties of a single feeding experiment, we must still admit that silage compared with roots is a cheap and useful food for fattening steers. While roots may be more expensive than silage, we would be sorry to miss them from the bill of fare provided for our stock. They are very beneficial to the health of breeding stock, and are especially valuable for young animals."

In the second test peas and corn were compared. Four steers, averaging about 1,120 lbs. each in weight, gained 1,160 lbs. in 35 weeks on a grain ration of pea meal. Four similar steers in the same time gained 1,254 lbs. on a ration of corn meal and 4 steers on a ration of corn and peas (1:1) gained 1,219 lbs. In addition to the grain all the steers were given like amounts of hay, silage, and roots. The 3 lots consumed 4.139, 3.823, and 3.901 lbs. of grain, respectively, per pound of gain. According to the author "in this experiment, corn maintains its reputation as a fat producer. When the main object is the production of fat, probably no single kind of grain excels corn. Peas may generally be depended upon to do better in combination with other grains than when fed singly. The close, heavy nature of pea meal renders it difficult to digest, and consequently it should be mixed with something of a lighter nature, such as oats or bran. Mixing corn meal with pea meal apparently improved the fattening value of the latter, although corn meal, in a somewhat less degree, possesses the objectionable heavy nature of pea meal, and can not be regarded as an ideal substance to mix with it." This test was a continuation of previous work (E. S. R., 13, p. 379).

Steer feeding, H. E. Stockbridge (*Florida Sta. Rpt. 1901, pp. 35–43, pl. 1*).—Using 4 lots of 4 steers each, the comparative merits of sweet potatoes and cassava roots were tested, and the relative value of corn meal and shelled corn. On a ration of 10 lbs. of pea-vine hay, 4 lbs. of cotton-seed meal, and 35 lbs. of sweet potatoes and costing 21.4 cts. per head daily, lot 1 gained 496 lbs. in 70 days. On a ration containing 35 lbs. of cut cassava roots in addition to the same amount of pea-vine hay and cotton-seed meal, as above and costing 13.5 cts., lot 2 gained 576 lbs. On a ration of 20 lbs. crab-grass hay, 5 lbs. cotton-seed meal, and 5 lbs. of corn meal costing 19.5 cts., lot 3 gained 542 lbs., and lot 4 on a ration containing the same amounts of crab-grass hay and cotton-seed meal with 5 lbs. of shelled corn and costing 18.7 cts., gained 552 lbs. All the steers weighed about 450 lbs. each at the beginning of the test. As pointed out by the author, the greatest gain was made on the cassava ration, which was also much the cheapest. The importance of the cassava crop for stock feeding is insisted on, earlier work of the station being quoted (E. S. R., 12, p. 778).

Cattle food substitutes, a warning to feeders, L. A. Voorhees and J. P. Street (*New Jersey Stas. Bul. 156, pp. 7*).—Analyses are reported of several commercial feeds which, judged by their composition, are very costly in proportion to their true feeding value. They were found to contain comparatively little protein and fat and a high percentage of carbohydrates. The authors note that each dollar expended per ton for standard feeds at present prices should secure 1 per cent protein and 0.2 per cent fat. Wheat bran, it is calculated, would furnish many times as much protein and fully as much fat at much less cost than the carbohydrate feeds under discussion.

"The criticism will be naturally made here that the purchaser is not getting the carbohydrates in this small tonnage of high-grade feed that he should and would get in the lower-grade goods. But comparisons of feeds in general with the standard feeds are usually made on the supposition that the object of the purchase is protein and fat. That the purchase of protein is the usual purpose of purchased feeds can hardly be denied, since materials of considerable protein content are the only ones suitable as additions to the feeding materials of the farm. These usually comprise an abundance of carbohydrate feed to such an extent, indeed, that more native carbohydrates of better quality are often wasted on the farm by being used as bedding, etc., than are furnished by the feed substitutes under discussion. Materials, then, which are low in protein, and hence contain relatively large amounts of carbohydrates, are useful only to those who raise nothing themselves—for example, city feeders of horses and stall-fed cattle."

Value of condiments in the feeding of bullocks, J. A. Voelcker (*Jour. Roy. Agr. Soc. England, 62 (1901), pp. 299–307*).—In view of the high value attributed by many feeders to condimental feeds, locust-bean meal and molasses, the author tested such materials with 4 lots of 4 steers each, weighing on an average 1,095 lbs. at the beginning of the trial. Lot 1 was fed a basal ration consisting of linseed meal, decorticated cotton-seed cake, and maize meal, 1 : 1 : 1. The amount at first was 6 lbs. per head daily and later larger amounts. In addition, hay, oat-straw chaff, and wheat were fed *ad libitum*. Lot 2 was fed the same ration, except that one-half the maize meal was replaced by locust-bean meal. In addition to the basal ration, lot 3 was fed a condimental mixture made up of licorice, aniseed, gentian, fenugreek, coriander, caraway, cumin, and ginger. On an average, an ounce of this mixture was fed per head daily sprinkled over the other feeds. Lot 4 was given a little cane-sugar molasses diluted with an equal amount of warm water and mixed with the chaff. The feeds used were analyzed. The test began November 22. On March 25 the steers in lot 3 were thought ready for market and were disposed of for slaughter. Others were disposed of at intervals, the last on April 29. The average gain in weight of the 4 lots was 281, 229, 226, and 253 lbs. The percentage of carcass to live weight was 58.85, 58.52, 57.25, and 59.34, respectively.

"The result of this experiment is clearly to show that no case can be made out from it for any of the virtues supposed to belong to spice and condimental foods, but that bullocks will fatten just as well and as economically on a well-chosen mixture of ordinary foods. The average gain per head was higher with the ordinary feeding than with any of the others, and the money return practically as high, too. Nor did it turn out that the use of the condiments enabled the bullocks to consume more bulky food like straw and hay chaff. Of the additional materials the best was molasses, this giving results practically equal to those of the ordinary feeding. There is, however, with its use a tendency to "looseness" in the animals, which must be checked by not giving it in too great a quantity. One pound per day of molasses among 4 bullocks was found to be about the limit.

"Spice did not do so well as molasses, and though it is true that the animals fed with it were judged to be soonest ready for the butcher, their carcass percentage was the lowest of all, and the money return not so great in the end. The earlier bringing out was probably due to the individual animals rather than to their food. Judgment must be withheld in respect to the use of locust-bean meal, owing to 2 of the bullocks fed on it being indisposed during part of the experiment, but there is nothing in the general results as regards the others, and the ultimate return from them, to warrant the belief that it would have shown better results than the ordinary feeding.

1302—No. 11—02——6

"Lastly, it may be interesting to note (as the question of feeding bullocks in boxes as against open yards has often been raised in connection with the Woburn experiments) that the box-fed lot did quite as well as those in the yards."

Ocean transportation of cattle and horses (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 87–90, pls. 6*).—A brief descriptive article.

Early feeding of mangels to sheep; and gorse as food for sheep, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England, 62 (1901), pp. 308–316*).—Continuing earlier work on the value of mangel-wurzel and gorse for sheep (E. S. R., 11, p. 773), a test was begun with 4 lots of 12 sheep each, weighing on an average 111 lbs. Lots 1 and 4 were fed mangel-wurzels; lots 2 and 3 Swedish turnips; lots 1 and 2 gorse; and lots 3 and 4 meadow hay, while all the lots were given linseed cake. The feeds were analyzed. The test began November 9. Some of the sheep were fed February 15, others at intervals, the last on March 18. The average gain per head in the 4 lots was $35\frac{5}{6}$, $32\frac{4}{11}$, $33\frac{1}{4}$ and $39\frac{6}{11}$ lbs. The author notes that mangel-wurzels gave better results than Swedish turnips, and that gorse was inferior to hay. "One pound of gorse did not replace $\frac{1}{4}$ lb. of hay chaff with any advantage."

Experiments with swine, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 58–62*).—In the first of the 2 tests reported the value of roots as part of a ration was studied with 2 lots of high-grade Yorkshire pigs, averaging 42 lbs. each in weight, and 2 lots of 5 similar animals averaging 55 lbs. each in weight. Lots 1 and 2 were fed barley and middlings, and lots 3 and 4 corn and middlings, lots 2 and 4 receiving an amount of raw pulped mangel-wurzels in addition, equal in quantity to the grain ration. Early in the test the corn or barley and middlings were fed in the proportion of 2 : 1, latter in the proportion of 1 : 1, and at the close of the test in the proportion of 1 : 2. In 28 weeks the average daily gain per pig in the 4 lots was 0.639, 0.857, 0.677, and 0.757 lb., respectively. The corresponding dry matter eaten per pound of gain was 4.39, 3.80, 4.25, and 4.03 lbs. The pigs were slaughtered and the quality of the bacon judged by an expert. According to the author "the feeding of equal weights of roots and meal gave more rapid and more economical gains than the feeding of meal alone. The hogs fed roots produced bacon of superior quality to those which were not fed roots.

"In connection with the above it must be remembered that the quality of roots used was a very moderate one, and the excessive use of roots might have an opposite effect."

Continuing earlier work (E. S. R., 13, p. 380), a test was undertaken to compare feeding pigs on pasture and in pens, and to determine the effect of rape fed with meal upon the firmness of bacon. As in earlier work, 6 breeds commonly raised locally for the export bacon trade were included. The larger and stronger animals, numbering 16, were pastured; the smaller and less thrifty, numbering 18, were fed in pens. The test began July 6. The larger pigs were sold October 14, the remainder were fed until November 12. All the pigs were given dry barley and middlings 2 : 1, *ad libitum*. Those fed indoors received all the green feed they would eat in addition, at first tares and later rape, consuming on an average 4 lbs. per head daily. The pigs fed out of doors were pastured at first on rape and tares, later on rape, consuming on an average 4.33 lbs. of green feed per head daily. The 2 lots consumed, respectively, 3.95 and 5.23 lbs. of grain per pound of gain. The pigs were slaughtered and the bacon judged by an expert, the breeds ranging as follows: Yorkshire, Berkshire, Duroc Jersey, Poland China, Tamworth, and Chester White. The principal conclusions follow :

"In this experiment, feeding hogs on pasture proved a very expensive method, whereas feeding in pens with the same kinds of food gave reasonably economical gains. The outside hogs ate more meal and made slower gains than those fed inside. . . . All the hogs produced bacon of satisfactory firmness. This result confirms the result of a previous experiment with rape, and goes to show that a reasonable supply of green feed with a liberal meal ration produces a good quality of bacon. Succulent food tends to keep animals thrifty, whether it be green food or roots, and thriftiness is conducive to firmness in the bacon produced. . . . [As the] proportion of green feed to meal is practically the same as the proportion of roots to meal which we have used with good results, it seems safe to assume that the use of equal weights of succulent food and meal tends to produce bacon of firm quality. The time required to attend to the outside hogs was just about half of that required for those inside."

Feeding experiments, H. E. Stockbridge (*Florida Sta. Rpt. 1901, pp. 16–22, pl. 1*).—Statements are made concerning steer-feeding tests not yet reported in full. The author also briefly reports a test of the comparative gains made by 5 razorback and 6 Duroc Jersey pigs, fed alike from birth until they were 14 months old. At this time the average live weight of the razorbacks was 214.4 lbs., and the Duroc Jersey 216.3 lbs.; the average dressed weight of the former 170.6, of the latter 164.2 lbs. "The native razorback animal produced on an average from the food consumed 6.4 lbs. more of marketable meat than his full-blooded rival, quite contrary to usual expectation." In discussing the comparative merits of native and blooded stock, the author calls attention to the fact that the blooded pigs possess advantages, especially in the matter of early maturity, which make them especially valuable for crossing with native stock. "It is an unquestioned fact, however, that the meat of the native is of incomparably superior quality, and that when properly handled and given suitable and adequate feed and attention the native crowds his blooded rival in the race, and can be made as profitable as he is hardy."

Tankage as a food for pigs, C. S. Plumb and H. E. Van Norman (*Indiana Sta. Bul. 90, pp. 205–216*).—Using 4 lots of 4 pigs each, weighing 58 lbs. on an average, the authors studied the value of tankage as a part of a ration. The tankage used was of the sort known as "crushed," and is generally sold as a fertilizer. Like all such material, it contained a high percentage of nitrogen and phosphoric acid. Lots 1 and 4 were fed grain and tankage 10 : 1, the grain ration of the former consisting of corn meal and of the latter of corn meal and shorts 1 : 1. Lot 2 was fed corn meal and tankage 5 : 1, and lot 3 corn meal only. The feed was mixed with water to a thin slop. In the 127 days covered by the test the average daily gain of the 4 lots was 1.16, 1.23, 0.67, and 1.14 lbs. per head. The largest amount of grain, 15.75 lbs. per day, was consumed by lot 4; the smallest, 14 lbs. by lot 3; lots 1, 2, and 4 consuming, respectively, 1.54, 2.98, and 1.57 lbs. of tankage daily. The cost of feed per pound of gain in the 4 lots was 3.8, 4, 5.2, and 3.6 cts., respectively. At the close of the test 2 pigs in each lot were slaughtered and the organs, etc., examined. The conclusion was drawn that as regards the carcass no differences were observed which could be attributed to the rations fed. According to the authors the condition of the pigs during the test was of much interest. The lots fed tankage had noticeably silkier hair, and the appearance of the skin was fresher and mellower than that of the corn-fed lot. In marked contrast to the others the corn-fed pigs did not eat with relish after the experiment was well started. That this was due to the corn ration was shown by a supplementary feeding test in which the 2 pigs remaining in lot 3 (the corn-fed lot) were put upon a ration of corn meal and tankage 5 : 1, and fed for a period of 49 days. After the tankage was added to the rations, the authors state that the condition of the pigs was markedly improved and the 2 pigs gained on an average 1.79 and 1.3 lbs. per head daily.

Separator skimmed milk as food for pigs, L. A. Clinton (*New York Cornell Sta. Bul. 199, pp. 137–156*).—From 1898 to 1901 the comparative merits of different proportions of grain and skim milk for producing pork economically were studied. The first test was preceded by a preliminary period of 6 days' duration, during which raw and cooked potatoes were compared when fed with a corn-meal and skim-milk ration. Each of the 4 lots used contained 4 pigs each. In 2 lots the animals weighed on an average some 77 lbs. and in the remaining lots some 40 lbs. On cooked potatoes the heavier lot gained 1.4 lbs., the lighter lot 10.9 lbs. On raw potatoes corresponding gains were 3.1 and 11.7 lbs. Considering the period as a whole, the total gain on a ration containing potatoes was 27.1 lbs., the feed required per pound of gain being 16.2 lbs. potatoes, 17.9 lbs. skim milk, and 1 lb. corn meal.

"In view of the fact that potatoes, cooked or uncooked, are often used as a food for pigs, it may seem strange that such unfavorable results were secured in the present case. When, however, we study the weather conditions which prevailed while the experiment was in progress, and consider that the pen in which the pigs were kept was somewhat damp and cold, the cause of the trouble is not difficult to locate."

After feeding all the pigs on corn meal and skim milk until they were in good condition, they were again divided into 4 lots of 4 each. For 46 days lots 1 and 3 were fed gluten meal and skim milk and lots 2 and 4 corn meal and skim milk, the proportion of skim milk to grain in each case being about 3 : 1. At the beginning of the test the 4 lots weighed, respectively, 349, 362, 190, and 194 lbs. The total gains made were 214, 297.5, 157.5, and 219 lbs., the cost of a pound of gain being 2.7, 2.5, 2.4, and 1.9 cts.

In the second test 9 lots of 4 pigs each were used. Lots 1 and 4 were fed skim milk and corn meal, 6 : 1; lots 2 and 5, skim milk and mixed grains, 6 : 1, the grain mixture consisting of 4 parts of corn meal to 1 part of wheat middlings; lots 3 and 6, skim milk and corn meal, 3 : 1, and lots 7, 8, and 9 the same rations, respectively, as lots 1, 2, and 3, with bone meal in addition in the proportion of 1 oz. per 100 lbs. live weight. At the beginning of the trial, which covered 45 days, the lots ranged from 197 lbs. in the case of lot 5 to 303 lbs. in case of lot 9. The total gain ranged from 207 lbs. with lot 9 to 275 lbs. with lot 8. The average cost of a pound of gain in all the lots was 2.9 cts. According to the author, gains were made most economically when the ration of grain to milk was about 1 : 3.

In the third test, which was made with 8 lots of 4 pigs each and covered 65 days, the most economic gains, costing 2.7 cts. per pound, were made with lot 3, when corn meal and skim milk were fed in a proportion of 1 : 6.7. The most expensive gains, costing 3.9 cts. per pound, were made with lot 6, fed corn meal and skim milk, 1 : 2.3. The average gain ranged from 107 lbs. with lot 7 (fed grain to skim milk 1 : 6.8) to 133 lbs. with lot 3. The total weight of the 8 largest pigs at the beginning of the trial was 663 lbs.; the total gain was 632, or 95 per cent of their weight at the beginning. At the beginning of the trial the 8 smallest pigs weighed 465 lbs., and gained 578 lbs., or 124 per cent of their weight at the beginning. In other words, the larger gains were made by the smaller pigs. "The most profitable returns from pigs are usually secured by turning them off when they reach a weight of from 150 to 175 lbs."

The fourth test, which covered 74 days, was made with 6 lots of 6 pigs each, the ratio of grain to skim milk in the ration ranging from 1 : 2.4 with lot 2 to 1 : 8.2 with lot 3. The grain ration consisted of corn meal or corn meal and wheat middlings, 4 : 1. For a part of the test a ration of corn meal, beet-sugar molasses, and skim milk, 2 : 3 : 5, was fed to lot 2. After 3 days 2 of the pigs died, apparently from poisoning, as was shown by a post-mortem examination. Two pigs were added to the lot in place of these, and after the bad effects of the molasses had been overcome the lot was included in the test proper. Considering the test as a whole, the cheapest gains, costing 3.2 cts. per pound, were made on corn meal and skim milk, 1 : 2.5, with bone meal in addition, the most expensive gains costing 4.4 cts. per pound on corn meal and skim milk, 1 : 6.6.

The fifth test was made with 5 lots of 6 pigs each and covered 75 days. Lot 2 was fed corn meal and skim milk, 1:3, the other lots grain and skim milk, 1:6, the grain ration consisting of corn, except in the case of lots 4 and 5, when corn meal and wheat middlings, 4:1, were fed. Lots 3 and 5 received some bone meal in addition to the other materials. All the lots were fed large amounts from the start. The cheapest gain, costing 4 cts. per pound, was made by lot 3, the most expensive, costing 5.1 cts. per pound, by lot 5. In this and all the tests the live weight and dressed weight were compared.

"As a result of 5 years' work it is found that most economic returns are secured with skim milk when corn meal is the grain used. The proportion of corn meal to skim milk may be varied without apparently affecting results. In no case should the amount of skim milk fed be greater than the pigs can quickly and easily consume."

The value of corn, skim milk, and whey for fattening swine, A. M. Soule and J. R. Fain (*Tennessee Sta. Bul., Vol. XV, No. 1, pp. 16, figs. 6*).—During a period of 60 days the possibility of feeding pigs under local conditions was tested with 3 lots of 3 and 1 lot of 2 grade animals. Lot 1 was fed corn meal mixed with water, lot 2 the same grain mixed with skim milk. Lot 3 was fed skim milk and corn meal at first, and later whey, corn meal, and wheat meal. Lot 4 was fed skim milk, cowpea hay, and corn meal. The attempt was made to feed lot 3 some sorghum silage in addition to the ration noted, but as only 5 lbs. was eaten in 15 days, it was discontinued. At the beginning of the test all the pigs weighed some 145 lbs. each. In 60 days the average daily gain per pig in the 4 lots was, respectively, 1, 2.3, 2.2, and 2 lbs. The corresponding cost of a pound of gain was 3.9, 4.2, 3.4, and 5.2 cts. Lot 1 required 4.6 lbs. of grain per pound of gain. Lot 2 required 2.2 lbs. of grain and 11.2 lbs. of skim milk. Similar values for lot 3 were 1.7 lbs. corn meal, 0.4 lb. wheat meal, 2.5 lbs. skim milk, and 8.5 lbs. whey. Lot 4 required 2.9 lbs. of corn meal, 1 lb. chopped cowpea hay, and 12.5 lbs. of skim milk.

As shown by slaughter tests the food had a marked effect on the carcass, the dressed weight in the 4 lots being 73.6, 78.5, 76.2, 77.4 per cent, respectively, of the live weight. Rating pork at 5.5 cts. per pound, the authors calculate that corn meal was worth 66.7 cts. per bushel and skim milk 28.3 cts. per hundred pounds. According to the authors the experiments indicate that pig feeding can be made profitable on Tennessee farms, that ordinarily enough feed is wasted on the farm to fatten a number of pigs, "that intelligent methods of feeding bring a fair profit, and that the farmer should ordinarily finish his own animals, as they will then bring the highest market prices."

Market classes of horses, G. M. Rommel (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 37, pp. 32, pls. 12*).—The condition of the horse market in recent years and at the present time is spoken of. The author also discusses the general essentials of market horses, paying special attention to the different classes. Of these the more important are draft animals and harness and saddle horses. It is stated that the bulletin consists chiefly of information gathered from breeding establishments, horse markets, and hunt clubs.

Report of manager of poultry department, W. R. Graham (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 112–124, figs. 20*).—Brief statements are made concerning the poultry kept during the year at the Agricultural College, the eggs produced, and the chickens hatched. Feeding tests are also reported. On an average the eggs produced by 2 lots of 12 Barred Plymouth Rock hens during May, June, and July cost 6.32 cts. per dozen; those produced by the same number of Andalusians, 5.38 cts. per dozen. In each case a cock was kept with the hens, and both lots were given the same care and were fed similar rations.

Different grain rations were tested with chickens fed in coops for periods of 2 weeks. The following table summarizes the results obtained. In the case of ration

No. 2 the figures quoted represent the average of 2 trials, in all other cases of 3 trials, with lots containing 12 chickens each:

Comparative merits of grain rations for chickens.

Rations.	Average weight of lot at beginning.	Total gain in two weeks.	Grain eaten per pound of gain.[a]	Cost of a pound of gain.
	Pounds.	*Pounds.*	*Pounds.*	*Cents.*
Ration No. 1: Corn meal, shorts, pearl oat dust, animal meal, 5 : 4 : 1 : 1	47	11.5	3.3	3.91
Ration No. 2: Corn meal, ground buckwheat, pearl oat dust, 2 : 2 : 1	48.3	15.8	2.6	3.46
Ration No. 3: Corn meal, ground buckwheat, pearl oat dust, 2 : 1 : 1	47.5	11.7	3.4	4.61
Ration No. 4: Corn meal, pearl oat dust, 2 : 1	48	9.3	4.3	5.75
Ration No. 5: Pearl oat dust	48.2	12.8	3.0	4.84

[a] In every case an amount of milk practically equal to the grain was also eaten.

According to the author, ration No. 1 was economical, but it was objectionable since it had a tendency to produce yellow flesh, which is regarded as undesirable in the best local markets. Ration No. 2 was regarded as the most palatable and produced fine, white flesh at a moderate cost. Ration No. 3 was similar to No. 2, except that it contained more corn meal and hence was less suitable for warm weather. The author notes that it produced a somewhat cream-colored flesh. Ration No. 4 was regarded as the least satisfactory of all. On account of the excess of corn it was not palatable and was undesirable for warm-weather feeding. When oats are moderate in price, ration No. 5 is regarded as satisfactory.

Tests were also made with chickens of different weights to learn the comparative merits of different methods of feeding. Each lot contained 12 chickens, the average weight of the chickens in the different lots ranging from 2.75 to 4.33 lbs. at the beginning of the trial. In 24 days the greatest gain, 22.75 lbs., was made by the lot fed in fattening crates for 2 weeks from a trough and for 10 days with a cramming machine. These chickens averaged 4.33 lbs. each at the beginning of the trial. The cost of a pound of gain was 5.68 cts. and the selling price 11 cts. per pound. The smallest gain, 9.75 cts., was made by the lot fed in a pen, each chicken having a floor space of about 5 sq. ft. The average weight of the chickens in this lot at the beginning of the trial was 2.75 lbs., the cost of a pound of gain 7.78 cts., and the selling price 9 cts. per pound. Considering the results as a whole, the author concludes that chickens weighing 3.5 lbs. are most desirable for fattening purposes; that the practice of fattening in crates is to be commended, and that by using a cramming machine a chicken can be finished and given a finer appearance when dressed than when fed in the ordinary way.

"It was also shown that the crated birds, and those fed by the machine in addition, were far more profitable than those fed loose. Some experiments have also been conducted where a supply of roots was added to the grain ration. The results thus far obtained seem to indicate that there is no advantage in feeding roots. Potatoes, however, give an extra amount of gain in flesh, and at a moderate cost may be regarded as an economical food."

Brief statements are made concerning the ducks raised during the year. When 10 weeks old Pekin ducks dressed 5.5 lbs., Rouens 4.5 lbs., and Indian Runners 4 lbs. According to the author the Pekin ducks gain more rapidly than the others. The Rouen ducks are as large when mature, but grow more slowly. The Indian Runner ducks are a small breed, but lay remarkably well. A test was briefly reported on forcing young ducks from the seventh to the tenth week by feeding them with a cramming machine. According to the author this showed that a "duck will eat as much of its own free will as we were able to give it by the machine. The results might be very different with older ducks."

Poultry west of the Rockies, F. B. Clewette (*Los Angeles: Author, 1902, pp. 123, figs. 6*).—A treatise on poultry raising with special reference to local conditions. The experience of a number of individuals is included.

Chinese incubators, G. D. Brill (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 247–253, pls. 3, figs. 3*).—A descriptive article on incubators and the management of chickens and ducks in China.

International live stock exposition of 1900 (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 63–68, pls. 9*).—A descriptive article.

DAIRY FARMING—DAIRYING.

Market milk: A plan for its improvement, R. A. Pearson (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 158–193, pls. 10*).—The importance of a pure milk supply is emphasized and a plan for the improvement of market milk somewhat similar to one already in operation in several cities is fully outlined.

"A responsible body of citizens who are interested in an improved milk supply, and having the confidence of the community, should be organized as a milk commission, to have full control of the work proposed. The commission should select and secure the advice and assistance of four experts—a veterinarian, a physician, a bacteriologist, and a chemist—all more or less familiar with the conditions and possibilities on dairy farms. The commission should send to each dairyman who supplies milk to the city a circular naming all the particular conditions which should be found on every farm where milk is produced for city use, and announcing that when any dairyman notifies the commission that he is fully conforming to the conditions specified, or endeavoring to do so, his dairy will be inspected; and, if it is found to comply in letter and spirit to all the requirements, his name will be placed upon an 'approved' list and he will receive an official indorsement in the form of a certificate . . . which he can use in any proper manner to assist in securing new trade." The proposed measure is entirely voluntary on the part of the dairyman.

The personnel and duties of the milk commission and other features of the plan are discussed and a set of requirements suitable for incorporation in an agreement between the dairyman and the commission is given. An account is also given of dairies under similar supervision in Philadelphia and New York City, circulars of information, forms of reports, etc., used in each case being given in appendixes.

The author discusses under methods of purifying milk the removal of dirt and bacteria by centrifugal separation and the use of filters, the prevention of bacterial growth by the use of antiseptics and cold, sterilization and pasteurization of milk, etc. "Upon the whole, the expediency of pasteurization as well as sterilization of milk, except in special and exceptional cases, may be considered doubtful."

On the increase in the fat content of milk during the same milking, M. Skov (*Mälkeritid., 14 (1901), No. 48, pp. 789–794*).—The evening milk from one cow in advanced lactation was separated into 13 portions and the morning milk into 17 portions, and the fat content of the different samples was determined. The former series of samples increased from 0.7 to 8.9 per cent, and the latter from 0.7 to 9.6 per cent. The author finds that the results of fat determinations in different portions of the same milking show 4 periods. In the first, consisting of 2 or 3 samples, the milk contains less than 1 per cent of fat. In the next 2 samples there is a sudden rise in the fat content. In the following 8 or 10 samples the fat content is quite uniform, being somewhat above normal. In the last sample taken there is a sharp rise in the fat content of 4 or 5 per cent. Experiments with several fresh cows showed similar results, except that the third interval was somewhat longer. Extremes of 0.8 per cent of fat in the first portion of a milking and 13 per cent in the last portion were repeatedly observed.

Portions of the four different parts of the milkings mentioned were collected separately until enough cream was secured to make churnings, and the butter fat obtained in each case was examined by the Reichert and Huebl methods, and for refractive index. The Reichert numbers found did not differ materially, and but small differences were observed in the iodin absorption numbers and the refractive indexes for the 4 samples, the former being 38.4, 39.7, 39.2, and 38.2 for samples 1 to 4, respectively, and the latter 52.6, 53, 53, and 52.5.—F. W. WOLL.

The dairy maid's book, N. OEDEGAARD (*Budeibogen. Christiania, Norway, 1902, 2. ed., pp. 60*).—A prize essay on the feeding and handling of dairy stock, written especially for dairy maids (*Budeier*).—F. W. WOLL.

Successful dairying, J. KLEIN (*Erfolgreiche Milchwirtschaft. Berlin: Paul Parey, 1902, pp. 358, figs. 95*).

The liberation of volatile sulphid from milk on heating, L. F. RETTGER (*Amer. Jour. Physiol., 6 (1902), No. 6, pp. 450–457*).—The author finds, in confirmation of the observations of Niemann and Oppenheimer, that sulphid is given off on heating normal milk above 85° C. This is believed to be in all probability hydrogen sulphid, and to be due to the partial decomposition of the milk proteids. The amount of sulphur liberated was very small, but was sufficient to be easily recognized by the blackening of lead acetate paper and lead acetate cotton as well as of the decoloration of dilute potassium permanganate solution. As might be expected from the low content of proteids, pure milk yielded much less of the volatile sulphid than whole milk, while skim milk when perfectly fresh gave off more sulphid. Alkalis and alkaline-reacting phosphates were found to facilitate this decomposition of the proteids, while acids and acid-reacting phosphates retarded it. Hence the amount of sulphid liberated depends largely on the reaction of the milk.

"What part this liberation of sulphid may take in rendering milk injurious is a question of practical significance. The reaction is in itself conclusive evidence that the milk suffers a change in composition. The important question arises: 'Does sterilization and pasteurization render it injurious for prolonged use?' There is some evidence that scurvy in infants results from the use of milk sterilized by boiling. May this result be connected with alterations in the proteids, permitting the liberation of volatile sulphid?"

On the thermal death point of tubercle bacilli, B. BANG (*Mälkeritid., 14 (1901), No. 42, pp. 677–679*).—Experiments were made with tuberculous milk heated in a closed metal vessel, through the cover of which a thermometer was inserted. The apparatus was kept in a deep water bath of constant temperature and shaken steadily so as to insure a uniform heating of all particles of milk. Tuberculous milk heated to 60° C. for 1 minute or less caused pronounced tuberculosis by inoculation into the abdominal cavity of rabbits. Milk kept at 60° for 5 minutes also caused tuberculosis, but to a less extent. Heating for 15 minutes reduced the effect still more, only half the number of animals becoming tuberculous. Milk heated to 65° for a moment caused a rather slight, but still recognizable tuberculosis. On heating at 65° for 5 minutes the bacilli were killed. The same result followed heating for a moment to 70, 75, 80, and 85°. Feeding experiments with milk heated to 60° for 2 minutes gave negative results.

In case of continuous pasteurization the author considers 80° the lowest safe temperature for destroying tubercle bacilli, and believes that the Danish pasteurization law may be modified without danger to allow pasteurization at this temperature in creameries, the Storch color test (E. S. R., 10, p. 384) being used to ascertain whether the skim milk has actually been exposed to this temperature.—F. W. WOLL.

Report of the professor of dairying, H. H. DEAN (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 44–55*).—Experiments in cheese and butter making are reported and a record is given of the dairy herd for the year ended November 30, 1901.

Experiments in the care of milk for cheese making led to the following conclusions: "Aeration of milk without cooling below 70° is not sufficient to prevent milk from becoming overripe during the night in hot weather. Cooling night's milk to a temperature below 70° is necessary in order to have the milk reach the cheese factory in a condition suitable for the manufacture of good cheese. Cooling to 50° and the addition of a culture to control flavor has not yet proved entirely satisfactory."

In each of 12 experiments during May and July from 600 to 1,500 lbs. of milk was divided into 2 lots, to one of which $3\frac{1}{3}$ oz. of rennet per 1,000 lbs. of milk was added at a temperature of 86° and the curd cooked to 98°, and to the other lot 5 oz. of rennet per 1,000 lbs. of milk was added at a temperature of 82° and the curd cooked to 94°. "The use of an extra amount of rennet and the adoption of lower temperatures than is customary for renneting and cooking gave an increased yield of cheese, but as cured in an ordinary curing room it developed too much acid, and the quality was inferior. In the one trial where cheese was cured in cold storage, the quality of the cheese was equally good, and there was a gain in the amount of cheese produced equal to about $1\frac{1}{4}$ lbs. per 1,000 lbs. milk."

Washing curds in experiments during 1901 caused a loss on an average of about 1 lb. of cured cheese per 100 lbs. of curd. There was little difference in the quality of the cheese from washed and unwashed curds.

In each of 16 experiments during May and June 2 cheeses were made from the same lot of milk, one of which was cured in a well-lighted room at an average temperature of 64.6° and an average percentage of moisture of 79.3, and the other in a dark room at an average temperature of 66° and a percentage of moisture of 76.4. There was little difference as regards loss of weight in curing, quality of cheese, and amount of mold between the cheese cured in the light and in the dark rooms.

In a series of experiments cheeses were placed in cold storage at 40° fresh from the press and after being kept 1, 2, and 3 weeks in an ordinary curing room. One cheese in each experiment was also cured in the ordinary way at 65°. The details of the experiments are to be published later in bulletin form when the work is completed. "We may anticipate these results by saying that, so far as the work has gone, it indicates that cheese may be cured at a temperature of 40°, in about 3 to 4 months' time, and that the quality of cheese cured in cold storage is superior to that cured at ordinary temperatures. The results also indicate that the sooner the cheeses are placed in cold storage after being made, especially in hot weather, the better the quality of the cheese, and the less loss by shrinkage."

In experiments in butter making 5, 10, 15, 20, and 25 per cent of pure culture was added to the cream. The comparison showed that with 5 per cent of culture the cream ripened in about 15 hours and with 25 per cent in about 5 hours. The highest average score for flavor was obtained by ripening at a low temperature with the smallest amount of culture. Several different pure cultures were compared in another series of experiments. A culture prepared at the station with a mixture of whole milk, skim milk, and buttermilk gave no better results than one prepared with skim milk alone.

Experiments to determine the effect of different methods of making butter upon the content of moisture and salt are briefly reported and summarized as follows: "There was very little difference in the average moisture and salt content of butters churned at temperatures between 44 and 58°. Butter churned into lumps had the lowest moisture content, and that in fine grains the lowest salt content. The lots churned into the size of corn grains had both the highest moisture and highest salt content of any in the series. The moisture and salt content was about the same when washed with water at temperatures between 40 and 60°. The same is true of samples washed once and twice, other conditions being equal. Butters unsalted contained the least moisture and those salted at the rate of three-quarters of an ounce per pound of butter contained the most moisture. The salt content of the finished butter does not appear to have any constant relation to the amount of salt added to the butter. On the average, more than half the salt applied to the butter passed off in the working. In some determinations of the moisture pressed out by working, it was found to contain from 23 to 24.5 per cent salt. . . . The butters made from unpasteurized milk had a higher percentage of moisture than those made by pasteurizing at from 140 to 160°, less than the lots pasteurized at 186°, and about the same as those made by heating the milk to 195° before separating."

Notes are given on tests of the "Virginia Cattle Food" and the Columbia air churn, on the milk supply of the college dairy, and on feeding experiments with calves.

The average yearly production of the 19 cows in the dairy herd was 8,114 lbs. of milk and 283.44 lbs. of fat. The largest yield was 11,379 lbs. of milk and 380.06 lbs. of fat produced by a pure-bred Holstein.

On the advantages of a low ripening temperature for cream in butter making, L. F. Rosengren (*Landtmannen, 12 (1901), No. 1, pp. 7–11*).—The writer finds that cream may be ripened to advantage below 12° C. in 20 to 22 hours by the addition of 8 per cent of a pure-culture starter. The best arrangement as to temperature of the cream during ripening is to start the ripening process at such a temperature that the cream at the end of the ripening period will have the right temperature for churning. A low ripening temperature was not found less favorable than a high temperature as regards the quality of the butter, while the clean and fresh odor in both ripening vat and churns obtained at the low temperature was very noticeable.

It was observed in a number of trials that cream pasteurized at 85° C., and then cooled to 10° C., afterwards increased 1 to 2° in temperature, irrespective of the room temperature. It is suggested that this increase may be due to a gradual change taking place in the physical condition of the butter fat, which is accompanied by liberation of heat.—F. W. WOLL.

Experiments in butter making and cheese making, F. B. Linfield (*Utah Sta. Bul. 73, pp. 54, pls. 3*).—This is the first bulletin of the station dealing particularly with butter and cheese making and covers work extending over a number of years.

Butter making (pp. 5–19).—Average data are given for some 80 tests of 6 makes of power seperators and 22 tests of 2 hand separators from which the conclusion is drawn that "all styles of separators will do close skimming if they are properly run." The tests of the power separators were made in various creameries throughout the State. Suggestions are given for getting the best results from a separator.

The fat content of skim milk, buttermilk, and whey was determined by the Babcock test, using different kinds of bottles and by chemical analysis. The comparison showed an average of 0.2 per cent more fat by chemical analysis than by the Babcock test with the double-necked bottle.

The results of 30 churning tests at creameries and 50 at the station are arranged according to the fat content of the cream and averaged. "These tests would appear to show that under average conditions, cream testing 30 per cent fat will churn more exhaustively than cream with a low per cent of fat." The results of experiments are noted as showing that the temperature of churning may vary considerably with satisfactory results. In 67 tests with cream showing an acidity of 0.4 to 0.64 per cent, the acidity seemed to have little or no effect upon the exhaustiveness of churning. A preliminary test of the quality of butter made from cows fed on alfalfa as compared with that from cows fed on corn fodder is reported. The butter from cows fed on alfalfa had a higher color and a firmer body than the butter from cows fed on corn fodder. It had a pronounced and peculiar flavor which, however, was not considered objectionable to those accustomed to it.

Method of making Cheddar cheese (pp. 21–40).—The making of Cheddar cheese is discussed at some length, the principal object being to call attention to points frequently overlooked by cheese makers.

Experiments in cheese making (pp. 41–51).—Data are given for 165 trials showing the yield of cheese from milk containing from 3.4 to 4.8 per cent of fat. One hundred pounds of milk testing 3.4 per cent of fat made 10.15 lbs. of green cheese, or 2.94 lbs. for each pound of fat in the milk, and 100 lbs. of milk testing 4.8 per cent of fat made 12.09 lbs. of green cheese, or 2.52 lbs. for each pound of fat in the milk. On an average 100 lbs. of milk made 11.31 lbs. of green cheese, or 2.77 lbs. for each pound of fat in the milk. The loss in weight in cheese cured at the station for 1 month was 6.94 per cent and for 6 months 9.30 per cent.

Cheese made by the "dip-curd" process, in which the curd is stirred for 10 or 15 minutes after dipping, salted and pressed immediately, cured quickly but was soft and lacked uniformity. It lost 13.5 per cent in weight in 1 month.

The fat lost in whey averaged 0.15 per cent, practically no difference being observed in this respect in milk testing 3.4 to 4.7 per cent of fat. A temperature of 86° F. for renneting was found most satisfactory. In experiments during 1900 cheese was cured in (1) cold storage at 45 to 50° F., (2) in a curing room at 60 to 65° for 1 month and then in cold storage, and (3) in the curing room for the whole time, data for the physical examination for the cheeses being given. The loss in weight was practically the same in each case. The results of curing at a low temperature were not entirely conclusive.

A study of enzyms in cheese, L. L. Van Slyke, H. A. Harding, and E. B. Hart (*New York State Sta. Bul. 203, pp. 215–244*).—Enzyms in cheese are shown to come from bacteria, milk glands of cows, and rennet. In the investigation here reported bacterial action was for the most part excluded by the use of antiseptics. Of the 2 phenomena of cheese ripening, namely, the chemical decomposition of casein and the formation of flavors, the study was concerned chiefly with the former. The literature of this phase of the subject is briefly reviewed, and the methods of chemical analysis used are outlined.

Chloroform was added to skim milk containing only a trace of fat in amounts varying from 2.5 to 30 per cent by volume and the percentage of nitrogen in soluble form in the different samples was determined at frequent intervals for 192 days. The bacterial content was small in all cases. In general, there was a marked progressive increase during this period in the amounts of soluble nitrogen, which varied but little in samples treated with different percentages of chloroform, indicating that the restraining action of chloroform upon enzyms is slight. Two series of samples were prepared from whole milk and melted butter fat to contain, respectively, 10 and 20 per cent of fat. Chloroform was added to each series in amounts ranging from 2.5 to 20 per cent. Determinations of the soluble nitrogen and the bacterial content of the samples for 112 days showed practically no influence upon the antiseptic value of the chloroform due to the different amounts of fat. The germ content was higher than in the preceding series of experiments, but several reasons for this are offered.

In one series of experiments with whole milk a comparison was made of the effect of 15 per cent of ether, 3 per cent of chloroform, and a mixture of 2.9 per cent of ether and 2.1 per cent of chloroform upon the activity of enzyms. The increase in soluble nitrogen was more rapid where the ether was used, but the bacterial development, consisting almost entirely of one kind, was also greater. "This experience has made us slow to accept as trustworthy any results obtained with the use of ether, when the conditions are not constantly controlled by quantitative examination of the bacterial content." In another series of experiments a similar comparison was made of 4 per cent of chloroform and 0.1 per cent of formalin. The total soluble nitrogen at the end of 152 days averaged 45.62 per cent in the formalin series and 60.63 per cent in the chloroform series, showing a greater restraining influence of the formalin upon enzym action. The bacterial content in all cases was low.

In connection with the last series of experiments the relation between bacteria in the udder and enzyms in the milk was investigated. It was found in additional experiments that the number of bacteria in the strippings from different quarters varied greatly, the back right quarter showing usually above 500 per cubic centimeter and the front left quarter less than 100. Determinations at intervals for 105 days showed a corresponding variation in the production of soluble nitrogenous products in the milk from the different quarters. "It may be held that the presence of these bacteria has merely stimulated the production of an extra amount of galactase, but many of these bacteria are able to bring about the liquefaction of gelatin, a fact which suggests that they have played a part in enzym formation within the udder. However, it is impossible to assign even an approximate value to the work performed by bacteria within the udder in the production of their enzyms until we understand the conditions which relate to the normal formation of galactase."

Cheese was made from 125 lbs. of milk to which 3.5 lbs. of chloroform had been added, and was ripened under a bell jar in an atmosphere of chloroform. The cheese was found to contain 15 per cent of chloroform. The composition of the cheese was compared at different intervals with that of a normal cheese cured under ordinary conditions, and with a cheese coated with paraffin to lessen the loss of moisture and make it in that respect similar to the chloroform cheese. The amounts of nitrogen rendered soluble in the 3 cheeses during 15 months after they were taken from the press were, respectively, 27.70, 38.66, and 44.14 per cent of the total nitrogen. The ripening process in the chloroform cheese was proportionately much slower during the early portion of the period. In a similar experiment 0.2 per cent of lactic acid added to the milk increased the ripening process to a marked degree. At the end of 12 months cheese made with chloroform showed 22.60 per cent and cheese made with chloroform and lactic acid 31.65 per cent more soluble nitrogen than when fresh. In each of the above experiments the chloroform cheese was unsalted. In salted cheese made with chloroform and compared with the above the soluble nitrogen formed in 12 months was reduced from 22.60 to 17.20 per cent, and in the chloroform cheese made with lactic acid from 31.65 to 19.65 per cent, showing a restraining influence of salt upon the activity of enzyms.

Data are given showing the character of the chemical changes taking place in normal and in chloroform cheese. The following comparison is given:

"(1) In the normal cheese at the age of 1 month the amount of amids was 1.8 lbs. for each pound of albumoses and peptones. This ratio increased until at 9 months it was 8.7, nearly 5 times as great as at the end of 1 month.

"(2) In the chloroform cheese the amount of amids was not quite one-fourth of the amount of albumoses and peptones at the age of 1 month. The relative amount slowly increased, until at the end of 9 months the amount of amids was nearly equal to that of albumoses and peptones.

"(3) In the chloroform cheese no ammonia had appeared at the end of 9 months; in the normal cheese nearly 1 per cent of the total nitrogen was present as ammonia at the end of 1 month, and this amount steadily increased."

The authors conclude that there is some agent at work in normal cheese which is not active in cheese made with chloroform, and state that their efforts are being directed to the identification of this agent.

Conditions affecting weight lost by cheese in curing, L. L. VAN SLYKE (*New York State Sta. Bul. 207, pp. 275–305, figs. 6*).—A systematic study of this subject has been made at the station for the past 3 years. The curing rooms and the means of controlling temperature and moisture in use at the station are described, as is also the determination of atmospheric moisture by the hygrometer.

The chief conditions affecting the loss of weight in cheese during curing, which for practical purposes may be considered as due entirely to the loss of moisture by evaporation, as stated by the author, are (1) the percentage of moisture originally present in the cheese, (2) the texture of the cheese, (3) the temperature of the curing room, (4) the size and shape of the cheese, and (5) the proportion of water vapor present in the air of the curing room.

Considerable experimental data concerning these conditions are reported. It was found that cheese containing the most water loses the most in weight. In one experiment cheese containing originally 55 per cent of water lost 16.8 per cent in 4 weeks, while cheese containing 35 per cent of water lost only 5.7 per cent. The more open the texture of the cheese, the greater the loss of water by evaporation. An increase in the loss of weight follows an increase in the temperature of the curing room. In one test reported cheese cured at 55° F. lost 8.1 per cent in weight in 6 months, while cheese cured at 70° under conditions similar in other respects lost 11.1 per cent. In another test cheese cured at 32° lost 3 per cent in weight in 5 weeks, while cheese cured at 55° lost 4.6 per cent. Two cheeses 3 and 7 in. in height and uniform in diameter lost, respectively, 17 and 12.4 per cent of moisture in 6 months. Cheeses having diameters of 7 and 15 in. and approximately the same heights lost, respectively, 13.1 and 10.1 per cent of moisture in 6 months when cured at 65°. The results show an increase in the loss of weight corresponding to a decrease in either height or diameter of the cheese. Cheese cured in an atmosphere saturated with moisture gained nearly 2 per cent in weight during 15 months, while cheese cured in a room containing 75 to 80° of moisture lost over 11 per cent. Many other illustrations of the above points are given.

The results are discussed in regard to their practical application to dairymen and consumers of cheese. The author considers that cheese should contain not less than 33 per cent of moisture at the time of consumption.

In discussing the prevention of loss of moisture in curing cheese the advantages of central curing rooms are pointed out and the construction of special curing rooms in each cheese factory is considered, the description being based upon Wisconsin Station Bulletin 70 (E. S. R., 11, p. 186), from which illustrations are also taken.

Some problems in cheese curing, F. H. Hall, L. L. Van Slyke, H. A. Harding, and E. B. Hart (*New York State Sta. Buls. 203, 207, popular ed., pp. 16, fig. 1*).—A popular summary of bulletins 203 and 207 of the station noted above.

Assistance offered to creameries and cheese factories, F. C. Harrison (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 77–79*).—Brief notes are given on difficulties which have arisen in cheese factories in different parts of the Province. These have included gassy fermentations, bad flavors, and pigment in cheese, a fishy flavor in butter, etc.

Dairy products of the Paris Exposition of 1900, H. E. Alvord (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 194–222, pls. 6, maps 7*).—A full descriptive account is given of the dairy exhibit at the Paris Exposition, together with statistical data and other information concerning the dairy industry in the countries represented. A list of awards made to exhibitors of dairy products from the United States is appended.

VETERINARY SCIENCE AND PRACTICE.

The historical development of the theory of animal diseases, W. Dieckerhoff (*Die Theorie der Thierkrankheiten in ihrer geschichtlichen Entwickelung. Berlin: August Hirschwald, 1902, pp. 30*).—This pamphlet contains an address delivered in the Veterinary High School at Berlin on the occasion of the recent celebration of the birthday of the German Emperor. The history of various theories proposed for explaining animal diseases is discussed from the earliest times to the present. Especial attention is given to the theories entertained by Greek and Latin writers and by the continental writers from the time of the middle ages up to the middle of the past century.

Twelfth annual report on the veterinary service in Hungary, F. Hutyra (*Jahresber. Vet. Ungarn, 12 (1900), pp. 154*).—This report contains an account of the organization and number of veterinarians in government service, the extent of various diseases in the country, and rules and regulations adopted for preventing the spread of infectious diseases. Special attention is given to rinderpest, anthrax, rabies, glanders, foot-and-mouth disease, pneumonia, sheep pox, mange, swine erysipelas, swine plague, and hog cholera. A brief report is given on experiments in preventive inoculation against anthrax, swine erysipelas, and blackleg.

Annual report on investigations in the field of veterinary medicine, Ellenberger et al. (*Jahresber. Leist. Geb. Vet. Med., 20 (1900), pp. 267*).—A classified discussion of the literature on the subject of veterinary science during the year 1900. Bibliographical references are given and author and subject indexes are appended to the volume.

The Tenth International Congress of Hygiene and Demography, E. A. de Schweinitz (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 260, 261*).—Brief notes on this Congress which was held in Paris from August 10 to 16, 1900. The work of the Congress was conducted in 8 sections devoted to parasitology and the biology of micro-organisms as applied to hygiene. Notes were given on papers which were presented on toxins in preserving meats, on yellow fever, and other subjects.

Studies on the content of red blood corpuscles in the blood of domesticated animals, A. Storch (*Inaug. Diss., Univ. Bern, 1901, pp. 52*).—The author made an extended series of counts of the number of red blood corpuscles in a given quantity of blood, in the case of different animals. These studies were made by means of improved devices especially designed for this purpose. The average number found in a cubic millimeter of blood of different animals in different stages of life is given in tabular form. These statistics cover the different sexes as well as the different ages of domesticated animals. In general it was found that male animals have more red blood corpuscles than female animals. A general belief that new-born and young animals possess relatively more red blood corpuscles than mature animals was not corroborated, as a whole, for the blood of sheep, goats, and hogs during the first few days of life contain fewer red blood corpuscles than later. The calf possesses a relatively larger number of red blood corpuscles than the mature beef animal.

The occurrence of metachromatic granules in spore-bearing bacteria, and contributions to the knowledge of the Babes-Ernst corpuscles, E. Krompecher (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), Nos. 10, pp. 385–395; 11, pp. 425–428, pls. 7*).—In cultures of *Bacillus anthracis*, *B. concentricum*, and *B. anthracoides* on agar, potato, and gelatin, the author demonstrated the presence of granules which were stained bright red with carbol-methylene blue, and retained their color even when the staining solution was raised to a comparatively high temperature. First one granule appears in the central portion of the bacillus; after 2 days the color of the granule is gradually changed from a diffuse rose to an intensive red. Later other granules appear in the central portion of the bacillus, and these granules may considerably increase in number and persist after the cell body of the bacillus is gradually disintegrated. It is believed that these granules are in some manner related to the formation of spores, for the reason that the granules appear among spore-bearing cultures, and that they show a decided resistance to the action of heat. The Babes-Ernst corpuscles may exist in the body of the bacillus at the same time with the granules which are described by the author, but the first-named corpuscles are easily distinguished from the granules by the position of the former in the periphery of the body of the bacillus. Babes-Ernst corpuscles were found in spore-bearing bacilli, in *B. anthracis* and *B. alei*. According to the author's observations, the Babes-Ernst corpuscles are not distinctly related to the degree of virulence of the bacilli.

A classification of forms of hemorrhagic septicæmia, J. Lignières (*Ann. Inst. Pasteur, 15 (1901), No. 9, pp. 734–736*).—The organisms which produce hemorrhagic septicæmia are considered as having a number of characteristics in common. They are not stained by the Gram method, do not liquefy gelatin, and produce acute septicæmic lesions. The author classifies the diseases which should be included under this term into the following groups: (1) The type of fowl cholera which is also common to all birds and rabbits; (2) swine plague; (3) hemorrhagic septicæmia of sheep; (4) cattle plague; (5) typhoid fever or influenza of horses, including its various forms and complications, such as contagious pleuro-pneumonia and pneumonia-enteritis, and (6) dog distemper.

Animal parasitology, M. NEVEU-LEMAIRE (*Parasitologie animale. Paris: Société d'Éditions Scientifiques, 1902, pp. 212, figs. 88*).—The author gives a discussion of the life history and habits of the Amœbæ and other protozoa, as well as the various tapeworms, trematodes, round worms, mites, myriapods, and insects which are known to be constantly or occasionly parasitic in man. A large proportion of the species which are considered are also parasitic in various domesticated animals.

Eleven miscellaneous papers on animal parasites, C. W. STILES, A. HASSALL, W. A. FRANKLAND, and LOUISE TAYLER (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 35, pp. 61, pls. 5, figs. 38*).—This bulletin contains the following articles:

Treatment of round worms in sheep, goats, and cattle (pp. 7–14).—Previously noted from another source (E. S. R., 13, p. 593).

The disinfection of kennels, pens, and yards by fire (pp. 15–17).—It being known that the burning of grass on the prairies is sufficient to disinfect pastures of parasitic nematodes, it is recommended that pens and yards in zoological parks be periodically burned over at intervals of 10 to 30 days by means of a cyclone burner, such as was used by the gypsy-moth commissions of Massachusetts.

Brief notes are also given on *Eimeria stiedæ;* species of Eimeriella; on various parasites; trematodes parasitic in the human eye; a case of vinegar eel infection in the human bladder; a number of parasitic worms of oriental distribution, which may possibly infest American soldiers in the Philippines; and spurious parasitism due to partially digested bananas.

The protozoa as parasites and pathogenic organisms, considered from a biological standpoint, F. DOFLEIN (*Die Protozoen als Parasiten und Krankheitserreger nach biologischen Gesichtspunkten dargestellt. Jena: Gustav Fischer, 1901, pp. 274, figs. 220*).—In this volume the author discusses the classification of protozoa, parasitism, the influence of parasitism upon the parasites, and protozoa as parasites. The greater part of the volume is occupied with a detailed discussion of special groups and species of protozoa which are concerned in producing diseases of animals and plants. Among the more important diseases which are discussed as due to the presence of protozoa are tsetse-fly disease, dourine, surra disease, blood dysentery of cattle, malaria of birds and of man, Texas fever, horse sickness, the pox disease of carp, and silkworm disease. The volume includes a discussion of a large number of parasitic protozoa of less economic importance and gives details of the structure, life history, and parasitic habits of all species concerned. Full bibliographical references are given in connection with the different chapters.

The Strongylidæ in the fourth stomach of domesticated ruminants and the stomach-worm diseases, W. STÖDTER (*Die Strongyliden in dem Labmagen der gezähmten Wiederkäuer und die Magenwurmseuche. Hamburg: A. Leferre, 1901, pp. 108, pls. 14*).—This is an inaugural dissertation, and in it an attempt is made to give a systematic monograph of the genus Strongylus. The author recognizes 7 species of this genus, viz, *contortus, ostertagi, curticei, harkeri, retortæformis, oncophorus,* and *filicollis.* In addition to the species of Strongylus, the author discusses *Œsophagostomum venulosum* and *Monadontus phlebotomus.* In a discussion of the systematic position of these species 16 names are considered, part of which are reduced to synonyms of the 9 species which are believed to be well defined. Detailed notes are given on the anatomical characters, life history, and injurious effects of each species. The prophylactic and therapeutic treatment usually recommended for the various species is also discussed. Experiments were made on *S. contortus,* during which the conclusion was reached that this species is not viviparous. A bibliography of 126 titles is given.

Researches on the attachment of certain Uncinariæ to the walls of the intestines, A. Rizzo (*Atti. R. Accad. Lincei. Cl. Sci. Fis. Mat. e Nat., 9 (1900), II, No. 3, pp. 107–115, figs. 2*).—The author investigated the method of attachment and pathological effects caused by *Uncinaria radiata* and *U. cernua.* He found that the first species produces a papilla in the walls of the intestines, at the expense of the submucous connective tissue. The hooks and chitinous teeth with which the worm is provided serve to lacerate the tissue of the intestinal wall. At the point of attachment a constant inflammatory reaction is produced, but this effect is not very marked or of great extension. The lesions produced by *U. radiata* are much more serious than those caused by *U. cernua.*

Pathological conditions found in meat inspection, D. E. Salmon (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 52–62*).—This is an article which was read at the meeting of the American Medical Association held in Atlantic City, N. J., June 5 to 8, 1900. Detailed notes are presented on a number of cattle, sheep, and hogs inspected by the Bureau of Animal Industry, the diseases which were discovered during this inspection, and the number of cases condemned. During the 2 years from July 1, 1897, to June 30, 1899, 8,831,927 cattle were inspected. Of this number 19,454 entire carcasses were condemned and 23,106 additional carcasses were condemned in part. During the same period 11,110,776 sheep were inspected and 8,394 carcasses were wholly condemned; also 44,841,779 hogs were inspected, and 106,555 carcasses wholly condemned. Of the whole number of cattle carcasses which were condemned 26 per cent were affected with actinomycosis and 36 per cent with tuberculosis; and of those cases in which only parts of the carcass were condemned, 13 per cent were affected with actinomycosis and 1 per cent with tuberculosis. The beef cattle which are sent to large abattoirs are remarkably free from tuberculosis, only 1 case in 1,500 or 2,000 being found by inspection for the 2 years. Brief notes are given on a number of other diseases found during inspection. Special mention may be made of pseudotuberculosis of sheep, nodular tæniasis, and various animal parasites, such as the common tapeworms in their larvel and adult stages, the hydatid disease caused by echinococcus, and trichina.

A practical guide to meat inspection, S. Stockman (*New York: William R. Jenkins, 1902, pp. 295, pls. 14, figs. 79*).—This volume, published as the fourth edition of the text-book of T. Walley, has been rewritten and somewhat enlarged by the editor. The subjects which are discussed in the book include the historical development of meat inspection, the method of inspection, general pathological conditions, post-mortem changes in meat, inflammatory conditions, diseases of the blood, bacterial diseases, diseases caused by animal parasites, unclassed diseases, and food poisoning in man. A brief bibliography of the literature of meat inspection is appended to the volume.

Verminous diseases of cattle, sheep, and goats in Texas, C. W. Stiles (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 356–379*).—An unusual outbreak of disease due to parasitic worms occurred in certain parts of Texas and an investigation of the cause of the trouble was made by the author. The outbreak had already been studied to some extent by Dr. W. Folsetter, and his report on the circumstances of the outbreak, the post-mortem findings, and various treatments which were tried is included in the present article. It was found upon investigation that the cattle and sheep were attacked by a number of parasitic worms in the fourth stomach, intestines, and bronchial tubes, or in all of these organs at the same time. In cattle the fourth stomach was infested in about one-third of the cases with *Strongylus contortus;* in some cases hundreds of the parasites were found in a single stomach. *S. ostertagi* was found in all the cattle which were examined during the second investigation of the matter. This species is smaller than *S. contortus* and may be free in the stomach but is usually found encysted in the stomach wall. Experiments in treating cattle for this parasite were all failures. The fourth stomach of sheep was found be infested with *S. vicarius* as well as *S. contortus*. No post-mortem examination was made on goats, but it is believed that they were infested with the same parasites which were found in sheep. In the intestines of cattle 2 worms were found, *Uncinaria radiata* and *Œsophagostoma columbianum*. In the intestines of sheep the last-named species of worm was found, as well as *U. cernua* and a tapeworm (*Thysanosoma actinioides*). In the bronchial tubes of cattle *S. micrurus* was found in considerable numbers, while in sheep *S. filaria* was found.

The author gives a general discussion of the various lines of treatment which have been proposed by different authors for lungworms. From the experience of Drs. Folsetter and Knight as well as from that of the author, it is believed that the value of tracheal injections in the treatment of lungworms has been much overestimated. The use of gasoline expelled many intestinal worms but apparently had no effect on lungworms. Turpentine and oil of cloves also gave negative results. In one instance a steer was kept under the influence of chloroform for $\frac{3}{4}$ hour without producing any effect upon the lungworms. In the treatment of intestinal worms various remedies have been recommended, including bluestone, gasoline, coal-tar creosote, thymol, and other substances. In experiments with coal-tar creosote it was found that if the liquid entered the lungs the animal died promptly. When administered carefully, as much as $6\frac{2}{3}$ oz. may be given to an adult sheep without fatal results. In the author's experiments sheep treated with this substance showed marked improvement within a few days after receiving a single dose. Tests were made with thymol to determine the proper size of dose to be administered and the effectiveness of the chemical. It was found that as much as 80 to 100 grains may be administered to a sheep and 240 grains to full-grown cattle without causing ill effects. In the author's experiments thymol was administered in solution in alcohol in doses of from 32 to 48 grains. Thymol appeared to be unusually effective in destroying intestinal worms, but was without effect on tapeworms. The experiments of Theobold indicate that thymol is also of great value in expelling round worms from hogs and horses. Brief notes are given on the various methods of drenching animals, on the life histories of the parasites mentioned, and on measures of preventing infestation by these worms. It is recommended that all affected animals should be immediately separated from the rest of the stock, that pure water should be furnished for drinking purposes, and that low, wet pastures should be properly drained in order to remove the conditions which are favorable for the development of the lung and stomach worms.

The cattle ticks (Ixodoidea) of the United States, D. E. Salmon and C. W. Stiles (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 380–491, pls. 25, figs. 192*).—The authors give detailed biological and economic notes on the species of cattle ticks which are known to infest cattle in the United States and on a number of other species which may at any time be imported from neighboring countries. Ixodoidea is accepted as the name of a superfamily containing 2 families, Argasidæ and Ixodidæ. An analytical table is given for the determination of the species belonging to these families. Thus far 8 species of ticks are reported as infesting cattle in the United States, viz: *Argas miniatus*, *Ornithodoros megnini*, *Boophilus annulatus*, *Dermacentor reticulatus*, *D. electus*, *Ixodes ricinus*, *I. hexagonus*, and *Amblyomma americanum*. A general account is given of the anatomy and life history of ticks in general. Each of the 8 species mentioned is described in detail and notes are given on the habits, life history, and distribution of each species. A bibliography of literature relating to ticks is arranged in alphabetical order and appended to the paper.

Texas fever, M. Francis (*Texas Sta. Bul. 63, pp. 60, figs. 10, chart 1*).—In order to obtain good results from blood inoculation it is necessary to keep the cattle free from ticks until they recover from inoculation fever. This may be accomplished by confining the animals in a small pasture in which it is known that the ticks are exterminated. The best time of the year for importing Northern cattle is between November and March, for the reason that the inoculation fever is less severe during cool weather. The most suitable subjects for inoculation are young cattle from 10 to 16 months of age. Sucking calves sometimes endure several inoculations without serious results, but weaned calves from 4 to 6 months of age often develop serious symptoms during inoculation fever and lose flesh and strength to an excessive degree. The practice of the author is to vaccinate cattle for blackleg immediately on arrival; about 2 days later they are inoculated for Texas fever. The blood for this purpose is usually taken from a 2-year-old immune animal carrying a reasonable number of ticks. The first injection of blood should be small—from ½ to 2 cc., or 1 cc. as a standard size. During the period of inoculation fever the animals should be well-fed on a nutritious diet. The inoculation fever appears after from 8 to 10 days and persists for from 4 to 8 days. The fever usually terminates about 20 days after inoculation. At this time the temperature may fall rapidly and may become subnormal. Deaths frequently occur at this period if animals are neglected. When the temperature falls too low stimulants should be administered. A secondary period of fever may begin about 30 days after inoculation, and persist for 8 to 10 days. It is similar to the first and in calves may be as severe as the primary fever. A third period of fever may appear in from 37 to 46 days. Recovery usually takes place about 60 days after inoculation and animals should not be allowed to become infested with ticks before that time. If the inoculation fever is severe a second dose will not be necessary; the animals may simply be subjected to gradual infestation with ticks. Where second inoculation is resorted to it should be made about 67 days after the first inoculation, and the size of dose should be about 1 cc. During 2 years 1,251 animals have been inoculated at the Texas Station, and of this number 116, or 9.21 per cent, died. This may be accepted as a fairly approximate estimate of the death rate. The greater part of the bulletin is occupied with a detailed history of the inoculation fever in various animals upon which experiments were made.

Live stock sanitary service (*Missouri State Bd. Agr. Rpt. 1900, pp. 24–30*).—A brief account of the State veterinary law with reference to quarantine and control of contagious diseases of live stock. Especial attention is given to immunization of cattle against Texas fever, and to control of tuberculosis among cattle.

Immunizing pure-bred cattle against Texas fever for the Southern trade, J. W. CONNAWAY (*Missouri State Bd. Agr. Rpt. 1900, pp. 255–262*).—The author gives a general account of the experiments in progress at the Missouri station in the improvement of practical methods for immunizing cattle against this disease.

Missouri quarantine proclamations (*Missouri State Bd. Agr. Rpt. 1900, pp. 371–380*).—A statement of the regulations adopted in the State with reference to the control of Texas fever and tuberculosis.

The relation of bovine tuberculosis to that of man and its significance in the dairy herd, H. W. CONN (*Connecticut Storrs Sta. Bul. 23, pp. 1–8*).—This article contains a general discussion of the present attitude of investigators concerning the relationship between human and bovine tuberculosis. As the result of Koch's investigations, it has become apparent that the danger of transmission of the disease from animals to man or from man to animals has perhaps been exaggerated. The seriousness of tuberculosis in dairying, however, is as great as ever, and it is urged that the precautions which have hitherto been taken in preventing the spread of the disease among dairy cows should not be abandoned.

Transmission of tuberculosis, S. BIELER (*Chron. Agr. Canton Vaud, 14 (1901), No. 19, pp. 467–471*).—This is a controversial article occasioned by Koch's announcement of the differences between bovine and human tuberculosis. The position is taken that it is highly improper to abandon the various sanitary methods which are already in operation for preventing the transmission of tuberculosis from man to animals or animals to man.

Summary of results of experiments with tuberculous cows, C. S. Phelps (*Connecticut Storrs Sta. Bul. 23, pp. 9–20*).—The facts and conclusions contained in this article have been previously published in essentially the same form. (E. S. R. 13, p. 993.)

The bacillus of tuberculosis, E. A. de Schweinitz (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 262–280*).—This paper was read before the section of bacteriology and parasitology of the Thirteenth International Medical Congress held in Paris August 4 to 10, 1900. The author gives a general discussion of the source of infection with tuberculosis, varieties of tubercle bacilli, distribution and diagnosis of the disease, bovine tuberculosis, the relationship between bovine and human tuberculosis, and the treatment of the disease. On the last-named subject the author mentions details concerning various forms of treatment which have recently been advised for controlling tuberculosis in man.

The free distribution of blackleg vaccine, V. A. Nörgaard (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 35–51, figs. 4*).—During the fiscal year 1900 the Bureau of Animal Industry prepared and distributed 1,076,150 doses of blackleg vaccine among 6,142 stockmen in 40 States and Territories. The region which is worst infected with blackleg is the area between the Mississippi River and the Rocky Mountains, extending from Canada to the Gulf of Mexico. Among the Eastern States Virginia seems to be the only one in which the disease prevails to a serious extent. The disease has gradually increased in extent since stockmen began to improve native breeds and replace them with modern breeds of a less active nature and of a decreased resisting power to disease. Reports were received from 1,980 cattle owners, concerning 369,258 head of stock. The total amount of loss from vaccination was 0.69 per cent, but allowing for mistakes in vaccination, the loss is estimated at 0.55 per cent. Quotations are given from a number of letters written by prominent stockmen who used blackleg vaccine to a greater or less extent.

The Thirteenth International Medical Congress, E. A. de Schweinitz (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 254–259*).—A brief report of the proceedings of this Congress which met in Paris in August, 1900. During the sessions of the Congress more than 6,000 physicians from different countries were present, and the United States was third on the list in the number of members. Brief notes are given on some of the more important papers which were read during the meetings; these include discussions of toxins and antitoxins, tuberculosis, and malaria.

On the morphology of the anthrax bacillus, A. Hinterberger (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 11, pp. 417–424, pl. 1, fig. 1*).—The author was able to demonstrate clearly the capsule of the anthrax bacillus, by means of the silver-staining method of Van Ermengem. The clear double contour lines of the capsule, when treated in this manner, indicate that the capsule is to be considered an integral part of the bacillus and not a product of treatment by artificial methods. Besides the well-known capsule of the anthrax bacillus, the author described a much larger and broader membrane, of less definite character. The latter membranes are not produced by swelling of the capsule proper, but seem to be a distinct part or organ of the body of the bacillus. An elaborate method was devised for the demonstration of threads connected with the body of the anthrax bacillus. While it was not definitely determined by the author that these threads in all instances stand in organic union with the bacillus, the evidence points in that direction, and it is suggested by the author that the threads should be called mycelia and treated as homologous with the mycelia, or vegetative portion of higher fungi.

Does the anthrax bacillus form spores under strictly anaerobic conditions? R. Slupski (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 10, pp. 396–400, figs. 2*).—The author gives a detailed description of an apparatus for securing absolutely anaerobic conditions for making the cultures of bacteria. At first anthrax bacillus grew luxuriantly and formed spores in some cases. Upon examination, however, it was found that this was due to a defect to the apparatus, which had allowed oxygen to enter. After the defects were remedied no spores were formed. The anthrax bacilli which were cultivated under such conditions, grew out in long threads and showed a granulur disintegration.

Influence of alcohol on the natural immunity of pigeons to anthrax and on the course of anthrax infection, S. J. GOLDBERG (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), Nos. 18, pp. 696–700; 19, pp. 731–741*).—A critical review is given of the literature relating to physiological and toxic effects of alcohol, especially as demonstrated in the treatment of diseases. In order to determine the influence of alcohol upon immunity to infectious diseases and upon the course of such diseases, the author tried experiments on pigeons in their relation to anthrax. The general results of the experiments may be summarized as follows: Pigeons, which are naturally immune to anthrax, succumbed to inoculation with anthrax as soon as moderate or large doses of brandy were administered. Chronic alcohol intoxication was found to cause a considerable decrease in the natural resisting power of pigeons toward anthrax. Small doses of alcohol given along with fatal doses of anthrax culture for the purpose of determining its possible therapeutic effect showed that alcohol has no true therapeutic value in the treatment of this disease and that many of the pigeons which were given alcohol died sooner than those which were not so treated.

The geographical distribution of actinomycosis of cattle in Bavaria, J. MITTELDORF (*Inaug. Diss., Univ. Bern, 1901, pp. 30, pl. 1*).—The author made a careful survey to determine the distribution and relative frequency of this disease in various parts of Bavaria. The distribution is discussed in connection with a map of 4 colors, showing localities in which cattle are infested to the extent of from 0.01 to 0.09 per cent, from 0.1 to 0.9 per cent, from 1 to 2.9 per cent, and from 3 to 12 per cent, respectively. No differences were observed in susceptibility of native and pure bred races of various sorts to the disease. The highest percentages of infestation are observed in moist, swampy localities. Of the 3,621 cases of actinomycosis upon which notes are made in this dissertation, 75.5 per cent occurred in the head and neck, 23.3 in the tongue, 0.77 per cent in the abdomen, 0.05 per cent in the udder, 0.24 per cent in hogs, and 0.11 per cent in horses.

Coli bacteria and the common bacteria of mammitis in cows, H. STREIT (*Inaug. Diss., Univ. Bern, 1901, pp. 48*).—The author made culture studies of 12 races of coli bacteria and 9 of ordinary mammitis bacteria. The original cultures were obtained from a great variety of sources. Details are given concerning the culture of these different bacterial forms from various culture media. It was found during the author's investigations that the most frequent bacteria observed in mammitis of cows belong to the coli group. They occur in various forms which are peculiar to this group, the greatest number belonging to typical coli races. Other forms are found intermediate between these and aerobic forms. The character of different races undergoes important modifications by long-continued culture. By this means one form may be modified into a form which may be considered as belonging to another race. According to the author's investigations the bacteria of mammitis are frequently found in the intestines, and it is believed that they most frequently make their way into the udder from this point by means of the circulation and from the outside world through the milk openings.

Spotted kidney in calves, K. VAERST (*Inaug. Diss., Univ. Bern, 1901, pp. 21, figs. 12*).—The literature on the subject is reviewed, in connection with a short bibliography. Tables are presented showing the weight, length, breadth, thickness, and number of spots in the kidneys showing this affection. Great differences of opinion have prevailed regarding the cause of spotted kidney, and the fitness of such kidneys for food. Experiments made by the author showed that no infectious material was contained in such kidneys, and it is concluded that the white spots in these kidneys are embryonic tissue which has not undergone the usual modifications. Affected kidneys are not only harmless, but tests indicate that the flavor of spotted kidneys is better than that of normal kidneys.

Salt sickness, H. E. STOCKBRIDGE (*Florida Sta. Rpt. 1901, pp. 43–54, pls. 4*).—For a number of years complaints were made of the prevalence of a disease known as "salt sickness" in various parts of the State. The subject was investigated by the author, in connection with W. E. French and J. E. Ennis. As the result of these investigations it was found that so-called salt sickness was not a disease, but merely a condition of starvation due to animals being confined on poor pasture, consisting of dry wire grass and other inferior vegetation. When the animals were properly fed or changed to good range or pasture they uniformly recovered.

Lead ore in sugar-beet pulp, J. A. WIDTSOE and L. A. MERRILL (*Utah Sta. Bul. 74, pp. 55–62*).—Complaints having been made at the station concerning disease and death among cattle eating sugar-beet pulp, an investigation of the subject was made with the result that the trouble was found to be due to lead ore in the pulp. The freight cars in which the sugar-beet pulp was shipped had been previously used for transporting lead ore and had not been cleaned. As a result sufficient quantities of the lead ore were shoveled out along with the pulp to cause the death of a number of cattle. The material which was found in the sugar-beet pulp proved on analysis to be mainly sulphid of lead with an admixture of sulphid of iron. A faint trace of rasenic was also present, but no copper or other poisonous metals were found. The symptoms of the animals poisoned with these substances are described. Affected cattle first refused to drink, then withdrew from the herd and laid down with the head drawn toward the flank. Constipation was uniformly present. There was loss of control of the voluntary muscles and an increased quantity of saliva was observed. The mineral substances already mentioned were found lodged against the sides of the stomachs on post-mortem examination. Three ounces of lead ore were obtained from a piece of the first stomach 6 in. square. The desirability of having freight cars cleaned before being loaded with sugar-beet pulp is suggested. As treatment for lead poisoning large doses of Epsom salts (2 lbs. per animal) are recommended. When symptoms of recovery appear iodid of potash may be given in 2-dram doses 3 times per day for the period of a week.

The work against sheep scab, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 69–86*).—The author gives a copy of an order of the Bureau of Animal Industry concerning the dipping of sheep which are affected with sheep scab. In order to make the work against sheep scab more thorough and effective special sheep inspectors were stationed at various points where greatest demand was made for dipping diseased sheep. Details are given in tabular form concerning the number of sheep dipped in various locations and the effectiveness of the treatment. Of 515,112 sheep subjected to only one dipping, 86 per cent were cured and 14 per cent remained infested with the scab mite. Three dipping solutions were used in treatment for scab, viz, nicotin and sulphur; extract of tobacco and sulphur; and lime and sulphur, prepared according to the formula of the Bureau of Animal Industry. All these dips proved to be about equally effective.

The treatment of sheep scab, REGENBOGEN (*Berlin. Thierärztl. Wchnschr., 1901, No. 33, pp. 501–503*).—Statistics are presented showing the great prevalence of sheep scab in different parts of Germany since the year 1879. The methods which have been recommended for treating the disease are considered as defective in many particulars. In general, 2 forms of treatment have been adopted—the hand treatment by smearing insecticide substances upon scab areas, and complete dipping into an insecticide substance. The author experimented with a proprietary substance sold under the name of "Akaprin." This substance in a 4 per cent solution with water at a temperature of 30° C. destroys the scab mites in one dipping of from 4 to

5 minutes' duration, in connection with brisk rubbing of the affected parts of the skin with brushes. No poisonous effect of the solution was observed, either in the ordinary dipping or in cases where some of the solution happened to be swallowed. The normal condition of the wool was not affected, either in its firmness or color. The cost of the solution is believed to be such as to make it suitable for practical application.

Malaria of horses, A. THEILER (*Inaug. Diss., Univ. Bern, 1901, pp. 32, pls. 4*).—The symptoms and course of this disease in horses are described from the author's observations and from general experience with the disease. Malaria of horses is considered distinct from surra, since the latter is not caused by malarial parasites, but by flaggellate infusoria. The appearance of the plasmodium of the disease in its different stages is described in detail. Malaria is considered identical with the disease described by Wiltshire in 1883 under the name anthrax fever, and also with the disease commonly called biliary fever. Ordinary malaria affects only certain individual horses in a herd, but it may occur in an epizootic manner. The diagnosis can be made with certainty only by demonstration of the parasites in the blood. Acute cases run a course of from 2 to 5 days, while chronic cases may result in death after a period of from 2 to 4 weeks. The prognosis in the case of this disease will be determined largely by the quality and frequency of the pulse. If the animal successfully passes through the period of fever, a secondary period of icterus persists for a considerable time, and may prove fatal. If the disease is observed during its earliest stages, the administration of quinin 3 times per day in doses of from 6 to 10 gm. will frequently effect a cure.

The elbow boil of horses and its treatment, D. KALLMANN (*Inaug. Diss., Univ. Bern, 1900, pp. 7, figs. 11*).—In an investigation of this subject the author found that comparatively few cases of the disease occur when horses stand in stalls furnished with stone floors. The symptoms, course of development, and pathological anatomy of the disease are described in detail. It was found that as a rule this affection is a form of bursitis olecrani, and is not due to bruises from any part of the shoe. The term elbow boil is considered, therefore, more applicable than calk boil. The best results in treating this disease were obtained by the injection of tincture of iodin. The fluid contents of the boil were first removed by a hypodermic needle, and the iodin was then injected into the bursa. If no subsequent discharges were observed, no further treatment was required; otherwise, the injection may be repeated, or if suppuration takes place the bursa may be cut open and removed, in which case the wound will require daily treatment for about 2 weeks. A bibliography of 62 titles is appended to the dissertation.

The constant occurrence of pathogenic micro-organisms, especially the bacillus of swine erysipelas, in the tonsils of pigs, C. BAUERMEISTER (*Inaug. Diss., Univ. Bern, 1901, pp. 53*).—The author's studies were made largely upon material obtained while practicing meat inspection in the abattoir at Hanover. It was found that the tonsils of pigs almost always contain pathogenic organisms, especially the bacillus of swine erysipelas. The organisms were for the most part found in the ducts of the tonsilar glands and those of the soft palate. It was frequently observed that stiff portions of food, such as crushed and split grains, etc., had become inserted into the ducts of these glands or into the tissue of the tonsils, in some cases causing slight lesions. The penetration of these foreign bodies furnishes excellent conditions for pathogenic organisms to obtain a foothold in such locations. Inoculation experiments upon various experimental animals showed that the micro-organisms found in such places are pathogenic. The most interesting fact in connection with the bacillus of swine erysipelas is that this organism was found in a large percentage of the perfectly healthy pigs. Under ordinary circumstances it does not seem to spread from the tonsils so as to cause a general infection, but it is believed that its frequent occurrence there may account for many outbreaks of this disease which have been observed where the method of infection could not be determined.

Apoplectiform septicæmia in chickens, V. A. Nörgaard and J. R. Mohler (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 36, pp. 24, pls. 4*).—An acute and fatal chicken disease occurred on a farm in Virginia and caused the death of about 200 birds. The authors made post-mortem examinations on chickens which had died of the disease. Hemorrhages were found in the subcutaneous and muscular tissue. A blood-colored exudation was found in the body cavity. The liver was enlarged and covered with a plastic exudate. The meninges of the brain were injected with blood and the cerebral ventricles contained a large amount of discolored serum. Pullets seemed to be most susceptible, hens next, and roosters and capons least. The disease in the latter assumed a less acute form. The period of incubation was not definitely determined, but the interval between infection and death appeared to be from 24 to 48 hours. In many cases death occurred so suddenly that the preliminary symptoms were not observed. Where the course of the disease was longer the feathers became ruffled and the bird exhibited a state of extreme depression. Affected fowls lay down and died without a struggle. A specific micrococcus in the form of a streptococcus was isolated and cultures of the organism were made. It is aerobic or facultatively anaerobic. It grows both on solid and liquid media, growth being most rapid at a temperature of 37° C. Detailed notes are given on the behavior of the organism upon various culture media. Exposure of the organism for 11 minutes to a temperature of 60° C. is fatal, but growth occurs after a 10-minute exposure to this temperature. Cultures were sterilized by exposure of 4 minutes to a temperature of 70° C. Cultures were also sterilized by drying over night in an incubator. The organism was destroyed by an exposure for 30 seconds in a 2.5 per cent solution of carbolic acid, for 2 minutes in a 1 per cent solution of carbolic acid, for 1 minute in a solution of corrosive sublimate in the proportion of 1 to 2,000, for 4 minutes in a 1 per cent solution of creolin, or for 2 minutes in a 0.25 per cent solution of formalin.

Inoculation experiments were made on various animals. An intravenous injection of 0.1 to 0.5 cc. bouillon culture 24 hours old produced the disease in chickens and caused death in from 48 hours to 4 days. Intramuscular inoculations in chickens produced no effect. Feeding virulent cultures produced death in from 4 to 13 days. Chickens fed on the viscera of rabbits which had succumbed to the disease died in 10 days. Intravenous injections in ducks produced death on the twelfth day, but subcutaneous or intramuscular injections as well as feeding on virulent material produced no effect. Intravenous inoculations produced death in pigeons, but intramuscular inoculations were negative. In rabbits fatal effects were produced by intravenous or intrapleural inoculations. Inoculation in the body cavity of white or gray mice proved fatal in about 48 hours. Experiments with dogs showed that inoculation in these animals produced a lameness but not fatal effects. Sheep and guinea pigs appeared to be completely refractory. It was found by further experiments that immunity to the disease may be produced in susceptible animals by the use of the filtrate of bouillon cultures, sterilized bouillon cultures, or serum from artificially immunized animals.

Bacteriological studies on the bacteria of the alimentary tract of chickens, R. Rahner (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 6, pp. 239–244*).—The purpose of the investigation reported on in this article was to secure evidence on the question of the effect of various bacteria in the alimentary tract of chickens. It was found that the species of bacteria and the relative prevalence of different species varied exceedingly according to the amount and nature of the food from which chickens fed. The only species of bacteria which is considered by the author as constantly present in the alimentary tract of chickens is *Bacterium coli*. When other bacteria are present in large numbers, this species may temporarily lose its importance, but after a short time it rapidly multiplies so as to regain its usual importance.

The Brunswick chicken plague, JESS (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 19, pp. 755-757*).—A disease which bore certain resemblances to fowl cholera, roup, and arsenic poisoning, was investigated by the author. It was found that affected birds exhibit the first symptoms of disease about 3 days after exposure to infection. As a rule death occurred about 7 days after the beginning of the disease. A microscopic study of diseased fowls showed the presence of several pathogenic organisms, one of which appeared to be that of fowl cholera, while the others were distinct and were found in greatest abundance in diseased patches which occurred in the throat. The author believes that the disease is therefore due to a mixed infection. Attention is called to the necessity of exercising care in disinfecting poultry yards and buildings in order to prevent the spread of the disease.

The diseases of the cat, J. W. HILL (*New York: William R. Jenkins, 1901, pp. 123, pls. 10*).—In this volume the author has brought together a discussion of the symptoms, causes, and remedies for all of the diseases which commonly affect domesticated cats. Special chapters are devoted to diseases of the respiratory organs, diseases of the stomach, of the intestines, of the skin, of the ear, of the eye, mammary glands, and nervous system. The problems connected with abandoned cats, with the feeding and washing of cats in health, and the destruction or disinfection of diseased cats are also discussed. One chapter is devoted to general diseases, infectious or otherwise; and accidents, together with their treatment, as well as poisons and the proper antidotes also receive due consideration.

A method for simple determination of the value of chemical disinfectants, T. PAUL (*Entwurf zur einheitlichen Wertsbestimmung chemischer Desinfektionsmittel. Berlin: Julius Springer, 1901, pp. 54, figs. 8*).—Especial attention is called to the desirability of simple methods for rapid determination of the real value of disinfectants which are proposed for practical use in the destruction of pathogenic organisms in houses and stables, after the occurrence of infectious diseases. As a rule the methods proposed for such determination are considered defective, or as based upon inconclusive experiments. It is urged that experiments along this line should be conducted in a more uniform manner and with all factors under better control, in order that reliable results may be obtained. The virulence of the organisms to be used in the experiments must be carefully determined and care must also be exercised in an accurate determination of the solution in which the organisms are placed, and the strength of the solution of the disinfectant.

Studies on bacillol, F. PASZOTTA (*Inaug. Diss., Univ. Bern, 1901, pp. 35*).—From the numerous experiments conducted by the author, it was concluded that bacillol is soluble in water under all circumstances, and forms constant solutions. When bacillol is applied, in concentrated form, to the skin it is slightly caustic like lysol. It is considered a powerful antiseptic and deodorizer. It is to be obtained more cheaply than most other similar drugs. It should be administered in the same way as lysol or creolin. When given internally it causes a slight increase in salivation and an increased cardiac and respiratory action. In large doses it may cause motor paralysis or trembling. It is rapidly excreted by means of the kidneys.

Zoological materia medica. History of drugs of animal origin, H. BEAUREGARD (*Matière médicale zoologique. Histoire des drogues d'origine animale. Paris: C. Naud, 1901, pp. 396, figs. 145*).—The general anatomical characters of mammals are discussed, with special reference to the structures which are concerned in the production of substances used for medical purposes. In connection with the consideration of various species of mammals, reptiles, fishes, crustaceans, insects, worms, and sponges, the anatomical and chemical character of the various drugs which are obtained from each species are mentioned and critically discussed. The work contains a valuable and convenient summary of the present state of knowledge concerning various drugs of animal origin.

Contagious diseases of animals in foreign countries, G. F. Thompson (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 492–502*).—Brief statistical notes concerning the prevalence of diseases among domestic animals in Great Britain, Switzerland, France, Sweden, Denmark, Belgium, Netherlands, Germany, Norway, Hungary, and Italy.

The literature of veterinary science and related subjects, from April 1, 1889, to December 1, 1901, R. Schoetz (*Die Litteratur der Veterinärwissenschaft und verwandter Gebiete vom 1. April 1889 zu 1. Dezember, 1901. Berlin: Author, 1902, pp. 112*).—This bibliography includes a list of the books which have appeared on the subject of veterinary science from April 1, 1889, to December 1, 1901, a list of periodicals in which veterinary articles appear almost exclusively, and an alphabetical list of the literature according to subjects. The first list of books is arranged alphabetically according to authors.

TECHNOLOGY.

Manufacture of chocolate, P. Zipperer (*Die Schokoladen-Fabrikation. Berlin: M. Krayn, 1901, 2. ed., pp. 306, pls. 2, figs. 99*).—After a brief discussion of the geographical distribution of cocoa, appearance of the tree and fruit, cultivated varieties, commercial importance of the industry, composition of cocoa beans and shells, and the food or other materials added to chocolate in its preparation, the author takes up at length and in great detail the manufacture of various cocoa preparations, giving many illustrations of the machinery used in the different processes. Following this, chapters are given on the preservation and packing of prepared cocoa, motive power, arrangement of manufacturing establishments, chemical and microscopical investigations of cocoa preparations, and laws relative to cocoa commerce. In the appendix analyses are given of 74 preparations, in which cocoa enters, and a bibliography of 14 papers on cocoa and chocolate. The volume is intended more especially for the use of manufacturers, food chemists, and builders of cocoa manufacturing establishments.

Fruit growers' manual for canning fruit, etc. (*Auburn, Cal.: Hemlow-Meriam Co., 1901, pp. 78*).—This is a concise manual giving estimates as to the cost of canning factories of various sizes, and recipes for the canning of fruits, vegetables, meats, fish, eggs, milk, etc.

Improvements in sugar refining during the last twenty-five years, T. L. Patterson (*Jour. Soc. Chem. Ind., 20 (1901), No. 11, pp. 1088–1091*).

The manufacture of maize starch, G. Archbold (*Jour. Soc. Chem. Ind., 21 (1902), No. 1, pp. 4–9, fig. 1*).

The preparation of orange essence (*Rev. Cult. Coloniales, 9 (1901), No. 82, pp. 85, 86*).—A note on methods of preparation observed in Sicily.

Some practical hints on cider making, R. N. Grenville (*Jour. Roy. Agr. Soc. England, 62 (1901), pp. 40–49*).—The author reports the results of his experiments in cider making for a number of years. He strongly advises that cider pomace be strained through cotton cloths instead of through manila cloths or straw, as is commonly done. Between every 4 cloths a wooden grating is placed, which helps to keep them in place and distribute the pressure. Cider has been very successfully filtered by the use of Lumley's German filter, using paper pulp as a medium. The cider seems to be in best condition for bottling when the specific gravity ranges between 1.025 and 1.015.

Cider making, F. Ingoult (*Semaine Agr., 21 (1901), Nos. 1062, pp. 301, 302; 1063, pp. 310, 311*).—The author presents in a popular manner the results of his 30 years' experience in making cider. All the details, from gathering the fruit by hand to the cellar storage of the cider in bottles, are included.

Normandy cider, HERTSLET (*Jour. Agr. and Ind. South Australia, 5 (1901), No. 2, pp. 124–128*).—This is a general review of the cider industry in Normandy, with special reference to the methods pursued in the department of Calvados. Methods of gathering the apples, crushing them, pressing the pulp, fermentation, and storage of cider are briefly touched upon.

Use of casein in clarifying wines, A. MUNTZ (*Dairy, 14 (1902), No. 158, pp. 41, 42*).—In experiments by the author casein was used very satisfactorily in clarifying wines. Both white and red wines are reported as completely clarified by casein without any depreciation in quality. Casein is considered as having the advantage over similar products used for this purpose of not acting on the tannin. Other advantages are its purity, keeping properties, and low cost. Directions for using are given.

The mannitic fermentation of wine, P. SCHIDROWITZ (*Analyst, 27 (1902), No. 311, pp. 42–48*).—An account is given of this sickness or disease of wine due to bacteria, with analytical methods for the detection and estimation of mannitol.

The expressed oil industry in the United States, K. PIETRUSKY (*Oesterr. Chem. Ztg., 4 (1901), No. 9, pp. 204–206*).—A description of the production of cotton-seed, linseed, maize, peanut, castor, olive, and cocoanut oil in the country indicated. Some statistics are included.

AGRICULTURAL ENGINEERING.

Practical hints on the construction of drains, S. F. MOORE (*Drainage Jour., 23 (1901), Nos. 7, pp. 179–183, figs. 3; 8, pp. 207–211, figs. 4; 9, pp. 237–240, figs. 5; 10, pp. 268–272, figs. 2; 11, pp. 299–301, figs. 3; 12, pp. 324–326*).—This article gives directions and suggestions regarding the laying of tile on curves, cutting tile, surface inlets, location of inlets, lands most favorably situated for drainage, and testing tile.

Results of irrigation in Wisconsin, G. H. PATCH (*Forestry and Irrig., 8 (1902), No. 5, pp. 198–202, figs. 4*).—An account of irrigation by means of canvas hose under the direction of Professor King, of the Wisconsin station.

Water storage of Cache Creek, California, A. E. CHANDLER (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 45, pp. 48, pls. 10, figs. 8*).—This paper discusses the topography and physical features of the region studied, stream measurements, irrigation works, underground waters, tributaries to Cache Creek in Capay Valley, and the suitability of Clear Lake for storage purposes.

Reconnoissances of Kern and Yuba rivers, California, F. H. OLMSTED and M. MANSON (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 46, pp. 57, pls. 8, figs. 18*).—This bulletin contains 2 papers. The first, by F. H. Olmsted, relates to the physical characteristics of the catchment area of the Kern River. "In this paper the author describes the drainage basin and estimates the amount of water coming from it and the power available from a complete utilization of the various portions of the stream. He also discusses the utilization of this power in pumping for irrigation." The second paper, by M. Manson, relates to Yuba River, and "discusses the physical conditions and storage possibilities of this stream, bringing out particularly the importance of preserving the forest cover on the upper catchment basin and, if possible, increasing this by artificial means, and shows by estimates the possible increase of available water through complete afforestation of the area."

Operations at river stations, 1900 (*Water Supply and Irrig. Papers, U. S. Geol. Survey, Nos. 47, 48, 49, 50, 51, 52, pp. 575*).—These bulletins contain data similar to those published in previous reports (E. S. R., 12, p. 897).

Geology and water resources of Nez Perces County, Idaho, I. C. RUSSELL (*Water Supply and Irrig. Papers, U. S. Geol. Survey, Nos. 53, 54, pp. 141, pls. 10, figs. 14*).—These papers discuss the geology, physiography, water supply, and economic geology of this region. They include also a bibliography of artesian waters and appendixes giving elevations in Nez Perces region and notes on Portland cement.

Geology and water resources of a portion of Yakima County, Washington, G. O. SMITH (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 55, pp. 68, pls. 7, figs. 8*).—This is a continuation of studies reported by I. C. Russell in 1893 and 1896 (E. S. R., 9, p. 737), and relates to the geography, geology, and water resources (surface and underground).

Methods of stream measurement (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 56, pp. 51, pls. 12, figs. 4*).—This material has been compiled from various reports and letters of instruction, and is intended to embody not only a description of the operations, but in some cases minute directions which may assist the hydrographers and serve to increase the accuracy of results. It is designed not only to assist and guide the hydrographers employed by the Survey or working in cooperation with it, but also to exhibit as nearly as possible the degree of accuracy of the operations and of the computations of results.

Preliminary list of deep borings in the United States. Part I, Alabama-Montana, N. H. DARTON (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 57, pp. 60*).—This is a preliminary list of borings to a depth of 400 ft. or more.

Storage of water on Kings River, California, J. B. LIPPINCOTT (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 58, pp. 101, pls. 32, figs. 2*).—This is a report of investigations in which "the drainage basin of Kings River has been explored and preliminary surveys and estimates prepared sufficient to justify the statements that works can or can not be economically constructed at certain localities. . . . The situation on Kings River is to a certain extent typical of that along a number of important streams of the West, and as a result of this investigation it is believed that the reclamable area can be greatly extended by the construction of storage works and also of power plants by means of which, through electrical transmission, pumps can be operated at small expense out on the broad valleys."

The hydrography of Colorado, A. L. FELLOWS (*Forestry and Irrig., 8 (1902), No. 5, pp. 205–210, figs. 2*).—A brief account of methods and results of water measurements.

The silt problem in connection with irrigation storage reservoirs, J. C. NAGLE (*Trans. Texas Acad. Sci., 4 (1901), No. 3, pp. 33–46*).—A brief discussion of this subject based on results of investigations carried out under the supervision of E. Mead, in charge of irrigation investigations of this Department, and reported in detail elsewhere (E. S. R., 13, p. 999).

Brack land in relation to irrigation and drainage (*Agr. Jour. Cape Good Hope, 20 (1902), No. 7, pp. 397–405*).—This is a discussion of the nature and reclamation of alkali lands found in certain parts of South Africa. In the opinion of the author "the only and radical cure for brack land, and preventive of slow accumulation of alkali by irrigation, is an adequate system of underdraining."

Machinery at the general agricultural conference at Paris, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 3 (1902), Nos. 17, pp. 537–541, figs. 5; 18, pp. 574–579, figs. 9; 19, pp. 602–606, figs. 11*).—Brief descriptions with illustrations are given of seeding and tillage implements, harvesting machinery, motors and mills, and miscellaneous farm machinery displayed at the last agricultural conference at Paris.

The German agricultural machinery industry at the beginning of the twentieth century, H. PUCHNER (*Vrtljschr. Bayer. Landw. Rath., 7 (1902), No. 2, pp. 111–119*).—A brief discussion of this subject.

Roller and ball bearings in agricultural machinery, A. NACHTWEH (*Fuhling's Landw. Ztg., 51 (1902), Nos. 1, pp. 28–30; 2, pp. 41–43*).—A discussion of their relative merits.

Agricultural machines for peanuts, F. MAIN (*Jour. Agr. Trop., 2 (1902), No. 10, pp. 103–105*).—Discusses briefly the essential features of machines for harvesting, thrashing, and hulling peanuts.

Tests of rice hulling machines, M. RINGELMANN (*Agr. Prat. Pays Chauds, 1 (1901), No. 3, pp. 286–292*).—Tests of 3 different makes of rice hullers are reported.

Test of a machine for preparing fiber, M. RINGELMANN (*Agr. Prat. Pays Chauds, 1 (1901), No. 3, pp. 293–301, figs. 2*).—Tests of a machine invented by H. J. Boeken, Düren, Germany, on leaves of *Agave rigida* var. *sisilana* and *Fourcroya gigantea*, and the stems of *Musa paradisiaca* are reported.

Road improvement (*Missouri State Bd. Agr. Mo. Bul., 1 (1902), No. 10, pp. 32, figs. 5*).—Report of proceedings, including abstracts of address delivered at the tenth annual meeting of the Missouri Road Improvement Association. The subjects discussed were dirt roads, road making in southeast Missouri, qualifications of road overseers, roads and rural mail delivery.

Ventilation of farm stables, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 11–15, figs. 3*).—A system of ventilation by means of pipes extending to the floor of the stable and terminating at the peak of the roof in revolving cowls is described. The pipes are so arranged that the air enters for the most part at the floor in front of the stalls, the foul air passing out by means of pipes leading from the ceiling of the stable to the roof of the barn.

Cold storage, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1901, pp. 6–11, figs. 3*).—A brief report of the results obtained with the Hanrahan system of cold storage installed at the college (E. S. R., 13, p. 394) is given, attention being called especially to the importance of a good system of air circulation in order to prevent dripping and mold and to insure a supply of comparatively dry and pure cold air.

MISCELLANEOUS.

Agriculture, W. P. BROOKS (*Springfield, Mass.: The Home Correspondence School, 1901, vol. 1, pp. XVII+199, figs. 55, map 1; vol. 2, pp. XXIV+201–541, figs. 119, map 1; vol. 3, pp. XXI+543–855, figs. 122*).—This series of books was prepared for use in the correspondence course in agriculture offered by the Home Correspondence School of Springfield, Mass. They deal in simple language with the scientific principles which underlie the various operations of a farm, and furnish "sources of practical information permanently valuable for reference." Volume 1, entitled Soils and how to treat them, "treats of the composition and food of plants and tells from what sources the necessary elements are derived. This serves as an introduction to the study of soils, which embraces a brief consideration of the action of the various agencies which have helped to form and to improve them. Especial attention is paid to the action of agencies which are now active; and the means which the farmer may take to promote such action are carefully pointed out. The peculiarities of the different classes of soil and their suitability to different crops are discussed. Then follows a careful study of soils in their relation to air, water, and heat. The chemistry of soils, with especial reference to composition and the more important chemical changes which go on in them, is treated at length. Following this the various operations which have for their object the amelioration of the soil are fully treated. This section includes a careful explanation of the objects, results, and methods of tillage and a description of the principal tillage implements. Drainage is treated at considerable length, as also is irrigation."

Volume 2, entitled Manures, fertilizers, and farm crops, is intended for use in connection with volume 1 and deals with the composition, adaptations, and proper methods of use of manures and fertilizers. Green manuring and crop rotation are given special attention. Plant diseases and insect injuries are considered and the nature, uses, soil adaptations, and manuring of each important farm crop is discussed, with details as to planting, culture, and harvesting. The implements found most useful in connection with the culture of the various crops are briefly referred to.

Volume 3, entitled Animal husbandry, discusses the general principles of stock feeding, breeds of cattle, horses, sheep, swine, poultry, the principles of animal breeding, feeds and feeding standards and related topics.

Tropical agriculture, H. A. A. NICHOLLS (*New York: The Macmillan Co., 1900, pp. XXIV+312, figs. 16*).—This work was written as a text-book on tropical agriculture for the West Indies, adapted for use in the colleges and higher schools of that colony. The first part of the work discusses soils, plant life, manures, irrigation, tillage, pruning, budding, and grafting, and the principles of agriculture generally; while the second part is devoted to detailed cultural operations for various tropical products, such as coffee, cacao, tea, sugar cane, fruits, spices, tobacco, drugs, dyes, and tropical cereals and other food plants. Especial attention has been given to the details of the different cultural operations, the book being intended more particularly as a guide for the young and inexperienced.

Fourteenth Annual Report of Arkansas Station, 1901 (*Arkansas Sta. Rpt. 1901, pp. 6+123*).—This includes the organization list of the station, a brief report of the director, and a financial statement for the fiscal year ended June 30, 1901. Reprints of Bulletins 66–70 on the following subjects are appended: Oat experiments (E. S. R., 13, p. 545), investigations of swine diseases in Arkansas (E. S. R., 13, p. 896), soil improvement and forage experiments (E. S. R., 13, p. 840), some muskmelon experiments (E. S. R., 13, p. 850), and cowpea experiments (E. S. R., 13, p. 843).

Annual Report of Florida Station, 1901 (*Florida Sta. Rpt. 1901, pp. 97*).—This includes the organization list of the station; a report of the director reviewing briefly the work and publications of the station during the year; a subject list of station bulletins; financial statements for the fiscal years ended June 30, 1900 and 1901; and reports of the agriculturist, chemist, entomologist, and the botanist and horticulturist, giving the results of work noted elsewhere in this issue. Reprints of Bulletins 56–58 of the station on the following subjects are appended: The cottony cushion scale (*Icerya purchasi*) (E. S. R., 13, p. 472), top-working pecans (E. S. R., 13, p. 559), and pomelos (E. S. R., 13, p. 557).

Fourteenth Annual Report of Louisiana Stations, 1901 (*Louisiana Stas. Rpt. 1901, pp. 12*).—An account is given of the work at the Sugar Station at Audubon Park, the State Station at Baton Rouge, and the North Louisiana Station at Calhoun. The report also contains the organization lists of the stations and a financial statement for the fiscal year ended June 30, 1901.

Seventeenth Annual Report of Maine Station, 1901 (*Maine Sta. Rpt. 1901, pp. 200*).—This is made up of reprints of Bulletins 70–78 of the station as follows: Oats as grain and fodder (E. S. R., 13, p. 240), feeding stuff inspection (E. S. R., 13, p. 270), fertilizer inspection (E. S. R., 13, p. 236), experiments with fungicides upon potatoes in 1900 (E. S. R., 13, p. 360), the manurial value of ashes, mucks, seaweed, and bone (E. S. R., 13, p. 332), analyses of miscellaneous food materials (E. S. R., 13, p. 577), the horticultural status of the genus Vaccinium (E. S. R., 13, p. 648), fertilizer inspection (E. S. R., 13, p. 634), and finances, meteorology, index (E. S. R., 13, p. 1002).

Twentieth Annual Report of Ohio Station, 1901 (*Ohio Sta. Rpt. 1901, pp. XXI*).—This includes the organization list of the station, a financial statement for the fiscal year ended June 30, 1901, a brief report of the director, and a list of acknowledgments.

Thirteenth Annual Report of Texas Station, 1901 (*Texas Sta. Rpt. 1901, pp. 113–137*).—This includes the organization list of the station; a report on the publications, organization, and work of the station by the director; resolutions adopted by agricultural organizations in Texas concerning the station, departmental reports, a subject list of station bulletins, and a financial statement for the fiscal year ended June 30, 1901.

Seventeenth Annual Report of the Bureau of Animal Industry, 1900 (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 642, pls. 98, figs. 238*).—This contains the report of the chief, reviewing at some length the work of the

Bureau during the year; 16 articles noted elsewhere in this issue and 4 articles already noted from other sources as follows: Plant poisoning of stock in Montana (E. S. R., 13, p. 283), rabies—its cause, frequency, and treatment (E. S. R., 13, p. 286), poultry raising on the farm (E. S. R., 13, p. 983), and information concerning the Angora goat (E. S. R., 12, p. 1077); brief miscellaneous articles entitled Mexican cattle industry, American horses in Switzerland, horse breeding in Belgium, American horse meat in Denmark, sheep and wool statistics of Russia, how sheep scab was stamped out in New Zealand, poultry raising in Belgium, eggs, poultry, and meat in Great Britain, egg exports from Russia, meat in South Africa, the ingredients of oleomargarine, oleomargarine in France, the utilization of packing-house offal, largest refrigerating plant in the world, Cape Angora goatskins, exports of deerskins from British Columbia, export of bones and bone ash from Uruguay, egg exports from Madeira, horse and dog meat as food in Germany, and muzzling of dogs in Germany and Great Britain; a translation of the Imperial German meat inspection law; statistics of the animal industry of Australasia; tables showing the receipts and shipments of live stock at the leading stock centers and estimates of the production of wool in 1900, and the rules and regulations of the Bureau of Animal Industry issued in 1900.

Proceedings of the sixth annual meeting of the American Association of Farmers' Institute Workers, held at Buffalo, New York, September 18 and 19, 1901, edited by A. C. TRUE, D. J. CROSBY, and G. C. CREELMAN (*U. S. Dept. Agr., Office of Experiment Stations Bul. 110, pp. 53*).—This includes a list of the officers and members of the association, the constitution and by-laws, a brief historical note on the organization and the previous meetings of the association, and the detailed proceedings. The membership comprises the superintendents of farmers' institutes in the different States. W. L. Amoss, of Maryland, is president; W. L. Hutchinson, of Mississippi, vice-president; and G. C. Creelman, of Ontario, secretary-treasurer.

Press bulletins (*Ohio Sta. Bul. 128, pp. 233–247*).—Press bulletins on the following subjects were issued during the year: Present situation in Ohio with respect to the ravages of the chinch bug, a seven-year comparison of varieties of wheat, a warning against fraud, suggestions to wheat growers, fertilizers on wheat, tuberculosis in cattle, announcement concerning sugar beets, Ohio sugar-beet work for 1900 and 1901, seeding lawns and permanent pastures, a bulletin on plant diseases, alfalfa, and treatment for the cankerworm.

Review of the world's commerce, introductory to commercial relations of the United States with foreign countries during the year 1901 (*U. S. Dept. State, Bureau Foreign Commerce, 1902, pp. 227+III*).

Imports and exports of animals and animal products, G. F. THOMPSON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1900, pp. 535–556*).—A statistical review for the year 1900.

Agricultural returns for 1900 (*London: Board of Agriculture, 1901, pp. 41*).—Statistical tables showing acreage under crops and grass and number of horses, cattle, sheep, and pigs in the United Kingdom, with particulars for each county of Great Britain.

The world's hop crop of 1901, G. E. BALDWIN (*U. S. Consular Rpts., 67 (1901), No. 255, pp. 525, 526*).—Tabulated statistics.

Observations on agriculture and stock raising in Northern Mexico, T. VON NATHUSIUS (*Deut. Landw. Presse, 28 (1901) Nos. 87, pp. 727, 728, figs. 4; 90, pp. 751–753; 93, pp. 775, 776, figs. 2*).

Agricultural conditions in France, GRANZ (*Deut. Landw. Presse, 28 (1901), Nos. 73, pp. 615–617; 74, pp. 623, 624; 75, pp. 629, 630*).—A discussion from an economical point of view giving some statistics concerning the size of farms.

Agricultural industry, F. CONVERT (*L'industrie agricole. Paris: J. B. Baillière & Son, 1901, pp. 444*).—An inventory of the agricultural resources of France at the beginning of the twentieth century. It discusses climate, soil, population, cereal crops, potatoes, sugar beets, oil-yielding plants, fiber crops, hops, chicory, tobacco, the vine, the olive, and animal industry.

Portugal from an agricultural standpoint, B. C. C. DA COSTA and L. F. DE CASTRO (*Le Portugal au point de vue agricole. Lisbon: Government, 1900, pp. 965, pls. 72, figs. 140, maps 16*).—This extensive work on agriculture in Portugal was published by order of the Portuguese Commission to the Paris Exposition of 1900. The work is divided into 3 parts, treating of the soil, agricultural products, and rural life, respectively. Agriculture in the Azores and on the island of Madeira is included in the discussions.

Agriculture in Denmark, R. SCHOU (*L'agriculture en Danemark. Paris: Librairie agricole de la maison rustique, 1900, pp. 329+47+58, pls. 23*).—This work, prepared under the auspices of the Danish Commission to the Paris Exposition of 1900, discusses in a general way the different phases of Danish agriculture. The text is in Danish and French.

Agriculture in Finland at the close of the nineteenth century, G. GROTENFELT (*L'agriculture en Finlande vers la fin du 19 siècle. Helsingfors, 1900, pp. 131, pls. 13, maps 5*).

The management of an estate in Silesia, H. BÜTTNER (*Mitt. Landw. Inst. Univ. Breslau, 1 (1901), No. 5, pp. 53–187*).—An extensive article treating in detail of the management of a large estate. The article is intended as a contribution to the study of farm management and agricultural bookkeeping.

Agriculture in Japan (*L'agriculture au Japon. Paris: M. de Brunoff, 1900, pp. 117*).—This treatise on Japanese agriculture was published under the direction of the Imperial Commission of Japan to the Paris Exposition of 1900.

Agriculture in Indo-China, A. GREVERATH (*L'agriculture en Indo-Chine. Paris: Augustin Challamel, 1900, pp. 166, map 1*).—A planter's guide-book discussing briefly the agricultural regions of the country, the opportunities for colonizing and improving certain sections and the crops to be cultivated.

Farming in India, W. A. VINCENT (*Agr. Students' Gaz., n. ser., 10 (1901), No. 5, pp. 140, 141*).—A popular note on the condition of the Indian farmer.

Markets and marketing, D. TALLERMAN (*London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd., 1899, pp. VIII+108, pl. 1*).—This volume contains a number of papers describing methods by which the author believes farmers may more profitably market their products.

Successful farming; how to farm for profit, W. RENNIE, Sr. (*Toronto: Wm. Rennie's Sons, 1900, pp. 312, figs. 133*).

Catalogue of the periodicals and other serial publications in the Library of the U. S. Department of Agriculture, JOSEPHINE A. CLARK ET AL. (*U. S. Dept. Agr., Library Bul. 37, pp. 362*).—The catalogue includes the periodicals and other serial publications up to the end of the year 1900, exclusive of the publications of the United States Government and of the agricultural colleges and experiment stations.

Convention of Farmers' Institute Workers.—The American Association of Farmers' Institute Workers held a three-day session in Washington, D. C., June 24–26. About 70 members were present, including representatives from Canada and nearly all parts of the United States. Assistant Secretary J. H. Brigham, of this Department, delivered the address of welcome.

The annual address of the president of the Association, W. L. Amoss, dealt with the purposes of the convention, the improvement and possible unification of methods, and the general progress of farmers' institute work. Following his address five-minute reports by the different members were presented, showing the work of the various States and provinces during the preceding year along farmers' institute lines.

During one of the evening sessions of the association, Secretary Wilson delivered an address on the work of the U. S. Department of Agriculture and its relation to agricultural education, especially as calling attention to the need of it. Secretary Wilson insisted that agricultural education must begin with the child. He commended the plan observed in Missouri of summer meetings in which many teachers were given instruction in agriculture at the college.

W. J. Spillman spoke on The farmers' institute worker and his methods. One of the essentials of an institute worker is that he be practical. It is not necessary, however, that he be a worker on the farm. The best man to send out in the beginning is a scientific man who is practical. Ability is worth more than experience. In the discussion of this subject, Mr. G. McKerrow stated that in Wisconsin they wanted a man that stood high morally in the community and who stood out prominently as the best corn, potato, or clover grower, or the best breeder, dairyman, or all-around farmer. Wisconsin also required that its institute workers keep in close touch with the work of the experiment stations and of this Department. Extensive use is made in that State of charts showing good forms of farm animals, buildings, and appliances, and models of these when possible. More can be taught in a few minutes from an object lesson than from a long talk. Feeding and fertilizer charts are also used. Prizes are offered at many of the institutes for certain farm products and these judged and criticised in the presence of the audience. Hon. John Hamilton stated that in Pennsylvania their ideal corps of institute workers consisted of (1) a good all-around scientific and practical man, (2) a man who thoroughly understood the scientific side of agriculture, and (3) a successful practical farmer of high moral standing actually engaged in farming.

In presenting the subject of the farmers' institute as a factor in creating a desire for an agricultural education, Hon. John Hamilton, of Pennsylvania, stated that the need of such an institution must first be felt. Farmers' institutes can help in creating this desire by securing institute workers who are superior to the audience in the things they discuss. They must then present superior matter in a superior way. It was urged that abstracts of the latest bulletins should be read at farmers' institutes, and farmers encouraged to write for these publications. The great need of the present is to create a desire in the child for agricultural education.

Dr. E. B. Voorhees discussed the farmers' institute as a promoter of closer intimacy between farmers and experiment stations. He brought out the point that station work must be practical in order to inspire confidence in the farmer. Larger plats must be used—large enough to be called a crop. Station workers also often get ideas as to lines of work to follow at farmers' institutes.

Director A. C. True, of the Office of Experiment Stations, discussed the subject of the farmers' institute as a medium for developing the mutual interests and relations of farmers and the U. S. Department of Agriculture. Doctor True urged the necessity of a permanent organization in this Department whose purpose should be to work to secure a more thorough organization of the farmers' institutes in the States and Territories and of the present association of farmers' institute workers, so that it might become in a real and true sense international, and constitute a link between the Department and the farmers. Such an organization would act as a clearing house for the association. As it now is, only one meeting is held each year. An agency is needed in the Department to work all the time. Such an agency would be a cooperating one. It would collect and publish information along farmers' institute lines, both in this country and abroad, furnish institute workers regularly with literature, advise and assist institute workers by reason of its broader outlook, and endeavor to establish the work in States where it is not now carried on. Such an organization could send out lecturers to the round-up institutes. Work along the lines here indicated has already been begun in a small way. It is developing along the lines of the Office of Experiment Stations' work and is now being supervised by that Office.

The subject of agricultural teaching in the public schools was discussed by Prof. C. C. James and Dr. E. B. Voorhees. Instruction along agricultural lines should be given teachers in the normal school. This teaching should deal with the science and not the practice of agriculture. The normal school will train teachers in agriculture just as soon as there is a demand for such teachers. Farmers and farmers' organizations should, therefore, create this demand and then see that agriculture is placed on the programme of the rural school.

Other papers read and discussed at the meeting were Teaching of domestic science in the rural districts in Virginia, by Miss Breed, and Methods of teaching such subjects, by Miss Emma S. Jacobs; Livestock judging in Canada, by G. C. Creelman; and Farmers' institutes by the railroads, by M. T. Richards.

At the business session of the meeting, Prof. W. C. Latta was chosen president for the ensuing year and J. G. Lee vice-president. G. C. Creelman was reelected secretary-treasurer. It was decided to hold the next meeting in Toronto the last full week in June, 1903.

The Washington meeting was the largest ever held by the association, and counted one of the most profitable.

Miscellaneous.—The Summer School of Chemistry and Biology at Wesleyan University opened auspiciously early in July. Thirty-seven persons were enrolled for the course, most of them teachers. They came from four State universities, one medical school, a considerable number of colleges, technical schools, high schools, and other institutions.

The Bureau of Plant Industry of this Department will establish a wild garden of native shrubs, herbaceous plants, and annuals on the Monument grounds adjacent to the Department. These will be arranged for landscape effect rather than by orders, and, together with a collection of economic plants, which is to be established also, will constitute a modified form of the botanic garden. Prof. Charles F. Wheeler, of the Michigan Agricultural College and Experiment Station, has been appointed in the Bureau and will have charge of these economic gardens and collections. In addition to the above, Professor Wheeler will determine the distribution to be made of new kinds and varieties of seeds and plants introduced by the Bureau under the seed appropriation, and will work up some of the reports which have accumulated on the tests of these introduced plants at various places in the country.

The Dairy Division of this Department has recently had made under its supervision 200,000 lbs. of butter for the Navy Department. This butter is for the officers' use and is the year's supply. It was made largely from pasteurized cream, and was packed in 3-pound cans, without any preservative. The butter was made by a Kansas creamery. Butter similarly put up has kept well for a year and over, some cans recently opened being in good condition.

E. E. Faville, who for three years past has been superintendent of the National Farm School at Doylestown, Pa., has resigned his position.

We note from a recent number of *Science* that at the meeting of the Royal Society of Canada, Section of Geological and Biological Sciences, in the latter part of May, Dr. William Saunders, director of the Central Experimental Farm at Ottawa and of the four branch farms connected with it, gave an interesting illustration of the progress which is being made in introducing fruits and plants into the Northwest. A hardy Siberian apple, which bears a fruit little larger than an Ontario haw, has been crossed with the Ontario apple. The result was the production of a fruit about an inch in diameter. About 400 of these have been crossed, and last year there were 30 trees and this year there will be about 70 bearing fruit. The cross retains the hardiness of the Siberian apple, but the more it is crossed the nearer the product comes to the Ontario fruit. Results of experiments in crossing English and American currants and gooseberries, plums, and cherries with hardier varieties of these plants have not in all cases been successful, but enough has been accomplished to show that hardy varieties of Ontario fruits may be produced in the Canadian Northwest.

Through an oversight attention has not been called to the new scientific review devoted to dairy subjects, which was inaugurated late in 1901. The publication is a bimonthly of 24 pages, entitled *Revue générale du lait*. It is devoted exclusively to scientific works relating to milk and its products, and contains original articles as well as reviews. A classified bibliography is also given in each number. It is published at Brussels under the direction of M. Henseval, director of the dairy station at Gembloux; H. Weigmann, director of the dairy station at Kiel; and L. Gedoelst, professer in the veterinary school at Cureghem-Brussels, and with the collaboration of a number of prominent investigators, including H. W. Conn and H. L. Russell in this country. The numbers thus far received indicate it to be a high-grade journal which should prove of much value to specialists desiring to follow up the scientific contributions on milk and its products.

A novel publication, and one which marks a new departure in the literature of science, is the *Revue bibliographique des sciences naturelles pures et appliquées*, the initial number of which appeared in April. The purpose of the review is to give lists of the titles of papers published in the principal French, German, English, Italian, Swiss, and Spanish periodicals. The field covered is that of general biology, anatomy and physiology, zoology, botany, agriculture and the agronomic sciences, geology, mineralogy, and mining industry. The contents are arranged topically and by countries, and each number contains an index and a list of the periodicals reviewed. Comments on the character of many of the papers sufficient to give an idea of their scope are given by specialists. The review is published in the French language and will appear monthly. Judging from the first three numbers, agriculture and the sciences relating to it will receive a large amount of attention. This subject is subdivided into general articles and agronomy, arboriculture and horticulture, viticulture, zootechny, aviculture, apiculture, etc. The review should prove helpful in following up the current periodical literature, and as time goes by will become valuable as a means of looking up the fragmentary literature on any subject.

A new edition (the fifth) of Dr. Adolf Mayer's *Lehrbuch der Agrikulturchemie* is being issued, the first part, on the nutrition of plants, having been received. This work, which has become one of the classics in agricultural literature, was first published in 1870. The present edition, as indicated by the first part, is thoroughly revised and enlarged and brought up to date. One fault of the previous editions has been the lack of an index, which even the quite full table of contents does not take the place of in so large a work. The present edition, unfortunately, is open to the same objection.

BULLETINS OF THE OFFICE OF EXPERIMENT STATIONS.

Experiment Station Record, Vols. I–XII, with indexes. Vol. XIII, Nos. 1–8.

Bulletins.—No. 1, Organization and History of the Stations, No. 2, Digest of Annual Reports of the Stations for 1888, in two parts; No. 3, Report of Meeting of Horticulturists, 1889; No. 4, List of Station Horticulturists; No. 6, List of Station Botanists; No. 8, Lectures on Investigations at Rothamsted Experimental Station; No. 9, The Fermentations of Milk; No. 10, Meteorological Work for Agricultural Institutions; No. 11, A Compilation of Analyses of American Feeding Stuffs; No. 14, Proceedings of Convention of National League for Good Roads, 1893; No. 15, Handbook of Experiment Station Work; No. 17, Suggestions for the Establishment of Food Laboratories; No. 18, Assimilation of Free Atmospheric Nitrogen by White and Black Mustard; No. 21, Methods and Results of Investigations on the Chemistry and Economy of Food, No. 22, Agricultural Investigations at Rothamsted, England; No. 25, Dairy Bacteriology; No. 26, Agricultural Experiment Stations: Their Objects and Work; No. 28, The Chemical Composition of American Food Materials; No. 29, Dietary Studies at the University of Tennessee in 1895; No. 31, Dietary Studies at the University of Missouri in 1895; No. 32, Dietary Studies at Purdue University in 1895; No. 33, The Cotton Plant; No. 34, The Carbohydrates of Wheat, Maize, Flour, and Bread; No. 35, Food and Nutrition Investigations in New Jersey in 1895 and 1896; No. 36, Notes on Irrigation in Connecticut and New Jersey; No. 37, Dietary Studies at the Maine State College in 1895; No. 38, Dietary Studies of the Negro in Alabama, 1895 and 1896; No. 40, Dietary Studies in New Mexico in 1895; No. 42, Cotton Culture in Egypt; No. 43, Losses in Boiling Vegetables, and the Composition and Digestibility of Potatoes and Eggs; No. 44, Investigations on the Metabolism of Nitrogen and Carbon in the Human Organism; No. 45, A Digest of Metabolism Experiments; No. 46, Dietary Studies in New York City in 1895 and 1896; Nos. 48, 62, 82, and 94, Reports to Congress on Agriculture in Alaska; No. 52, Nutrition Investigations in Pittsburg, Pa., 1894–1896; No. 53, Nutrition Investigations at the University of Tennessee in 1896 and 1897; No. 54, Nutrition Investigations in New Mexico in 1897; No. 55, Dietary Studies in Chicago in 1895 and 1896; No. 56, History and Present Status of Instruction in Cooking in the Public Schools of New York City; No. 57, Varieties of Corn; No. 58, Water Rights on the Missouri River and its Tributaries; No. 60, Abstract of Laws for Acquiring Titles to Water from the Missouri River and its Tributaries, with the Legal Forms in Use; No. 63, Description of a New Respiration Calorimeter and Experiments on the Conservation of Energy in the Human Body; No. 66, The Physiological Effect of Creatin and Creatinin and their Value as Nutrients; No. 67, Studies on Bread and Bread Making; No. 68, A Description of Some Chinese Vegetable Food Materials and their Nutritive and Economic Value; No. 69, Experiments on the Metabolism of Matter and Energy in the Human Body; No. 70, Water-Right Problems of Bear River; No. 71, Dietary Studies of Negroes in Eastern Virginia in 1897 and 1898; No. 72, Farmers' Reading Courses; No. 73, Irrigation in the Rocky Mountain States; No. 75, Dietary Studies of University Boat Crews; No. 77, The Digestibility of American Feeding Stuffs; No. 79, Farmers' Institutes: History and Status in the United States and Canada; No. 80, The Agricultural Experiment Stations in the United States; No. 81, The Use of Water in Irrigation in Wyoming and its Relation to the Ownership and Distribution of the Natural Supply; No. 84, Nutrition Investigations at the California Agricultural Experiment Station, 1896–1898; No. 85, A Report of Investigations on the Digestibility and Nutritive Value of Bread; No. 86, The Use of Water in Irrigation; No. 87, Irrigation in New Jersey; No. 89, Experiments on the Effect of Muscular Work upon the Digestibility of Food and the Metabolism of Nitrogen, Conducted at the University of Tennessee, 1897–1899; No. 90, Irrigation in Hawaii; No. 91, Nutrition Investigations at the University of Illinois, North Dakota Agricultural College, and Lake Erie College, Ohio, 1896–1900; No. 92, The Reservoir System of the Cache la Poudre Valley; No. 95, Report on the Agricultural Resources and Capabilities of Hawaii; No. 96, Irrigation Laws of the Northwest Territories of Canada and of Wyoming; No. 98, The Effect of Severe and Prolonged Muscular Work on Food Consumption, Digestion, and Metabolism, and the Mechanical Work and Efficiency of Bicyclers; No. 100, Report of Irrigation Investigations in California; No. 101, Studies on Bread and Bread Making at the University of Minnesota in 1899 and 1900; No. 102, Experiments on Losses in Cooking Meat, 1898–1900; No. 103, The Evolution of Reaping Machines; No. 104, Report of Irrigation Investigations for 1900; No. 105, Irrigation in the United States; No. 106, Results of Investigations on the Rothamsted Soils; No. 107, Nutrition Investigations among Fruitarians and Chinese at the California Agricultural Experiment Station, 1899–1901; No. 108, Irrigation Practice Among Fruit Growers on the Pacific Coast; No. 109, Experiments on the Metabolism of Matter and Energy in the Human Body, 1898–1900; No. 110, Proceedings of the Sixth Annual Meeting of the Association of Farmers' Institute Workers; Nos. 5, 12, 13, 19, 23, 27, 39, 47, 59, 74, 88, and 111, Organization Lists of Stations and Colleges, 1890, 1892, 1893, 1894, 1895, 1896, 1897, 1898, 1899, 1900, 1901, and 1902; Nos. 7, 16, 20, 24, 30, 41, 49, 65, 76, and 99, Proceedings of Association of Colleges and Stations, 1891, 1892, 1893, 1894, 1895, 1896, 1897, 1898, 1899, and 1900; Nos. 50, 61, 83, and 93, Reports on the Work and Expenditures of the Agricultural Experiment Stations, 1897, 1898, 1899, and 1900;
