EXPERIMENT STATION RECORD.

Vol. XIII. No. 1.

The loss of domestic animals from poisonous plants has long been recognized as a more or less serious obstacle to stock raisers, especially in the Rocky Mountain and Pacific coast regions. In the more thickly settled regions of the Eastern States the land is more extensively cultivated, and there are comparatively few areas left in their natural condition and covered with native vegetation. Under such circumstances the existence of poisonous plants in large areas is practically impossible. On the Western cattle ranges, however, cattle, sheep, and horses depend almost exclusively for their sustenance upon the native forage of the country, which includes a number of plants which have been found to be poisonous when eaten in large quantities.

A great difference of opinion has prevailed with reference to the identity of the plants which are responsible for stock poisoning and as to the best antidotes or remedies to be applied in actual cases of poisoning. Considerable work along these lines has been done by the Washington, Oregon, Colorado, South Dakota, and Montana stations, and during the season of 1900 an investigation of the poisonous plants of Montana was undertaken by the Division of Botany of this Department. The experiments conducted during this investigation, in the field and in the laboratory, established the poisonous nature of a number of common plants and indicated a convenient and effective remedy in most cases.

The problem of plant poisoning in a State like Montana is perhaps as important as any connected with stock raising, and has been only partially solved. A number of interesting and highly important lines of work remain for investigation by veterinarians and botanists of States which are most affected by plant poisoning. Among these may be mentioned a determination of the poisonous or nonpoisonous character of a considerable number of native plants which have been suspected of being poisonous by stockmen; experiments in the eradication of these plants by irrigation, displacement by means of aggressive forage plants, or other methods which may be practically applied with some hope of success under the local conditions which prevail in different cases; experiments on the nature and cause of "loco" disease; experiments on the exact localization of the poisonous principles contained in lupines and the time when these substances are most active; and experiments in perfecting simple and effective antidotes.

The investigations which were made during the season of 1900 indicated clearly that a considerable proportion of the loss by poisonous plants might easily be avoided by a more general diffusion of the knowledge which already exists concerning such plants. In general, however, stock could not at present be managed on any fixed basis with reference to poisonous plants, on account of the great difference of opinion which prevails not only among stockmen, but among veterinarians and botanists, as to the poisonous nature of particular species and as to the time of year when they are most dangerous. Further investigations along this line will probably show that many of the plants which at present are suspected of being poisonous are quite harmless, and that a few species of plants are responsible for nearly all of the serious stock poisoning.

In order to determine the poisonous or nonpoisonous character of a given plant, it is not sufficient to obtain positive or negative results from a few experiments on rabbits or guinea pigs. As is well known, rabbits are easily excited, and many peculiarities of their actions after being fed with extracts from plants are due to the fright or nervous excitement of the operation. Carefully controlled feeding experiments, either with extracts from poisonous plants or with the plants themselves, on sheep or cattle, and conducted under conditions as similar as possible to natural field conditions, should yield results which will be much more convincing to the practical stockman and to other investigators of this subject. In a sheep-raising region the animals necessary for such experiments are readily furnished by sheepmen, and feeding experiments, as well as experiments with remedies, could be conducted upon sheep at the same time that cases of poisoning occur under natural conditions, and therefore with plants in the stage of growth in which they are eaten by sheep or cattle on the ranges. Many feeding experiments with poisonous plants are open to the criticism that they were made with suspected plants in a different stage of growth from those which were eaten by the poisoned animals.

In future experiments with poisonous plants it would be well to bear in mind that the active principles of such plants may vary exceedingly in different stages of growth of the plant, and even during different hours of the day. The possibility of a plant being poisonous at one time and not at another must constantly be reckoned with if experiments with these plants are to yield conclusions which will be established beyond criticism.

Experiments during the season of 1900 showed pretty conclusively that potassium permanganate, if administered soon after the symptoms of poisoning develop, may be depended upon, as a rule, to oxidize and destroy the plant alkaloids contained in the stomach and to prevent the progress of the symptoms of poisoning. This substance was administered by direct injection through the body wall or by drench. Further experiments on a larger scale with potassium permanganate should be undertaken, for the purpose of determining the best method of applying it and the actual plant alkaloids toward which it is most destructive.

The account of the Hungarian experiment stations given in the present issue will be of interest to students of the experiment station systems of different countries, and will serve to show how well organized and efficient a system has been worked out for the benefit of the agriculture of Hungary. We are indebted for this account to Dr. Peter Fireman, who recently visited a number of the stations in that country, and to the kind assistance of Mr. Alajos Paikert, royal Hungarian commissioner, who represents the agricultural interests of his country in the United States.

Although still in their infancy, the Hungarian stations have become a recognized power for the promotion of agriculture and the improvement of agricultural practice in that country. The first station for plant culture was established less than ten years ago, and up to 1898 confined itself to conducting practical experiments in cooperation with farmers; and the plant-culture stations since established have been in operation only two or three years. The laboratories are not elaborate in their equipment, and have not made original research a prominent feature of their work. But the stations are, to a greater extent than those of most other European countries, on a practical basis, and are working in the direct interest of the farmers. Their aim has evidently been to promote the interests of agriculture in all proper ways, to assist the farmer in procuring pure seed and fertilizers and the best varieties of plants, and to work out better methods of practice. They are reported to have been successful in reaching the farming population and winning their confidence in a quite remarkable degree. In spite of the natural conservatism of the farmers in so old a country, they have not failed to profit by the teachings of the stations, and are putting the results of their work into practice. In their aims and tendencies and their relations to the practical agriculturists, Mr. Paikert declares that the Hungarian stations resemble those of the United States more closely than any other country.

Incidentally the Hungarian stations are carrying on an increasing amount of work which is of interest to investigators at large. The accounts of their work are published for the most part in the official organ of the stations (*Kisérletügyi Közlemények*), and the fact that this is printed only in the language of the country, and does not appear to be reviewed regularly by any German or French periodical, has caused much of their work to be lost sight of. It has been our desire to include reviews of the Hungarian work in the Record, but considerable difficulty has been experienced in obtaining the services of a translator competent to review the more or less technical articles. Arrangements have now been made, however, by which, it is hoped, the principal articles of general interest in the official publication may be noted in brief in these columns.

AGRICULTURAL EXPERIMENT STATIONS OF HUNGARY.

There are in Hungary 5 experiment stations corresponding to those in this country, each containing departments for agricultural chemistry and seed control, and often others. These stations are located at Altenburg (Magyar-Óvár), Debreczen, Kaschau (Kassa), Keszthely, and Klausenburg (Kolozsvár). Besides these there are the Central Chemical Experiment Station, the Station for Animal Physiology and Feeding, the Entomological Station, and the Seed-Control Station, each having only a single department, and all located at Budapest, the Station for Vegetable Physiology and Pathology at Altenburg, and the Chemical Station at Pressburg (Pozsony).

The different departments of the 5 stations mentioned first are each organized as separate institutions and are designated in the Hungarian official publications as individual stations, each with its own director. On this basis there are in Hungary 8 agricultural chemical stations, 6 seed-control stations, 1 entomological station, 1 plant-culture station, 1 station for vegetable physiology and pathology, 1 for tobacco culture, 1 for animal physiology and feeding, and 2 for agricultural machines, or 21 in all.

The experiment stations in Hungary are government institutions. Most of them are designed to promote the advancement of the agriculture of the country, mainly by practical experiments but also by original research, and to give advice to the farmers on various agricultural questions. In addition, the chemical and seed-control stations are called upon to examine agricultural supplies and agricultural products. The Central Commission of Experiment Stations exercises a directing and supervisory power over the individual stations, and acts as the representative of the Minister of Agriculture in matters relating to the organization and work of the stations. The commission consists of a president, secretary, and about a dozen permanent members, all appointed by the Minister of Agriculture. In this commission each branch of experiment station work is represented by a station director, the remaining members being prominent specialists in particular branches of agriculture. Since its creation in 1898 the commission has published a journal, *Kisérletügyi Közlemények*, embodying the reports of the work of the various stations.

CHEMICAL STATIONS.

All the chemical stations are charged with the examination of agricultural and other industrial products, both for the Government and private persons. Of the 8 stations, those at Pressburg, Klausenburg, and Fiume are occupied exclusively with control work, while the other 5 conduct scientific investigations along diverse lines pertaining to agriculture in addition to their control work. Of the latter the one at Budapest, designated as the Institute of the Hungarian Kingdom and Central Chemical Experiment Station, differs from the others in having a much larger staff of workers, a considerably wider field of action, and additional duties as an advisory agency to the Minister of Agriculture. All of the chemical stations except the Central chemical station at Budapest are intimately connected with educational (mostly agricultural) institutions, the professor of chemistry being the director of the station in all cases.

Chemical Experiment Station at Budapest.—This station was established in 1881 in connection with the Veterinary Institute, the professor of chemistry being the director of the station and performing all the work. As the work increased assistants were added, and in 1887 the station became independent of any educational institution, and is now located in the department building. Its present organization dates from 1892. The staff consists of a director, Dr. L. Liebermann, 2 chemists, 7 assistant chemists, including 3 agricultural chemists, and a number of laboratory helpers.

In addition to the analytical work growing out of the control and inspection duties in executing the law against falsification of agricultural and other industrial products the station examines the foreign wines subject to duty, as well as the wines destined for export; it examines the purity of sugars which receive the export bounty, and furnishes expert information to the Government on chemical questions relating to commerce, finance, and customs. The following table shows the number and kinds of materials analyzed by the station during the ten years from 1889 to 1899:

Food articles and spices	10,784
Other examinations in the interest of hygiene or ordered by the tribunals	381
Must of raisins and wine	7,693
Other alcoholic beverages and alcohol (beer, brandy, liquors, champagne, etc.)	931
Feeding stuffs	984
Soils and fertilizers	5,930
Agricultural plants	728
Products of agricultural industries (sugar, starch, dextrin, yeast, etc.)	12,122
Water analyses for hygienic and industrial purposes	2,139
Industrial and mining products	3,069
Lighting and heating materials	628
Expert opinions and miscellaneous examinations	4,737

The scientific activity of the station covers a large number of lines. Much attention is given to the elaboration of new methods of chemical analysis and to the testing of methods recommended by others. The methods adopted by the station become official in the sense that they must be employed by all the other chemical stations. The staff of the station has elaborated and published new methods for the analysis of milk, wine, whisky, meat, red pepper (paprika), soils, feeding stuffs, fertilizers, petroleum, lubricating oils, crude carbolic acid, caoutchouc, dextrin, and other materials. Numerous analyses of agricultural plants and feeding stuffs cultivated in Hungary, and of factory refuse materials which can be employed as feeding stuffs have been made and the results published. The station has, by a large number of analyses, ascertained the composition of the musts and wines of Hungary. It has examined the lime contents of the soil in many localities, and by a method elaborated by itself it has examined a large part of the sandy areas of Hungary which are suited to the cultivation of grapes, and established the fact of the immunity of these areas from the phylloxera. It has also devoted much attention to researches relating to physiological chemistry; a number of articles have been published on embryo-chemistry, on the determination of nucleins and the acid which they contain, on the chemistry of yeast cells, the formation of gastric juice, the secretion of urine, iodized starch, the so-called animal caoutchouc, etc.

Chemical Station at Altenburg.—This is the oldest station in Hungary, having begun its activity in 1873, and is next in importance to the Institute of Chemistry at Budapest. It is connected with the Agricultural Academy at Altenburg. The staff of the station consists of a director (now Prof. T. Kosutány) and three assistants. In the course of its existence it has made a thorough study of the chemistry of wine and of the methods of wine examination; has carried out a series of investigations relating to yeasts and their influence on fermentation; it has made contributions on the question of the formation of vegetable albumen, studying among other things the influences which affect the biological functions of plants. It has also conducted extensive and thorough researches with reference to the development and chemical composition of tobacco, and has published valuable works on the chemistry of certain agricultural plants, on oil cakes, and on the process employed in Hungary in the production of oils. Much attention has been given to the examination of fertilizers and soils.

Chemical Station at Kaschau.—This station was established in 1884 as a department of the Agricultural Institute at Kaschau. The scientific work of the station is mainly devoted to investigations in its experimental distillery, installed for that purpose. The staff consists of a chief and one assistant.

Chemical Station at Keszthely.—This was founded in 1889, and is immediately connected with the agricultural institute of that town.

The researches of this station relate to the plants cultivated in Hungary, their physiology, and need for fertilizers. The chief performs all the work of the station.

Chemical Station at Debreczen.—This was established in 1894, and is attached to the Agricultural Institute of Debreczen. The original investigations of the station relate to the composition of Hungarian flours, and to the methods of examining tobacco. The staff consists of the chief and one assistant.

Chemical Station at Klausenburg.—This station was founded in 1887 as a department of the university at Klausenburg. It is almost exclusively occupied with control work. The staff consists of the chief alone, who is occasionally assisted by the laboratory instructors of the university.

Chemical Station at Pressburg.—This was established in 1883 in connection with the Technical High School of Pressburg. It performs only control duties. The staff consists of the chief alone.

Chemical Station at Fiume.—This was established in 1900, especially for analysis of wines and other products imported through this seaport.

An indication of the activity of the control stations is furnished by the following table, showing the number of analyses made by several of them during the eight years from 1890–1897:

Number of analyses made by Hungarian control stations, 1890–1897.

Station.	1890.	1891.	1892.	1893.	1894.	1895.	1896.	1897.
Altenburg	126	266	107	182	425	277	215	699
Kaschau	139	72	66	53	80	167	98	397
Keszthely	293	218	235	125	229	175	85	118
Debreczen	....	....	....	....	....	....	412	702
Klausenburg	83	82	280	1,319	1,466	1,955	1,105	2,330

SEED-CONTROL STATIONS.

The beginning of seed testing in Hungary dates from 1871, the tests being made by the Agricultural Institute at Debreczen. In 1878 a special laboratory for seed testing was fitted up at the Agricultural Academy at Altenburg, and in 1882 a seed-control station was founded at Budapest in connection with the Veterinary Institute, which was made entirely independent in 1891. In 1884 similar institutions were established at Kaschau, Debreczen, Keszthely, and Klausenburg. The work of the seed-control stations received a great impetus in 1892 upon the enactment of a law prohibiting the sale of clover or alfalfa seed not entirely free from cuscuta (dodder), under penalty of a maximum fine of 200 crowns (1 crown = 20.3 cents); and again in 1895, when a new law was enacted against the adulteration or misbranding of food articles, providing heavier penalties.

It is the business of the seed-control stations, in the first place, to do all the seed testing required to safeguard the interests of the farmers, horticulturists and sylviculturists in the sense of the above laws, and, besides, to make experimental studies relating to the formation, maturity, germination, and germinative ability of seeds, to determine the noxious weeds of the country and their seeds; to disseminate information regarding protection against weeds and plant parasites, and regarding good apparatus and machines for purifying seeds; and to make botanical analyses of different kinds of hay and other feeding stuffs.

All the Hungarian seed-control stations, except the one at Budapest, are attached to agricultural institutes. The permanent staff of the station at Budapest, which is now known as the Central Seed-Control Institution, consists of the director (now Dr. Árpád de Degen), 3 assistants, 1 microscopist, and 4 helpers; to these are added in the winter 6 aids and 2 boys. The personnel of the other stations is limited to the director, who is professor of botany in the agricultual institute with which the station is connected.

Each station possesses a standard collection of the seeds of cultivated plants and weeds, a library, analytical and volumetric balances, a set of optical instruments, thermostats, farinometer, and a collection of feeding stuffs.

The number of samples of seeds tested has increased from 62 in 1881, to 32,487 in 1898, and is steadily growing. By far the largest number are tested at the Central Institution at Budapest.

The rules and regulations prescribed by the Minister of Agriculture for seed testing are practically identical with those adopted by the German Seed-Control Commission. The tariff for seed tests varies from 1 crown (20.3 cents) for single tests to 8 crowns for a complete analysis of sugar-beet seed.

As the sale in Hungary of clover or alfalfa seed which is not free from cuscuta is prohibited, merchants are required to keep the seed of these plants in bags provided by the stations, with tags showing their purity. The tags are also furnished to merchants, on application, for use on other seeds, provided they come up to the following prescribed standards of purity and germinative ability:

Hungarian standards for seeds.

	Purity.	Germinative ability.		Purity.	Germinative ability.

EXPERIMENT STATION FOR AGRICULTURAL MACHINES AT ALTENBURG.

This station was established in 1869 in connection with the Agricultural Academy at Altenburg. Its object is to test newly invented agricultural machines and implements, or those already in use, from both the theoretical and practical points of view, to determine their fitness for the operations for which they are designed. The station examines all machines and implements referred to it by the Minister of Agriculture, or submitted by agricultural associations or private parties. It is further the business of the station to supply to the agricultural population as complete and detailed information as possible on all questions relating to agricultural machines in actual use. From 1870 to the present year (1900), the station has tested 241 machines. The duties of the director of the station devolve upon the professor of agricultural-mechanical engineering, now Prof. V. Thallmayer.

Another experiment station for agricultural implements is located at Budapest in connection with the Polytechnicum.

PLANT CULTURE EXPERIMENT STATION AT ALTENBURG.

This station is the only one in Hungary primarily designed for general culture experiments. It was established in 1891 as a department of the Agricultural Academy. Its work was at first limited to variety testing, but in 1895 fertilizer experiments were undertaken. Up to 1897 the work of the station was exclusively practical in its nature, but in that year it received an appropriation for the installation of pot culture experiments, and since the spring of 1899 it has been able to take up the investigation of a number of scientific agricultural problems.

In accordance with the practical and theoretical objects which the station pursues it is divided into two sections. One is charged with the direction of experiments carried out with the cooperation of farmers, while the other is occupied with experimental investigations. The staff of the station consists of the chief, Prof. A. Cserháti, three assistants, and a chemist.

In the experiments carried out with the cooperation of farmers the latter receive the seeds and fertilizers free of charge, and in return conduct the experiments and keep records of them in accordance with instructions from the station. In 1899 495 variety tests and 100 fertilizer experiments were carried out in cooperation with farmers.

The fertilizer experiments have shown that the Hungarian soils are mostly in need of phosphoric acid, whose application alone materially increases the yield.

The station has been successful in its endeavors to introduce the culture of sugar beets into Hungary. It has demonstrated that, contrary to the general opinion, the seed raised in Hungary is in no respect inferior to that raised abroad, and it has induced many farmers to take up the growing of beet seed.

EXPERIMENT STATION FOR TOBACCO CULTURE AT DEBRECZEN.

In contrast with the rather modest equipment of other Hungarian stations of a much wider scope, the tobacco station is generously appointed. It was founded in 1898. Its object is to promote the tobacco industry of Hungary, ascertain the best conditions for the cultivation and the most suitable methods for curing the plant, to aid tobacco growers in the selection of varieties and in the raising of tobacco seed, and to contribute to the improvement of the quality of the leaf. The station is further charged with the training of workmen and officials for the administration of the government tobacco monopoly, and with supplying the tobacco growers with information and instructions as to rational culture.

In order to conduct the experiments simultaneously on the two most typical Hungarian soils, a substation (branch station) has been established at Békés-Csaba, which is under the control of the station at Debreczen. The soil in the latter place is sandy, while that at the substation is black and compact. It is planned to increase the number of substations in the future. Many experiments are also carried out with the cooperation of tobacco growers.

The station occupies about 29 acres of land belonging to the estate of the Agricultural Institute of Debreczen. Of this area the buildings occupy about 7 acres, the hotbeds 1.4 acres, the botanical garden 2.9 acres, a culture garden (for experiments on a small scale) 2.9 acres, and the field for culture experiments on a larger scale about 14.5 acres. The substation at Békés-Csaba has about 9 acres.

The central station has at present a main building with a laboratory, buildings for gardeners (6 separate cabins), 7 curing barns, 4 of which are of the various Hungarian systems, 1 of a Dutch, 1 of a German, and 1 of an American type; appliances for the Macedonian air-cure process, 2 storage houses, and 1 building for sorting and handling the leaves. In the near future a building for fermentation will be added, and later a school building designed for training gardeners in the cultivation of tobacco, and tobacco manipulators.

The botanical garden presents on small plats 209 different varieties of tobacco, the aim being to include every kind of tobacco cultivated on the globe.

The personnel of the station consists of the director (Prof. K. Kérpely), 3 other officers, 1 foreman, and 4 gardeners.

ENTOMOLOGICAL STATION AT BUDAPEST.

The entomological station began its activity as the "Phylloxera Station," which was called into existence in 1880 to combat the phylloxera. When toward the end of 1899 the entomological study of the phylloxera was practically concluded and it became evident that protection against the insect was more a question of general viticulture, the phylloxera station was reorganized into an entomological station.

The station is concerned, in the first place, with the common injurious insects which are most prevalent. The life histories of these are studied and experiments conducted to ascertain the surest and cheapest means for their destruction.

Work is also conducted on the repression of injurious mammals, such as the *Arvicola* and the *Spalax typhlus*. Furthermore, when a new injurious insect suddenly appears which requires prompt action to prevent serious ravages, the director of the station is authorized to take the necessary steps promptly without waiting to obtain permission from the higher authorities before he acts, as is otherwise the case. Measures of this kind have been required in the case of outbreaks of the following insects: *Haplothrips*, *Tychea*, *Entomoscelis adonidis*, *Cleonus punctiventris*, *Zabrus gibbus*, *Heliothis dipsaceus*, *Botis nubitatus*, *Argas reflexus*, *Cecidomyia destructor*, *Oscinis frit*, *Chlorops tæniopus*, *Chortophila sepia*, *Cheimatobia crenata*, *Phryganidæ*, *Gryllotalpa vulgaris*, *Tipula maculosa*.

Another duty of the station consists in supplying to all persons interested information on all matters relating to protection against injurious insects. In order to disseminate information on this subject the station publishes popular bulletins from time to time.

The personnel of the station consists of the director (Prof. J. Jablonovszky), assistant director, and 3 assistant entomologists. The work of the station is made more effective by the services of permanent correspondents located in different parts of the country who report all cases of injuries coming under their notice, and also assist in disseminating practical information regarding their control. These correspondents are mostly farmers or agriculturists interested in economic entomology, who serve voluntarily and without compensation. In the case of the government forest agents, however, the duties of permanent correspondents are obligatory.

STATION FOR PLANT PHYSIOLOGY AND PATHOLOGY AT ALTENBURG.

This station was organized in 1897 by the chief of the Seed Control Station at Altenburg, and the two stations together have received the official name of Public Station for Seed Control and Plant Physiology and Pathology. Both stations are under the management of Prof. G. Linhart, as director, who is professor of botany in the agricultural academy.

The chief object of the Station for Plant Physiology and Pathology is the study of all questions relating to nutrition, growth, and propagation of cultivated plants, the breeding of high-grade sugar beets, the effect of unfavorable conditions of life on plants, the origin of parasitic fungi and the injuries which they cause to cultivated plants, the control of outbreaks of these injurious diseases, and the measures likely to prevent their attacks. Lastly, it is the duty of the station to supply to parties interested full information on this subject free of charge.

The station examines diseased plants sent in by agriculturists, horticulturists, viticulturists, and sylviculturists, furnishes a description of the disease and gives instructions for defense against it. The station also conducts investigations on the nature and cause of plant diseases, its researches on the bacterial disease of sugar beets being worthy of special mention.

The buildings of the station are situated in a garden occupying 7,500 square meters (nearly 2 acres), of which 4,800 meters are available for experiments. The main building includes, besides a working office of the director and a large room for the examination of seeds, etc., mycological and bacteriological laboratories. The station has a greenhouse for germination experiments, collections of diseased plants and seeds, photographic apparatus, etc.

The staff consists of the director and one assistant, temporary helpers being employed as necessary.

STATION FOR ANIMAL PHYSIOLOGY AND FEEDING AT BUDAPEST.

This station, which was established in 1896, pursues the study of the rational feeding of domestic animals, giving special attention to the local conditions, i. e., to the animals raised in Hungary and to the feeding stuffs there cultivated or manufactured. The station has stables for the animals used in the experiments and a laboratory. The stables are provided with scales for weighing the animals, and the laboratory is equipped with everything necessary for the analysis of feeding stuffs, feces, and urine. The chemical analysis is accompanied by determination of the fuel value by means of a Berthelot-Mahler calorimeter.

Experiments thus far have been made with horses, swine, sheep, and poultry. The personnel consists of the director, Prof. F. Tangl, who is professor of physiology in the Veterinary Institute, and 2 assistants.

It will be seen that Hungary has a comprehensive system of experiment stations, which are rendering efficient service to the agriculture of the country. In addition to these stations an agricultural museum is maintained at Budapest, somewhat on the plan of the Philadelphia Commercial Museum, but managed by the Government. This museum is for the convenience of purchasers of various kinds of agricultural supplies, and includes collections of photographs, implements, samples, etc.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The determination of phosphoric acid in fertilizers, soils, and ash by direct weighing of the ammonium phosphomolybdate, N. von Lorenz (*Landw. Vers. Stat., 55 (1901), No. 3, pp. 183–220*).—Previous methods based on this principle are briefly discussed and the method proposed by the author described in detail, with an account of investigations of the principles on which it rests and tests of its operation in laboratory work. The reagents required are as follows: (1) Sulphate-molybdic solution, prepared by dissolving 100 gm. of pure, dry ammonium sulphate in 1 liter of nitric acid, specific gravity 1.36 at 15° C., and pouring into it a solution of 300 gm. of pure, dry ammonium molybdate in 1 liter of water, the volume being made up to 2 liters, allowed to stand 48 hours, and filtered; (2) nitric acid of specific gravity 1.2 at 15° C.; (3) a mixture containing 30 cc. of sulphuric acid of specific gravity 1.84 in 1 liter of nitric acid of specific gravity 1.2; (4) a 2 per cent solution of pure ammonium nitrate rendered slightly acid by a few drops of nitric acid; (5) alcohol of 90 to 95 volume per cent which leaves no residue on evaporation and is not alkaline; (6) ether which leaves no residue on evaporation, is alcohol-free, not alkaline, and contains little water. Solutions of the substances to be examined are prepared as follows: In case of water-soluble phosphoric acid in superphosphates, dissolve 20 gm. in 1 liter of water and use 10 cc. for the determination. With double superphosphates use 10 gm. per liter and 10 cc. of the solution for the determination. For the determination of citrate-soluble phosphoric acid in Thomas slag, prepare the solution according to Wagner's method and use 15 cc. of the solution for the determination of phosphoric acid; in case of superphosphates, precipitated phosphates, etc., follow Petermann's method, using 10 cc. of the solution for the determination. For citric-acid-soluble phosphoric acid in Thomas slag, prepare the solution according to Wagner's method and use 15 cc. for the determination. For total phosphoric acid in superphosphates and Thomas slag, dissolve 5 gm. in 35 cc. of concentrated sulphuric acid without addition of nitric acid, or in 100 cc. of nitric acid, make up the solution to 500 cc. and use 15 cc. for the determination. In case of bone meal, spodium, mineral phosphate, precipitated phosphate, double superphosphate, guano, and all other substances containing more than 10 per cent of phosphoric acid, dissolve 5 gm. in 50 cc. of concentrated sulphuric acid, or in 100 cc. of nitric acid, make the solution to 500 cc., and use 10 cc. for the determination. With ground horn and other fertilizers containing less than 10 per cent of total phosphoric acid, dissolve 10 gm. of the substance in 50 cc. of sulphuric acid, or 100 cc. of nitric acid, making the solution to 500 cc., and using 15 cc. for the determination. For soils and other substances with less than 1 per cent of total phosphoric acid, treat 25 gm. with not more than 200 cc. of nitric acid, then add about 200 cc. of water, cool, and add 10 cc. of concentrated sulphuric acid, make the volume to 500 cc., and use 50 cc. for the determination. If the solution is made with sulphuric acid the aliquot taken for the determination is made to a volume of 50 cc. with nitric acid of specific gravity 1.2. In all other cases, including water-soluble, citrate-soluble, citric-acid-soluble phosphoric acid, as well as solutions in nitric acid for total phosphoric acid, the volume is made up to 50 cc. by the addition of the sulphuric-nitric acid mixture described above. In case of soil solutions no further addition of acid is made.

The 50 cc. of phosphoric acid solution is heated until bubbles of gas begin to form, swung a few seconds so that the sides of the beaker are not overheated, and 50 cc. of the sulphate-molybdic solution is poured into the middle of the solution and the beaker covered. As soon as the larger part of the precipitate has settled, which usually requires not more than 5 minutes, the solution is vigorously stirred for half a minute with a glass rod. After 2 to 18 hours, the longer period being required for soil solutions containing less than 3 mg. of phosphoric acid, the solution is rapidly filtered through a platinum Gooch crucible according to the Kilgore method, using paper disks, and the precipitate washed about 4 times with 2 per cent ammonium nitrate solution. The crucible is then filled once full and twice about half full with alcohol, care being taken each time not to allow the alcohol to be entirely drawn out of the filter before a fresh supply is added. The precipitate is then treated in the same way with ether, the precaution noted in connection with the alcohol washing being especially important in this case, as the precipitate dries so quickly and is in form of such fine powder that it may be drawn through the filter. The precipitate is dried for 30 minutes in a vacuum desiccator containing no absorbents and weighed. The ammonium phosphomolybdate obtained by this method contains 3.295 per cent of phosphoric acid.

The results obtained by the method were found to agree very closely with those given by Wagner's molybdic method, but were uniformly somewhat lower than those yielded by Reitmair's citrate method.

The determination of clay in soils, A. Pagnoul (*Ann. Agron., 27 (1901), No. 2, pp. 94–96; Bul. Sta. Agron. Pas de Calais, 1900, pp. 1–4*).—The author describes a modification of Schloesing's method, which he has used with success, as follows: To an amount of the sifted soil, corresponding to 5 gm. of dry soil, in a small dish add a small portion of a solution of 1 cc. of ammonia in 100 cc. of distilled water, rub up the soil against the sides of the dish with the finger, and pour off the liquid after standing 10 to 15 seconds. Repeat this operation three times and collect the soil and the washings in a second dish and boil for 2 or 3 minutes. After cooling, add 1 cc. more of ammonia, and wash the soil and solution into a 100 cc. cylinder having a side tube with stopcock at the 20 cc. mark (from the base), complete the volume to 100 cc. of distilled water, shake vigorously, and allow to stand for 5 minutes. Then draw off by means of the stopcock 80 cc. of the muddy liquid free from coarse sand and containing the clay in suspension. Add 20 drops of acetic acid and allow to stand for 10 to 15 minutes for the clay precipitate to settle. Collect on a filter and wash until all lime is removed. Then dry and calcine the filter. In this method the coarse sand is eliminate by decantation, the lime by filtration, and the organic matter by calcination. The weight obtained is therefore considered to represent the clay in suspension in 80 cc. of the decanted liquid. From this data the percentage of clay in the original soil may be readily calculated.

On the Adie and Wood method for the determination of potassium, C. Baskerville and I. F. Harris (*Jour. Elisha Mitchell Sci. Soc., 1900, No. 1, p. 18*).—The authors report comparisons of this method (E. S. R., 12, p. 18) with the official method with very satisfactory results.

The testing of drinking water with the Erdmann reagent, A. Ferman (*Oesterr.-Ungar. Ztschr. Zuckerind. u. Landw., 29 (1900), pp. 861–863; abs. in Chem. Centbl., 1901, I, No. 8, p. 475*).—Attention is called to the unreliabilty of Erdmann's reagent (E. S. R., 12, p. 18), due to the fact that very small amounts of organic matter and other substances will give the nitrite reaction. The author recommends the use of m-phenylendiamin, for, while this reagent is less sensitive than Erdmann's, it is less likely to give misleading results on account of reaction with other substances besides nitrites.

Fitch's salt analysis, a rapid method for the estimation of salt in butter, A. Vivian (*Wisconsin Sta. Rpt. 1900, pp. 98–101*).—A method for the determination of salt in butter, designed for factory use. A standard solution of silver nitrate is made by dissolving 2 tablets prepared for this purpose in 100 cc. of water. The tablets as put up by a Chicago firm contain 0.0509 gm. of silver nitrate in combination with potassium nitrate and gum acacia. The indicator is prepared by dissolving 1 gm. of potassium chromate in 1 liter of water. The sample of butter, weighing 3.5 gm., is treated with 180 cc. of boiling water, and 17.6 cc. of the mixture, when cool, is taken for titration. The quantities used are such that each cubic centimeter of the standard solution corresponds to 0.1 per cent of sodium chlorid. The number of cubic centimeters of the standard silver nitrate solution used divided by 10 gives, therefore, the percentage of salt in the butter. Comparative determinations by this method and the official method gave closely corresponding results.

A quick method for estimating sodium chlorid in meat, F. Glage (*Ztschr. Fleisch u. Milchhyg., 11 (1901), No. 4, pp. 111–114*).—A practical method for obtaining quick results by the use of an ammoniacal solution of silver nitrate.

A comparison of the calculated with the analytical results in estimating the solids of milk, H. Lührig (*Molk. Ztg., 14 (1900), Nos. 50, pp. 869–871; 51, pp. 889–891*).—Results with milk from various sources and different degrees of freshness.

The estimation of dry matter, fat, and ash in milk, H. Timpe (*Ztschr. Oeffentl. Chem., 5 (1899), p. 413; abs. in Hyg. Rundschau, 10 (1900), No. 15, p. 748*).—In milk analysis the use of asbestos as an absorbent material is advocated in lieu of sand or filter paper.

Estimation of fat in milk, R. Lézé (*Répert. Pharm. et Jour. Chim. Med., 3. ser., 13 (1901), p. 1; abs. in Chem. Ztg., 25 (1901), No. 16, p. 52*).—A practical application of Ramchen's method, employing a solution of potash, ammonia, ethyl and amyl alcohols for separating the fat.

The guiac test for pasteurized and unpasteurized milk, F. Glage (*Milch Ztg., 30 (1901), No. 12, pp. 182, 183*).—A large number of tests were made of the color reaction produced in milk by the addition of guiac tincture. It was found that in pasteurized milk no blue color was produced. In the unpasteurized milk the results were variable. In some cases a dark-blue color was produced, in some a very light-blue color, and in others no color at all. Different preparations of the tincture were tested.

A modification of Ritthausen's method for the determination of albuminoid nitrogen, F. Barnstein (*Landw. Vers. Stat., 54 (1900), No. 5–6, pp. 327–336*).—The modification proposes the addition of a known quantity of soda solution after the addition of copper sulphate to the heated mixture to be tested. The operation is carried out as follows: To 1 to 2 gm. of the substance in 50 cc. of water heated on the water bath there is added 25 cc. of a copper sulphate solution made up of 60 gm. of crystallized copper sulphate and 1 liter of water. After stirring, 25 cc. of soda solution of the strength 12.5 to 1,000 is added. After settling, the supernatent liquid is run through a filter, the precipitate washed by decanting, brought on the filter and washed with warm water until the filtrate gives no precipitate with barium chlorid.

By this method of adding soda solution in excess the copper is thrown down as a hydrate and not as a basic salt. Quite a number of comparative analyses of different substances are shown of the method proposed and of the method of Stutzer. The results show a higher average nitrogen content in the proposed modification.

Tables for use in Kjeldahl method for determination of nitrogen, A. Vivian (*Wisconsin Sta. Rpt. 1900, pp. 261–265*).—Tables are given showing the percentage of nitrogen corresponding to any titration and for the conversion of nitrogen into ammonia and protein.

The chemistry of proteids, A. Cohenheim (*Chemie der Erweisskörper. Brunswick: F. Vieweg & Son, 1900; rev. in Oesterr. Chem. Ztg., 3 (1900), No. 21, p. 518*).—The chemical properties and behavior of albumen toward reagents, micro-organisms, metabolic processes, etc., are discussed.

The proteids of vetch, T. Osborne and G. Campbell, translated by V. Griessmayer (*Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 1, pp. 63–67*).—Abstracted from another publication (E. S. R., 10, p. 214).

The proteids of peas, lentils, horse beans, and vetch, T. Osborne and G. Campbell, translated by V. Griessmayer (*Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 1, pp. 68–76*).—Abstracted from another publication (E. S. R., 10, p. 214).

The microscopy of the more commonly occurring starches, H. Galt (*New York: W. Wood & Co., 1901, pp. 112*).

The anatomy of maize cob, with especial reference to the detection of ground cobs in wheat or rye bran, A. L. Winton (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 186–195, figs. 9*).—A botanical study of the corncob is reported.

The estimation of tartaric acid in wine, L. M. de la Source (*Ann. Chim. Analyt., 5 (1900), No. 8, pp. 281–285*).—A modification of the Berthelot-Fleurieu method of estimating tartaric acid whereby potassium bromid is substituted for the potassium hydroxid employed.

Determination of salicylic acid in wines, L. Zanardi (*Ann. Soc. Chim. Milan, 1899, p. 134; abs. in Ann. Chim. Analyt., 5 (1900), No. 10, pp. 394, 395*).

Volumetric estimation of boric acid, J. Wolff (*Ann. Chim. Analyt., 5 (1900), No. 8, pp. 293, 294*).—A volumetric method using ferrisodium salicylate as an indicator, it giving with the alkaline salts of the borates a red or yellowish red solution.

The estimation of cacao hulls in cacao preparations, F. Filsinger (*Ztschr. Oeffentl. Chem., 1899, p. 27; abs. in Hyg. Rundschau, 10 (1900), No. 23, p. 1159*).—Five grams of cacao or chocolate is extracted with ether, and the residue repeatedly treated by washing and decanting with successive portions of water. The heavier particles remaining in the beaker are transferred to a watch glass, dried and weighed. This residue may then be examined microscopically and the percentage of hulls estimated.

The chemical composition of materials, H. A. Huston and A. H. Bryan (*Indiana Sta. Rpt. 1900, pp. 80–88*).—Analyses are reported of 1 sample each of alkali incrustation, black-eye cowpeas, dwarf soy beans, ash of oat clippings and oat dust, ash of corncobs, dry distillers' grain, hominy chop, and oat feed, 2 samples of water, 5 of limestone, 3 of formaldehyde, and 2 of hothouse tomatoes, with a brief discussion of the results in each case.

On the identification of minute quantities of carbon monoxid in blood and air, S. Koster (*Archiv. Physiol. [Pflüger], 83 (1901), Nos. 10–12, pp. 572–608, figs. 3*).—Experimental methods are reported. The article contains a bibliography.

On the measurement of higher temperatures by means of the spectrum apparatus, W. Hempel (*Ztschr. Angew. Chem., 1901, No. 10, pp. 237–242, figs. 3*).

A convenient micro-polariscope for food examination, A. L. Winton (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 195–198, figs. 2*).—Noted from another publication (E. S. R., 12, p. 516).

The essential oil industry of Michigan, A. M. Todd (*Michigan Bd. Agr. Rpt. 1900, pp. 400–403*).—The history and present status of the peppermint oil industry in the State, together with methods of culture and manufacture.

BOTANY.

The resumption of root growth in the spring, E. S. Goff (*Wisconsin Sta. Rpt. 1900, pp. 291–294, figs. 3*).—In a previous report (E. S. R., 11, p. 511) the results of investigations made in the spring of 1898 upon the roots of perennial plants were shown. The winter had been, for that region, an unusually mild one and as a result the roots of all plants examined were found to have started growth at the points where growth had ceased in autumn. The succeeding winter was an extremely severe one, and examination showed that the roots of only the hardiest plants started growth from their tips. The roots of all fruit trees at the station were more or less damaged, and of many trees examined only a single root of a Whitney crab was found to have started growth from its tip. The roots of the other trees were injured in all degrees, from total destruction to the destruction of the smaller root branches. The author concludes from his observations that the question as to whether or not the roots of perennial plants resumed growth in spring at their tips depends, in many species, wholly upon the character of the winter and except in the hardiest species it is probable that there is more or less root killing in the average winter.

Investigations on the root growth of plants, Müller-Thurgau (*Jahresber. Vers. Stat. u. Schule, Wädensweil, 1897–98, pp. 79–82*).—The author conducted a number of experiments with gourd and pea seedlings to determine the effect of a mixture of salts upon the growth of the roots. The salt mixture consisted of dibasic phosphate of potash, sulphate of lime, sulphate of magnesia, phosphate of iron, sodium chlorid, and ammonium nitrate. Different proportions of this combination were added to water cultures in which the plants were grown. The development of the roots was noted from time to time, the growth of the primary and secondary roots being measured and comparisons made with roots grown in distilled water. The concentration of the solution seems to exert a detrimental effect upon root growth, in general the best results being with the weaker solutions. The overfertilization of potted plants with easily soluble nutrient salts will not only impede the transpiration of the plants, but will check the formation of new roots, rendering their growth unsatisfactory.

Investigation of flower buds, E. S. Goff (*Wisconsin Sta. Rpt. 1900, pp. 266–285, figs. 32*).—In continuation of the investigation conducted by the author in a previous season (E. S. R., 12, p. 22), the investigations on the origin and development of the flowers of the cherry, plum, apple, and pear have been continued and extended to include the peach and strawberry. The effect of temperature on the development of the flowers was a subject of investigation, and the variation between the appearance of the flowers in the two seasons was observed. The author found that the anthers of the cherry and apple did not begin to swell perceptibly until the maximum temperature had reached 70° F. The pollen of the mother cells in the plum and cherry underwent some changes before the temperature reached 50° F. The embryo flowers of the cherry and plum appeared a little earlier than in 1899, while the date of the first appearance of the embryo flowers of apple and pear was not positively determined. In some cases they appeared as early as July, and in others in September. The summer and autumn periods of flower formation may prove distinct, and the late-formed flowers of the apple and pear may alone produce a good fruit crop the following season. Side buds, developed on the fruit spurs of apple, formed embryo flowers on several varieties before the middle of October. In the Clyde strawberry, the first indication of flower formation appeared September 20, flowers appearing on the rooted runner plants at practically the same time as upon the parent plant. Experiments in which pear trees were partially defoliated early in July hastened rather than retarded the formation of embryo flowers, and the partial defoliation of the fruit spurs of plum and cherries, as embryo flowers were commencing to form, did not prevent their formation but slightly reduced their size. The embryo flowers of the peach and strawberry began to be formed with the advent of cool nights in September. Flower buds, although apparently not structurally different from leaf buds, seldom, if ever, revert to leaf buds. In the case of apple buds, they may develop into flowers the first, second, or any subsequent season. However, if heavily shaded, flowers may never be formed. In seasons favorable for flower formation many of the buds formed, and nearly all those formed the preceding two seasons that have not already flowered will become flower buds. An excessive apple crop is followed by a light one on account of the supply of reserve buds being exhausted.

Studies on the formation of nitrogenous compounds in plants, A. EMMERLING (*Landw. Vers. Stat., 54 (1900), No. 3–4, pp. 215–281; abs. in Ann. Agron., 24 (1900), No. 10, pp. 517–522*).—The author conducted a series of investigations on the formation of nitrogenous bodies in different parts of the plant during various stages of development. The plant chosen for the experiments was *Vicia faba*. Analyses were made on 9 different dates, representing stages in the development of the plant from the day it had developed 3 or 4 leaves to its maturity.

In the first and second periods, the dry matter of the plant was at the minimum. The leaves contained their minimum content of total nitrogen, and active nitrogen assimilation had not yet begun. The roots, stems, and leaves contained about the same quantities of amido acids. Combined nitrogen was most abundant in the leaves and buds. The third period was when the plants were in flower, and at this time nonproteid nitrogen was found abundantly in all parts of the flower, and amido acids exceeded all other nitrogenous compounds in the leaves. During the second to the fourth period, inclusive, the nitrogenous bodies increased about three times. The leaves maintained their relative excess over the other parts. At the end of this period assimilation was at its height. Amido acids were formed more actively than bases, and the nitrogenous content of the roots was slowly increased. At the end of the period, some fruits had been formed in which the proportion of nonproteid and total nitrogen in the seeds and hulls was about equal. During the fifth period there was a marked increase in the dry matter of the fruits, and much nitrogenous matter was required by the seeds. The daily increase in nitrogen at this period was greater than in the preceding ones, and there was an active consumption of inorganic nitrogen for the formation of albumen. The fruits at the end of this period contained nonproteid bodies as their reserve material, and basic nitrogen was more abundant in the seeds than in the hulls. The quantity of nonproteids at this time was about the same in the leaves, hulls, and seeds. In the sixth period the dry matter of the fruits increased rapidly, and the daily increase of nitrogen attained its maximum. At this time the dry matter of the leaves about equaled that of the fruits. The proteid nitrogen increased in the seeds and hulls, while the nonproteids increased but little. Amido acids diminished very appreciably in the leaves and fruits. During the sixth and subsequent periods, until maturity, there was a gradual increase in the dry matter of the seeds. An increase in the nitrogenous constituents was found only in the seeds, and it was made at the expense of the nitrogen of the leaves, stems, hulls, etc. The amido acids in the seeds are transformed during the period of ripening, and they are said to be employed for the development of the seeds. The leaves and hulls seemed to act as reserve organs for the amids. At maturity the amid compounds decreased throughout the entire plant.

An extensive review of the literature relating to the subject is given, and the methods of experimentation are described in detail.

Albuminous substances and their transformations in the plant in connection with respiration and assimilation, D. N. PRIANISHNIKOV (*Izv. Moscow Selsk. Khoz. Inst., 5 (1899), pt. 3, pp. 284–389*).—Descriptions are given of experiments with *Pisum sativum*, *Vicia faba*, and *Lupinus luteus*, lasting for 18 days and made in order to study the connection between the energy of the decomposition of the albuminous substances and the age of the plants. The author concludes:

(1) The process of the decomposition of the albuminous substances in the vegetation of seeds has its maximum period, which is characterized by a high curve.

(2) The process of the accumulation of asparagin is represented by a similar curve, its maximum coinciding with the maximum of the former curve.

(3) Both curves reach their highest points a few days earlier than the curve of the respiration of carbonic acid.

(4) At the end of the period of vegetation, the energy of the accumulation of

asparagin, or more accurately, nitrogen in the form of asparagin, exceeds the rapidity of the decomposition of the albumins.

Another series is described in which 4 experiments were made with *Pisum sativum*, in order to ascertain the influence of the temperature upon the energy of the decomposition. Comparative experiments at 20°, 28°, and 35° C. were made with the following results: The increase of temperature produces on the process of the decomposition of albumin an influence analogous to that which temperature produces on the respiration, but unlike the influence on the process of growth.

The formation of albumins, in the process of assimilation, from the products of their decomposition, is described. Numerous experiments were made in the years 1895, 1896, 1897, and 1898 with *Vicia faba*, *Pisum sativum*, *Phaseolus multiflorus*, *Lupinus luteus*, and *Cucurbita pepo*. The results can be summed up as follows:

Plants which germinate in the light destroy albuminous substances just as energetically as those germinating in the dark; at a later period, when the leaf surface has developed, there begins the regeneration of albumin. In some plants this stage occurs 10 to 15 days from the beginning of the germination, while in others, Vicia and Faba, considerably later. The regeneration of albumin takes place at the expense of asparagin, as well as of other amido compounds, or the consumption of asparagin falls behind the consumption of other amido compounds. The leaves must be considered as the place of the most energetic regeneration of the albuminous substances, and analyses corroborate this a priori conclusion.

In the fourth and last chapter are communicated the results obtained in an experiment undertaken to verify results obtained by Zaleski in his study of the germination of *Allium cepa* in the dark. The work of the author corroborates the results communicated by Zaleski, namely, that in the germination of *A. cepa* in the dark, albumin is formed the first reported case of formation of albumin in the dark. After a survey of the literature on this subject, the author concludes that the observations which Zaleski made on the germinating *A. cepa* have for the first time proved that a regeneration of albumin is possible without the aid of light; but the observations of Zaleski, as well as of others, have not yet furnished clear evidence that a synthesis of albumin in the dark from nitrates and ammonia is possible in higher plants.—P. FIREMAN.

Upon the gaseous exchange between plants and the atmosphere, T. SCHLOESING, Jr. (*Compt. Rend. Sci. Paris, 131 (1900), No. 18, pp. 716–719*).—The author has made a study of the effect of different forms of nitrogen upon the gaseous exchange of plants, using for his experiments buckwheat and *Tropæolum minus*. Plants were grown in sand cultures and given approximately the same amount of nitrogen in the form of nitric nitrogen and ammoniacal nitrogen. It was found that the plants were able to utilize the ammoniacal nitrogen almost as readily as the nitric nitrogen, the development of the buckwheat being essentially the same in both media. As a whole the volume of oxygen given off by the plants was greater than the carbon dioxid taken up, and there appeared to be a relationship between the amount of gaseous exchange and the available mineral matter contained in the soil. The author states in conclusion that there is a direct relationship between the gaseous exchange which causes the formation of vegetable tissues and the composition of the mineral salts which are in contact with the roots of the plant.

The action of dry and humid air on plants, EBERHARDT (*Compt. Rend. Acad. Sci. Paris, 131 (1900), Nos. 3, pp. 193–196; 11, pp. 513–515*).—A report is given of an extensive series of experiments conducted by the author to ascertain the effect of dry and humid air on the growth of beans, lupines, spiræa, cytisus, acacia, and castor beans. Comparisons were made with the same plants grown under normal conditions. It was found that humid air increased very materially the development of the plants, both stems and leaves, while the diameter of the stem was diminished. There was a tendency to greatly increase the leaf surface and diminish the chlorophyll contained in the leaves, as well as to greatly reduce the root system. On the other hand, the dry air checked the growth and development of stems and leaves, increased the diameter of the stems, diminished the leaf surface, and greatly increased the number and distribution of the roots. In the later paper, the effect of the same factors on the structure of plants was shown. Dry air increased the thickness of the epidermis and the number of stomata. It also increased the production of ligneous tissue, hastened the differentiation of the sclerenchymatous tissue and also the pith. There was under the influence of the dry air a much greater development of palisade tissue in the leaves. In the humid air these structures were less differentiated than under normal conditions.

A closed-circuit respiration apparatus, S. M. Babcock and H. L. Russell (*Wisconsin Sta. Rpt. 1900, pp. 142–146, figs. 3*).—A description is given of a form of apparatus devised by the authors for conducting experiments in the respiration of vegetable tissues, particularly for the study of the phenomena attending the production of heat in silage. In the processes of their investigations it was found desirable to economize in the production of gases used, which was accomplished by the use of an apparatus in which a closed circuit permitted a limited quantity of gas to be used over and over, with or without the addition of volatile substances. The circulation of the gas was secured by utilizing a Bunsen pump. Instead of the ordinary Pettenkofer absorption tube, a special form of tube for the absorption of carbon dioxid was used with good results. The tube presents numerous irregularities which break up and hold the air, so that the carbon dioxid is more readily absorbed.

A preliminary list of the Spermaphyta, seed-bearing plants of North Dakota, H. L. Bolley and L. R. Waldron (*North Dakota Sta. Bul. 46, pp. 591–681*).—A list is given of the seed-bearing plants of the State, in which 340 genera and 775 species and varieties are enumerated. Notes are given on the economic value of many of the species and their distribution throughout the State indicated. The principal points of collection are shown upon a map of the State.

Some Cercosporæ of Macon County, Alabama, G. W. Carver (*Alabama Tuskegee Sta. Bul. 4, pp. 8*).—A list is given of about 75 species of Cercospora, with their host plants.

Origin of the cultivated plants of Argentina, C. Lemée (*Bol. Ofic. Agr. Gan., 1 (1901), Feb., pp. 3–9*).

The improvement of agricultural cultivated plants, C. Fruhwirth (*Die Züchtung der landwirtschaftlichen Kulturpflanzen. Berlin: Paul Parey, 1901, pp. X + 270*).

ZOOLOGY.

Infestation by mice and means for destroying them, G. Del Guercio (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 109–123, fig. 1*).—It is reported that *Microtus terrestris* is becoming annually more destructive in certain parts of Italy. Experiments were made for the purpose of determining the most practicable means of destroying these animals. Poisons which were used for this purpose included arsenious acid, arsenite and arsenate of potash, arsenite and arsenate of copper, sulphate of copper, and corrosive sublimate. The experiments were conducted under conditions as near the normal as possible, fresh vegetation being sprinkled with solutions of the poison. Arsenite of potash proved the most effective and arsenious acid came next in effectiveness. Good results were also obtained from the use of poisonous gasses, such as sulphurous anhydrid and bisulphid of carbon.

Experiments were conducted in infecting mice with a disease due to *Coccobacillus murium*, and under favorable conditions this method promises favorable results. Detailed directions are given for the practical application of fluid poisons, gaseous poisons, and the bacterial virus.

Combating field mice, wood mice, and house mice by means of Löffler's bacillus of mouse typhus, K. KORNAUTH (*Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 2, pp. 123-132*).—The laboratory methods for preparing pure cultures of this bacillus have been much improved and it is now possible to distribute cultures of a more uniform virulence and at a smaller price. During 1899, 20,471 agar cultures of this bacillus were distributed in 468 localities. Circular letters of inquiry concerning the effectiveness of these cultures were sent to 324 persons, and satisfactory replies were received from 214. Of the 115 replies which referred to field mice, it was stated in 71 cases that the action of the cultures was good, while about 15 per cent of the replies stated that the cultures had no effect. Of the 24 replies which referred to wood mice, 18 reported good effects; and of the 73 relating to house mice 57 reported good results. A detailed statement covering the statistics relating to these agar cultures is presented in tabular form. The author states that the distribution of cultures was made late in autumn, and therefore at a time of the year when the disease was less apt to spread rapidly than in the spring.

The feathered denizens of the orchard, O. WIDMANN (*Missouri State Hort. Soc. Rpt. 1900, pp. 146-156*).—Brief notes on the biological relations of woodpeckers, sapsuckers, chickadees, wrens, and other common birds.

The insectivorous birds of Western Australia, R. HALL (*Jour. Dept. Agr. West. Australia, 2 (1900), No. 6, pp. 388-397, figs. 3; 3 (1901), No. 1, pp. 18-23, fig. 1*).—Brief notes are given on the feeding habits and biology of martins, swifts, swallows, and wood swallows.

The food of the variegated crow (Corvus cornix), G. STAES (*Tijdschr. Plantenziekten, 6 (1900), Nos. 1, pp. 12-22; 3-4, pp. 98-105*).—A critical review of the literature of the subject, together with a brief summary of the results thus far obtained from the study of the feeding habits of this bird.

METEOROLOGY.

The eclipse cyclone and the diurnal cyclones, H. H. CLAYTON (*Proc. Amer. Acad. Arts and Sci., 36 (1901), No. 16, pp. 307-318, figs. 6*).—This article summarizes the results of meteorological observations on the solar eclipse of May 28, 1900. The meteorological effects of the eclipse are shown to be important, because (1) they confirm Ferrel's theory of the cold-air cyclone, and show (2) the wonderful rapidity with which cyclonic phenomena can develop and dissipate in the atmosphere, and demonstrate (3) that cyclones do not necessarily drift with the atmosphere, but move with their originating cause, which in the eclipse had a progressive velocity of about 2,000 miles an hour.

"The discovery that the brief fall of temperature attending a solar eclipse produces a well-developed cyclone which accompanies the eclipse shadow at the rate of about 2,000 miles an hour suggests that the fall of temperature due to the occurrence of night must also produce or tend to produce a cold-air cyclone. Since the heat of day produces or tends to produce a warm-air cyclone, there must tend to occur each day two minima of pressure, one near the coldest part of the day and another near the warmest part of the day, with areas of high pressure between them due to the overlapping of the pericyclones surrounding the cold-air and the warm-air cyclones, respectively. These causes must produce entirely or in part the well-known double diurnal period in air pressure. At any rate, in view of the fact that an eclipse causes a cyclone over half a hemisphere, it will be necessary before rejecting such a theory to show that the fall of temperature at night does not produce a cyclone, or that this cyclone and the corresponding warm-air cyclone of the day do not appreciably influence the barometer."

The points in favor of the theory that the double diurnal period in pressure is due to 2 diurnal cyclones, one developed by the cold of night and the other by the heat of day, are briefly stated.

West Indian hurricanes, with some observations on the hurricane of the 10th of September, 1898, at Barbados (*Bot. Sta.* [*Barbados*], *Misc. Bul. 10, pp. 1–13, figs. 4*).

On the theory of precipitation on mountains, F. Pockels (*Ann. Phys., 4. ser., 4* (*1901*), *No. 3, pp. 459–480*).—In this article an attempt is made to reduce the well-known theory of condensation of moisture from the air on mountain slopes to a quantitative mathematical basis. The conclusion is reached that there is a zone of maximum precipitation on each mountain slope and that the amount of precipitation depends more upon the inclination of the surface than upon its absolute height. It is claimed that the latter conclusion is borne out by actual observation, especially on the higher mountain ranges.

Report on radiation, presented by the international meteorological committee at St. Petersburg in 1899, J. Violle (*Ann. Chim. et Phys., 7. ser., 22* (*1901*), *Mar., pp. 329–370*).—This report briefly reviews investigations on the subject of radiation, and discusses the various instruments and apparatus which have been used for its measurement, as well as the formulas used for the calculation of results of observations.

It is stated that we have excellent apparatus for measuring and recording solar radiation in the observatory as well as transportable instruments for scientific researches, but it is questioned whether we have actinometers which combine the features of simplicity, strength, and ease of use required by meteorologists in ordinary observations. Attention is called to the unreliability of all proposed formulas for calculating the solar constant. Observations at higher elevations permit an approach to the truth, and it is therefore urged that such observations be multiplied.

Prevention of hailstorms by cannon, J. C. Covert (*U. S. Consular Rpts., 65* (*1901*), *No. 246, pp. 334–336, fig. 1*).—The almost unanimous indorsement of this method of preventing hailstorms by the "hail congress," held at Padua, Italy, in November, 1900, is reported, and a new form of cannon, which uses acetylene gas as an explosive, is briefly described.

Frost protection (*California Cult., 16* (*1901*), *No. 10, pp. 145, 149–151, fig. 1*).—Papers by E. W. Holmes, E. A. Meacham, and J. H. Reed before the Riverside Horticultural Club on the protection of citrus-fruit orchards from frost.

Meteorological and experimental observations on beets, M. Hoffmann (*Bl. Zuckerrübenbau, 8* (*1901*), *No. 1, pp. 1–7*).

Phenological observations, Canada, 1899, A. H. MacKay (*Proc. and Trans. Nova Scotia Inst. Sci., 10* (*1899–1900*), *No. 2, pp. 303–318, fig. 1*).

Annual summary of meteorological observations in the United States, 1900 (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 28* (*1900*), *No. 13, pp. X + 585–599, charts 7*).—This number gives a table of contents, list of corrections, additions, and changes, and an index for volume 28; and a summary of observations on temperature, pressure, precipitation, wind movement, cloudiness, and other meteorological phenomena "based essentially upon data received from about 160 regular stations, 28 regular Canadian stations, and a number of voluntary stations."

Meteorological observations, J. E. Ostrander and C. L. Rice (*Massachusetts Hatch Sta. Met. Buls. 145, 146, 147, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during January, February, and March. The data are briefly discussed in general notes on the weather of each month.

Meteorological observations at the Michigan Agricultural College for 1899 (*Michigan Sta. Rpt. 1900, pp. 93–117*).—Tabulated daily and monthly summaries of observations during 1899 on temperature, pressure, precipitation, humidity, cloudiness, wind movement, etc. The summary for the year is as follows: Mean temperature, 47.76° F.; humidity, 89.1 per cent; atmospheric pressure (reduced to 32° F.), 29.088; cloudiness, 47.9 per cent; amount of rain or melted snow, 24.73 in.; snowfall, 39.15 in.; number of thunderstorms, 5.

Meteorological charts of the Great Lakes (*U. S. Dept. Agr., Weather Bureau Doc. 237, pp. 23, charts 14*).—This is a summary for the season of 1900, and includes data on opening and closing of navigation, storms and storm warnings, atmospheric precipitation and lake levels, fogs, ice, and wrecks and casualties.

Meteorological observations taken in Hertfordshire in the year 1899, J. Hopkinson (*Trans. Hertfordshire Nat. Hist. Soc., 10 (1900), No. 6, pp. 223–232*).—The results of observations on temperature, humidity, rainfall, and in some cases, sunshine, at 4 stations are tabulated and discussed.

Report on the rainfall in Hertfordshire in the year 1899, J. Hopkinson (*Trans. Hertfordshire Nat. Hist. Soc., 10 (1900), No. 6, pp. 213–222*).—Monthly records of rainfall at 45 stations are tabulated and discussed.

Meteorological observations during the year 1898-99 at the meteorological observatory of the University of Naples, G. Di Paola (*Bol. Soc. Nat. Napoli, 14 (1900), No. 1, pp. 5–18*).—Observations on temperature, pressure, elasticity and tension of vapor, relative humidity, direction of the wind, rainfall, and cloudiness are reported.

Meteorological observations (*Mem. An. Estac. Enol. Haro, 1900, July, p. 31*).—A monthly summary of observations at Haro, Spain, during the year ended June 30, 1900, on pressure, temperature, radiation, humidity, wind movement, rainfall, evaporation, cloudiness, storms, etc.

Meteorological reports for 1898 and 1899 (*Bot. Sta. [Barbados], Misc. Bul. 10, pp. 14–31*).—This includes tabular monthly summaries of observations at Dodd's Botanical Station, Barbados, on temperature, pressure, tension of vapor, humidity, rainfall, rainy days, and velocity of the wind, and monthly summaries of observations on rainfall at a large number of places in different parts of the island. A table is also given which shows the average annual rainfall, the value of the chemical manures applied, the crop of the island the following year, and the number of hogsheads of sugar obtained for each inch of rain which fell the previous year for 19 years, 1881–1899. From this table it appears that the average rainfall on the Island during this period was 67.08 in., the average value of the commercial fertilizers used was £57,723 ($280,533.78), the number of hogsheads ($\frac{7}{8}$ ton) of sugar produced per inch of rain, 885.

Psychrometric tables for obtaining vapor pressure, relative humidity, and temperature of the dew-point, C. F. Marvin (*U. S. Dept. Agr., Weather Bureau Doc. 235, pp. 84, figs. 2*).—The methods and apparatus used in the measurement of atmospheric moisture are briefly discussed, the methods of computing the results are explained, and tables for the reduction of psychrometric observations at stations of the Weather Bureau and cooperating observers are given.

Weather forecasts in Australia (*Rev. Sci. Paris, 4. ser., 15 (1901), No. 10, p. 310*).—Refers to report of the Royal Astronomer of West Australia as claiming that the night and morning forecasts have attained an accuracy of 82 to 89 per cent.

WATER—SOILS.

Soluble salts of cultivated soils, F. H. King and A. R. Whitson (*Wisconsin Sta. Rpt. 1900, pp. 204–226, figs. 7*).—This is an account of a continuation of investigations of the previous year (E. S. R., 12, p. 28), including studies of the influence of tillage, season, and cropping on the total amounts, relative proportions, and distribution of nitric nitrogen and soluble salts in soils.

"The chief effort has been devoted to a study of the amount of nitric nitrogen in field soils under crop conditions throughout the season, at the same time following a parallel control series of studies in plant house cylinders as a check upon the field work.

"Work in the field was begun as soon as the frost was out of the ground and the nitric nitrogen content of the 9 field plats, covering 10 acres, has been determined at the middle and beginning of each month from April 18 to September 18, or 11 times.

"In 8 of these cases samples were taken in 1 ft. sections to a depth of 4 ft., at the other intervals at a depth of 2 ft. By doing this we have secured a detailed record of the changes in the amount and distribution of nitric acid through an entire growing season for 3 plats of corn, 2 plats of potatoes, 2 plats of clover, 1 plat of alfalfa, and 1 plat of oats. . . .

"Side by side with the nitric acid determinations we have made a study of the total soluble salts as indicated by the electrical resistance, the two sets of determinations being usually made on each set of samples.

"The amounts of water present in the field soil have been recorded at each interval and for each depth, and the total amount of dry matter produced on each plat has also been recorded; so that we are now in possession of a fairly accurate set of data showing the amount of nitric acid and the amount of water present in the soil, throughout the season, upon which known amounts of nine crops have been grown."

The experiments on tillage were made in the plant house with cylinders 52 in. deep and 18 in. and 3 ft. in diameter in 3 series, as follows: (1) Not cultivated, (2) cultivated 3 in. deep once a week, and (3) cultivated 3 in. deep once in 2 weeks. The soil used was a clay loam and had in different cases previously borne crops of corn, clover, oats, potatoes, and timothy and beets following beans. No water was applied and there was no drainage from the cylinders during the experiment. The gains and losses of nitric nitrogen and soluble salts during the 93 days of the experiment are recorded.

"The general conclusions suggested by this study may be stated as follows:

"(1) Nitrification has taken place at all depths down to 3 ft. below the surface, and hence that in these cases it is not a process limited to the surface few inches.

"(2) As a general rule there has been the highest increase of nitric nitrogen in the surface foot and the increase in the third foot has generally exceeded that in the second foot.

"(3) The increase of nitric nitrogen has been greater at all depths, as a rule, where the soils have not been cultivated than where they have.

"(4) In two groups of cylinders there has been a tendency for the nitric nitrogen to decrease rather than increase.

"(5) There has been 22 per cent more nitric nitrogen developed from the soil after clover than from the soil after corn, and 13 per cent more than from that after oats during the 93 days.

"(6) But the soil after growing corn the same number of years that the other had grown clover began the experiment with nearly three times as much nitric nitrogen in it as the soil after clover did and it closed the cultivation period with 17 per cent more nitric nitrogen.

"(7) The soil, after oats, began the experiment with 2.6 times as much nitric nitrogen as the clover soil did and it closed the cultivation period with 13.8 per cent more nitric nitrogen.

"(8) The fertilizing power of clover appears to depend more upon the amount of nitrogenous material left in the soil which is capable of rapid nitrification than upon nitric nitrogen accumulated by it.

"(9) With the marsh soil yielding poor crops there was in both cases a heavy gain of nitric nitrogen in the first foot, but in the soil giving better yields there was only a small gain in the not cultivated ground and a loss in the surface foot of cultivated ground. Indeed there was a total mean gain in the poorer soil of 37.47 parts per million but one of only 2.97 parts per million in the better soil for all three feet, while in the case of the clay loam the total mean gain was 8.77 parts per million of nitric nitrogen."

Similar observations on cylinders filled with sand or pine barrens soil on which clover and alfalfa had been grown and turned under as green manure confirmed the above conclusion that "the clovers leave a soil in such a condition that the rate of development of nitric nitrogen in them is more rapid than after other crops, like oats and corn." The soil stirred once a week developed more nitric nitrogen than that stirred once in 2 weeks, but there is no evidence that tillage exerted any notable influence in increasing nitrification or the formation of soluble salts in the soil below the stirred layer.

The influence of the frequency and depth of tillage on the nitric nitrogen and soluble salts was studied on uniform clay loam, using the cylinders described in a previous report (E. S. R., 12, p. 521). The experiment was begun in December, 1899, and lasted 258 days. The amounts of nitric nitrogen in the surface foot in the cylinders at the close of the 258 days were as follows: Not cultivated, 325.48 lbs. per acre-foot; cultivated once a week, 1 in. deep, 217.60 lbs.; cultivated once a week, 2 in. deep, 323.44 lbs.; cultivated once a week, 3 in. deep, 441.24 lbs.; cultivated once a week, 4 in. deep, 387.96 lbs.; cultivated once in 2 weeks, 1 in. deep, 213.29 lbs.; cultivated once in 2 weeks, 2 in. deep, 199 lbs.; cultivated once in 2 weeks, 3 in. deep, 401.68 lbs.; cultivated once in 2 weeks, 4 in. deep, 245.26 lbs.

The nitric nitrogen was determined August 22, 1899, and April 30, 1900, in the first, second, third, and fourth foot of soil of 9 fallow plats described in a previous report (E. S. R., 12, p. 31), which were surrounded by trenches and raised border at the beginning of winter to prevent washing and to secure as much leaching as possible from the natural precipitation. The results show "that there was more nitric nitrogen in the soil at the beginning of May, 1900, than was found after being cultivated every week or 2 weeks from May, 1899, until August 22 of that year with no crop on the ground."

"If an average of the amounts of nitric nitrogen found in the surface 4 ft. of the 9 field plats in the spring is compared with the amounts found in the upper 4 ft. of the 9 fallow plats, they will stand as given in the table below:

The differences in the amounts of nitric nitrogen in fallow ground and in that bearing crops after the winter and early spring rains.

[In pounds per acre. Calculated to dry soil.]

	First foot.	Second foot.	Third foot.	Fourth foot.
Fallow plats	212.00	56.22	21.91	13.11
Plats not fallow	25.24	15.08	10.00	7.24
Difference	186.76	41.14	11.91	5.87

Studies of the seasonal changes of nitrates and other soluble salts were continued during 1900 with crops covering the entire surface, so that intertillage could not be practiced, and with cultivated crops. The studies began in April, just after the frost had left the ground, and continued until September 19, when most of the crops had completed their growth. The combined results obtained are shown graphically. The nitrates increased rapidly in the surface foot of the cultivated ground until July 1, then fell rapidly until August 1, when the crops were making the most rapid growth. From this date they rose slowly until corn was cut, September 1, and then more rapidly until September 19, when the last observations were taken. With uncultivated crops, such as clovers, on the other hand, the nitrates of the first foot increased much more slowly, reaching a maximum June 1, or a month earlier, then declining slowly, reaching a minimum on August 1, after which they again rose until the end of the season. The most rapid increase in nitrates in case of the corn and potato soil occurred in the surface foot. When, however, the crops came into vigorous growth, the nitrates in the surface soil were rapidly reduced. Similar, but less marked, fluctuations occurred in case of the uncultivated crops—clover, alfalfa, and oats.

The total salts in the surface foot of the cultivated soil reached a maximum July 1, from which date they rapidly declined until they reached a minimum August 1. In case of the uncultivated crops—clover, alfalfa, and oats—the soluble salts increased rapidly at the beginning of the season, reaching a maximum about May 1. From this date they slowly decreased until the 1st of July, and then remained stationary until August, after which they rose again until September 1, when they were practically the same as at the beginning of the season.

"If comparison is made between the changes in nitrates in the second, third, and fourth feet and in the total soluble salts for corresponding depths it will be seen that the curves generally go through the same phases throughout the season under both the cultivated and not cultivated crops, each rising and falling together, but through a much greater amplitude with the total salts where the amounts are so much larger.

"The most striking difference between the seasonal changes, both of nitrates and total salts, in the first foot of soil, and in the next 3 ft., is found in the much greater fluctuations recorded for the surface.

"The relation existing between the amount of nitric nitrogen in field soils computed as calcium and magnesium nitrates and the total soluble salts as indicated by the electrical resistance appears to be widely variable under different conditions.

"The ratio of total soluble salts to the nitrates in the surface foot of the five cultivated fields is, on the average for the whole season 2.14 to 1, while in the surface foot of the clover fields it is 4.8 to 1. For the second, third, and fourth feet for the season the ratio is 7.29 to 1 for the corn and potato fields, and 9.97 to 1 for the clover, alfalfa and oats."

It was found that the largest yield of corn was not associated with the highest percentage of nitrates in the soil, but with the largest amount of soluble salts.

The results of the season's observations show that extremely small amounts of nitric nitrogen may occur in a soil on which plants make vigorous growth and produce large yields. With the right amount and distribution of water large yields may be produced when the nitrates in the surface foot of soil are as low as 24 lbs. per acre in case of corn, 45 lbs. in case of clover, 19 lbs. with alfalfa, and 105 lbs. with potatoes.

Influence of potash salts on black marsh soils, F. H. KING and A. R. WHITSON (*Wisconsin Sta. Rpt. 1900, pp. 197–203, fig. 1*).—In continuation of previous experiments (E. S. R., 12, p. 32), tests were made at the station of the relative effectiveness of (1) potassium sulphate, potassium chlorid, potassium-magnesium carbonate, and kainit; and (2) potassium sulphate and chlorid applied in different ways and at different rates. The potash salts were applied to corn at the following rates per acre, furnishing equal amounts of potash: Sulphate, 263.3 lbs.; chlorid, 171 lbs.; potash-magnesium carbonate, 649.8 lbs.; kainit, 644.6 lbs. Comparing the yields of the fertilized rows with the parallel unfertilized rows, counting the latter yield as 1, the following results were obtained:

Increased yield of corn with potash salts, counting yield without potash as 1.

	Increase of stalks.	Increase of ears.
With equal amounts of potash:		
623.3 lbs. potassium sulphate	2.04	4.43
171 lbs. potassium chlorid	1.89	3.66
649.8 lbs. potassium-magnesium carbonate	1.84	3.04
644.6 lbs. kainit	1.81	2.52
With different amounts of potash:		
640 lbs. potassium sulphate	1.70	2.29
320 lbs. potassium sulphate	1.51	1.91
171 lbs. potassium chlorid	1.41	1.48
85.5 lbs. potassium chlorid	1.33	1.48
In hills *vs.* broadcasting:		
Potassium sulphate applied in hill	1.72	2.37
Potassium sulphate applied broadcast	1.81	1.91
Potassium chlorid applied in hill	1.44	1.82
Potassium chlorid applied broadcast	1.42	1.24

Potassium sulphate at rates of 77.2 lbs. per acre, chlorid, 86.5 lbs., and nitrate 91.1 lbs., were each applied at the surface and at depths of 3, 6, and 9 in. to corn growing in 3 ft. cylinders of marsh soil. From the results reported it appears that:

"(1) The untreated soils have given yields only about one-half those from the treated soils.

"(2) While the yields on the untreated poorest soils are less in every case than those from the better soil, the same amount of potash given to the poorer soil as that given to the better has in nearly every case produced a larger mean yield than the better soil did.

"(3) The salts when applied at the surface have produced the least general increase in yield, the 9 in. depth standing next, while the 3 in. depth has given the largest general average.

"(4) The data appear to indicate that the corn can not utilize the potash as well for food when applied at the surface or 9 in. below as at intermediate depths, or else that the salts exert an influence between 2 in. and 6 in. which is helpful in other ways than as plant food."

In experiments with potash salts on a variety of crops on marsh soils on 3 farms in different parts of the State it was found that the potash salts were beneficial when worked into the soils.

On the absorption of monocalcium phosphate by arable soil and by humus, J. Dumont (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 7, pp. 435–437*).—This article reports tests of the absorptive power of different kinds of soil for monocalcium phosphate by the following method: Fifty grams of the fine dry soil (passing a 1 mm. sieve) was shaken up with 350 cc. of a solution of monocalcium phosphate containing 0.815 gm. of phosphoric anhydrid, and at intervals of from 2 hours to 15 days phosphoric acid was determined in 20 cc. of the solution.

It was found that in humus soils containing variable amounts of lime, absorption was greater than in ordinary soils and that removal of humus by incineration greatly reduced the absorptive capacity. Apparently absorption depends upon the relative proportions of humus and lime, i. e., the greater the proportion of humus to lime, the greater the absorption.

The fixation of the phosphoric acid was not due exclusively to reversion, and an abundance of humus reduced the amount of reversion.

The chemical composition of Maryland soils, F. P. Veitch (*Maryland Sta. Bul. 70, pp. 63–114*).—This is a report on a chemical investigation of 60 samples of soil representing the typical soil formations of the State. The analyses were made in the laboratory of the Division of Soils of this Department. The bulletin discusses the importance, object, and scope of soil work; the purpose and methods of chemical examination of soils; describes the samples, and discusses their classification with reference to geological formations, typical crops, and chemical and mechanical composition. In the chemical examination of the soils 3 methods were used, (1) fusion method,[1] (2) concentrated (1.115 sp. gr.) hydrochloric acid method,[2] and (3) fifth-normal hydrochloric acid method.[2] The average results obtained with the different classes of soils are given in the following table:

Soluble in 1.115 sp. gr. HCl	84.05	.14	.10	.07	.04	3.07	5.26	.046	

a Total silica in case of fusion method, insoluble silicates in case of the concentrated hydrochloric acid method, and the sum of the soluble and insoluble silica in case of the 1/5 normal hydrochloric acid method.
b Not determined.

The author concludes from the results obtained that the ultimate chemical analysis (by fusion) of a soil "affords absolutely no reliable basis for a classification."

"The solubility of the essential plant foods in strong acids is shown to afford a grouping and an arrangement within the groups that is about as valuable as the results based upon the physical properties alone. The solubility in weak hydrochloric acid affords about as satisfactory a grouping as either of the above methods. The systematic classification of these soils upon the combined influences of their physical and chemical properties is as yet impossible. There are evidently undetermined factors whose influence is great enough to vitiate this classification."

The results indicate that these soils are most in need of lime or lime and organic matter. "Phosphoric acid is probably the substance which, after lime, is indicated as being most needed."

"In the order of economic importance the next need of our soils is nitrogen. While we have no data upon the actual nitrogen content of these soils, some information upon this point may be gained by the amount of volatile (organic) matter which they contain and which approximately determines their nitrogen supply. . . .

"From the results of the chemical analysis it is evident that the addition of potash is the least needed of the several plant foods. In all the soils it is present in great quantities. Its solubility in the two solvents, concentrated and fifth-normal hydrochloric acid, is indicative of its presence largely in an available form in all but the light sandy soils of the State."

A chemical study of the phosphoric acid and potash contents of the wheat soils of Broadbalk field, Rothamsted, B. Dyer (*Proc. Roy. Soc. [London], 68 (1901), No. 442, pp. 11–14*).—Determinations of phosphoric acid and potash soluble in strong hydrochloric acid and in 1 per cent citric acid in samples of soils from the first, second, and third 9 in. of the soil of 12 plats, manured in different ways and unmanured, that had been cultivated in wheat for 50 years consecutively, are reported. (See also E. S. R., 10, p. 933.) Examinations of samples of the same soils collected in 1865 and 1881 are also reported.

"The difference between the total percentages of phosphoric acid in different soils, unmanured and variously manured, corresponds fairly well with their history, but in the absence of a knowledge of such history these differences would not suffice to give any indication of the profound differences known to exist in the phosphatic condition and fertility of the soils. The relative proportions of citric acid soluble phosphoric acid, however, appear to afford a striking index to the relative phosphatic fertility of the soils."

The superiority of the citric acid method for determining the phosphoric acid requirements of a soil was more strikingly shown in case of the subsoils than of the surface soils. In the surface soils the average ratio of the total phosphoric acid in plats which had received phosphatic fertilizers to that in plats receiving no phosphates for 50 years was 1.65 : 1; of citric acid soluble phosphoric acid, 5.46 : 1. The results obtained indicate that a soil containing as low as 0.01 per cent of citric acid soluble phosphoric acid in the surface soil needs phosphatic fertilizer, while that containing as much as 0.03 per cent is in no immediate necessity of such fertilizing. The results generally indicate also that the greater proportion of the unconsumed phosphoric acid accumulates in the first 9 in. of soil. In case of barnyard manure and of superphosphates accompanied by potash, soda, and magnesia salts, the fertilizing constituents were diffused to a considerable extent throughout the second and even the third 9 in.

"Strong hydrochloric acid as a solvent for potash in soil analysis is shown to be practically useless as a gauge of potash fertility where there is an abundance of total potash in mineral combination, as silicates, etc. . . . The results obtained by citric acid, however, are strikingly instructive and consistent. . . . The ratio of the average quantity of hydrochloric acid soluble potash in the surface soil of 3 potash-dressed plats to the average quantity found in 7 plats not dressed with potash was 1.20 : 1. The citric acid soluble potash ratio, however, was 6.75 :1. The plat dressed with dung for 50 years and 9 years, respectively, gave, as compared with the same 7 nonpotash plats, hydrochloric acid soluble potash ratios of 1.27 : 1 and 1.23 : 1, while the citric acid soluble potash ratios were 10.67 : 1 and 9.17 : 1."

The results indicate that when the first 9 in. of the soil contains as much as 0.01 per cent of citric acid soluble potash, applications of potash fertilizers are not needed. The larger part of the unused potash was accumulated in the surface soil, although a considerable proportion was found by the citric acid method to be diffused throughout the second and third 9 in.

The valuation of arable soils on a scientific statistical basis, G. Thoms (*Zur Werthschätzung der Ackererden auf naturwissenschaftlich-statistischer Grundlage. Mitt. III. Riga: N. Kymmel, 1900, pp. 115, map 1, charts 6*).—This is a continuation of previous investigations (E. S. R., 8, p. 573) and reports the results of analyses of 234 samples of soils collected during 1893, 1894, and 1895, on 39 estates in Courland. The results are charted as well as tabulated. The following table gives a summary of the average results obtained:

Average composition of Courland soils of different productive capacities.

	Best soil.		Medium soil.		Poorest soil.		Average of surface and subsoil.		
	Surface soil.	Subsoil.	Surface soil.	Subsoil.	Surface soil.	Subsoil.	Best.	Medium.	Poorest.
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Phosphoric acid	0.1332	0.0937	0.1099	0.0743	0.1011	0.0652	0.1134	0.0921	0.0831
Lime	.9973	.7290	.4393	.5585	.3401	.4918	.8631	.4989	.4159
Potash	.2849	.3638	.2437	.3308	.1785	.2500	.3243	.2872	.2142
Nitrogen	.1916	.0666	.1582	.0551	.2012	.0477	.1291	.1066	.1244
Magnesia	.5318	.6294	.3962	.6164	.2814	.4030	.5806	.5063	.3422
Water in the soil in the field	13.44	9.80	12.69	8.01	12.80	8.73	11.62	10.35	10.76
Loss on ignition	6.10	2.99	4.73	2.68	6.04	2.32	4.54	3.70	4.18
Absorptive capacity for ammonia	42.91	57.23	37.85	50.05	36.61	38.96	50.07	43.95	37.78
Clay	27.46	31.77	25.51	27.98	18.06	18.96	29.61	26.74	18.51
Depth of surface soil	29.80	....	22.76	....	17.33	....	....	....	....
Productive capacity observed	14.83	....	11.64	....	7.49	....	....	....	....
Productive capacity on basis of examination	12.87	....	12.02	....	10.90	....	....	....	....

The results show a direct relation between the productive capacity of the soil and its content of plant food as shown by analysis. This is especially true as regards the phosphoric acid, but is also shown in the case of potash, lime, magnesia, and nitrogen (in subsoil).

Waters for table use sold in bottles or jugs, H. E. Smith (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 201–215*).—Analyses of a number of samples.

FERTILIZERS.

Swamp muck, H. A. Huston and A. H. Bryan (*Indiana Sta. Rpt. 1900, pp. 73–75*).—The muck beds which are found in different parts of Indiana, in areas varying from a fraction of an acre to over 5,000 acres, are briefly described and their value as manure is discussed, the nitrogen in 6 samples of water-free muck being reported. The nitrogen varied from 2.75 per cent to 4.14 per cent. For purposes of comparison, 2 samples of muck and 1 of pure peat moss in an advanced state of decay, secured in Maine, were also analyzed. The nitrogen in water-free material in these samples was 1.75 and 1.83 per cent in case of the muck, and 0.67 per cent in the peat moss. Suggestions regarding the composting of the muck are made.

Marls, H. A. Huston, W. J. Jones, and A. H. Bryan (*Indiana Sta. Rpt. 1900, pp. 76, 77*).—The character of the calcareous marls found in Indiana are briefly described and the range in composition of 10 samples of such marls is reported as follows:

Composition of Indiana marls.

	Per cent.
Moisture	0.34 to 0.80
Organic matter	3.25 to 6.63
Insoluble matter	.44 to 3.30
Carbonate of lime	85.68 to 92.74
Magnesia	.98 to 1.76
Sulphur trioxid	.70 to 1.02
Iron and alumina	.46 to 1.64

As the analyses show, the value of these marls depends mainly upon their lime content. The utilization of the marls as fertilizer and for the manufacture of cement is discussed.

Observations on the action of sulphate of ammonia on succeeding crops, E. Kloepfer (*Fühling's Landw. Ztg., 50 (1901), No. 4, pp. 154–158*).—The results of a series of plat experiments are reported which indicate that an excess of sulphate of ammonia applied to a crop is absorbed and retained by the soil and is utilized by the succeeding crop.

Field experiments with fertilizers, Baessler (*Ber. Thät. Agrchem. Vers. Samencontrolstat. Köslin, 1899, pp. 16–135*).—This includes detailed accounts of cooperative experiments on typical soils with different crops. In these experiments the fertilizer requirements of different soils were studied by means of field experiments and by chemical and mechanical analysis. Comparative tests were made of 40 per cent potash salts and kainit. Tests were made of the effect of applying lime and marl and of the Schultz-Lupitz method of fertilizing sandy soils.

On fertilizer experiments, Behrens (*Mitt. Deut. Landw. Gesell., 16 (1901), Nos. 4, pp. 14, 15; 5, pp. 17–19; 6, pp. 21, 22*).

Fertilizers for Tennessee, C. A. Mooers (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 76–80*).—A brief popular discussion.

Analyses of commercial fertilizers, W. C. Stubbs (*Louisiana Stas. Bul. 63, pp. 483–576, 592–595*).—This bulletin discusses the sources of nitrogen, phosphoric acid, and potash and the valuation of fertilizers, and reports analyses of 1,817 samples of fertilizing materials, including mixed fertilizers, acid phosphates, bone meal, bat guano, tankage, cotton-seed meal, cotton seed, dried blood, fish scrap, nitrate of soda, kainit, sulphate of potash, wood ashes, and ground oyster shells. Statistics of the consumption of fertilizers in the different parishes of the State are given. These show that 30,302 tons of fertilizers were sold in the State during the season of 1899–1900. Of this 12,338 tons was tankage. Blanks used in the inspection are given.

Analyses of licensed commercial fertilizers, F. W. Woll and A. Vivian (*Wisconsin Sta. Rpt. 1900, pp. 257–260, 336, 337*).—A report of analyses of 7 samples of fertilizers examined during the year, with notes on the fertilizer inspection in Wisconsin and the text of the State fertilizer law.

Perchlorate in nitrate of soda, T. Wetzke (*Oesterr. Chem. Ztg., 4 (1901), No. 4, p. 83*).—The author takes exception to Dafert's conclusion (E. S. R., 12, p. 325) that perchlorate was not a common impurity of nitrate of soda until within recent years. He reports finding perchlorate in 8 samples of museum specimens of caliche which he examined by the following method: The chlorin was removed with silver nitrate and the excess of the latter with sodium carbonate. The filtered solution was evaporated to dryness and the residue fused and dissolved in water. The solution was acidified with nitric acid and tested with silver nitrate for chlorin. The appearance of a precipitate or cloudiness was taken to indicate the presence of perchlorate or chlorate. Dafert in a note on the above article calls attention to the fact that in the method employed no account was taken of the iodates which might be present and would give the observed reaction with silver nitrate.

The world's production and consumption of potash fertilizers, L. GRANDEAU (*Jour. Agr. Prat., 1901, I, No. 10, pp. 305–308*).—This article notes briefly the sources of potash, the discovery of the Stassfurt deposits, the extraction, preparation, and production of the Stassfurt salts; and gives tables showing the composition, production, and consumption of the different products. It is stated that the total production of crude Stassfurt salts in 1899 was 2,737,965.38 tons (of 2,000 lbs.). This includes 64,679.877 tons of carnalite and kieserite used for agricultural purposes in Germany, and 5,082.37 tons exported to other countries for the same purpose, besides 1,385,293.041 tons converted into concentrated potash salts; and 791,051.485 tons of kainit and sylvinite used for agricultural purposes in Germany, and 347,080.319 tons exported to foreign countries for the same purpose, besides 144,778.286 tons converted into concentrated salts.

FIELD CROPS.

Farm notes, W. W. COOKE (*Colorado Sta. Bul. 57, pp. 39*).—This bulletin is a résumé of the results of different experiments with alfalfa, corn, potatoes, and sugar beets, carried on at the station during the years 1894 to 1899. This work has all been considered in former bulletins with the exception of the cooperative work on sugar beets in 1899. The results of these tests show that beets planted on May 5 gave a larger yield with a higher percentage of sugar and purity than beets planted earlier or later. Planting in rows alternately 27 and 11 in. apart gave 4.4 tons of beets more per acre than placing the rows uniformly 24 in. apart. The furrows for irrigating the beets were made in the 27 in. spaces. Seed irrigated when planted gave better results than seed not irrigated, but the author believes that in this respect no definite rule is applicable for all parts of the State since the results showed considerable variation, and he advises to irrigate the seed if within 5 days after planting there are no indications of sprouting. The varieties Zehringen, Vilmorin No. 1, Vilmorin No. 2, and Kleinwanzlebener were tested at the station. On heavy clay soil Vilmorin No. 1 showed the highest percentage of sugar in the juice and of purity, while on a clay loam soil Vilmorin No. 2 stood at the head. The average of 10 tests gave an increase of 18 per cent in the weight of the crop as a result of subsoiling.

Field experiments at Ghent, Belgium, P. DE CALUWE (*Exposé Cult. Exper. Jard. Gand., 1898–99, pp. 82, pls. 3, dgm. 1*).—The annual report on the work at the experimental garden for the province of East Flanders. Fertilizer tests were made with rye, oats, maize, peas, rape, chicory, fodder beets, and potatoes. In some cases variety and culture tests were made in connection with the fertilizer experiments. The experimental culture of comfrey and sacchaline was conducted as in previous years, but these crops received no fertilizer applications. A series of fertilizer tests were made on meadows, and the injurious effects of nitrate, perchlorate of soda, and perchlorate of potash were studied. Daily meteorological observations for the year beginning October 1, 1898, are tabulated, and the weather conditions for each month are discussed. The results of a variety test with potatoes are given in a table. The use of potassium chlorid in the fertilizer application produced a considerable and favorable effect on the yield of rye in every respect, but especially on the weight of the grain. The rye from the plats having been furnished potash weighed 4.43 kg. per hectoliter more than the grain from plats having received no potash. Thomas slag increased the yield of oat straw as compared with mineral phosphates, but the yield of grain was about the same. Alinit had no appreciable effect on the yield of oats.

Potassium chlorid as a fertilizer for peas increased the yield by 8.56 kg. of peas and 16.8 kg. of straw per acre. Among several varieties of chicory, Smouter gave the largest yield and Palingkop the highest percentage of dry matter.

In the experiments with rye nitrate of soda proved injurious in proportion to the amount of perchlorate of potash added. The perchlorate applied alone was injurious only in a small degree. In general, the injurious effects of perchlorate of potash were more pronounced than those of potassium chlorid, and less so than sodium perchlorate. Oats was much less sensitive to these substances than rye.

Influence of the right amount and the right distribution of water in crop production, F. H. King (*Wisconsin Sta. Rpt. 1900, pp. 185–188*).—This is a report on the yields of hay, corn, and potatoes grown under different degrees of soil humidity. The rainfall for the years 1898, 1899, and 1900 is compared, and the amount of water applied in irrigating this season is given. The year was not favorable for hay and small grain on account of only a small rainfall early in the season, but these conditions are considered as having favored the development of nitrates in the soil, which was beneficial to the corn crop. Corn has been grown on the same plats since 1894, and for the entire period the average yield of water-free substance per acre was 1,993 lbs. greater on irrigated ground than on ground not irrigated. The first four years of the experiment the average gain due to irrigation was 3,543 lbs. of water-free substance per acre, but for the last three years it was only 62.2 lbs. On the sandy portion of one of two potato plats there was an increase of 81.4 bu. per acre due to irrigation, but on the heavier soil of the plat there was a decrease of 56 bu. per acre. The plats were irrigated twice and the last irrigation was followed by rains, which is considered the cause of the decrease in yield on the heavy soil. On the other plat, which also had a heavy soil, the results were in favor of no irrigation. Flat culture gave a larger increase in yield than irrigation, but irrigation increased the yield of potatoes 11.6 bu. per acre over ridge culture. The different quantities of water applied by irrigation to supplement the rainfall, and the yields obtained from the various plats, are given in tables.

A five-year rotation of crops, H. J. Wheeler and J. A. Tillinghast (*Rhode Island Sta. Bul. 76, pp. 105–128*).—This bulletin describes an experiment with a 5-year rotation carried through its first course on 5 different plats, and gives the yields obtained in tabular form. The history of the different plats is given, showing that at the beginning of these experiments in 1893 corn grown without fertilizers was unable to attain a height of more than about 5 in. during the entire season. The order of the rotation tested was corn the first year, potatoes the second, winter rye the third, and grass the fourth and fifth years. The various fertilizer applications, consisting of chemicals and commercial fertilizers only, are given for the different plats for each season. During the first course of the rotation only two of the five plats gave profitable returns. In the summary, the authors report a yield of 13.78 bu. of corn and 1.3 tons of stover per acre in 1893; 72.57 bu. of grain and 2.4 tons of stover in 1896, and 65.71 bu. of grain and 3.9 tons of stover in 1900. The potato crops showed the largest gains. The smallest crop of marketable potatoes, 60 bu. per acre, was produced in 1893, and the largest crop, 283.33 bu. in 1900, when the total yield amounted to 321.66 bu. The results with rye were irregular but are considered as indicating the increase of assimilable nitrogen in the soil. From the fact that the grass crops have remained small it is believed that they received an insufficient amount of fertilizer. This rotation was not as profitable as the three and four year rotations previously reported (E. S. R., 12, p. 1030). The changes suggested by the author are beginning the rotation with rye, increasing the fertilizer application for the grass crops, and applying the fertilizers for the potato crops entirely in the drill.

Results obtained in 1900 from trial plats of grain, fodder corn, field roots, and potatoes, W. Saunders (*Canada Cent. Expt. Farm Bul. 36, pp. 5–51, figs. 4*).—This report is a record of cooperative variety tests in continuation of those previously reported (E. S. R., 12, p. 134). The plan of the experiments has remained unchanged, but owing to unfavorable weather conditions at the Brandon and Indian Head farms no results are reported from these places for this season.

The yields of each crop at the other experimental farms are tabulated. The varieties giving the largest yields at the different stations were as follows:

Oats.—Holstein Prolific, Black Beauty, Early Blossom, Golden Giant, Cromwell, Buckbee Illinois, Oderbruch, California Prolific, Hazlett Seizure, Thousand Dollar, Joanette, and Bavarian. Average yield per acre, 69 bu. 29 lbs. *Two-rowed barley.*—Beaver, Danish Chevalier, Canadian Thorpe, French Chevalier, Bolton, and Nepean. Average yield per acre, 48 bu. 2 lbs. *Six-rowed barley.*—Mansbury, Common, Royal, Odessa, Albert, and Petschora. Average yield per acre, 50 bu. 15 lbs. *Spring wheat.*—Huron, White Russian, Preston, Laurel, Countess, Red Fife, Red Fern, White Connell, Monarch, Pringle Champlain, Wellman Fife, and Colorado. Average yield per acre, 32 bu. 44 lbs. *Peas.*—White Wonder, Duke, Prince, Archer, Crown, Chancellor, Carleton, Harrison Glory, Daniel O'Rourke, German White, Agnes, and Early Britain. Average yield per acre, 27 bu. 57 lbs. *Indian corn.*—Thoroughbred White Flint, Early Mastodon, Superior Fodder, Champion White Pearl, Mammoth Cuban, and Cloud Early Yellow. Average yield per acre, 21 tons, 1,341 lbs. *Turnips.*—Carter Elephant, Perfection Swede, Champion Purple Top, Drummond Purple Top, Skirvings, and Hartley Bronze. Average yield per acre, 25 tons, 1,339 lbs. *Mangels.*—Giant Yellow Intermediate, Giant Yellow Half Long, Sutton Yellow Globe, Canadian Giant, Champion Yellow Globe, and Mammoth Yellow Intermediate. Average yield per acre, 29 tons 480 lbs. *Carrots.*—Giant White Vosges, Half Long White, Improved Short White, New White Intermediate, Green Top White Orthe, and Ontario Champion. Average yield per acre, 30 tons, 1,053 lbs. *Sugar beets.*—Improved Imperial, Red Top Sugar, Wanzleben, and Danish Red Top. Average yield per acre, 23 tons, 132 lbs. *Potatoes.*—Seattle, American Wonder, Northern Spy, Irish Daisy, Irish Cobbler, Vanier, Uncle Sam, Rural Blush, Rose No. 9, Carmen No. 1, Seedling No. 230, and Holborn Abundance. Average yield per acre, 398 bu. 13 lbs.

The average results obtained for the different crops for 5 and 6 years are also given. The varieties which have given the highest averages during this period are as follows:

Oats.—Banner, American Beauty, Bavarian, Golden Giant, Holstein Prolific, Buckbee Illinois, Columbus, Golden Beauty, Early Golden Prolific, White Schonen, Oderbruch, and Wallis. Average yield per acre, 70 bu. 31 lbs. *Two-rowed barley.*—French Chevalier, Danish Chevalier, Beaver, Canadian Thorpe, Newton, and Sidney. Average yield per acre, 43 bu. 30 lbs. *Six-rowed barley.*—Mansbury, Trooper, Odessa, Common, Royal, and Oderbruch. Average yield per acre, 47 bu. 39 lbs. *Spring wheat.*—Preston, Monarch, Wellman Fife, White Fife, Goose, Red Fife, White Connell, Huron, White Russian, Rio Grande, Hungarian, and Pringle Champlain. Average yield per acre, 31 bu. 47 lbs. *Peas.*—Crown, Carleton, Pride, New Potter, Early Britain, Duke, Mummy, Centennial, Trilby, Archer, King, and Paragon. Average yield per acre, 32 bu. 52 lbs. *Indian corn.*—Red Cob Ensilage, Thoroughbred White Flint, Selected Leaming, Giant Prolific Ensilage, Angel of Midnight, and Champion White Pearl. Average yield per acre, 21 tons, 1,604 lbs. *Turnips.*—Selected Purple Top, Perfection Swede, Bangholm Selected, East Lothian, Hartley Bronze, and Skirvings. Average yield per acre, 29 tons, 585 lbs. *Mangels.*—Yellow Intermediate, Yellow Giant Intermediate, Gate Post, Selected Mammoth Long Red, Giant Yellow Half Long, and Giant Yellow Globe. Average yield per acre, 31 tons, 21 lbs. *Carrots.*—Half Long White, Giant White Vosges, Improved Short White, Mammoth White Intermediate, Iverson Champion, and Green Top White Orthe. Average yield per acre, 20 tons, 335 lbs. *Sugar beets.*—Danish Red Top, Danish Improved, Red Top Sugar, and Wanzleben. Average yield per acre, 23 tons, 14 lbs. *Potatoes.*—Seedling No. 230, Irish Daisy, American Giant, American Wonder, Empire State, Carmen No. 1, Late Puritan, State of Maine, New Variety No. 1, Seattle, Vanier, and General Gordon. Average yield per acre, 352 bu.

Experiments with grain and forage crops, R. A. MOORE (*Wisconsin Sta. Rpt. 1900, pp. 227-238, figs. 2*).—Experiments with grain consisted of tests for hardness and productiveness of 35 varieties of oats, 15 of barley, 10 of spring wheat, 6 of peas, 2 of speltz, and 1 of spring rye. The yields of straw and grain and other data connected with the experiments are given in a table and discussed.

The best varieties of oats were Swedish, Poland White, and Tobolsk, and of barley, the Oderbrucker and Mandshury varieties. The observations on varieties of barley listed as Mandshury, Manshury, and Mandschuri indicate that they are all the same variety. Speltz stooled abundantly and grew rapidly. Sowing oats at the rate of $2\frac{1}{2}$ to $3\frac{1}{2}$ bu. per acre had no effect on the tendency to lodge, but sowing at the rate of 1 bu. was very effective in preventing lodging. Treating seed oats with a solution of 1 lb. of formalin to 50 gal. of water was found to be absolutely effective in this experiment. A comparative test of Victoria and Dwarf Essex rape indicated that Victoria rape is probably Dwarf Essex under a different name. A test was made of sowing rape at the time of seeding and two weeks later. Where rape was sown with oats on the same day the yield of oats was 50.3 bu. per acre, and where the rape was sown 2 weeks later the yield was 60.3 bu. The same variety of oats without rape yielded 64.5 bu. per acre. A good yield of rape for fall fodder was obtained in both instances. Clover was sown with oats as a nurse crop, with oats that were cut for hay while green, and without a nurse crop. Clover sown with a nurse crop gave the best result, and where the oats were cut for hay a much better stand of clover was obtained than where the oats were left to ripen. Black, yellow, and green soy beans were grown experimentally. The black and green varieties matured seed, while the seed of the yellow did not ripen. The green soy bean yielded 9.9 tons of green forage per acre.

Experiments with corn, forage crops, and spring cereals, A. M. SOULE, P. O. VANATTER, and J. R. FAIN (*Tennessee Sta. Bul., Vol. XIV, No. 1, pp. 31, figs. 13*).—This bulletin reports the results of tests with varieties of corn, sorghum, Kafir corn, Durra, broom corn, cowpeas, millet, Canadian field peas, and spring varieties of wheat, oats, and barley. In connection with these trials tests were made of sowing rape, oats, and barley at different dates, and of seed corn taken from different parts of the ear. The draft these crops make on the soil and the root systems of corn, sorghum, cowpeas, and soy beans were also studied.

Of 31 varieties of corn, Florida gave the largest yield, 18 tons per acre. No. 3889, Ellis, and Huffman all yielded over 14 tons. The best grain-producing varieties were No. 3889, yielding 72.09 bu. per acre; Improved Golden Beauty, 68.07 bu.; and the Improved Leaming, 56.69 bu. The varieties giving the highest percentage of grain in the whole crop were Three-eared with 20.48 per cent and New Klondike with 17.72 per cent. New Klondike gave the smallest total yield and the Florida and Huffman, two of the varieties giving the largest total yields, produced only 7.90 per cent and 5.64 per cent, respectively, of grain in the whole crop. Seed corn from the North gave smaller total yields, but a higher percentage of grain than Southern varieties. Several of the Northern varieties ripened in 97 days, while 119 days were required to mature the best yielding Southern varieties.

Among the different forage crops, teosinte gave the best yield of green crop, 26.25 tons per acre, followed by rape with 18.50 tons, corn and cowpeas together 17.70 tons, corn alone 17.60 tons, and cowpeas alone with 14.10 tons per acre. There was no advantage in growing cowpeas together with rape, corn, or millet, the yields being practically the same when the crops were grown alone. There was also the difficulty of obtaining crops maturing at the same time. The results showed that a succession of forage crops may be had in that region from the middle of June until November. The best yield of sorghum was 11.85 tons per acre, and of Kafir corn 8.01 tons. The varieties of cowpeas giving the largest yields of peavine hay were Taylor, Wonderful, Clay, Blackeye, and Whippoorwill, in the order given, the yields varying from 2.3

to 3.1 tons of hay per acre. There was a loss of from 5,000 to 6,000 lbs. in the production of hay per acre as compared with the weight of the green crop. Soy beans did not prove as profitable a crop as cowpeas. Japanese millet yielded 2.62 tons, but the imported Japanese varieties did not give satisfactory yields. Rape on fall-plowed land yielded 8½ tons of green crop per acre.

Of 10 varieties of spring oats, Texas Rust Proof gave the largest yield of grain, 42.26 bu. per acre, followed by Big Four with 36.38 bu., which variety also yielded the most straw, 1.93 tons per acre. Early sowing of both oats and barley gave better results than late sowing. Wellman Fife spring wheat stood at the head of varieties tested with a yield of 17.91 bu. per acre. The highest yields of digestible protein per acre were as follows: Cowpeas, 504 lbs.; soy beans, 380 lbs., and corn, 352 lbs. Corn was richer in carbohydrates and fat than soy beans or cowpeas. Sorghum was inferior in digestible nutrients to most of the crops tested. The greatest draft on the soil was made by the corn crop, which removed 144.3 lbs. of nitrogen, 52.8 lbs. of phosphatic acid, and 116.2 lbs. potash. Cowpeas came second, with 75.60 lbs. of nitrogen, 28 lbs. phosphatic acid, and 86.6 lbs. potash. It is concluded that while sorghum and millet do not draw so heavily on the soil as corn they are shallow feeders and tend to exhaust the surface foot of soil.

Experiments with forage crops, J. H. SKINNER (*Indiana Sta. Rpt. 1900, pp. 89–94*).—Red clover, alsike, alfalfa, and crimson clover were sown in 1898 on the 15th of each month, from April to September, inclusive. In 1899 the work was continued, but owing to the season was a failure. The results indicate that red and alsike clover may be sown as late as June 15. It was found more difficult to obtain a stand of alfalfa and crimson clover than of red and alsike clover. All except alfalfa winterkilled. Alfalfa stood the winter much better the second year than the first, when many of the roots were broken by the lifting of the soil, due to freezing. Culture and variety tests were made with cowpeas, soy beans, sorghum, and corn, and the results are briefly noted. Sorghum yielded the most forage, with common corn second, and Stowell Evergreen third.

Crops for summer forage, G. HEUZÉ (*Jour. Agr. Prat., 1901, I, No. 8, pp. 248, 249*).—A brief note on growing summer forage crops in Northern France.

Influence of the size of the seed on the yield, EDLER (*Landw. Ztschr. Rheinprovinz, 2 (1901), No. 1, pp. 1–3*).—This is a report on experiments with seeds weighing 50.9 and 33.9 gm. per thousand. In one test the same number of grains of the heavy and the light seed were sown, and in another test equal weights of the two kinds of seed. The heavy seed produced the heavier plants, having a larger number of productive stems and producing heavier and a larger number of grains than plants from the light seed. The conclusion is drawn that when equal weights of heavy and light seeds are sown the heavier seed will generally give the best results.

The improvement of cereal crops, T. H. MIDDLETON (*Jour. Newcastle Farmers' Club, 1901, pp. 1–29*).—A paper on the improvement of field crops.

Fertilizer experiments with different forms of potash (*Jahrb. Deut. Landw. Gesell., 15 (1900), pp. 27–42*).—A review and discussion of experiments comparing different potash salts as fertilizers for cereals, sugar and forage beets, potatoes, and meadows. The results of tests on marsh soils were also considered. The work here reviewed was done at different German experiment stations.

Causes operative in the production of silage, S. M. BABCOCK and H. L. RUSSELL (*Wisconsin Sta. Rpt. 1900, pp. 123–141*).—This is a report and a discussion of experiments in making silage under laboratory conditions for the purpose of studying the changes which occur in the formation of good silage. Work bearing on this subject done by other investigators is reviewed and the method of conducting these experiments is described. The results show that good silage can be made under conditions which exclude bacterial activity, and that the initial heating of silage is due mainly to the respiratory processes of the cut plant tissues themselves.

"The gases of a silo are carbon dioxid and nitrogen, the carbon dioxid being evolved by the intramolecular respiration of the ensiled tissues, while the nitrogen is simply due to the entangled atmospheric air that is originally present when the silo is filled. In good silage, where putrefactive changes do not occur, the gases associated with bacterial fermentation are not found."

First-class corn silage was made in numerous instances in small receivers, the temperature of which never exceeded 75 to 80° F. The changes that characterize the formation of good silage are considered due to the changes inaugurated and under the more or less direct control of the protoplasm of the plant tissues that are ensiled. It is concluded that the acids of silage are a product mainly of the intramolecular respiration, and that the degree of acidity is dependent upon the duration of the respiration of the cells. These facts are considered as explaining the presence of large amounts of acids in silage from immature and succulent crops. The putrefactive changes occurring in silage are due to bacteria capable of developing under anaerobic conditions in the succulent tissues. That the peculiar aroma of good silage can be produced under conditions in which all vital processes are suspended is taken as an indication that enzyms are operative in this connection.

"The unavoidable losses in silage are due to the formation of water, carbon dioxid, and volatile organic acids, which are produced as a result of the intramolecular respiratory processes of the ensiled tissues."

The avoidable losses are due mainly to the decomposition of organic matter by bacteria and molds. The admission of air by imperfectly constructed silos facilitates the growth of these organisms and prolongs the direct respiration of the plant tissues. Bacterial activity, instead of being essential, was found deleterious, being most marked where putrefactive changes occurred.

Unavoidable losses in silage, F. H. King (*Wisconsin Sta. Rpt. 1900, pp. 189-196, figs. 2*).—The work here reported consisted of a series of experiments in the production of silage with small quantities of different materials under the complete exclusion of air, but permitting so much as would be entangled in the material when filling the silo. The materials were ensiled in Mason jars. In the first experiment with peas, cowpeas, oats, rye, and corn, all in a comparatively early stage of growth, the results show the greatest loss in weight during the first 15 days on oats, rye standing second, and corn last. The loss on cowpeas was also small. The author concludes that in 100 tons of corn silage under similar conditions the loss of dry matter would have been between 1.27 and 1.62 tons. In this first test the material was not compressed sufficiently to crush the tissues and express the juices. In the second experiment peas, cowpeas, oats, and corn were treated as in the first, except that the plants were 27 days older. Alfalfa from 6 to 8 in. high was added to the test. The materials were packed to have a mean weight of 33.6 lbs. per cubic foot. The loss calculated on the green weight ranged from 0.91 per cent in 108 days of hot summer weather for the cowpeas to 4.93 per cent for the corn, the average loss being 2.71 per cent. The object of the third trial was to determine the effect of the closeness of packing on the losses, and the test was made with mature corn packed closely and loosely, but the results obtained were not conclusive. In the fourth and ninth experiments the gaseous products given off from the corn silage were measured. In experiment 4 the corn was in the milk stage and in experiment 9 fully matured when ensiled. In 105 days number 4 lost 3.31 per cent of its green weight and number 9 3.24 per cent in 59 days. The total amount of gas collected in experiment number 4 was 20.10 cu. ft., and in experiment number 9 17.05 cu. ft., or from 3 to 4 times the volume of the silage. On the average 74.02 per cent and 72.24 per cent of the gas given off by the silage in experiments Nos. 4 and 9, respectively, was carbonic-acid gas. Experiment number 8 consisted in the measurement of gaseous products given off from clover silage. On June 18 medium clover was packed so as to give 22.5 lbs. per cubic foot in an air-tight iron cylinder. After 28 days it had lost 0.8 per cent of its original weight and after 58 days 1.19 per cent. During the first 58 days it gave off 15.7 per cent cubic feet of gas, or about double the volume occupied by the silage. The first 5 hours 2,400 cc. of gas were given off per hour, but during the 22 days preceding September 6 the average rate per hour was only 91 cc. The first 5 days the ratio of carbon dioxid to other gases was 47.10 to 52.90, but for the rest of the time it averaged 78.41 to 21.59.

Management of ensilage crops, A. M. Soule (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 68–75, figs. 5*).—This article discusses in a popular manner the growing of silage crops and points out the value of silage for feeding purposes. Corn, oats, cowpeas, sorghum, Kafir corn, and teosinte are considered in this connection.

The textile agaves of Algeria (*Bul. Soc. Nat. Agr. France, 61 (1901), No. 1, pp. 52–54*).—A series of brief descriptive notes of various textile plants belonging to the genus Agave, which are grown in Algeria.

Corn culture, R. J. Redding (*Georgia Sta. Bul. 51, pp. 273–293*).—Cultural, variety, seed, and fertilizer tests with corn are reported. The work is in continuation of that previously noted (E. S. R., 11, p. 1030). Weather indications are reported as exceedingly favorable. Among 16 varieties of corn tested in 1900, Cocke Prolific, Sanders, Tennessee Yellow, Georgia Cracker, and Virginia Horsetooth, given in the order of their productiveness, yielded from 45.20 to 51.31 bu. of shelled corn per acre; Hoffman White ranking last, yielded 34.75 bu. The yields obtained from 11 varieties for several years, including this season, are given in a table. A comparison of several methods of harvesting showed that cutting and shocking corn about the middle of August gave a greater yield of shelled corn and stover than harvesting the leaves separately at that time, or harvesting the stalks with the leaves after the plant has become dry.

A fertilizer application containing 45 per cent acid phosphate, 2 per cent muriate of potash, and 53 per cent of cotton-seed meal applied at the rate of 600 lbs. per acre on uplands increased the yield 1.45 bu. as compared with 400 lbs. and 2.61 bu. as compared with the yield from 200 lbs. A test of applying fertilizer broadcast or in drills led to the conclusion that fertilizers properly applied in the drill will give as large a yield as double the amount broadcasted. As in previous years, nitrate of soda, cotton-seed meal, and dried blood were compared as sources of nitrogen. Dried blood was a little more effective than the other two fertilizers but it was less profitable. Cotton-seed meal at from $17 to $20 per ton is considered the cheapest source of nitrogen for a corn crop. Fertilizer formulas for corn on different Georgia soils are given.

From the results of experiments on the relative value of planting corn at different distances, the author concludes that a distance 2 by 4 ft. is preferable to other distances on upland soils capable of producing from 35 to 40 bu. of shelled corn per acre, but that on the unimproved and badly worn soils the distance between hills should range from 5 by 4 ft. to 5 by 5 ft.

No advantage was observed in selecting kernels for seed from either the butt end or the middle of the ear, but kernels from the third of the ear, including the tip, were more prolific than kernels from the other parts.

The effects of continued use of immature seed corn, E. S. Goff (*Wisconsin Sta. Rpt. 1900, pp. 297–299*).—A study of this subject was begun in 1896. The results obtained during 5 years are tabulated, and the effects upon the yield of corn and stalks and upon the time of maturity are discussed. The variety grown was King Philip, a variety of flint corn. The very immature seed gave smaller yields of corn and stalks and slightly earlier maturity than the fully matured seed. Larger yields were obtained from seed corn gathered slightly immature.

Corn growing (*Sci. Amer. Sup., 51 (1901), No. 1310, pp. 21000, 21001*).—A résumé of the result of 12 years' work at different experiment stations in the United States, with conclusions based upon the results.

Cotton culture, R. J. Redding (*Georgia Sta. Bul. 52, p. 32*).—A continuation of previously reported work (E. S. R., 12, p. 137). Frequent and heavy rains interfered to some extent with the results. In 1900 21 varieties of cotton were tested. Prize, Sehley, Moss, Improved, Russell Big Boll, and Lee Improved, mentioned in the order of the value of total products, outranked the rest of the varieties in profitable returns. As in the preceding year the largest percentage of lint—39 per cent—was produced by Moss Improved. Corput Find and Griffin Improved were the earliest varieties and the least profitable. As a rule the late varieties gave better results than the early ones. Each variety is briefly described, and directions for selecting a variety and selecting seeds in the field are given.

The results obtained in a composite seed test were equally significant with those obtained in 1898 and 1899, and confirm the conclusion previously drawn that if the seeds of 2 equally productive varieties, one an early and the other a late cotton, be mixed, the yield will be greater than that of either variety planted alone.

The results of distance experiments show that cotton planted 4 ft. by 1½ ft., one plant in a place, gave a better yield than when planted 4 ft. by 3 ft., two plants in a place, and that for the years 1899 and 1900, on the soils covered by the experiments, planting 12 in. apart in rows 4 ft. apart gave better results than 16, 20, or 24 in. between plants in the row.

Dividing the fertilizer application gave results confirming the conclusion drawn from previous experiments, namely, that commercial fertilizers should be applied not less than 1 week before planting, but that nitrate of soda may sometimes be profitably applied a month or more after planting. Applying commercial fertilizer in the bedding furrow was found preferable to broadcasting the application. A general fertilizer test did not give definite results, but the author thinks they tend to the conclusion that a formula consisting of 3.33 parts of phosphoric acid, 1 part of potash, and 0.93 part of nitrogen, all in available form, is best suited to middle Georgia uplands in high condition.

Culture tests with several varieties of lupines, vetches and peas for green manuring, O. Pitsch (*Orgaan. Ver. Oudleer. Rijks. Landbouwschool, 13 (18901), No. 151, pp. 29–33*).—The results for 1897 and 1898 are reported in tabular form and discussed. In 1897 blue lupines produced the largest amount of dry matter of nitrogen. In 1898 the amount of dry matter and nitrogen produced by blue lupines was greater than the amount yielded by yellow and white lupines, but smaller than in the case of vetch and peas. The roots of lupines were richer in nitrogen than the roots of vetches and peas.

The culture of colza and lupines, Schribaux (*Bul. Soc. Nat. Agr. France, 61 (1901), No. 1, pp. 41–44*).—An article presenting a paper by Wagner, professor at the Agricultural School at Ettelbrück, Luxembourg, on the utility of the culture of colza and lupines on the value of green manure and the advantage of plowing shallow when turning under organic manures.

Experiments with varieties of oats to determine the value of seed exchange, F. F. Bruijning, Jr. (*Verzamel. Verslag. Rijk Gesubsidiëerde Proefvelden, etc., 1899–1900. Department Binnenlandsche Zaken, Netherlands, pp. 549–586; also published as a Separate, Wageningen, 1900, pp. 37*).—The question of the use of seeds raised under different conditions from those under which the crop is to be grown has usually been approached from the quantitative standpoint. In the present work variations in quality were studied. A portion of the seed first imported was reserved as a type and the quality of each year's product compared with the standard thus established.

The experiments were carried on in 1899 with five standard varieties of oats in use in the Netherlands. The seeds of these varieties were distributed to 16 farmers who planted them in the regular course of their farm rotation, without special preparation. Details as to the nature of the soil, fertilizers, weather, cultural conditions, growth, etc., are tabulated as are also data as to the purity, weight of the grain, percentage of straw to grain, etc.

It is shown that in most cases the seed sent in by farmers who had conducted the work was inferior to the original seed and in some cases the samples fell much below the standard. They contained more impurities, had a smaller hectoliter weight and a smaller weight per 1,000 seeds and a greater percentage of hull than the original seed.

The year 1899 was, however, a poor year for oats, many of the flowers were not fertilized and many seeds were shrunken.

The author further compares the standard seed and the seed produced in 1899 in regard to the character of the seed. He recognizes 5 classes, 3 of which are based upon the position of the seed in the spikelet and called, respectively, lower middle, and upper seeds, besides single and double seeds. A single seed is one developed in the lowest flower of the spikelet when the other flowers are abortive; the double seed is formed by the middle seed becoming enclosed in the glume of the lower seed of the same spikelet. The lower seeds are the heaviest and best developed, being even larger than the single seeds.

A careful analysis of the original seed and that of the 1899 crops of all varieties showed that the former contained a larger proportion of lower and single seeds than did the new crop as sent in by the farmers. This crop could, however, be made equal to the standard by selecting the heaviest seeds with a fanning mill. This is the secret of maintaining a variety constantly up to its original quality and is the means of improving it.

This is the first year of the experiment.—H. M. PIETERS.

Commercial fertilizers for potatoes, W. H. JORDAN (*New York State Sta. Bul. 187, pp. 215-232*).—This bulletin is a report on experiments made in 1899 and 1900 in continuation of work previously reported (E. S. R., 11, p. 235). The plan and purpose of the experiments have been heretofore described. The results of the yields for the 2 years are given in detail in tabular form. The author summarizes the results as follows: "Experiments in potato growing conducted for 4 years on 4 Long Island farms with fertilizers varying in quantity from 500 lbs. to 2,000 lbs. per acre show that on the average the largest profit was realized from the use of 1,000 lbs."

The so-called Long Island formula, containing 4 per cent of nitrogen, 8 of available phosphoric acid, and 10 of potash, proved to be superior to a potato formula containing 7, 4, and 10 per cent, respectively, of these different elements.

"Experiments with varying quantities of potash gave results which do not justify the use of such large quantities of this ingredient as are now being applied in potato growing by many Long Island farmers whose conditions are similar to those under which these tests were made.

"It is clearly evident that a large supply of available plant food does not necessarily insure a satisfactory crop. Other conditions which largely pertain to culture, such as texture, humus, and water supply, exercise a controlling influence, and when these conditions are unfavorable their effect is not overcome by heavy applications of fertilizer."

Profitable potato fertilizing, III, F. H. HALL and W. H. JORDAN (*New York State Sta. Bul. 187, popular ed., pp. 5*).—This is a popular summary of the above bulletin.

The influence of selecting seed potatoes from plants with well-developed stems and large tubers, C. VON SEELHORST (*Jour. Landw., 48 (1900), No. 2, pp. 97-103*).—A report is here given of experiments made in 1898 and 1899 with seed potatoes from large and from small plants. In some of the tests the seed had been selected from large or small plants since 1892. The results in nearly every case indicated that the productivity of the parent plant is transmitted, the seed tubers selected from the larger plants giving the best yields.

A chemical investigation of the rice plant and of the product and by-products of the rice industry, C. C. McDonnell (*South Carolina Sta. Bul. 59, pp. 16*).—This bulletin contains notes on the history and production of rice and a brief description of the processes employed in milling or cleaning the grains. Analyses of 21 samples, comprising parts of the plant and various by-products, were made at the station and the results are given in tables. The work included analyses of the ash. A table showing the average composition of some of the most important feeding stuffs, taken from other sources, is presented for the purpose of comparison. The value of the different parts of the rice plant and of the by-products is briefly discussed. From an investigation on the percentage relation of the various parts to the entire plant, the author finds that nearly one-half of the harvested crop is grain and that three-fifths of the straw are leaves. The ash analyses showed a very large percentage in silica, especially in the hulls. The polished grain had very little silica, but an unusually large percentage of phosphoric acid. All the samples showed but a small amount of lime. From the results of the chemical analyses reported the quantities of fertilizing constituents removed per acre by a crop of 35 bu. of rice and 1,800 lbs. of straw are calculated and presented.

Rice culture in the South, S. A. Knapp (*Rice Industry, 2* (*1901*), *No. 13, pp. 9–11*).—An article discussing rice culture in the South.

Pedigreed sorghum as a source of cane sugar, A. T. Neale (*Delaware Sta. Bul. 51, pp. 3–24*).—This bulletin gives a comparison of sugar cane, sugar beets, and sorghum as sources of sugar, describes a method of raising sorghum, points out how its value for sugar production is determined, and discusses the machinery needed to extract sorghum sugar, with estimates of its cost and suggestions as to its management. The author reviews the work that has been done along this line and summarizes the results obtained in Delaware, which have been partly reported in previous bulletins (E. S. R., 10, p. 345; 11, p. 141). In 1898 two selections of seed were made, one from stalks whose juices averaged 19.85 per cent of sugar with a purity of 83.5, the stalks weighing 23 oz. each, and the other from stalks containing 19.54 per cent of sugar in the juice with a purity of 83.1, the stalks averaging 18.6 oz. in weight. In 1899 seeds from the first selection were used on the Packard, Killen, and Neale farms, and seeds from the second selection were used on the Corbit farm. This same year seeds were selected on the Packard farm from 38 canes having an average sugar content of 16.50 per cent in the juice, a purity of 82.8, and an average weight of 24 oz. per cane. These seeds were used in 1900. The results are given in the following table:

Results from pedigreed sorghum seed in 1898, 1899, and 1900.

Grower.	Yield per acre.	Sugar per ton.	Available sugar per ton.	Available sugar per acre.	Purity of mill juice.	Number of stalks per acre.	Number of stalks in 100 ft. of row.	Distances between rows.	Full stand of cane.	Full yield of sugar.

The author summarizes the directions for growing sorghum for sugar as follows:

"Use seed from cane testing as high as possible in sugar, from 15 to 18 per cent, with juice purities in excess of 80 degrees. Select land which will produce 50 bu. or more of corn after repeated manuring with crimson clover, which crop may have been pastured down or plowed under, or cured as hay. Fertilize with muriate of potash broadcast at rate of 160 lbs. per acre. To this add 150 lbs. of nitrate of soda, provided some crop other than crimson clover has immediately preceded sorghum. Seed during the last fortnight in May, in rows 36 in. apart. Let each row consist of two lines of plants 4 in. apart, and in these lines let the plants stand at regular intervals of 6 in. To each plant would then be given 108 sq. in. of soil surface. Cultivate as if for Indian corn. Prepare to begin milling during the last fortnight in September; provide cane for 60 days' work, to close November 15. Such a field so planted and tilled should yield raw sugar in excess of 5,000 lbs. per acre.

Germination experiments with sugar-cane cuttings, Z. Kamerling (*Meded. Proefstat. Suikerriet West Java, 1900, No. 41, pp. 6–17*).—Two series of experiments were carried on, the first to ascertain the influence of fertilizers on the growth of sugar-cane cuttings (bibits), and the second to determine the effect of applying tar or Bordeaux mixture to the cut surface of the cutting.

For the first series of experiments 40 pots were used, in each of which 2 cuttings of 3 eyes each were planted. The manures used were potassium phosphate, magnesium sulphate, and sulphate of ammonia. These were applied to the pots in different combinations, 10 gm. of salt in solution being used in each case. The salts had no effect upon the growth of the cuttings.

In the second series of experiments 85 pots planted with 2-eyed cuttings were used. The cut surface of some of the cuttings were coated with tar, others were first washed for ½ hour and then coated with tar. A third set was treated with Bordeaux mixture, while a fourth was treated with Bordeaux mixture after having been washed for ½ hour. Of the cuttings treated with Bordeaux mixture, 81 per cent of the eyes started as compared with 62 per cent when the cuttings had been treated with tar. The former also started more promptly. When the cuttings were soaked and then treated with Bordeaux mixture a greater number of buds started than in the unsoaked lot and they also began growth more quickly. The soaking before applying tar hastened the commencement of growth, but did not materially increase the total germination. The author attributes the harmful effect of the tar to a clogging of the water vessels at the cut surface.—H. M. PIETERS.

Cane farming in Trinidad, P. Carmody (*West Indian Bul., 2 (1901), No. 1, pp. 33–41*).—A paper discussing the financial and economical phases of the industry.

A soil study of sugar beets, W. P. Headden (*Colorado Sta. Bul. 58, pp. 46*).—This bulletin is in continuation of work reported in Bulletin 46 of the station (E. S. R., 10, p. 743). An outline of the previous work and some of the conclusions drawn therefrom are given in the preface. The experiments here reported were made in 1898 and 1899 on the same plat that had been used in 1897. They embrace a study of irrigation, manuring, and alkali content of the soil in connection with sugar-beet culture, and an investigation on the influence of drying and soaking the beets and the size of the beets on the composition. During these seasons the crop received but one irrigation and was cultivated less frequently than in 1897. In 1898 the plat was divided into sections, the alternate ones receiving an application of 64 tons of barnyard manure to the acre. One section received a dressing of cut straw at the rate of 14 tons per acre. No further application of manure was given in 1899. Irrigation was unnecessary in 1899, but water was applied from August 31 to September 2 and the ground then left to bake and harden. The year before the plat received about 8 in. of rain and irrigation water. The plat also received subirrigation.

The results show that the application of manure mitigated the effects of the alkali and improved the stand of beets in general, but produced beets of inferior shape and quality. It did not, however, prevent an absence of a stand in some spots. The mechanical effect of the cut straw on the soil was nearly as great as that of the manure, but in other respects was less effective. The second season the influence of the manure was less evident, but, owing to soil conditions retarding its decay, the percentage of sugar and the purity of the beet were affected about the same as during the first season. The results corroborate the conclusions of 1897, that the quantity of alkali in the soil of the plat had no injurious effect on the percentage of sugar in the beet, and that it had no influence on the maturity. The average sugar content of 1898 was 13.62 per cent and of the crop grown on alkali soil 13.65 per cent. There was an increase of 4.9 per cent of dry matter in the beet in 1898 and of 3.8 per cent in 1899 over the percentage of dry matter in 1897. It is stated that beets weighing 2 lbs. or more are as rich as those weighing less than 1 lb. grown under the same conditions. The fact that an increase in sugar at the time of ripening, observed in 1897, was not noticeable in these crops is attributed to differences in the seasons. Beets grown in a single row with several feet of space on either side were lower in sugar content than beets of the same varieties grown in rows 20 in. apart.

The chemical work done in this connection showed that continued cropping and cultivation of the plat had slightly decreased the percentage of ash in the beet and changed its composition, particularly lowering the percentage of chlorin. The percentage of pentoses in beet pulp after the extraction of the sugars was found to be higher in beets rich in sugar than in beets of a low sugar content. It was found that beets soaked for 7 days in water cooled by ice showed an actual increase in sugar content. The leaves of the sugar beet were found to contain some glucose and maltose, but very little sucrose.

Influence of mineral fertilizers on the yield of sugar beets, P. PETROV (*Selsk. Khoz. i Lyesov., 197 (1900), May, pp. 327–377*).—The experiments here described were conducted on the estates of P. I. Kharitonenko in the Kharkov government, Russia. In studying the influence on the yield of sugar beets of calcium superphosphate, waste products from beet-sugar factories, and a mixture of these two substances when applied as fertilizers, it was found that the mixture gave the best results as to quantity and quality. The results further showed that a large application of calcium superphosphate improved the quality of the beets, while a small application lowered it. The author explains this result by stating that phosphoric acid has a deteriorating influence on the quality of sugar beets, while lime has the opposite effect, and that in heavy applications the beneficial influence of the lime overcomes the injurious effect of the phosphoric acid, while in light applications this is not the case.

Notes on sugar beets for 1899, R. H. McDOWELL (*Nevada Sta. Bul. 50, p. 13*).—This bulletin contains a report on several cooperative culture tests with sugar beets in Nevada. The possibilitities of growing sugar beets in the State and of establishing sugar factories is considered.

Sugar-beet culture in Wisconsin during 1899, F. W. WOLL (*Wisconsin Sta. Rpt. 1900, pp. 239–256, figs. 3, map 1*).—The work with sugar beets for 1899 consisted of analyses of samples grown by farmers in different parts of the State, and of variety and fertilizer tests with sugar beets made at the university farm. The results of all analyses and the meteorological data for the season are given in tables. The results of analyses for the years 1890 to 1899 are arranged by counties and further indicated on a map.

The analyses of 178 samples of beets from 56 counties show an average of 14.68 per cent of sugar in the juice, with a purity of 80.5 per cent. The average weight of topped beets in the samples was 1.34 lbs., and the average yield per acre 16.1 tons.

The experiments at the university farm show a depressing influence of an application of 20 tons of barnyard manure per acre on the quality of the beets, and an improvement in the quality due to a special fertilizer containing phosphoric acid and potash and to an application of phosphoric acid alone, each used at the rate of 200 lbs. per acre. Vilmorin, Kleinwanzleben and Rölker Dippe Elite produced beets of early maturity and exceptional richness. The Rölker Dippe Elite grown without fertilizer contained 19 per cent of sugar in the juice with a purity coefficient of 92.9 per cent.

The culture of beets on the experimental field at Grignon in 1900, P. P. Dehérain (*Ann. Agron., 26 (1900), No. 12, pp. 593–603*).—The work here reported consisted of a test of 3 varieties of beets grown at different distances. Each variety occupied 6 different plats fertilized with barnyard manure at the rate of 40,000 lbs. per hectare. A report on similar work has been previously given (E. S. R., 10, p. 839). Meteorological data for the year, which was characterized by a dry summer, are given. The results show that the variety Giant Rose gave a much better yield than the Small Leaved Globe or the Giant White. The Giant Rose and the Giant White varieties are known as *demi-sucrières*, indicating that their sugar content is high but not high enough for the manufacture of sugar. For Giant Rose the distance of 35 cm. in rows 40 cm. apart gave the best results. The author states, however, that no definite conclusions as to distance can be drawn from this season's results.

The conservation (drying) of beet tops (*Deut. Landw. Presse, 27 (1900), No. 86, pp. 1059, 1060*).—In a paper read by L. Wüstenhagen before the Agricultural Society of Bernberg, the following phases of the subject were considered: Cleaning the tops from dirt, small stones, etc.; decreasing the oxalic acid content of the leaves; preserving the sugar content of the root crowns; cutting up the crowns and tops to facilitate drying, and drying the same for storage.

The method of handling the beets is as follows: The tops are gathered in small heaps and left lying in the field for a week or so. Here the leaves wilt, thus losing a part of their moisture content and at the same time part of the oxalic acid contained in them. Whether the decrease in the oxalic acid content of the leaves is due direct to oxidation or to the action of micro-organisms was not determined. The tops are taken from the field to the factory, where they are put into a revolving sieve cylinder and brought in contact with a blast of hot air. The dirt, sand, and stones are largely removed by this process and the further decomposition of the oxalic acid in the leaves hastened by contact with the hot air. The tops are then cut up and the drying continued at a lower temperature, in order not to decompose the sugar in the root crowns, until only about 15 per cent of water remains.

That the oxalic acid content of the leaves is greatly reduced by this drying is shown by the analyses of the leaves before drying and of the finished product. In one instance the leaves before drying contained 2.93 per cent of oxalic acid; afterward, 0.6 per cent, and the average for a whole week for the dried product was only 0.3 per cent of oxalic acid.

Examination of protuberances on sugar beets, H. A. Huston and A. H. Bryan (*Indiana Sta. Rpt. 1900, pp. 78, 79*).—Comparative analyses are reported of normally grown sugar beets and of beets which had one or more protuberances on the upper portion of the roots, the protuberances and the beet proper having been analyzed separately. All the samples were of the same variety. The results show that the quality of the beet is very seriously impaired by the presence of protuberances.

List of publications on sugar-beet culture published in 1900, H. Briem (*Bl. Zuckerrübenbau, 8 (1901), No. 3, pp. 33–38*).—A bibliography of 149 publications bearing directly upon the culture of the sugar beet.

The beet-sugar industry in Michigan, 1900, C. D. Smith (*Michigan Bd. Agr. Rpt. 1900, pp. 380–391*).—A paper discussing the relation of the manufacturer of beet sugar to the farmer and laboring classes.

The sunflower plant: its cultivation, composition, and uses, H. W. Wiley (*U. S. Dept. Agr., Division of Chemistry Bul. 60, pp. 31, pl. 1, figs. 2*).—This bulletin treats of the botanical, agricultural, and commercial relations of the sunflower.

The uses of the plant are considered, and full directions for its culture are given. A series of letters on the culture of the crop, its expenses and returns, are presented, and investigations of sunflowers by experiment stations in the United States and Canada and the Division of Chemistry of this Department are reviewed and the results noted. The investigations by the Division of Chemistry comprise measurements of the plant and its different parts, the determination of the weight of the seeds, kernels, and shells, and chemical analyses of the various parts of the plant, including the ash.

Variation in the nitrogen content of cultivated wheats, P. DE VILMORIN ET AL. (*Bul. Soc. Nat. Agr. France, 61 (1901), No. 1, pp. 73–101*).—A comprehensive discussion of this subject at a meeting of the National Agricultural Society of France. The results of physical and chemical analyses of a list of varieties of wheat are given in a table.

The production of wheat in Michigan, O. C. HOWE (*Michigan Bd. Agr. Rpt. 1900, pp. 375–379*).—A general discussion of the subject.

Domestic supply of sugar for Michigan, R. C. KEDZIE (*Michigan Bd. Agr. Rpt. 1900, pp. 391–400, map 1*).—This article is an abstract of a paper presented before the United States Industrial Commission in 1900. The history, progress, and present condition of the beet-sugar industry in Michigan are reviewed.

Management of the estate of Ellenbach, A. CARON (*Jahrb. Deut. Landw. Gesell., 15 (1900), pp. 43, 44*).—A paper read at a meeting of the German Agricultural Society in 1900.

HORTICULTURE.

Report of the horticulturist, A. L. QUAINTANCE (*Georgia Sta. Rpt. 1900, pp. 305–351, pls. 4*).—This is a report on work at the station with peaches, plums, grapes, cantaloupes, onions, and celery. Analyses with reference to sugar, water, and starch content are also given for 43 varieties of sweet potatoes, and some illustrations given showing the development of the fruit buds of the peach at different stages of growth between May 23 and the following December. Of the 65 varieties of native and European plums tested at the station, Munson, Wild Goose, Hughes, and Nebraska are considered the most desirable.

The work with grapes is in continuation of that previously reported (E. S. R., 12, p. 50) and consists (1) of a study of the degree of self-fertility of the different varieties, and an examination of the stamens as to whether they were upright or reflexed; (2) a test of the keeping qualities of the different varieties; (3) a study of the effects on the fruit of ringing grapevines; and (4) analyses of the different varieties with reference to the sugar content of the juice. In the self-fertility test, out of 271 varieties grown, 144 are recorded as having bunches above 80 per cent perfect. These were all varieties with upright stamens. The author states that those varieties which have a percentage of self-fertility less than 80 should be planted with other varieties of the same blooming period. When inclosed in sacks varieties with reflexed stamens failed entirely to produce fruit. In some other instances the bunches from the inclosed flowers were often larger and more perfect than where the flowers were exposed to pollen of other varieties, and there was almost every gradation from this condition to complete self-sterility. In the test of the keeping qualities of grapes, there was no great degree of uniformity with the results secured the preceding year. This question is being further studied.

The fruit from ringed and unringed canes is compared in point of size, quality, and date of ripening in a number of tables. The ringing was begun when each variety was about one-third grown. "Great variation was noticed in the effects produced on the different varieties. In some the ripening of the fruit was much earlier, while in other varieties it was actually retarded."

Twelve methods of training grapes were compared, and notes are given on the results secured with each. Caywood or arbor system, umbrella Kniffin, and the true or three-wire Munson system were most satisfactory.

Work with cantaloupes consisted of a test of 43 varieties planted at different dates. The first seed was planted in Neponset pots on March 24. On April 7 a second planting was made, and these were transplanted in the field April 30, at which date seed was also planted in the ground. The average yield per vine for the different plantings was as follows: March 24, 3.89 lbs.; April 7, 4.97 lbs.; April 30, 4.06 lbs.

Thirteen varieties of onions were tested; one-half of each plat was fertilized in 1899 with lime at the rate of 50 bu. per acre, and in 1900 at the rate of 25 bu. per acre. The best yields were made by Prize Taker, 391 bu. per acre on the limed soil, and by Gigantic Gibraltar with a yield of 252 bu. per acre, also on limed soil. The greater part of the latter crop rotted in the field. The effect of lime on the whole was contradictory.

Of a number of varieties of celery grown, Golden Self-Blanching, Giant Pascal, and Boston Market are considered the best.

Report of the chief of the division of horticulture, botany, and entomology, W. F. Massey (*North Carolina Sta. Rpt. 1900, pp. XXI–XXIX*).—The author reviews the work of the year, mentioning briefly the results in some instances. A large number of orchard fruits have been planted, and experiments in bulb culture, tomato growing, and seed growing carried out. Good narcissus bulbs have been produced, and very favorable results secured in the bulb culture of the Bermuda Easter lily. In experiments with tomatoes, limed plats were entirely free from the bacterial blight known as "Southern blight," while on unlimed plats nearly all of the plants died of the disease. The following season when tomatoes were planted on both limed and unlimed plats, without further addition of lime, the plants on both plats died, showing that the lime to be of benefit must be renewed each year. Some experiments in seed production seemed to show that some of the late-blooming flowers may be profitably grown for seed in that State.

The effects of continued use of immature tomato seed, E. S. Goff (*Wisconsin Sta. Rpt. 1900, pp. 295–297*).—Experiments with Cook Favorite tomatoes in 1891 (E. S. R., 4, p. 155) with seed from mature and immature fruits, through six generations, indicated that the use of immature seed reduced the growth of the plant, increased its prolificacy, and promoted early maturity. In the fall of 1891, samples of seed from mature fruit, and from fruit that had not commenced to redden, were saved from Cook Favorite, Little Gem, and Potomac varieties. With the Potomac variety, the seed from fruit that had just commenced to redden was also saved. These were planted the following season and seed again saved for the next year's crop, the mature seed being taken from plants grown from the mature seed, and the immature seed from the plants grown from the immature seed. This method of selection has been continued up to the present time. The yield of fruit per 100 lbs. of vine, percentage of crop that reddened before frost, and the percentage of fruit gathered in the first four pickings, from both the mature and immature seeds, are arranged in tabular form. A study of these data shows results entirely at variance with those reported in 1891. The use of the immature seed in this second experiment had no uniform effect "on the prolificacy or the maturing season of the plants, and no effect could be seen at any time upon the vigor of the plants."

The horizontal training of tomatoes, G. Quinn (*Jour. Agr. and Ind., South Australia, 4 (1901), No. 7, pp. 583–585, figs. 3*).—Wire netting with large meshes is stretched horizontally about a foot above the tomato rows. The vines grow through the meshes and are thus kept off the ground. Good results have been obtained by the author by this method of training.

Fertilizer and cultural tests with different varieties of tomatoes, J. Troop (*Indiana Sta. Rpt. 1900, pp. 56–72*).—Results are here reported of fertilizer and cultural tests with 12 varieties of tomatoes in plat experiments. The plants were grown from seed in the greenhouse, except 2 varieties which were started from cuttings. A portion of the plants were transplanted once from the seed bed into pots before planting them out in the open ground. The results secured in the fertilizer test with each variety are recorded in 9 tables, but no conclusions are drawn. The results of the experiment in transplanting versus nontransplanting with 7 varieties of tomatoes are in favor of the nontransplanted plants as regards the average yields per plant of all the varieties. The Stone variety yielded 15 lbs. per plant from cuttings, as compared with 11.32 lbs. per plant from seed—a difference in favor of cuttings of 3.68 lbs. per plant.

Tomatoes were grown in the greenhouse and a portion subwatered. The results show a decided gain in the weight of fruit from the subwatered plants as compared with the surface-irrigated plants, although the latter produced the greater number of fruits. In connection with these experiments, the author investigated the variations which occur in individual plants. "Fourteen plants were selected from a lot that was as nearly uniform in size and vigor of growth as possible, and these were planted in the greenhouse and treated exactly alike so far as it was possible to do so. The results of these tests gave a maximum variation in number of fruits produced by each plant of 75 per cent. Some individual plants produced nothing but small fruits throughout the season. The maximum variation in the weight of fruit produced by each plant was only 1¼ lbs." Some data are also included on results of fertilizer experiments with tomatoes in the greenhouse, no conclusions from which are drawn.

Notes on celery, E. Walker (*Arkansas Sta. Bul. 64, pp. 77–94, figs. 5*).—A number of cultural, fertilizer, and irrigation experiments were made at the station with celery, and notes are given on the results of the different experiments, together with brief suggestions on growing celery. The rainfall record for the months of July, August, and September is appended. The author's experiments seem to indicate that pithiness of the stalk may be caused by a deficiency of water during a late stage of growth. Early sown celery rotted when it was bleached by earthing up in warm weather or by the use of boards. This difficulty was obviated by planting self-blanching varieties close together, as in the "new celery culture."

The cabbage plusia, parsley worm, and the celery-leaf blight (*Cercospora apii*) were held in check by applications of Bordeaux mixture containing Paris green. A rot occurred among young transplanted celery, following severe topping. It occurred at the base of leafstalks next to the ground, in cases where the whole blade had been cut away, leaving a leafless petiole. "It was checked by pulling out plants most affected and many of the affected leafstalks, cleaning up between the rows, and spraying with Bordeaux mixture." The author states, in this connection, that the tops should not be sheared off too close in transplanting. It is recommended to prepare the seed bed as for tobacco. Giant Pascal is considered one of the best of the green varieties of celery.

Duration of the growth period in fruit trees, F. Cranefield (*Wisconsin Sta. Rpt. 1900, pp. 300–308, figs. 2, dgms. 2*).—The length of the growing period of apple, pear, cherry, and plum trees has been studied by the station for the past 2 years. The growth of the branches was determined by careful measurements of selected branches at intervals of 2 to 4 days, until no further growth in length could be observed. On the trees under observation, no increase in the growth of the pear occurred after June 1, nor the cherry after May 27. With the apple, the branch growth ceased about June 4, and with the plum June 23. Examination of several hundred other orchard trees during the following July and August showed no indications of further growth. The author points out in this connection that these observations were taken after one of the most severe winters ever known in Wisconsin.

During the season of 1900 no growth on any of the trees under observation occurred after July 10, while with the pear tree growth ceased June 18, and with the apple and plum June 29. Other trees in the same orchard, however, continued to grow until October 1, "at which time most of the terminal buds examined appeared to be plump and fully formed." This second growth on the other trees in the orchard began about July 15, and out of 325 trees examined 66 per cent of the trees on cultivated soil and 21.1 per cent of those in sod made a second growth. "Several of these second-growth shoots were measured as in the previous case and were found to be growing rapidly, in some cases at the rate of ½ in. per day."

"No second growth was found in the cherry orchard, consisting mainly of Russian varieties, nor on any native plum trees, but all of the Japan plums developed a strong second growth. . . . Many apple grafts, top-worked on orchard trees in the spring of 1900, continued to grow several weeks later than the stocks. No flowers opened at any time, showing that only the leaf buds developed, and of these only the terminal buds."

In connection with these experiments, observations were made to determine, "if possible, the earliest and latest date on which the bark would peel or separate from the wood readily enough to permit of budding, and if this condition prevailed continuously throughout the season; also to learn if the bark 'set' or tightened earlier on the smaller or larger branches. The method employed in the season of 1899 was to make T cuts similar to those employed in budding in branches of various sizes on trees of the various species previously mentioned. Several thousand of such cuts were made during the season, and as a result it was found that the bark could be peeled readily at any time on both large and small branches up to August 15; that after this date the bark was set on many of the smaller branches, although it could be easily peeled on the larger ones; that no difference appeared to exist between trees of different ages; that cultural conditions appeared to exert no influence; that a wide difference existed between trees of the same variety, age, and external appearance, and that the difference was often greater between different branches of one tree than between different trees."

During the season of 1900 the bark slipped readily on all branches up to September 15. After this date it was found impossible to slip the bark from branches ½ in. or less in diameter. On the larger branches it separated easily up to about September 25, and after October 3 it appeared firmly set on all branches, both large and small alike. "From this it would appear that the time when the bark sets varies with the season, as it could be peeled one month later in 1900 than in 1899. It would also appear that it sets first on the smaller branches."

The duration of the period of root growth was determined by digging a narrow trench on May 25 about 2 ft. from the trunks of the different trees. In doing this, many roots were cut. The trenches were then filled with well-enriched earth. This earth when examined, July 10, showed that many active new roots had pushed out into the soil from the cut ends, the most extensive root growth being found with the cherry, followed in order by the plum, pear, and the apple, which had made the least growth. The new growth of roots was then cut off and the trenches refilled. An examination of the roots August 22, and again October 6, showed that in all cases good root growth had been made, although no growth of twigs had occurred on any of the trees later than July 1, as determined by a careful system of measurements.

Trial orchards, W. G. VINCENHELLER (*Arkansas Sta. Rpt. 1900, pp. 111–113*).—These are orchards which are being established by the station throughout the cotton-growing sections of the State for the purpose of encouraging fruit growing. Thus far 27 orchards have been established in as many counties. Typical soils of the locality are selected, and the orchard so planned as to be a model as regards methods of cultivation, etc., for the neighborhood in which it is located. The station furnishes the trees, while the land is furnished by the owner, who is selected for his intelligence and promise to care for the trees in accordance with directions furnished by the station.

Under planting in orchards, C. A. Keffer (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 59–61, figs. 2*).—The author discusses the value of various crops for planting in the young orchard. Cowpeas planted in the orchard the last of June, plowed under the latter part of September, and followed by a seeding of rye, has been practiced at the university farm with good results. The soil cover of rye is designed to prevent the washing of the land during winter.

The effect of alfalfa and grass on the growth of orchard trees (*Ber. K. Lehranst. Obst, Wein u. Gartenbau, Geisenheim, 1899–1900, pp. 16–18*).—Trees in alfalfa and grass were compared with those in cultivation. The results as regards tree development and fruit production were decidedly in favor of cultivation.

Apples that originated in Ohio, W. R. Lazenby (*Jour. Columbus Hort. Soc., 15 (1900), No. 4, pp. 137–140*).—Descriptions of 8 varieties which originated in Ohio, with a list of summer, autumn, and winter varieties for the State.

The cherry in Kansas, with a chapter on the apricot and nectarine (*Topeka: State, 1900, pp. 128, figs. 3, map 1*).—This is a popular compilation of a number of articles on the culture, insects, and diseases of cherries, apricots, and nectarines, with statistics of Kansas production. The work is compiled and revised by W. H. Barnes for the Kansas State Horticultural Society.

Pickling green olives, F. T. Bioletti (*Pacific Rural Press, 61 (1901), No. 10, p. 148*).—The author describes a successful process for pickling olives so that they will maintain their green color.

Training the young lemon tree, Leffingwell (*Pacific Coast Fruit World, 11 (1901), No. 2, p. 3, figs. 4*).—The open-topped system of pruning lemon trees is briefly described and its advantages pointed out.

The artificial coloring of oranges, Pum and K. Micko (*Ztschr. Untersuch. Nahr. u. Genussmtl., 3 (1900), No. 11, pp. 729–735, figs. 11*).—Attempts to color oranges in imitation of blood oranges by injection with solutions of fuchsia, or with the coloring material in grapes or bilberries, resulted in failure. Even where the solutions were injected under considerable pressure, the colored portions were always local and of such an appearance as to deceive no one. The reaction secured with the juice from blood oranges and a number of chemical reagents is given in some detail.

Navelencia, a new citrus creation (*Pacific Coast Fruit World, 10 (1901), No. 25, p. 3*).—A new orange originated by A. C. Thompson by the union of buds of the navel with the Valencia orange. The new variety is said to have all the points of superiority of the navel with the shape and late-ripening habits of the Valencia.

Training the peach, C. A. Keffer (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 57–59*).—Methods of pruning the peach tree at different stages of growth are illustrated and described.

Peaches in Massachusetts, J. W. Clark (*Amer. Gard., 22 (1901), No. 327, pp. 229, 230*).—A paper discussing the history of peaches and the results secured by the author in growing peaches in Massachusetts. Peaches can be successfully grown in Massachusetts in certain locations on high ground, but the crop is frequently destroyed by winter temperature of —20° F.

Grafting (*Amer. Gard., 22 (1901), No. 324, p. 171*).—The writer states that he has successfully grafted two Wagner apple trees with Flemish Beauty pears. The pears grew much larger than on the original Flemish Beauty trees, and had no brown specks on them when ripe like those on the mother pear tree. The fruit was also much superior in flavor. The grafts bore every year for 6 years without intermission, while the mother pear tree bore no fruit some years, and the Wagner apple trees on which they were grafted bore apples only every second year. Grafts of Black Tartarian cherries on the American black wild cherry always died the third year.

An ideal method of pruning fruit trees, E. S. Goff (*Amer. Gard., 22 (1901), No. 325, p. 188*).

Where to cut in pruning, C. A. KEFFER (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 53–55*).—The author believes that the best method of cutting off limbs is through the base of the shoulder parallel to the trunk or limb on which the branch to be removed is growing.

On a hybrid of the Liberian and Arabian coffee tree obtained at Réunion, E. BORDAGE (*Rev. Cult. Coloniales, 8 (1901), No. 68, pp. 1–7, figs. 5*).—Illustrations and descriptions are given of the leaves, flowers, and fruit of a natural hybrid between the Liberian and Arabian coffee trees. The hybrid resembles the Arabian tree most in the form of its leaves, flowers, fruits, and the quality of the berries. On the other hand, it is much more resistant to insect attacks and fungus diseases than the Arabian coffee, and in these respects resembles the Liberian tree.

Liberian coffee; its culture and manipulation, V. BOUTILLY (*Le caféier de Libéria, sa culture et sa manipulation. Paris: A. Challamel, 1900, pp. 137, pl. 1*).—Includes also a bibliography on the subject.

The cultivated guavas and their botanical differences, J. B. DAVY (*Pacific Rural Press, 61 (1901), No. 11, p. 164*).—A brief account of the genus with a key to the species already introduced.

A tendency to bisexuality in strawberries, U. P. HEDRICK (*Amer. Gard., 22 (1901), No. 327, p. 226*).—The author has examined the history and sex of strawberries originated in America and has found that of the 185 varieties introduced between 1834 and 1870, 96 varieties, or 52 per cent, were pistillate. Of the 513 varieties originated between 1870 and 1900, only 136 varieties, or 30 per cent, were pistillate. Considering the whole period there was a somewhat uniform progressive tendency from beginning to end for varieties to become bisexual. No reasons could be assigned for this tendency, but climate, soil, cultivation, and the natural tendency of strawberries to bear perfect flowers, as do most other plants of the same order, are suggested.

Second report on experiment in pinching raspberry shoots, E. S. GOFF (*Wisconsin Sta. Rpt. 1900, pp. 286–290*).—The experiments along this line reported in 1899 have been continued (E. S. R., 12, p. 51), being modified only by allowing 5 shoots to grow to each plant instead of 4. The data for the two years are tabulated and summarized. "Judging from the first two full crops, high pinching, i. e., at 18 to 24 in., has apparently increased the yield of the Gregg raspberry, but has slightly decreased the yield of the Cuthbert. Low pinching, i. e., at 12 in., has decreased the yield of both varieties. Pinching appears to have slightly reduced the size of the berries in both varieties. Pinching has evidently increased the growth of superfluous shoots in the Gregg variety."

Making a cranberry bog, F. A. MAKEPEACE (*Agr. Epitomist, 20 (1901), No. 4, p. 23*).—The work of preparing the bog, grading, planting the vines, and harvesting the crop is discussed.

Grapes, F. S. EARLE and C. F. AUSTIN (*Alabama College Sta. Bul. 110, pp. 55–91, figs. 2*).—This bulletin discusses in a general way soils and planting, training and pruning, cultivation, marketing, and insects and diseases and their treatment. One of the most serious diseases at the station has been root rot. Out of 651 vines planted in 1894, 483 vines, or a little over 75 per cent, are now dead, and the death of the majority of them was caused by the root rot. Of the 16 varieties included in this planting, only 2, Herbemont and Rulander, were entirely resistant to the disease. It is thought that possibly these varieties may be used as stocks for less resistant kinds. Various fertilizers have been used to note their effect in the control of the disease. Among others heavy applications of kainit, lime, coal ashes, and stable manure have been made, but with no marked results so far as the disease was concerned. The southern part of the State seems to suffer more than the northern part from the disease, and it is worse on sandy lands than on clays.

Short descriptive notes are given on 94 varieties of grapes fruited in the station vineyard during 1900. Of these varieties Rockwood is considered deserving of special mention as the best of the very early black grapes. For market purposes, Concord, Ives, Delaware, Brighton, Moore Diamond, and Niagara are recommended.

Grapes, C. C. Newman (*South Carolina Sta. Bul. 58, pp. 27, pls. 18*).—A popular bulletin on grape culture, including the laying out of the vineyard, planting, cultivation, pruning, training, trellises, spraying, selection of varieties, etc.

Ringing (*Amer. Gard., 22 (1901), No. 328, pp. 245, 246*).—A general discussion of the effects of ringing plants to produce earliness of fruit, with a review of L. Daniel's experiments in ringing herbaceous plants. In Daniel's works, when cabbage and Brussels sprouts were ringed, the results of the operation were seen in the more open heart or head, combined with a decrease in size; with the kohl-rabi a bulb was formed above the wound, showing that the bulb is a product of the elaborated or descending sap. The bulb was modified in form somewhat, being drawn out something like a gourd. In the case of ruta-bagas the operation was performed below the tuft of leaves. As a result the leaves became elongated and the root developed in the form of an abundant mass of fibers. With these plants the conclusion is reached that ringing is of no practical value whatever. With eggplants the size of the fruit was nearly doubled by ringing, and with tomatoes the size was increased considerably, as was also the quantity, but the quality was somewhat deficient. The results with these plants point out the value of the operation in developing these fruits for exhibition purposes.

The Kniffin method of grape pruning, C. A. Keffer (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 56, 57, figs. 2*).—A popular description of this method.

Waxed paper bands for grafting grapes (*Ber. K. Lehranst. Obst. Wein u. Gartenbau, Geisenheim, 1899–1900, p. 42*).—Parchment paper bands were waxed with the following mixture: One-third resin, one-third beeswax, and one-third crude turpentine. The paper was 3 cm. wide and 20 cm. long. These strips were tightly bound around the grafts and gave very satisfactory results.

First steps in ampelography: A guide to facilitate the recognition of vines, M. Mazade (*Melbourne: Govt., 1900, pp. 95, figs. 43*).—Translated by R. Dubois and W. P. Wilkinson from the French. A simple guide for the recognition of the more prominent species and varieties of European and American grapes.

Introduction to Roumanian ampelography, G. N. Nicoleano (*Introduction a l'Ampélographie Roumaine. Bucharest: Govt., 1900, pp. 152, pls. 12, figs. 54*).—Treats of the varieties of grapes grown in Roumania, climate, soils of different provinces, history of grape culture in the State, production and value of the crop, and gives careful descriptions and plate illustrations of all the more important varieties, with analyses of many wines, etc.

Chestnut cultivation in France, J. C. Covert (*U. S. Consular Rpts., 65 (1901), No. 246, pp. 304–308*).—French varieties of chestnuts are briefly described, their uses—especially in confectionery—noted, and the belief expressed that French chestnuts might be profitably grown in many places in the United States, especially along the coast of Lake Erie near Cleveland. In the preparation of glacéd chestnuts the meats are peeled and boiled and placed for 3 days in vanilla sirup, after which they are drained, coated thinly with vanilla, and put up in fancy packages for shipment. It is believed this industry could be profitably undertaken in the United States, where sugar is 50 per cent cheaper than in France.

A practical guide to garden plants, J. Weathers (*London: Longmans, Green & Co. (1901), pp. XII + 1192, figs. 163*).—This work contains descriptions of the hardiest and most beautiful annuals and biennials; hardy herbaceous and bulbous perennials; hardy water and bog plants; flowering and ornamental trees and shrubs; hardy ferns, bamboos, and other ornamental grasses; also an account of the best kinds of fruits and vegetables that may be grown in the open air in the British Islands, with practical instructions as to culture and propagation. The work is well indexed. It is particularly intended for the use of amateur gardeners, and also for those engaged professionally in horticulture, as a book of reference.

The experiment stations and the florist trade (*Florists' Exchange, 13 (1901), No. 12, pp. 303–307*).—Reports from 40 experiment stations throughout the country, summarizing the work done at each station along the lines of floriculture. An account of the work done by the Division of Pomology and the Division of Vegetable Physiology and Pathology of this Department along the same lines is also included.

The question of color relative to flowers, F. S. MATHEWS (*Florists' Exchange, 13 (1901), No. 13, p. 361*).—Points out the differences occurring in supposedly authentic color charts as regards names of different colors.

Ether treatment of plants (*Gartenflora, 50 (1901), No. 4, p. 99*).—A brief account is here given of the successful use of ether vapor in forcing a number of greenhouse plants. It was especially valuable with *Viburnum tomentosum plicatum, Azalea mollis*, and *A. pontica*, but was without benefit with *Deutzia gracilis*.

Hybridization in Amarylleæ (*Gard. Chron., 3. ser., 29 (1901), Nos. 734, pp. 37, 38; 735, p. 53; 736, pp. 71, 72; 737, pp. 89, 90; 738, pp. 111, 112*).—The author deals with hybrids that have been raised in gardens between individuals of this suborder from warm, temperate, and tropical regions. Forty-seven genera are dealt with specifically.

Notes on cannas, F. K. LUKE (*Jour. Columbus Hort. Soc., 15 (1900), No. 4, pp. 150–159, pls. 3*).—Cannas are divided into 4 subgenera and a number of the more prominent varieties described.

Carnations, preparation for field planting, A. M. HERR (*Amer. Florist, 16 (1901), No. 668, pp. 1159, 1160*).—Directions for fertilizing and cultivation.

New chrysanthemums of 1900, H. DAUTHENAY (*Rev. Hort., 73 (1901), No. 5, pp. 121–123*).—This paper purposes to give a complete list of the different varieties of chrysanthemums introduced in 1900. Each variety is descriptively characterized.

Shasta daisies (*Pacific Rural Press, 61 (1901), No. 8, p. 113, figs. 2*).—This new creation by Luther Burbank is illustrated and described. It is said to be the result of crossing and selection between the weedy, free-flowering American species, the rather large but coarse European species, and the Japanese species. The flowers are very large, averaging from 3 to 4 in. in diameter, and are produced on stiff stems nearly 2 ft. in length. The petals are glistening white and arranged in three rows. The plant flowers freely and is hardy wherever oak is hardy. Some Shasta daisies with well-marked colors are now appearing.

Hydrangea hortensia, Jeanne d'Arc (*Amer. Gard., 22 (1901), No. 327, p. 225*).—A new pure white creation said to be a sport from the variety Thomas Hogg and especially suitable for pot culture.

DISEASES OF PLANTS.

Plant diseases in 1900, A. L. QUAINTANCE (*Georgia Sta. Rpt. 1900, pp. 351–361, pls. 3*).—Notes are given on a number of the more injurious plant diseases noted by the author during the season covered by the report. One of the most destructive diseases is the brown rot of peaches and plums (*Monilia fructigena*). Experiments have been reported (E. S. R., 12, p. 962) for the control of this disease on the peach, and in the present report the results of spraying plums of the Americana type are given. From the data at hand it appears that the spraying with Bordeaux mixture was practically without value upon plums of this race. As an explanation of the inefficiency of the fungicide the author suggests that possibly the fruit is infected by the fungus which may have been perennial in the fruiting spurs. A bacterial rot of onions, similar to that which has been described as occurring in New York (E. S. R., 12, p. 56), is reported, and in some cases has proved very destructive.

Notes are given on a number of diseases of peach, cherry, pear, grape, and apple. A cantaloupe blight, similar to that described in Colorado (E. S. R., 12, p. 261), is mentioned as occurring at the station. This blight is said to be due to *Macrosporium cucumerium*. The older leaves first showed small brown spots, which developed so as to kill the leaf in a week or ten days. The injury proceeded mostly from the older to the younger leaves, leaving the central part of the hill destitute of foliage. The quality of the fruit produced during the season was very inferior, and this depreciation is believed to be due to the presence of the disease.

A very destructive disease of tomatoes is reported as occurring at the station during the summer of 1900. It made its appearance in the tomatoes when about one-third grown and was first noticeable by the presence of small brown, slightly depressed spots with an irregular tessellated margin. The spots enlarge rapidly, the skin shrinks, becoming more or less cracked and wrinkled, making it possible for the entrance of numerous fungi. As yet no organism has been positively observed in the early stages of the disease. Experiments were conducted for the prevention of this disease, with the idea that it was possibly of bacterial origin and might be spread by insects. Tomatoes were sprayed with Bordeaux mixture and a number of insecticides, with the result that those plants receiving the Bordeaux mixture every 2 weeks had 48.6 per cent of their fruit rotted, while the untreated plants had 88 per cent rotten fruits. The plants which were sprayed with insecticides showed no improvement, and in one case a greater amount of disease was noticed on plants which received applications of the insecticide at intervals of from 5 to 7 days during the growing season.

A disease of apple trees, which is due to an unidentified fungus, is reported. It attacks the foliage, causing the leaves to fall, or causing them to dry up and remain upon the tree, giving an appearance resembling that of the pear blight. The fungus causing the trouble appears to be wholly superficial and is readily controlled by applications of Bordeaux mixture.

Notes on injurious fungi (*Agr. Bul. Malay Peninsula* [*Gard. and Forest Dept., Straits Settlements*], *1900, No. 9, pp. 284–286*).—Brief descriptions are given of a disease of clove trees, the destructive action of *Rosellinia radiciperda*, and a disease of nutmegs.

The disease of clove trees is characterized by the appearance of dark red spots on the under surface of the leaves. These spots attain a diameter of ⅛ to ¼ in. and later become white, resembling mildew. The leaves fall, and if large numbers are affected the tree soon presents a nearly leafless appearance. The shoots are attacked, die back, and the tree eventually becomes leafless and dies. The fungus causing this disease is not definitely known, but a crude treatment with Bordeaux mixture seemed to indicate that it would be efficient in preventing the disease.

The destructive action of Rosellinia is described, and it is stated that all plants growing beneath a large tree of *Ficus dubia* were observed to be seriously affected. Examination showed that on an area of about 10 yards all plants had been killed, and that the base of the stem and the roots of the fig tree had become black. To extirpate the pest, the ground was cleared of all dead and dying plants, trash, etc., the affected roots of the tree were cut off and all affected material burned, after which the ground was dug over and lime liberally applied. Bordeaux mixture was liberally poured over the base of the tree and over the ground, and the disease seems to have been checked, no further spread being noticed.

The disease of nutmegs is attributed to the attacks of a fungus forming brown spots on the husk. It is caused by a species of Melanconieæ. The fungus causes the premature dehiscence of the fruit, the valves not growing as rapidly as usual. The tension between the seed and husk increases more rapidly in diseased fruits than in sound ones, resulting in the splitting of the husk prematurely. This disease being rather troublesome, planters are warned to pay attention to the spotting of the husk and to destroy all infected fruits as speedily as possible.

Report of the vegetable pathologist, H. TRYON (*Queensland Dept. Agr. Rpt. 1899–1900, pp. 30, 31*).—Brief notes are given on the occurrence of a number of diseases upon various economic plants.

The sterile fungus Rhizoctonia as a cause of plant diseases in America, B. M. DUGGAR and F. C. STEWART (*New York Cornell Sta. Bul. 186, pp. 51–76, figs. 9; New York State Sta. Bul. 186, pp. 30, figs. 9*).—This investigation was conducted by cooperation between the two New York stations. A brief account is given of the morphology of the fungus, and some of the more destructive of the American forms are described. Sterile Rhizoctonia produces diseases of the bean, beet, carrot, celery, cotton, lettuce, potato, radish, rhubarb, ornamental asparagus, china aster, carnation, sweet william, and violet, as well as being apparently the cause of diseases upon a number of other plants. In many cases Rhizoctonia is truly parasitic, and the diseases of beet, carnation, lettuce, and others have been repeatedly caused by the authors by placing pure cultures of the fungus in contact with the plants. In other cases the fungus is found associated with the disease, but as yet there is no proof that it is the chief cause of the trouble. The fungus is believed to be capable of prolonged existence upon decaying organic matter in the soil, and in this way it may be spread from plant to plant, even when culture or other means fail to spread it. Plants growing under favorable conditions of moisture, temperature, and nutrition will probably show marked resistance to the attack of the fungus, so that in seeking to prevent this disease good sanitary conditions are of the greatest importance. In the propagating and forcing benches, where the fungus is commonly present, a frequent change of soil is advisable. Should the fungus prove a serious pest in greenhouses, the sterilization of the soil with steam or hot water is recommended. The fungus grows readily upon acid media, and as a consequence liming of soil, while not thoroughly effective, will frequently prove beneficial.

Plant diseases due to Rhizoctonia, F. H. HALL, B. M. DUGGAR, and F. C. STEWART (*New York State Sta. Bul. 186, popular ed., pp. 11, pls. 2, figs. 2*).—This is a popular summary of the bulletin noted above.

A second preliminary report on plant diseases in the United States due to Rhizoctonia, B. M. DUGGAR and F. C. STEWART (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 249*).—Since the publication of the previous notes on diseases caused by Rhizoctonia (E. S. R., 11, p. 57), the authors have observed the fungus on a number of entirely new host plants. The principal host plants of this fungus are beans, sugar beet, cabbage, cauliflower, carrot, celery, cotton, lettuce, potato, radish, rhubarb, asparagus, china aster, carnation, coreopsis, sweet william, and violet, with about a dozen other plants of less importance. In many cases the Rhizoctonia proves to be truly parasitic and undoubtedly the cause of the disease, as is shown by abundant experiments, while in other cases innoculation experiments have not been performed. Studies are in progress to determine more carefully the physiology of the forms and the limitations of the species.

The wilt disease of cotton and its control, W. A. ORTON (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 27, pp. 16, pls. 4*).—The wilt disease of cotton is widely distributed through the South, having been reported from a number of places in South Carolina, Georgia, Florida, and Arkansas. The extent of loss from this source is very considerable, in some places cotton culture having been abandoned on infected soil. A description of the disease, together with its cause, is given. The nature of the fungus (*Neocosmospora vasinfecta*) has been previously described by the Division (E. S. R., 11, p. 944). In addition to cotton, this same disease is believed to occur on okra, and in both the okra and cotton it is sometimes complicated by the presence of root nematodes (*Heterodera radicicola*). The progress of the disease is relatively slow when compared with others, on account of its being a soil fungus. Natural and artificial infections from cultures of it are described, and experiments with fungicides for its prevention are outlined. Some of the common fungicides were applied to the soil in such quantities as to be practically prohibitive in ordinary practice without destroying the fungus or reducing the disease. The preventive measures suggested are rotation of crops, removal of diseased plants, avoidance of the spread of the disease by means of cattle, tools, etc., and care of the compost heap. Probably the most hopeful means for combating this disease is to be found in the resistant races of cotton. Experiments with a number of varieties have shown that some are much less subject to the disease than others. Experiments in this line are to be continued.

Formalin and hot water as preventives of loose smut of wheat, J. C. ARTHUR (*Indiana Sta. Rpt. 1900, pp. 17-24*).—The loose smut of wheat is said to sometimes cause losses amounting to 50 per cent of the crop, and quite commonly 10 per cent of the crop is destroyed year after year. Earlier experiments have seemed to indicate that the loose smut is more difficult to eradicate than the stinking smut, and experiments were conducted to test this subject. Smutted seed wheat was treated with hot water and various strengths of formalin, after which the seed was sown and the amount of smut in the subsequent crop ascertained. These experiments were repeated several years, and from the data at hand the conclusion is reached that the loose smut of wheat can not be removed from a crop by the treatment of the seed with formalin or hot water even when the treatment is so severe as to kill one-third or more of the seed. As indirect methods of preventing loose smut, it is recommended that seed should be sown only from fields known to be free from the smut and upon land that had not borne wheat for 2 or 3 years. In addition, it is recommended that wheat used for seed should be thoroughly screened, using a strong blast which would dislodge or blow out a large portion of the smut germs.

Formalin as a preventive of millet smut, W. STUART (*Indiana Sta. Rpt. 1900, p. 25*).—In the spring of 1899 the author treated millet seed from a badly smutted field with different strengths of formalin to test its value as a preventive of the smut. As a result of his experiments, the efficiency of formalin as a preventive of millet smut was established. Where the seed was treated for 1 to 2 hours in a solution of 1 lb. of formalin to 45 gal. of water there was no smut in the resulting crop. Where a weaker solution was used a small percentage of smut was noticed, but in no case was the disease as prevalent as in the check plats.

Inoculation experiments with grass-infesting ergots, R. STÄGER (*Bot. Centbl., 83 (1900), No. 5, p. 145*).—According to the author there are 5 species of grass-infesting ergots, namely, *Claviceps purpurea, C. microcephala, C. wilsoni, C. pusilla*, and *C. setulosa*. Inoculation experiments were conducted by means of ascospores and conidia with the first three, and a preliminary report is given of the results. It was found possible with ergot on rye to inoculate the following: Rye, *Anthoxanthum odoratum, Arrhenatherum elatius, Phalaris arundinacea, Poa pratensis, P. alpina, P. sudetica, P. hybrida, P. cæsia, Hierochloa borealis, Bromus sterilis, Dactylis glomerata, Hordeum murinum*, barley, *Briza media*, and *Calamagrostis arundinacea*.

It was found impossible to inoculate *Lolium* sp. or *Bromus erectus* with *C. purpurea* from rye, although reciprocal inoculations were made between Lolium and Bromus. On this account it is claimed that the *C. purpurea* reputed to occur on Lolium and Bromus is physiologically different from that of rye and other grasses and must be considered as a distinct biological species.

Ascospores of *C. microcephala* from *Phragmites communis* regularly infected *Nardus stricta*, and from *Molinia cærulea* they were successfully transferred to *Nardus stricta*, but all attempts to inoculate the grass hosts of *C. purpurea* with *C. microcephala* failed. *C. wilsoni* from *Glyceria fluitans* is said to be a distinct species readily infecting its host plants, but withstanding all attempts to transfer it to other species of grasses.

Damping off of beets in the field, J. C. ARTHUR (*Indiana Sta. Rpt. 1900, pp. 15, 16*).—The author's attention was called in May, 1900, to a serious trouble which affected the beets in some parts of the State. At the time of the attack the beets were in the first to third leaf following the seed leaves, and had been planted about 3 weeks. The roots and stems below ground became black and lifeless and the top dropped to the ground and withered. An examination of the roots showed the presence of the fungus mycelium, but in the absence of fruiting bodies it was impossible to identify it. The author believes it probable that the disease was conveyed through the seed, and suggests a treatment of the beet seed before planting. A second disease similar to the one just described is reported as affecting young sugar beets in Michigan. It passed under the name "black rot," and differed from the other outbreak chiefly in its failure to kill the plants outright. The surface tissues of the roots were blackened, but the central axis remained alive, and the plants in fields which had not been plowed up largely recovered. It is believed that this disease likewise is conveyed to the crop through the seed, and the use of either formalin or hot water on the seed would prove beneficial.

The diseases of sugar beets, A. STIFT (*Les maladies de la betterave. Paris: Cerf, 1900, pp. X + 111*).—This is a translation of a German publication relating to the diseases of the sugar beet.

The scab of sugar beets (*Bl. Zuckerrübenbau, 7 (1900), No. 4, pp. 61, 62*).

The asparagus rust, J. C. ARTHUR (*Indiana Sta. Rpt. 1900, pp. 10–14*).—The author notes the occurrence of the asparagus rust in the State and briefly outlines its life history. The rust was first noticed in Indiana in 1896. The æcidiospores, which are formed in the spring, are rarely met with, but the other forms are quite common and the disease promises considerable injury to the asparagus crop. Various methods are suggested for combating the disease, among them spraying the plants, destroying the spring spores, burning over the ground in autumn for the destruction of winter spores, and planting on soil which will supply an abundance of moisture during the summer. Other means are mentioned, such as the removal of all plants growing in hedge rows or fields, and the natural check to the rust by its parasites.

Diseases of tomatoes, H. TRYON (*Queensland Agr. Jour., 8 (1901), No. 2, pp. 136, 137*).—A description is given of a tomato black rot in which a number of fungi are associated. The principal one, however, proved to be *Macrosporium tomato*.

A bacterial disease of tomatoes, W. STUART (*Indiana Sta. Rpt. 1900, pp. 33–36, pl. 1, fig. 1*).—While studying the effect of chemical fertilizers upon tomatoes grown in the greenhouse, the author experienced considerable annoyance by a disease which attacked and destroyed many of the fruits. Usually the fruit showed no sign of injury until two-thirds grown, sometimes not until fully developed. The first indication of the disease was noticed in the appearance of slightly watery discolorations of tissue beneath the epidermis. As the disease progressed the affected portion assumed a darker color, followed by a gradual depression of the affected tissue, resembling in many respects the disease caused by the black rot. The entire fruit was rarely destroyed, but as a rule its maturity was hastened, the ripe fruit, however, being unmarketable. Generally the disease attacked the apical portion of the fruit, although in a few instances its appearance was noticed in the central or basal portions. An examination of the diseased tissues showed the presence of motile bacteria, which seemed to be fairly constant in all the tissues examined. The organism was isolated and cultures made of it, after which inoculation experiments were conducted with the pure cultures. The inoculation experiments were made by puncturing the epidermis of the fruit and introducing the germs, and a characteristic infection was established within a week or 10 days. In this time the greater portion of the tomatoes had become involved, and in 2 weeks thoroughly decomposed. In some respects the disease produced by the artificial inoculations differed from that occurring naturally; there was a decidedly offensive odor accompanying the rot of the inoculated plants and they were completely destroyed, while in the ordinary process of the disease no odor was perceptible and only rarely was the entire fruit involved. Inoculation was made upon one-half or two-thirds grown tomatoes still remaining on the vines, and produced the disease in all cases where the epidermis was punctured. All attempts to infect the fruit through the flower proved futile. Some doubt is expressed as to whether the two diseases are due to the same organism. This is to be a subject of further investigation. From the limited knowledge of the disease, no preventive measures are suggested.

A new method of combating club root of cruciferous plants, J. BURVENICH (*Bul. Arbor. et Flor., 1900, pp. 337–340*).

A disease of turnips caused by bacteria, W. CARRUTHERS and A. L. SMITH (*Jour. Bot.* [*London*], *39* (*1901*), *No. 457, pp. 33–36, figs. 2; and Jour. Roy. Soc.* [*England*], *3. ser., 11* (*1900*), *pt. 4, pp. 738–741, figs. 2*).—A disease of turnips has been the subject of investigation by the authors for a number of years. The injured plants had the crown of young leaves destroyed, and a cavity scooped out of the turnip occupied the top immediately below where the leaves had grown. This cavity was empty, its wall a dark-brown color, and the remaining tissues were protected by the development of a corky layer. There was no indication of injury in the turnip beyond the wall of the empty cavity. The first specimen of this disease submitted to the authors was in 1893. In 1900, in Yorkshire, the disease was very prevalent. In the worst cases the young leaves disappeared from the crown or rotted away. The outer older leaves showed signs of wilting, their stalks decaying at the base. As a rule, the outer skin of the turnip was sound. In some instances, where the top was scooped out, the depression was lined by a white slimy substance; in other cases the injury had penetrated farther through the turnip and the whole center was a mass of rotten pulp. A careful examination of the leaf and root showed the injury was due to bacteria, which had probably gained access to the plants between the bases of the young leaves or through the broken surface of the root. Sections taken from the diseased parts were swarming with bacteria. They were motile, cylindrical rods, measuring 0.65μ in width and 1 to 4μ in length.

Later a careful field examination was made, upon which it was found that in a field of 25 acres not one turnip in five had escaped. Yellow turnips had suffered very little. Cabbages growing near were somewhat diseased, but a strip of kohl-rabi through the center of the severely diseased area was without injury. At a later period the progress of the disease was to a large extent checked. This was probably due to the destruction of so many of the leaves, leaving the rows somewhat bare. The sunlight and air gained free access to the roots and the bacteria were dried up or destroyed. The well-known action of sunlight on bacteria is cited, and it is thought probable that the same influence had been exerted in the turnip field, for in many cases the only trace of injury observed was a clean walled cavity at the top of the turnip.

Experiments on the sulphur-lime treatment for onion smut, F. A. SIRRINE and F. C. STEWART (*New York State Sta. Bul. 182, pp. 145–172, figs. 2*).—The smut caused by *Urocystis cepulæ* is said to be exceedingly troublesome in the onion fields of some portions of New York. When onions have been grown continuously on the same land, the smut gradually continues to increase from year to year until crops can no longer be profitably grown. The organism is a soil-inhabiting fungus, and is rarely transferred except as carried on the bulbs. Numerous methods of combating this disease have been suggested and some of them practiced. It is a rather common practice to use larger quantities of seed than required, the idea being that a portion of them will escape the disease. Rotation of crops and deep plowing have been suggested. As the fungus attacks the onion in a very young stage as a seedling, it has been recommended that the young plants be started in beds where the soil is uninfested and thence transplanted to the field. This method is known to give freedom from the smut, but large growers do not practice it on account of the expense in transplanting. In order to ascertain some cheaper method of treatment, the authors began in 1896, and continued for 5 years, field experiments in which the value of sulphur, and sulphur and lime, as soil treatments were tested. Various amounts of sulphur and sulphur and lime were applied in the drills where the seed was planted, with beneficial results. The best results were obtained where 100 lbs. of sulphur and 50 lbs. of lime per acre were applied directly to the drills. With this treatment there was an average annual increase of fully 50 per cent in the product on soil that had previously given smutty crops. The application of sulphur and lime, when sown broadcast, was without particular value. It is recommended in the application of lime and sulphur for the prevention of smut that it be drilled in the drills at the same time the seed is sown, and an implement is described which was used with success for this purpose.

Experiments were conducted to ascertain the time when the plants were infected by the fungus, which showed that they were immune to attacks of the smut by the time the seedlings reached the surface of the soil. Soaking the seed or coating it with fungicides did not prove of any benefit in preventing the disease.

Sulphur and lime for onion smut, F. H. HALL, F. A. SIRRINE, and F. C. STEWART (*New York State Sta. Bul. 182, popular ed., pp. 8*).—This is a popular summary of the above bulletin.

Crown gall of apple, W. G. VINCENHELLER (*Arkansas Sta. Rpt. 1900, pp. 112, 113*).—The occurrence of crown gall on apple trees in orchard and nursery is mentioned. Investigations conducted by the author seemed to indicate that grafts made from whole or long roots and short scions are much more liable to injury than those made with short roots and longer scions. The short root and long scion placed the union 7 or 8 in. below the surface, and at that depth trees are apparently less subject to attack. The results of experiments with grafting 30 varieties of apples, 200 grafts each, showed that most of the varieties were free from the diseased growth. The author believes that propagating trees by the method suggested, as a means for the prevention of crown gall, is worthy of trial.

The New York apple-tree canker, W. PADDOCK (*New York State Sta. Bul. 185, pp. 205–213, pls. 4*).—This bulletin is the second report on the canker which affects apple trees, being a continuation of the investigations reported in Bulletin 163 of the station (E. S. R., 12, p. 59). It has been found that any part of the apple tree above ground, with the possible exception of the leaves, is subject to attack by the canker fungus, which has proved to be *Sphæropsis malorum*. When occurring on the limbs or trunks the injuries are known as cankers, and they are often quite conspicuous since the bark becomes thick and rough, and saprophytic fungi soon gain a foothold, causing the parts to turn black. The injuries are often several feet in length, and because of these striking characters the cankered limbs may be recognized at a considerable distance. The fungus can live in the outer bark of the tree where it does but little harm. An affected branch may be girdled by the fungus and saprophytic fungi complete the work of destruction. When it occurs on new growth the twigs are killed in a manner very much resembling the attack of pear blight. When the fungus occurs on the fruit of the apple it produces what is known as black rot, and numerous experiments have shown that it occurs not only upon the apple, but also upon the pear and quince fruit. The author's experiments have shown that the fungus causing the black rot and the canker fungus are identical. It is said that the leaves of apple trees are occasionally attacked by a species of Sphæropsis the identity of which is not thoroughly established, but the indications are that it is the same as that occurring upon the other parts of the tree. Inoculation experiments were conducted to determine if possible the relationship between the different forms of Sphæropsis occurring on various plants. Cultures were taken from cankered apple-tree limbs and from decaying apples, and inoculation experiments made upon apple, pear, hawthorn, apricot, peach, sumac, persimmon, and hop hornbeam. The inoculations were successful only where applied to the apple, pear, and hawthorn, but experiments with cultures of Sphaeropsis taken from all the other trees, with the exception of the peach, were found to readily produce the black rot of the apple fruit. Two explanations are offered for this behavior, one that the apple fruit is a very favorable medium for the growth of the different species, the other that Sphaeropsis is not parasitic on all of the trees. As a result of his experiments, conducted through 3 seasons, the author states that he has positive evidence that the Sphaeropsis occurring on apple, pear, and hawthorn trees and on apple, pear, and quince fruits is one and the same species. The relation between sun scald, sunburn, and canker is shown, in which it is believed that the canker fungus finds access to the living tissues through such injuries as sun scald and sunburn. To prevent these injuries it is recommended that trees be sprayed with a winter wash composed of lime 30 lbs., tallow 4 lbs., salt 5 lbs., diluted with enough water to make it spray readily. Experiments for the control of the canker were continued, but as yet no definite results have been obtained. The recommendations of the previous year, in which good orchard sanitation and spraying with Bordeaux mixture is advised, are repeated.

Accompanying the apple-tree canker, as mentioned in the previous report, is a second fungus, *Macrophoma malorum*. It resembles the canker fungus very closely, except in the character of its spores. Inoculation experiments on both apple and pear trees with cultures of Macrophoma gave negative results. These, however, should be repeated before deciding that the fungus is not parasitic.

The author reports the occurrence of the European canker, *Nectria ditissima*, upon apple trees in a number of portions of New York and in Nova Scotia, the preliminary report of which is given in E. S. R., 12, p. 262.

Apple-tree cankers, F. H. HALL and W. PADDOCK (*New York State Sta. Bul. 185, popular ed., pp. 4, pls. 2*).—This is a popular summary of the bulletin noted above.

The canker (Rostrella disease) of Coffea arabica, A. ZIMMERMANN (*Meded. 'S Lands Plantentuin, 37 (1900), pp. 24–62, figs. 19*).—The author describes a canker disease of coffee trees, shows that it is caused by a hitherto undescribed fungus, and suggests methods of treatment.

The disease is confined to the Java variety of coffee and usually attacks isolated trees. So far it has been known to attack only trees at least 10 years old. A yellowing and sudden drooping of the leaves indicates the presence of the disease, which is further characterized by the development of brown patches in the cortex of the stem and larger limbs. Death follows soon after the leaves droop. The brown patches may extend nearly around the tree and involve the entire cortex, including the cambium layer. The mycelium has not been found in the wood.

The fungus belongs to a hitherto undescribed genus of Ascomycetes, and the author names it *Rostrella coffea*. Four forms of reproductive bodies are developed, ascospores, macroconidia, microconidia, and a fourth form which the author calls rudimentary microconidia, produced by the breaking up of hypæ developed from the macroconidia and microconidia, each form being fully described.

Infection experiments were made by placing small portions of diseased tissue under the cortex of healthy trees or pieces of stem and later by inoculation with microconidia. All the infections were successful and the checks uniformly remained free from the disease. The characteristic symptoms appeared in from 4 to 8 days and frequently all the spore forms were developed. Infection experiments made on the leaves and young twigs, as well as on the older limbs and trunk, showed that in very moist air *Rostrella coffea* can develop on the leaves and young twigs of *Coffea arabica* when fresh wounds are present, but that the disease is checked on the young parts by the development of a cork layer. Hence the injury to the trees is always caused by the disease attacking the stem or larger limbs.

Experiments on *Coffea liberica* showed that while the fungus made a weak growth in fresh wounds on both stem and leaves, the mycelium did not penetrate beyond the wound. Open air experiments gave negative results. Experiments on shrubs or weeds growing in or near coffee plantations proved that the fungus would grow in wounds on *Erythrina lithosperma*, *Albizzia molukkana*, and *Cedrela serrata*, but only when the experiments were conducted in moist air. Open air cultures were unsuccessful. The fungus will not grow on sugar cane (*Saccharum officinarum*).

For treatment of the disease the author recommends burning all diseased trees; or, if this is not desirable, cutting out the infected parts and coating the wounds with tar. Tree trunks should be coated with Bordeaux mixture or lime to prevent insect injuries. All wounds due to pruning should be coated with tar. If diseased trees are allowed to remain in the plantation, the trunks should be coated with tar to prevent the dissemination of spores.—H. M. PIETERS.

Mulberry-dwarf troubles, U. SUZUKI (*Bul. Col. Agr. Imp. Univ. Tokyo, 4 (1900), No. 3, pp. 167–226, pls. 22*).—For 10 years or more there has been known in Japan a widespread disease of the mulberry which attacks the leaves and branches, checking the growth and finally causing the death of the plant. This disease has spread, causing great losses to silkworm raisers by almost entirely destroying the crop of mulberry leaves.

In 1897 the Japanese Government appointed a commission to investigate the subject, and the present bulletin is in the nature of a report. The first recognition of the disease is supposed to have been 20 or 30 years ago. Different varieties of mulberries are unequally affected. Generally speaking, those varieties which are most highly esteemed for leaf production are most subject to the disease, while those which are characterized by hard leaves and slow growth are comparatively free from it.

The different methods of cutting mulberries are described, and the belief expressed that the primary cause of the disease is attributable to the practice of subjecting the mulberry to repeated cuttings. This treatment results in a deficiency of reserve material in the twigs and tends to abnormal development.

Chemical analyses of healthy and diseased plants at various stages of growth are reported upon in considerable detail. Investigations were made on the reserve materials of the mulberry tree and their relation to the disease. It was found that the diseased leaves were remarkably poor in nitrogen and in the development of woody fiber. The deficiency in nitrogen in the diseased plants was not due to an insufficient supply of nitrogen in the soil, but is attributed to a diminution of the absorptive power of the roots and the chemical activity of the plant cells. The repeated cutting of twigs or plucking of leaves results in the exhaustion of the new shoots before they have attained a height and development sufficient to enable them to perform the function of assimilation. This statement, it is claimed, is supported by the fact that the disease always appears in new shoots after cutting in the growing season and is never observed in plants which have not been cut. Diseased plants may recover when kept from cutting for a number of years.

Differences in the susceptibility of varieties and the effect of different soils are mentioned. It appears that a plant becomes more liable to disease by accelerating its growth with abundant soluble manures. Young plants are rarely diseased. This is thought to be due to the rapid development of the roots and the large capacity for the absorption of nutrients by the young plants. Old plants have less power of developing new roots, and consequently there is a deficiency of reserve material which can not be supplied by the absorption of material from the soil and air.

Careful investigations were made, but no fungi or other micro-organisms were found constantly associated with the disease, the decay of the roots being considered secondary. Aside from the correction of methods of pruning which suggest themselves, no other means of prevention are described.

The black rot and mildew of grapes and their treatment, SCHLOESING (*Rev. Vit., 1900, No. 360, Sup.*).

Guignardia reniformis in the Caucasus, A. LEBEDEFF (*Centbl. Bakt. u. Par., 2. Abt., 6 (1900), No. 20, p. 652, fig. 1*).—A report is given of studies of grapes received from the Caucasus. Examinations were made of the perithecia, in which the author claims to have found the fungus *Guignardia reniformis*. The characteristics of the fungus are described, and it is affirmed that this fungus is undoubtedly that which causes the black rot of grapes in the Caucasus region.

Some diseases of New England conifers, H. von Schrenk (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 25, pp. 56, pls. 15, figs. 3*).—A preliminary account is given of studies made by the author in the forest region of the Northeastern United States, particular attention being paid to the coniferous trees. The extent of injury, evidences of decay, and relation of insect attacks to diseases are discussed. The vegetative conditions of the New England forests are described and notes given on the occurrence and habits of the prevailing coniferous trees, which are red and white spruce, balsam fir, hemlock, arbor vitæ, white pine, and tamarack. The fungi described as attacking these trees mostly belong to the group Polyporei. The species described are *Polyporus schweinitzii*, *P. pinicola*, *P. sulphureus*, *P. subacidus*, and *Trametes pini abietis*. The occurrence of these different fungi, the structure of diseased wood, characters of the fruiting organs, the effect of the fungus on the tree, and methods of combating are described in greater or less detail. In addition to the foregoing species, *Polyporus vaporarius*, *P. annosus*, and *Agaricus melleus* are briefly noted as causing disease upon the same species.

The author finds the forest conditions in New England very favorable to the growth and development of timber-destroying fungi. Trees are frequently cut high up on the stump and low in the top, leaving a great portion of the tree to the attacks of the fungi. From these dead trunks and limbs the spores are spread to standing trees which might otherwise remain sound. Attention should be given to the cutting of trees when they have become matured, as they are more liable to attacks of fungi after this period has been reached. In this way the depreciation due to attacks of fungi and insects may be greatly lessened.

A disease of Taxodium distichum, etc., known as peckiness, also a similar disease of Libocedrus decurrens known as pin rot, H. von Schrenk (*Missouri Bot. Gard. Rpt. 1900, pp. 23–77, pls. 6, fig. 1*).—The disease of cypress known as "pecky" or "peggy" is a species of decay to which it is very liable. When a diseased cypress tree is cut down the heart wood frequently appears as though a large number of holes had been bored through it. These holes vary in size from $\frac{1}{4}$ to $\frac{3}{4}$ in., and are found in the heart wood only. Young trees of Taxodium varying in age from 50 to 125 years are almost always free from defect, only the older ones being attacked. The holes in the wood extend longitudinally up and down the trunk, parallel to the wood fibers, never transversely. They are separated from one another by cells of apparently sound wood. The holes vary in length from $\frac{1}{4}$ to 6 in. or longer, most frequently from 4 to 5 in. long. The cavities are filled with a yellow-brown powder, which readily crumbles in the fingers. A fluffy white mycelium, covered with drops of liquid resembling dew, is sometimes present.

The structure of the diseased wood is described at considerable length. In the cells immediately surrounding the rotten areas certain parts of the holes are colored dark brown. This is thought to be due to the formation of humus compounds. The wood between the rotted areas is described and data given relative to the comparative strength of sound and pecky heart wood.

The progress of the disease is described. The constant presence of the colorless mycelium in the diseased trees makes it seem probable that it is the vegetable part of a fungus which causes the decay. The author states that certain ferments are associated with this disease, and he arrives at the conclusion that humus compounds found in the wood surrounding the holes are probably one of the effective means in preventing the unlimited spread and destructive action of the disease.

A somewhat similar disease of *Libocedrus decurrens* is described. The author summarizes his investigations as follows:

"In the foregoing, two forms of decay have been described, one destroying wood of *Taxodium distichum*, the other of *Libocedrus decurrens*. In both cases the wood is destroyed in localized areas, which are surrounded by apparently sound wood. The cell walls are changed into compounds which diffuse through the walls and fill the cells surrounding the decayed center; and these have been called humus compounds. In both, a fungus mycelium occurs with strongly marked characteristics, which flourishes within the diseased centers and grows between these centers without affecting the intervening wood. This wood can be utilized for many purposes even when much rotted, and in neither case does the mycelium grow after the tree has once been cut down. . . . The two forms of decay differ but slightly, and not more than might be expected in two woods of different character. Taking these facts into consideration, it appears probable that the two diseases are caused by one and the same fungus, the fruiting form of which has not yet been found."

A new species of Trimmatostroma, M. W. DOHERTY (*Bot. Gaz., 30* (*1900*), *No. 6, pp. 400–403, figs. 3*).—In the summer of 1898, the author's attention was called to a diseased condition of the balsam firs in the province of Ontario, Canada. The disease at this time had done but little damage and all efforts to collect fruiting material of the fungus was futile. In 1899, the author visited the same locality and found that trees which the previous season showed only an occasional dead branch had entirely succumbed and the disease was spreading rapidly, many new points of infection being noticed. At this time the diseased leaves showed the presence of numerous black warty tubercles, which proved to be fruiting masses of the fungus. A quantity of material was collected and subjected to further examination and study. From observations made on cultures, the author has decided the fungus is new and has given it the name *Trimmatostroma abietina*. The technical characters of the fungus are described, from which it appears that it belongs to the section Phragmosporæ of the Hyphomycetes. Thus far the only hosts on which the fungus has been observed are *Abies alba* and *A. balsamea*, but it is thought probable the spruces are not immune.

The rust of white pine, C. VON TUBEUF (*Agronome, 1900, pp. 377, 378*).

Studies on the hexenbesens of barberry, J. ERIKSSON (*Landt. Akad. Handl. Tidskr., 39* (*1900*), *No. 5–6, pp. 346–360, pls. 3*).—The results are given of inoculation experiments with *Æcidium graveolens* and *Puccinia arrhenatheri*.

Wakker's hyacinth germ (Pseudomonas hyacinthi), E. F. SMITH (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 26, pp. 45, pl. 1, figs. 6*).—In this bulletin the author gives an account of the morphology of the organism which causes the rotting of hyacinths known as "Wakker's disease." The organism was isolated, and several series of inoculation experiments begun in 1897 and carried through 1899 are described in detail. In these inoculation experiments hyacinths, onions, cabbages, and other plants were experimented with. The pathogenic nature of the organism is clearly established through the inoculation experiments, as the symptoms always began in that part of the plant which had been inoculated and proceeded downward, the bulb being the last part to show the disease, and because the organism was found present in the yellow bundles of the bulbs. The morphology of the organism is described at considerable length and a synopsis of its characters given. The organism is said to be closely related to the ones causing the bacterial brown rot of cruciferous plants and the bacterial disease of beans, and somewhat less so to that causing the bacteriosis of sweet corn. It is readily distinguished from the first two by its brighter color, lower thermal death point, and manner of growth. It is distinguished from the organism causing the bacteriosis of sweet corn by a brighter color, lower thermal death point, and different characters of growth.

On the coloring and spotting of rose leaves, C. WEHMER (*Gartenflora, 49 (1900), Nos. 9, pp. 225–229; 10, pp. 262–267, pls. 2*).—The author describes the various causes which produce discoloration of rose leaves. The different categories described are those due to parasitic organisms, to physical influence of the atmosphere, and to chemical influence of atmosphere, the normal autumnal change of color, and changes which are brought about by soil influences, drought, etc. The different injuries are described at some length and suggestions given for their prevention. The parasitic diseases mentioned are those caused by *Asteroma radiosum* and *Phragmidium subcorticium*.

A nematode disease of clematis, J. CHIFFLOT (*Semaine Hort., 1900, pp. 535–537*).—Describes attacks of *Heterodera radicicola*.

Concerning a bacteria-like fungus which destroys nematodes, G. LAGERHEIM (*Bihang Svenska Vetensk Akad. Handl., 26 (1900), No. 4; abs. in Bot. Centbl., 85 (1901), No. 9, pp. 282, 283*).—A description is given of a fungus which resembles Actinomyces, that has been found parasitic upon *Tylenchus agrostidis* in the flowering clusters of *Poa alpina*. The fungus seems very destructive to this nematode, and it is probable that it will prove destructive to others. Experiments are to be conducted to ascertain this fact.

Fungicides (*South Carolina Sta. Bul. 57, pp. 16*).—Notes are given on the use of fungicides for the prevention of various diseases of plants, together with formulas and directions for the application of a number of the more common fungicides.

Copper and sulphur in plant protection, J. E. WEISS (*Prakt. Bl. Pflanzenschutz, 1900, No. 8, pp. 60–62*).

Bordeaux mixture with linseed oil, CONDEMINAL (*Rev. Vit., 10, p. 765; abs. in Ann. Agron., 26 (1900), No. 4, p. 216*).—The formula is given for Bordeaux mixture, in which 15 to 20 gm. of linseed oil to each kilogram of lime is added. The adhesive property of the Bordeaux mixture is said to be considerably increased.

Suggestions for an international phytopathological commission, J. ERIKSSON (*Landt. Akad. Handl. Tidskr., 39 (1900), No. 5–6, pp. 361–368*).

ENTOMOLOGY.

Thirty-first annual report of the Entomological Society of Ontario, 1900 (*Rpt. Ontario Ent. Soc. 1900, pp. 112, figs. 46*).—This report contains the proceedings of the thirty-seventh annual meeting of the Entomological Society of Ontario, held in London, November 13, 14, and 15, 1900, and the proceedings of the second annual meeting of the Northwest Entomological Society, held at Lacombe, Alberta, Northwest Territory, January 16, 1901.

A discussion of the San José scale problem was given by G. E. Fisher (pp. 26–29). Whale-oil soap and kerosene were found to be somewhat unsatisfactory remedies for this insect. Crude petroleum gave most beneficial results. Trees were freed from the scale and case bearers and many other insects were destroyed by the use of a 25 or 30 per cent mixture of crude petroleum and water. The annual address of the president, T. W. Fyles (pp. 29–34) was devoted to a discussion of the beneficial action of insects toward plants. W. Lochhead (pp. 34–37) called attention to the necessity of making a systematic study of the forest insects of Ontario. F. M. Webster made a report on experiments in protecting apples from the attacks of the second brood of codling moths (pp. 37, 38). Two trees were selected in the center of an orchard, sprayed on the 22d of June, and one was covered with a netting on the next day. From the covered trees 627 apples were obtained, of which 466 were sound, while from the uncovered tree 1,544 apples were obtained, of which only 452 were sound.

Brief notes were given on the habits and life history of forest tent caterpillar, pea weevil, tussock moth, clover-root borer, and cabbage-root maggot. J. A. Moffat (pp. 42–52) presented notes on the habits and means of combating carpet beetles, and gave a detailed account of the life history of Archippus butterfly. The eggs of Chrysopa were found parasitized to a certain extent by an Ichneumon fly. T. W. Fyles presented an account of the dragon flies of Quebec (pp. 52–57). The possibility of silkworm industry in Ontario was discussed by W. Lochhead (pp. 57–59). It was concluded that the cost of labor and price of silk precluded the practicability of the establishment of the silkworm industry in Ontario. F. M. Webster (pp. 59–61) reported the results of experiments with petroleum by N. A. Hadden on Catawba Island. Peach trees were killed by spraying with undiluted crude petroleum on March 10, 1900, while 1 peach tree and some plum trees escaped injury after being sprayed on the same day. J. Fletcher (pp. 62–72) gave notes on the habits and life history of Hessian fly, cutworms in grain, white grubs, pea weevil, pea moth (*Semasia nigricana*), destructive pea aphis, clover-root borer, clover weevil (*Phytonomus punctatus*), imported cabbage butterfly, cabbage-root maggots, asparagus beetle, cabbage aphis, codling moth, plum curculio, palmer worm, etc. W. Lochhead (pp. 72–78) presented notes on fruit-bark beetle, San José scale, bean fly, (*Anthomyia radicum*), asparagus beetle, Hessian fly, pea weevil, bollworm, and imported cabbage butterfly and squash bug. F. M. Webster (pp. 81–84) reported observations on *Saperda vestita*, which was found injuring linden trees in nursery rows, and *Oberea bimaculata* as a pest of small fruits.

The habits of *Dermestes talpinus* and other species of this family were discussed. A brief account of the present status of the San José scale in Ontario was given, together with notes on *Tyroglyphus malus* as a parasite of San José scale.

Miscellaneous notes on injurious insects, V. H. Lowe (*New York State Sta. Bul. 180, pp. 113–136, pls. 8, figs. 2*).—The forest tent caterpillar (pp. 115–122) is reported as having been unusually destructive to orchard trees. Circular letters were sent to correspondents throughout the State for the purpose of obtaining information concerning the abundance and injuriousness of this species. The localities of its occurrence are given and the life history of the insect is briefly described. As remedies for this insect the author recommends the destruction of egg masses, which is most conveniently done at the time when the trees are pruned, banding the trees to prevent the caterpillars from crawling back after being jarred off, and spraying with arsenical poisons, such as Paris green, arsenite of lime, or arsenate of lead. Kerosene oil applied directly to the caterpillars on the trunks and branches of trees gave satisfactory results. Caterpillars may also be dislodged by streams of water from hydrants. The cocoons are conspicuous and may be readily gathered by children.

The fruit-bark beetle (pp. 122–128) is reported as attacking the branches of cherry, peach, and other fruit trees. During late summer and fall the beetles make short galleries in the thick bark of the trunk and large limbs and longer galleries in the sapwood of twigs and small limbs, in which the eggs are laid. In a peach orchard it was noticed that the most extensive injury was done to Crawford and Reeves Favorite varieties. Injury to twigs is shown by the death of the leaves and by drops of sap which exude from the burrows. The number of eggs in each burrow vary from 1 to 12. The number of broods per year for western New York was not determined. For studying the habits of the beetle under experimental conditions, half-inch curtain rings were fastened together and to the bark by means of melted paraffin, the beetles being placed in these cells and covered by a cover glass. Their habits of boring could then be observed. As remedies against this beetle the author recommends a liberal application of a caustic solution, such as whale-oil soap, 2 lbs. to the gallon of water, about the middle of July. Crude carbolic acid may be added to the solution in the proportion of 2 oz. to the gallon. The object of these applications is to prevent the beetles from burrowing into the bark. Severe winter pruning and burning of the twigs will destroy the eggs and hibernating insects.

A mealy bug attacking quince trees (pp. 128–130), a species of Dactylopius, was found injurious and its habits were studied. A quince orchard examined on April 27 showed that nearly all the trees were infested. The adult mealy bugs were noticed making cocoons and laying eggs on June 28. When the orchard was examined, on September 26, the numbers of the species had materially diminished. Brief descriptions of the insect in all its stages are given. As remedies the author suggests 1 or 2 applications of whale-oil soap, 1 lb. to 5 gal. of water, in the spring and scraping the trunk and large limbs during the winter, and painting with a strong solution of whale-oil soap.

Apple leaf miners (*Ornix prunivorella*) (pp. 131–135) were first reported from Brockport in 1900. The young larvæ of this species feed upon the parenchyma, usually on the upper side of the leaf. The epidermis of the leaf is uninjured, and a mine is produced which causes the distortion of the leaf. Before pupating the caterpillars line their retreats with a heavy coating of silk thread. A brief description is given of the caterpillars. Arsenical or other sprays would have little effect in the case of this species. Since it passes the winter in the leaves, the insect may be held in check by destroying the fallen leaves or plowing them under. *Tischeria malifoliella* is reported as very common in the leaves of apple orchards at Albion and Geneva. The mines are somewhat trumpet shaped in the upper side of the leaf.

The tarnished plant bug (p. 135) is said to have caused considerable damage to peaches. The bugs were watched by means of a hand lens and could be seen to puncture the fruits. The bugs usually confine their attacks to the under side of the fruit, making large numbers of punctures with their beaks. Shortly afterwards drops of sap exude from the punctures and the skin begins to wither. The peaches ultimately become deformed.

A few fruit-tree foes, F. H. HALL and V. H. LOWE (*New York State Sta. Bul. 180, popular ed., pp. 8, pls. 2*).—This is a popular summary of the above bulletin.

Insect notes, A. L. QUAINTANCE (*Georgia Sta. Rpt. 1900, pp. 361–371, pl. 1*).—The author gives brief notes on harlequin cabbage bug, leaf-footed plant bug, tarnished plant bug, squash bug, *Cicadula exitiosa*, bollworm, grape-leaf folder, imported cabbage worm, cabbage plusia, and codling moth.

The pickle worm is reported as having been injurious to squash, cucumber, cantaloupe, and watermelon, the vines of which were more or less injured, especially those of the cantaloupe and squash. The fruit of the pumpkin was not injured. In order to test the value of squash as a trap crop for the larvæ, 4 rows of summer squash were planted at equal intervals across a 1-acre field of cantaloupes. From June 19 until July 17 squash flowers were picked off, and the larvæ infesting them were counted. In all, 1,640 larvæ were thus captured, and the cantaloupes were practically free from pickle worms until July 14. Experiments with arsenites were again unsuccessful. Cantaloupes were thoroughly sprayed with Paris green, 1 lb. to 50 gal. of water, and with Disparene, 6 lbs. to 25 gal. of water. The pickle worm was not affected by the latter and only slightly by the Paris green.

Short notes are also given on the melon worm, squash vine borer, *Diatræa saccharalis*, striped cucumber beetle, *Ceratoma trifurcata*, Colorado potato beetle, false potato beetle (*Doryphora juncta*), plum curculio, and *Allorhina nitida*. An article on *Diabrotica 12-punctata* is reprinted from Bulletin 26, Division of Entomology of this Department (E. S. R., 12, p. 860).

Bugs injurious to our cultivated plants, O. LUGGER (*Minnesota Sta. Bul. 69, pp. 259, pls. 16, figs. 200*).—This bulletin contains a general account of the anatomy, life history, habits, and classifications of the order Hemiptera, including lice, Heteroptera, and Homoptera. Brief biological and economic notes are given on the more important species of the various families of these suborders. The bulletin constitutes a compendium of practical information upon these insects.

Beetles injuring trees in the Turkestan region and means of destroying them, N. N. Sokolov (*Zhuki porrezhdayushchie derevo v skladakh Turkestanskago kraya i sposobui ikh unichtozheniya. St. Petersburg: Minister of Agriculture and Imperial Domains, 1900, pp. 27; abs. in Selsk. Khoz. i Lyesov., 199 (1900), Oct., pp. 249, 250*).—The author gives an account of the life history and means of combating *Clytus faldermanni, C. herbsti, Dicerca aenea,* and *Ptilinus costatus.*

Report of the division of biology, T. W. Kirk (*New Zealand Dept. Agr. Rpt. 1900, pp. 276–346, pls. 26, figs. 8*).—The author gives brief notes on *Rhizobius ventralis* and *Cryptolæmus montrouzieri.* A brief statement is made of the purpose and effectiveness of the Orchard and Garden Pests Bill, which was passed in 1896. Imported fruit and nursery stock is inspected and, if necessary, subjected to fumigation. Inspection was also made for the presence of fruit flies. Brief notes are given on the plum curculio, Hessian fly, ox louse, bird flea, (*Pulex avium*), *Sarcoptes mutans,* and Phylloxera.

Since it had been asserted that fumigation injures the keeping qualities of the orange, a practical test was made with the result that fumigated oranges were found to remain sound for as great a length of time as untreated oranges. During the course of this work it was found that mites were able to withstand the full strength of the gas. The mites not only survived, but were found soon after fumigation feeding on scale insects.

In the treatment of Phylloxera with bisulphid of carbon, the cooperation of grape growers was found to be a matter of great importance.

Report of the entomologist, H. Tryon (*Queensland Dept. Agr. Rpt. 1899–1900, pp. 28–32*).—This report contains brief notes on a large number of injurious insects which attack fruit trees, garden crops, cereals, and other field crops.

The structure and biology of Anopheles maculipennis. The egg and larva, G. F. H. Nuttall and A. E. Shipley (*Jour. Hyg.* [*Cambridge*], *1* (*1901*), *No. 1, pp. 45–77, pls. 2*).—The authors give a brief critical review of the literature of this subject in connection with a bibliography. A detailed account is given of the anatomy and biology of the egg and larvæ of the species. The eggs are laid upon water which is suitable for the development of the larvæ and which is rich in vegetable matter, such as various algæ. On the second or third day after oviposition, the larva leaves the egg and begins to swim about in the water. The larva of Anopheles has only a single pair of maxillæ. This is the first pair, there being nothing which can be identified with the second pair. The chief occupation of the larva is feeding near the surface of the water. In this act the head is reversed so that the ventral surface lies uppermost, the body retaining its normal position. The food of the larva consists in the main of spores of algæ, diatoms, the decaying leaves of Lemna, and other minute organisms. The larvæ feed with the long axis of the body parallel to the surface of the water. When disturbed they wriggle rapidly to the bottom, tail first, where they lie motionless. They are, however, less readily frightened than the larvæ of Culex.

Extermination of malaria-breeding mosquitoes by petroleum and drainage, H. C. Weeks (*Sci. Amer. Sup., 51 (1901), No. 1305, pp. 20921, 20922*).—A popular account of work thus far done by way of experiments in the extermination of mosquitoes.

Remarks on Psorophora ciliata, with notes on its early stages, L. O Howard (*Canad. Ent., 32 (1900), No. 12, pp. 353–357, figs. 3*).—This mosquito is said to occur most abundantly in the austral life zone. Attempts to secure eggs and watch the process of egg laying were unsuccessful. Specimens of the larvæ were obtained from W. P. Seal, of New Jersey. These larvæ are larger than most mosquito larvæ and resemble those of Culex more nearly than those of Anopheles. The duration of the pūpal stage was from 4 to 5 days. The adult of the species is readily distinguished by the presence of vertical scales on the legs. The breeding places in which the larvæ were found were depressions in the bed of a small stream and in small ponds.

Phylloxera and its destruction by means of lysol, G. Cantin (*Le Phylloxéra. Sa destruction par le lysol. Paris: Librairie Agricole Maison Rustique, 1900, pp. 22, 23*).—The author gives a brief history of the ravages caused by phylloxera, and the life history of the insect. Notes are also given on the various methods of combating phylloxera which have been previously adopted. Experiments with lysol were conducted on a vineyard in Chavignol which had been badly invested with phylloxera since 1893. The first treatment consisted in painting all the stems by means of a brush with 5 per cent solution of lysol. The work of painting 6,500 grape stems required 25 kg. of lysol and cost about $13.50. The second treatment was given one week later, and consisted in spraying the stems and the moss and old bark which had been scraped off and was lying about the base of the stems. A 5 per cent solution of lysol was used for this purpose, and the moss and old bark was thoroughly saturated. This treatment required also 25 kg. of lysol, but as the labor was somewhat greater the expense was about $15.

On the theory that phylloxera depends for its propagation on the individuals that issue from winter eggs, this treatment of the stems with lysol promises success. The author estimates that the subterranean colonies of phylloxera will disappear by exhaustion after about 3 years, if not reinforced by young hatched out of the winter eggs.

The palmer worm, M. V. Slingerland (*New York Cornell Sta. Bul. 187, pp. 77–101, figs. 9*).—The name "palmer worm" has been applied in the United States to *Ypsolophus pometellus*. The author describes the larva, pupa, and adult moth of this species. The distribution of the insect seems to be confined to the United States. It is most common in New York and New England, where the greatest amount of damage is done; and it has also been reported from Ohio, Kentucky, and a few of the Southern States. During the past century it has occurred in injurious numbers only 3 times. Its food plants include apple, oak, plum, and cherry trees.

The larvæ feed upon the leaves in much the same manner as cankerworms. Occasionally a few of these are fastened together with silken threads, so as to form a nest within which the caterpillars feed. Considerable damage is also done to young apples, upon which the larvæ feed with great avidity. When the branches are jarred the caterpillars drop, but remain attached by means of a silken thread.

During the second half of June the insect passed into the pupal condition. The pupæ were formed on the leaves, being attached by means of a few threads. The insect remained in the pupal condition for about 10 days, and the moths emerged during the last week in June and the first 10 days of July. The moths were not active during the day unless disturbed. The author conducted breeding experiments for the purpose of determining the further life history of the insect. The moths remained alive in breeding cages from July 5 until November, which indicated that the species hibernates in the adult condition. It is believed, therefore, that there is but one brood of caterpillars annually. The egg-laying habit was not observed and no eggs were found.

The climatic conditions which are most favorable for the development of this species are dry and hot weather during April and May. A number of hymenopterous parasites were bred from pupæ of the palmer worm, which proved to be *Apanteles perplexus*. As an artificial remedy for this insect the author recommends spraying with Paris green at the same times at which such applications are made for the codling moth. A bibliography of the literature relating to this species is given.

The carpenter worm, S. B. Doten (*Nevada Sta. Bul. 49, pp. 12, figs. 7*).—This species, which commonly attacks cottonwood trees, is reported as doing considerable damage to young elms. The insect is described in its various stages, and brief notes are given on its life history. Since the carpenter worm attacks willows, infested willows in the vicinity of elms should be cut down and destroyed. Poplars and cottonwoods which have become badly infested should be cut down in the early autumn and burned for firewood, so as to prevent the escape of the insects. While the caterpillars are small and not deeply buried in the wood, they may be destroyed by a knife or a wire. The entrances to the burrows may be cleaned out and a wad of cotton saturated with bisulphid of carbon inserted. Woodpeckers are mentioned as feeding upon the caterpillars to some extent.

The codling moth or apple maggot (*Gard. Chron., 3. ser., 29 (1901), No. 733, p. 32, figs. 3*).—Brief notes on the habits and life history of this insect. For preventing the caterpillars from crawling up the trees, the author recommends the banding of trees with sacking. The bark of infested trees may be scraped and treated with caustic solutions.

The gypsy moth, S. Lampa (*Malmöhus Läns Kgl. Hush. Sällsk. Qvart., 1900, No. 1, pp. 116–123, pl. 1*).—The author presents in a popular manner various details concerning the appearance of this insect in its various stages, the injuries from serious outbreaks, its life history and habits, its natural enemies, and the more effective artificial remedies to be used for combating it.

Orchard insects, H. Osborn (*Jour. Columbus Hort. Soc., 15 (1900), No. 4, pp. 142–146*).—Economical and biological notes on the woolly aphis, round-headed apple-tree borer, oyster-shell bark-louse, scurfy scale, San José scale, apple maggot, and codling moth.

Spring treatment for orchards infested with the San José scale, W. M. Scott (*Georgia State Bd. Ent. Circ. 5, pp. 4, fig. 1*).—The treatment recommended by the author includes two winter applications, one soon after the foliage falls, and the other in late winter. Brief notes are given on digging up infested trees, kerosene and water treatment, and the use of crude petroleum.

Crude petroleum for the San José scale, M. V. Slingerland (*Rural New Yorker, 59 (1900), No. 2649, p. 732*).—The author gives brief notes on the use of this insecticide in spraying orchards. In one instance 1,000 large apple trees were sprayed with about 500 gal. of crude petroleum in April. The oil was used in a 25 per cent solution, and the total expense for the orchard was about $100. The application was very effective in the destruction of the San José scale.

Location of San José scale in Indiana, J. Troop (*Indiana Sta. Rpt. 1900, p. 72*).—San José scale has been found in 17 counties within the State. A few counties are apparently free from the insect, on account of the persistent efforts of fruit men to destroy the scale and prevent its further introduction.

Crude petroleum; the elm louse; the pear-leaf blister mite, J. M. Aldrich (*Idaho Sta. Bul. 26, pp. 15–24, figs. 1*).—The author experimented with commercial crude petroleum, purchased in San Francisco, with a specific gravity of 0.954 and a density of 16.8 Baumé. It was found impossible to spray this oil undiluted, since it was so gummy that 75 lbs. pressure to the inch was not sufficient to break the oil into a spray. The machines commonly used for making automatic mixtures of kerosene and water were useless for making mixtures of the crude oil and water. This oil was found, however, to pass into emulsion with soapsuds more readily than with kerosene. Spraying with emulsions for San José scale was made March 1 to 10, and the trees were inspected on September 21 following. At that time it was found that one large pear tree, which had been covered with a solid stream of pure petroleum, bore more and larger fruit than adjacent trees of the same variety which were not infested with the scale, and that the foliage was in good condition. One side of an apple tree sprayed with undiluted petroleum died after leafing out, while the other side, which was sprayed with a 50 per cent emulsion, was in good condition and free from scale. Experiments were made with emulsions of crude petroleum varying in strength from 3½ to 50 per cent. Branches of trees which had been sprayed with 3½ per cent emulsion, examined soon after, revealed no living scales.

The author believes, therefore, that the weakest solution used is sufficient to kill all scales with which it comes in contact. In some cases a marked stimulation of pear trees as a result of spraying with crude petroleum was observed. Spraying with a 33 per cent emulsion of petroleum was very effective in destroying apple aphis and elm aphis.

The elm aphis (*Schizoneura americana*) lays its eggs in crevices of the bark and passes the winter in the egg stage. During summer the attacks of this insect cause the leaves to roll up and some leaves contain a hundred or more plant lice of all sizes. About midsummer the plant lice develop wings and migrate. In September the return migration occurs. These return migrations produce a new brood, which deposits the egg. The only remedy recommended by the author for this species is crude petroleum, as already mentioned.

The pear-leaf blister mite is reported as having caused the death of some trees at the station. Experiments with kerosene emulsion were carried on and emulsions of $12\frac{1}{2}$, $16\frac{2}{3}$, and 20 per cent kerosene were used. The weaker solutions did not destroy all the eggs, while the 20 per cent solution was very effective.

Nectarophora pisi, E. D. SANDERSON (*Canad. Ent., 33* (*1901*), *No. 2, pp. 31–39, pl. 1*).—The author compared series of specimens from American and European sources with the result that the species previously described as *N. destructor* is considered the same as that called *N. pisi* by European authors. The specimens of *N. destructor*, upon which measurements were based in the original description, were larger than the average form. Details of measurements of specimens from different sources are given. The author discusses briefly the previous outbreaks of this species in the United States. The insect is described in its various forms, together with notes on the varieties found on various plants.

The pea aphis, J. C. CHAPAIS (*Nat. Canad., 28* (*1901*), *No. 2, pp. 17–20*).—Brief notes on the habits, life history, and remedies for *Nectarophora destructor*.

Some plant lice affecting peas, clover, and lettuce, E. D. SANDERSON (*Canad. Ent., 33* (*1901*), *No. 3, pp. 69–74, pl. 1, fig. 1*).—Descriptive and biological notes on *Nectarophora lactucæ*, *Rhopalosiphum lactucæ*, and *Myzus pergandii*. The last-named species is described as new.

Heliothis dipsaceus and certain other enemies of flax in northern Caucasus, I. M. KRASILSHCHIK (*Lyutzernovaya i li lnyanaya sobka i nyekotoruie drugie vrediteli lna na syevernon Karkazye. St. Petersburg: Minister of Agriculture and Imperial Domains, 1900, pp. 61; abs. in Selsk. Khoz. i Lyesov., 199* (*1900*), *Oct., pp. 251, 252*).—The author gives an account of the life history of this insect and refers to the remedies which have been found effective in combating it. Brief notes are given on Gordius and a fungus disease of the species. Brief mention is also made of *Cochylis epilinana* and *Plusia gamma* as enemies of flax.

Insect pests of sugar cane, H. MAXWELL-LEFROY (*West Indian Bul., 2* (*1901*), *No. 1, pp. 41–44*).—This paper contains notes on the habits, life histories, and remedies to be adopted against *Sphenophorus sacchari*, *Delphax saccharivora*, and the cane moth borer.

Anatomy and physiology of insects, H. SKINNER (*Sci. Amer. Sup., 51* (*1901*), *No. 1308, pp. 20965, 20966*).—A brief general account of insect parasitism and details of the anatomy and functions of various organs which constitute the insect's body.

The simple eyes of insects, R. HESSE (*Zool. Anz., 24* (*1901*), *No. 634, pp. 30, 31*).—The author reports the results of his studies on the structure of the simple eyes as found in the larvæ of a considerable variety of insects.

Biological notes on the predaceous Hymenoptera, G. ADLERZ (*Ent. Tidskr., 21* (*1900*), *No. 3–4, pp. 161–200*).—The author gives notes on the habits and life history of a number of species, including *Ammophila sabulosa*, *Miscus campestris*, *Cerceris labiata*, and species of Psammophila, Crabro, Pompilus, etc.

Biology of coprophagous insects, E. A. BOGDANOW (*Allg. Ztschr. Ent., 6* (*1901*), *No. 3, pp. 35–41*).—The author gives brief notes on the habits and life history of several species of flies and beetles. Experiments were conducted on some of these species for the purpose of determining their reaction to light, gravity, and other influences.

The spinning apparatus of larvæ of Lyda, N. Cholodkovsky (*Allg. Ztschr. Ent., 6 (1901), No. 2, pp. 17–19, figs. 4*).—The author gives a detailed description of the anatomy of the spinning glands and related structures in the larvæ of the genus Lyda, especially *L. erythrocephala*.

The stridulating organs of the Rhynchota, A. Handlirsch (*Verhandl. K. K. Zool. Bot. Gesell. Wien, 50 (1900), No. 10, pp. 555–560, figs. 7*).—The author studied the stridulating organs of a number of species and gives details of the anatomy of these structures. The study involved a large number of species.

Occurrence of Drosophila ampelophila in great numbers, L. Melichar (*Weiner Ent. Ztg., 20 (1901), No. 1–2, pp. 7, 8*).—This species of vinegar fly is reported as being abundant in southern parts of Germany. The author observed the species in great numbers during October, 1900, in and about a barrel in which wormy fruit had been left. A brief discussion is given of the literature relating to this species.

Cockchafers and means of combating them in forests, A. Sobolev (*Selsk. Khoz. i Lyesor., 199 (1900), Nov., pp. 389–408*).—The author reviews the literature relating to the life history and means of combating *Melolontha vulgaris* and *M. hippocastani*, and gives a list of years during which these insects were especially injurious. Especial attention is given to the habits of and remedies for the latter species, especially since there is so little literature on the subject. The methods of digging out and cutting out are described in detail, and notes are given on the agency of the fungus parasite *Botrytis tenella* in controlling the cockchafers.

Means of protection of plants against attacks by caterpillars, G. Lagerheim (*Ent. Tidskr., 21 (1900), No. 3–4, pp. 209–232, figs. 5*).—The author presents detailed notes on Coleoptera, Lepidoptera, Diptera, and Aphididæ, with reference to the frequency of their attacks upon various plants. Notes are also given on the bitter juices, hairs, tough tissues, and other devices by which different families of plants are to some extent protected against the insects' attacks.

Directions for treatment of insect pests and plant diseases, E. D. Sanderson and F. D. Chester (*Delaware Sta. Bul. 50, folio, figs. 8*).—Brief notes are given on the common insect and fungus diseases of the more important economic plants, together with formulas for making the standard insecticides and fungicides.

Paris green, W. C. Stubbs (*Louisiana Stas. Bul. 63, 2. ser., pp. 577–589, 595, 596*).—The author gives a copy of the Louisiana law regulating the sale and purity of Paris green as an insecticide, and reports the percentage of arsenious acid found in a large number of samples. The amount of Paris green sold in different parishes is mentioned, and it is stated that no evidence has thus far been obtained of violation of the law in adulterating Paris green.

A fumigator for small orchard trees, V. H. Lowe (*New York State Sta. Bul. 181, pp. 138–142, pls. 5*).—The author devised a fumigator with dimensions 10 by 6 by 6 ft. The frame was made of pine strips, one side of the bottom being left out, so that the box could be easily placed around the tree. A movable side was constructed so as to be easily fastened in place by means of wooden buttons. The frame is covered with any suitable gas-tight material, such as 8 oz. duck, which may be treated with raw oil and white lead, or shellac with oil and white lead. The canvas over the top may be protected by fastening wire gauze in the top of the box, to prevent the branches from tearing the canvas. A strip of canvas 18 in. wide is fastened to each side of the base of the fumigator, and when the box is in place these strips are covered by dirt or sand bags. The box is thus gas tight.

The cost of this fumigator varies from $13 to $18, according to the kind of material used for the cover. The box may be easily manipulated by 2 men. A bag of cyanid is placed over the dish of acid, and by means of a string passing through a small hole in one of the upright sticks may be pulled into the acid. The time required for moving the box from one tree to another is about 10 minutes. The advantages claimed for this fumigator are that its cubic contents may be accurately computed, that the same amount of chemicals will be used for each charge, thus avoiding extra weighings, that fewer men are required to handle it, and that the fumigator does not rest upon the tree and is therefore not likely to break the limbs.

Apiculture, A. GALE (*Agr. Gaz. New South Wales, 12 (1901), No. 1, pp. 213-217, pl. 1*).—The author gives a brief historical account of the development of apiculture in New South Wales, with reference to the more important bee diseases.

The natural history of the honeybee, G. KOZHEVNIKOV (*Materialui po estestrennoi istorii pchelui. Moscow: Imperial Society of Naturalists, Anthropologists, and Ethnologists, 1900, pp. 144, pls. 3, figs. 45; abs. in Selsk. Khoz. i Lyesov., 199 (1900), Oct., pp. 282, 283*).—The author discusses in detail the different forms of *Apis mellifica* occurring in the colony, and gives a brief account of *A. dorsata* and *A. florea*.

Do bees eat fruit? (*California Cult., 16 (1901), No. 5, p. 69*).—A. J. Cook discusses this subject by way of answering correspondence relating to the possible injury of fruit by bees. It is believed that the mouth parts of bees are so constructed that they might be used in injuring fruit, though the evidence at hand indicates that this is seldom the case.

Formaldehyde vapors for combating foul brood of bees, B. GALLI-VALERIO (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 4, pp. 127-129, figs. 2*).—In preliminary experiments with this substance the author made use of frames containing larvæ infested with foul brood. Small portions of the comb were exposed in glass vessels to the vapor of formaldehyde for one-quarter of an hour. This treatment was found to have destroyed the bacillus of foul brood. The experiments were repeated on a larger scale by a practical bee keeper with satisfactory results, and a lamp has been devised which is especially adapted for fumigating infested colonies in the hive. Very favorable results have been obtained from its use. A detailed description is given of the lamp.

Foul brood of bees, F. C. HARRISON (*Ontario Agr. Col. and Expt. Farm Bul. 112, pp. 32, pls. 4*).—This article has already been noted from another source (E. S. R., 12, p. 966).

Some experiments in the exportation of beneficial insects, F. M. WEBSTER (*Canad. Ent., 33 (1901), No. 2, pp. 58, 59*).—The author refers briefly to experiments in shipping species of lady bug beetles from Ohio to South Africa. Numerous specimens of several species were sent with good results in the case of *Pentilia misella*.

FOODS—NUTRITION.

Experiments on the effect of muscular work upon the digestibility of food and the metabolism of nitrogen, conducted at the University of Tennessee, 1897-1899, C. E. WAIT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 89, pp. 77*).—This bulletin is in continuation of previous work (E. S. R., 10, p. 171), and reports 16 experiments. With one exception they are divided into three periods, during two of which the subject (in every case a young man in health) performed little or no muscular work, while during the third period he had more or less exercise. The digestibility of the diet and the balance of income and outgo of nitrogen were determined in all the periods with a view to learning the effects of muscular work. During the majority of the work periods and some of the rest periods the outgo of nitrogen in the urine was determined in portions corresponding to 6-hour intervals.

"The muscular work performed during the work period of the experiments carried on [during the first year] was not at all severe. There was, moreover, a slight increase of nitrogen in the diet during the work period, in addition to a large increase of energy from additional fats and carbohydrates in the ration (in some cases as much as 1,000 calories per day). It was found that the digestibility of the diet was not appreciably affected under these conditions. As regards the income and outgo of nitrogen, there was almost invariably a gain of nitrogen during the period of work which amounted to as much as 5 gm. per day at times. Allowing for the slightly increased amounts of nitrogen in the daily diet during this period, as compared with the preceding rest period, there was at times a relative gain and at times a relative loss of nitrogen. In the experiments made [during the second year] the energy in the diet during the period of muscular activity was increased by about 500 calories per day, while the nitrogen remained practically the same as during the preceding rest period. The calculated energy required for the measured muscular work ranged from 127 to 147 calories and averaged 139 per day. The digestibility of the diet was again uninfluenced by muscular work. A study of the nitrogen balance shows that in the majority of cases if there was a gain during the rest period it was increased during the work period, and if there was a loss it was diminished. In other words, comparing the elimination of nitrogen in the periods of little muscular activity and normal diet with that during periods of increased activity and a diet furnishing energy largely in excess of the heat equivalent of the measured work performed, there seems to be a slight decrease under the latter condition. This is true even when we consider the possibilities of a small loss of nitrogen in the perspiration and a lag of considerable duration between the breaking down of nitrogenous material within the body and the excretion of nitrogen in the urine."

Concerning the influence of pasteurized grape juice upon general nitrogen metabolism, etc., body weight, and intestinal putrefaction in healthy man on mixed diet, M. MINAS (*Inaug. Diss., Dorpat, 1900, pp. 144; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 5. pp. 204, 205*).—Detailed analyses of pasteurized grape juice (including ash constituents) are reported, as well as a number of experiments in which grape juice was consumed as part of a mixed diet. Among other conclusions it was pointed out that a rational use of such pasteurized grape juice with a satisfactory mixed diet diminishes the cleavage of protein in the body. The power to protect protein depends upon the grape sugar present and is dependent not alone upon the quantity of grape juice taken, but also on the kind and amount of protein consumed. The richer the food in easily digestible protein, the greater the power of the grape juice to protect the protein. The effect of pasteurized grape juice on the digestibility of protein and other questions of interest from a dietetic standpoint are discussed at some length.

The available nourishment in foods, C. TURLE (*British Food Jour., 2 (1900), Nos. 23, pp. 311, 312; 24, pp. 348, 349*).—A general discussion of food and diet.

Nutrition and the nation's food, J. FRENTZEL (*Ernährung und Volksnährungsmittel. Leipsic: B. G. Teubner, 1900; rev. in Oesterr. Chem. Ztg., 3 (1900), No 20, p. 493*).—A series of six lectures.

The principles of metabolism and nutrition, L. BREISACHER (*Reprint from Phys. and Surg., 1900, Nov., pp. 20*).—The author discusses experiments carried on by himself and other investigators.

The methods of practical hygiene, K. B. LEHMANN (*Die Methoden der praktischen Hygiene. Wiesbaden: J. F. Bergman, 1901, 2. ed., pp. XVIII + 698, figs. 140*).—A revised and enlarged edition of this handbook and laboratory manual, which is designed to meet the needs of physicians, chemists, and others who have occasion to make examinations of air, animal and vegetable foods, etc., from a hygienic standpoint.

Fifth report on food products, E. H. JENKINS (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 105–114*).—The Connecticut food law and the law regulating the sale of commercial feeding stuffs are quoted. The work of the station during the year in the examination of food products is briefly reviewed. In all 824 samples were examined.

Food products examined for the dairy commissioner in the twelve months ended July 31, 1900 (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 216–218*).—Samples of a number of materials including butter, molasses, and vinegar were examined.

Bread and the principles of bread making, HELEN W. ATWATER (*British Food Jour., 2 (1900), Nos. 17, pp. 120–122; 18, pp. 150, 151; 19, pp. 180, 181; 20, pp. 215–217; 21, pp. 245, 246; 22, pp. 279, 280; 23, pp. 312, 313; 24, pp. 349, 350*).—A reprint of U. S. Dept. Agr., Farmers' Bul. 112 (E. S. R., 12, p. 279).

The Schweitzer system of grinding grain and making bread, A. MÜNTZ (*Bul. Agr. Algérie et Tunisie, 6 (1900), pp. 253–258*).—A descriptive article, with a report of the analysis of the crust and crumb of ordinary bread, and white bread made by the Schweitzer system as well as white bread made by ordinary methods.

Shredded entire wheat biscuit (*Connecticut State Sta. Rpt. 1900, pt. 2, p. 156*).—An analysis of this product is reported.

Buckwheat flour, A. L. WINTON (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 114–119*).—A total of 115 samples were examined of which 63 were not found to be adulterated.

Sugar as food, F. STROHMER (*Oesterr. Ungar. Ztschr. Zuckerind. u. Landw., 28 (1899), No. 3; abs. in Centbl. Agr. Chem., 29 (1900), No. 3, pp. 172–174*).—Noted from another publication (E. S. R., 11, p. 481).

Preserves, A. L. WINTON (*Connecticut State Sta. Rpt. 1900, pt. 2, p. 156*).—Notes on the analyses of samples of preserves.

Fruit eating (*Agr. Jour. Cape Good Hope, 17 (1900), No. 13, pp. 824, 825*).—Extracted from an article by Leriche in *Le Petit Jardin*.

Lard, A. L. WINTON and A. W. OGDEN (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 136–148*).—Of the 160 samples of lard examined during the year 6.2 per cent were found to be adulterated. As 36.5 per cent of the samples were found to be adulterated in 1896, it would appear that adulteration of lard has diminished since the food law went into operation.

Lard oil, A. L. WINTON (*Connecticut State Sta. Rpt. 1900, pt. 2, p. 148*).—A sample of lard oil, a fat which is said to be used by bakers for deep frying, was found to be adulterated by about half its weight with coal oil.

Olive oil, A. L. WINTON and A. W. OGDEN (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 148–155*).—Of the 105 samples examined 39 per cent were found to be adulterated.

Milk powder, A. L. WINTON (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 198–200*).—Samples of an egg substitute, which is said to be made from skim milk, were examined and analyses reported.

Adulteration of true mace with Bombay mace, A. L. WINTON (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 156, 157*).—Notes on the adulteration of samples of mace.

Baking powders, A. L. WINTON, A. W. OGDEN, and C. LANGLEY (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 157–180, pl. 1*).—Details are reported of the examination of 76 brands of baking powders.

Cream of tartar, A. W. OGDEN (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 180–185*).—Seventy-six samples of cream of tartar were examined.

The manufacture of vinegar, E. M. HAWKINS (*British Food Jour., 2 (1900), No. 24, pp. 347, 348*).—A descriptive article.

Coffee and coffee compounds, A. L. WINTON (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 118–122*).—Of the 5 samples of unground coffee examined during the year it is stated that 3 were unadulterated; of the ground coffees, 48 were not adulterated and 7 adulterated.

Chocolate meal, A. BEYTHIEN and H. HEMPEL (*Ztschr. Untersuch. Nahr. u. Genussmtl. 4 (1901), No. 1, pp. 23–25*).—A chemical examination of samples of so-called chocolate meal is reported.

Concerning Dutch cocoa, J. FORSTER (*Hyg. Rundschau, 10 (1900), No. 7, pp. 305–307*).—The process of manufacture and healthfulness of cocoa is discussed at some length. Analyses (proximate and ash) are briefly reported, as well as digestion experiments by artificial methods and with a healthy man. The average coefficients of digestibility of cocoa were: Dry matter 90, protein 80, fat 100, and ash 100 per cent. Twenty gm. of cocoa were found to be more thoroughly digested than a larger amount (60 gm.).

The author also studied the effect of consuming different quantities of cocoa on the digestibility of milk. When milk was consumed alone, the following coefficients of digestibility were found: Dry matter 91.6, protein 93, fat 96, and ash 56.7 per cent. When 20 gm. of cocoa was consumed per 100 gm. of milk, the coefficients of digestibility were as follows: Dry matter 92, protein 93.2, fat 96.3, and ash 66.1. When 60 gm. of cocoa per 100 gm. of milk were consumed, the corresponding percentages were: Dry matter 90.8, protein 92.4, fat 95.6, and ash 63.1. In other words, the consumption of cocoa with milk increased the digestibility of the latter food.

Zanzibar carbon, A. L. Winton (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 200, 201*).—This material, which is recommended by the manufacturers for giving the same color as smoke to meats and sausage and for other purposes, was found to consist chiefly of a coal-tar color, probably Bismarck brown, and common salt. An analysis of the material is reported.

Introduction to the microscopical examination of vegetable foods and condiments, A. F. W. Schimper (*Anleitung zur mikroskopischen Untersuchung der Vegetabilischen Nahrungs und Genussmittel. Jena: J. G. Fischer, 1900, 2. rev. ed., pp. 158, figs. 134; rev. in Oesterr. Chem. Ztg., 3 (1900), No. 20, p. 493*).—A handbook.

Protection of food products from injurious temperatures, H. E. Williams (*U. S. Dept. Agr., Farmers' Bul. 125, pp. 26*).—A popular summary of information available on the use of cold storage for preserving food products.

Pure-food laws of European countries affecting American exports, W. D. Bigelow (*U. S. Dept. Agr., Division of Chemistry Bul. 61, pp. 39*).—A comprehensive summary.

The imperial meat-inspection law (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 32, pp. 19*).—The German text and English translation of the new imperial German meat-inspection law.

Literature along domestic science and household economic lines, Minnie A. N. Stoner (*Industrialist, 27 (1901), No. 15, pp. 189–194*).—The article contains a bibliography.

Bibliography of domestic economy, R. K. Shaw (*New York State Library Bul. 52, Jan., 1900, pp. 170*).—An extended bibliography of the literature of domestic economy. Only works printed in England are included. One of the sections refers to food, cooking, etc.

ANIMAL PRODUCTION.

Condimental and medicinal cattle and poultry foods (*Connecticut State Sta. Bul. 132, pp. 7*).—Analyses are reported of 15 samples of condimental and medicinal cattle and poultry foods. As is pointed out, these foods consist of ordinary concentrated foods such as corn meal, linseed meal, and such drugs as ginger, fenugreek, sulphur, charcoal, salt, Epsom salts, and gentian. In proportion to the cost of the materials, the prices asked for these materials are very high, and there is no reason to suppose that the effect they produce is at all proportionate to the claims made for them.

Feeding stuffs, R. J. Davidson (*Virginia Sta. Bul. 107, pp. 211–233*).—In addition to a general discussion, the author reports the analyses of a number of samples of cotton-seed meal, cotton-seed hulls, linseed meal, bran, middlings, shorts, mill feed, corn meal, dried brewers' grain, pea meal, gluten meal, ship stuff, and a number of mixed and condimental feeds.

Computation of rations, A. M. Soule (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 44–51, figs. 3*).—Practical directions are given for computing rations.

Concerning the nature and value of the nitrogenous constituents of molasses, C. Beger (*Chem. Ztg., 25 (1901), No. 1, pp. 8–10*).—The total nitrogen in beet-sugar molasses was found to be 1.47 per cent. Of this, 29.3 per cent was nitrogen of organic bases, such as betein, and 48.3 per cent nitrogen of amid compounds, such as glutamin; while, as shown by the Stutzer method, 12.2 per cent was albuminoid nitrogen. If the ammonium sulphate method was used, only 5.3 per cent albuminoid nitrogen was found. The character of the remaining nitrogen, according to the author, has not yet been determined. Rabbits were fed molasses to which a salt mixture containing phosphates was added. The molasses was absorbed in filter paper. This supplied crude fiber and made the ration when dried easy to handle. It was not possible to maintain the body weight of the rabbits on this ration. When gluten meal was added to it, gains in weight were made and a nearly constant weight maintained. The nonalbuminoid nitrogenous compounds in beet molasses, the author concludes, can not replace protein. The tests do not show whether or not they have a power to protect protein similar to that of asparagin.

The proteids of the muscles of cold-blooded animals and their relation to heat rigor, O. von Fürth (*Ztschr. Physiol. Chem., 31 (1901), No. 3–4, pp. 338–352*).—Experiments are reported and discussed.

The principles of animal production with reference to farm animals, R. Müller (*Grundzüge der landwirthschaftlichen Thierproductionlehre. Berlin: P. Parey, 1900, pp. 439, figs. 184; rev. in Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 2, pp. 170, 171*).—A handbook for students and practical farmers.

Feeding native steers, A. M. Soule and J. R. Fain (*Tennessee Sta. Bul., Vol. XIII, No. 4, pp. 23, figs. 7*).—The comparative value of cotton-seed meal and cowpea-vine hay as sources of protein and the feeding value of finely ground cotton-seed hulls or cotton-seed bran were tested with 2 lots of 4 steers each. The animals used were ordinary steers, as it was desired to test the possibility of profitably fattening native stock. The test began January 1, and covered 98 days. At the beginning lot 1 was fed per day per thousand pounds a ration consisting of 6 lbs. cowpea-vine hay, 3 lbs. corn meal, and shredded corn fodder ad libitum. Lot 2 was fed 6 to 16 lbs. cotton-seed bran, 4 to 7 lbs. cotton-seed meal, and corn stover ad libitum. Later the grain ration consisted of 6 lbs. of cotton-seed bran, 3 lbs. cotton-seed meal, and 4 lbs. corn meal. The average weight of the steers in lot 1 at the beginning of the test was 759.7 lbs. and the average daily gain 1.99 lbs. The corresponding figures for lot 2 were 777.7 and 1.75 lbs., respectively. Lot 1 consumed 6.3 lbs. of coarse fodder and 3.17 lbs. of concentrated feed per pound of gain, while lot 2 consumed 7.56 lbs. corn fodder and 3.63 lbs. of concentrated feed per pound of gain. The amount of water consumed per head daily by the 2 lots was about the same, being 42.90 lbs. for lot 1 and 43.51 lbs. for lot 2. At the close of the test the steers were slaughtered and the results of the slaughter test recorded. The average percentage of valuable meat per carcass in lot 1 was 55.75 lbs. and for lot 2 55.59 lbs. The average weight of the liver and the intestinal fat in lot 1 was 10.1 and 20.7 lbs., respectively. Corresponding figures for lot 2 were 11.2 and 17.7 lbs. On the assumption that caring for the animals was worth 3 cts. per day, the profits with lot 1 were $6.15 and with lot 2 $3.62 per steer. Among the general conclusions reached were the following:

"This experiment indicates that native steers can be successfully fed at home at a fair profit. It further indicates that all the corn stover now wasting in the fields should be shredded and fed.

"Cotton-seed bran is too expensive for [coarse fodder], and has an unfavorable effect on digestion, producing impaction of the rumen. . . .

"Cowpea-vine hay made an admirable substitute for cotton-seed meal. As it is not so rich in protein, however, it should be fed at the rate of 2 to 3 lbs. of the former for 1 lb. of the latter.

"It is seen from these tests that a home-grown ration of shredded stover, cowpea-vine hay, and corn meal can be fed with success to a fair type of native cattle. . . .

"Cotton-seed meal gave the better results when combined with corn meal in the proportion of 1 lb. of the former to $1\frac{1}{4}$ lbs. of the latter than when fed alone. . . .

"The results of this experiment favor the use of a ration of corn stover, cowpea-vine hay, and corn meal in preference to one of shredded stover, cotton-seed bran, and cotton-seed meal."

Salt for fattening cattle, J. G. HANEY (*Industrialist, 27 (1901), No. 20, pp. 255–256*).—A general discussion, with brief notes on the amount of salt consumed by a number of grade calves.

The comparative feeding value of corn fodder, corn silage, roots and hay, for feeding breeding ewes in winter, A. L. CARLYLE (*Wisconsin Sta. Rpt. 1900, pp. 28–36*).—Using 3 lots of 12 and 1 of 11 ewes, a number of rations were compared for winter feeding, with especial reference to the value of corn fodder and silage. Lots 1 and 2 were fed corn fodder with bran and oats (1:1), lot 2 receiving corn silage in addition; lots 3 and 4 were fed hay, with bran and oats (1:1), the former receiving corn silage and the latter roots in addition. The ewes in lots 1, 2, and 3 were given $\frac{1}{2}$ lb. of grain per head daily, and those in lot 4, $\frac{3}{4}$ lb. In 10 weeks the lots gained 197, 122, 154, and 159 lbs., respectively. Data are recorded concerning the production of lambs by the different lots, also the weight and condition at birth. "There was not very much difference in the average length of time that the ewes of the different lots carried their lambs. . . . Nothing of any importance can be gleaned from these slight differences in this respect, and the same may be said of a comparison of the number of days in pregnancy of the ewes of different breeds on this experiment. There is also very little that is noteworthy in a comparison of the number or the condition of the lambs produced by the different lots, except the uniformity of increase and general vigor of the lambs from all the flock, irrespective of the kinds of feed given the ewes. . . .

"Well-cured corn fodder, of which about 65 per cent has had the ear corn removed, was a satisfactory feeding stuff. . . .

"Corn silage fed in conjunction with either corn fodder or mixed hay and the same ration of bran and oats is a very satisfactory and very cheap ration for winter breeding ewes that are pregnant. This experiment would also seem to indicate that hay and roots make a very expensive feed ration for wintering breeding ewes and that they do not give any better results than the other and cheaper rations fed. It would appear also that corn fodder containing a large proportion of ears should not be fed largely to breeding ewes until the ear corn had been removed, as well cured and unhusked corn fodder may have fully 50 per cent of its weight in the ear corn, and the ewes might readily get too much ear corn and become too fat."

Pig feeding experiments: Fattening value of certain foods grazed by pigs; feeding experiments to harden soft pork, R. L. BENNETT (*Arkansas Sta. Bul. 65, pp. 97–110*).—Tests of the value of forage crops for pigs (E. S. R., 10, p. 1065) have shown that pork produced by grazing on such foods as soy beans, peanuts, and chufas lacked the hardness of corn-fed pigs. A test was therefore undertaken to learn what quantity of corn was required, and how long it was necessary to feed it after grazing in order to secure carcasses of the desired quality. A lot of 10 mixed grade pigs averaging 116.7 lbs. in weight was pastured for 60 days on peanuts and chufas planted three rows of the former to one of the latter. The average daily gain per pig was 1.6 lbs. A similar lot of 10 pigs averaging 116.2 lbs. each at the beginning of the test was pastured 60 days on peanuts. At the close of the period the pigs in both lots were put on full corn fodder for 8 weeks, the amount of corn eaten being recorded. At intervals of 2 weeks the 2 fattest pigs were slaughtered and the melting point of samples of fat tested.

For purposes of comparison, three lots were pastured during the whole test on peanuts and chufas alone and combined. Four pigs weighing an average of 115.5 lbs. each when pastured on chufas for 60 days made an average gain of 1.38 lbs. Two pigs weighing 111.5 lbs. each when pastured on peanuts made an average daily gain of 1.37 lbs. Two pigs weighing 116.5 lbs. were pastured for 90 days on peanuts and chufas in the proportion of three rows of the former to one of the latter and made an average daily gain of 1.47 lbs. The melting point of the back fat and kidney fat of the pigs fed no corn was 22.9° C. and 32.2° C., respectively. The average melting point of the back fat and kidney fat of the pigs fed corn after the grazing period was 26.3° C. and 34.1° C., respectively. There was thus on an average 3.4° C. in favor of the pigs given corn after grazing. "What effect longer feeding than 8 weeks would have on the hardening of the fat was not ascertained, because to feed longer than 4 weeks is more expensive than the objects of the experiments would permit, which was to produce pork on a minimum quantity of corn and of a quality equal to full corn-fattened pork."

The animals used in the above tests were the average pigs of the region, and were scrubs with the exception of two or three which showed improved blood. The latter produced a somewhat better quality of pork and probably harder fat than the former. In a subsequent test the effect of feeding corn while grazing on peanuts and chufas, and the value of thoroughbred as compared with scrub stock, was studied. As the pigs when grazing had considerable exercise, the test also bears upon the question of the effect of exercise combined with corn feeding. Four pigs, weighing on an average 99.5 lbs., when pastured on peanuts and chufas in alternate rows and fed corn in addition for 75 days made an average daily gain of 1.7 lbs. per pig. They grazed over 0.78 acre and consumed 14 bu. of corn. Four pigs, averaging 95 lbs. each, when grazed on peanuts and chufas in alternate rows for 50 days gained 89.5 lbs. each. They were then fed corn for 25 days. During the whole test the average daily gain was 1.6 lbs. per pig. Fourteen bushels of corn were consumed and 0.71 acre were grazed over. One lot of four pigs weighing 96.3 lbs. each was pastured on peanuts for 75 days and fed corn in addition. The average daily gain was 1.78 lbs. Fourteen bushels of corn were consumed in addition to the feed received on 0.78 acre of a field of peanuts. When grazed on peanuts for 50 days, 4 pigs averaging 95 lbs. each, gained 95.5 lbs. They were then fed corn for 25 days. During the whole test the average daily gain per pig was 1.7 lbs., 14 bu. of corn and the peanuts on 0.71 acre being consumed. In comparison with the above lots, which were made up of ordinary scrub stock, 6 thoroughbred Berkshires averaging 96 lbs. each were grazed on peanuts for 75 days and fed corn in addition. The average daily gain was 1.6 lbs. per pig. This lot grazed over 1.19 acres and consumed 20 bu. of corn. The average melting point of the back fat of the pigs fed corn while grazing was 33.1° C. and of the kidney fat 38.4° C. Similar values for pigs fed corn after grazing were 32.5° C. and 37.8° C. According to the author the thoroughbred pigs or good grades, on peanuts and chufas, combined or alone and fed at the same time a quantity of corn equal to the amount required in four weeks, if fed exclusively, produced pork and lard that in appearance and cooking quality could not be distinguished from that produced by pork fattened on corn exclusively. Scrub pigs similarly grazed and fed produced an inferior flesh and fat, which was soft and oily.

"[A quantity of corn equal] to full feed for a month raised the melting point of fat a few degrees and hardened the flesh, but . . . a smaller quantity was of no material benefit; . . . a larger quantity for feeding longer than one month was too expensive and did not produce good effects to a proportionate extent as the first month of corn feeding."

Data concerning the melting point of the fat of pigs used in an earlier test (E. S. R., 10, p. 1086) are also reported.

Feeding pigs for the production of lean and of fat meat, W. L. Carlyle and A. G. Hopkins (*Wisconsin Sta. Rpt. 1900, pp. 12–24, pls. 6*).—It has been claimed by some that "the feeding of corn to hogs produces a carcass containing a much larger proportion of soft blubbery fat than is the case when feeds such as peas, barley, oats, and skim milk, etc., are fed, since these contain a greater percentage of nitrogenous or flesh-forming material than corn. There are also a number of authorities who insist that the percentage of lean meat is more dependent upon the breed and type of hogs fed than upon character of the feed given them."

In view of the growing demand for lean pork, especially for export purposes, a test was begun with 2 lots of 8 pigs each, to study the causes which influence the character of the gains made. Each lot contained Berkshires, Poland Chinas, and Yorkshires. During the 18 weeks of the test, lot 1 was fed corn meal and skim milk, 1:1; lot 2, wheat middlings and ground peas, 1:1, mixed with an equal amount of skim milk. The nutritive ratio of the rations fed the two lots was 1:7.7 and 1:3.6, respectively. The average amount of grain eaten per pig per day in the 2 lots was 3.92 and 3.94 lbs., and the average daily gain per pig, 1.26 and 1.17 lbs., respectively, the amount of food consumed per pound of gain being 6.32 and 6.81 lbs. As regards breeds, the Berkshires gained on an average of 1.34 lbs.; Poland Chinas, 1.21 lbs., and Yorkshires, 1.08 lbs. The pigs were slaughtered and a block test was made. Among the conclusions drawn were the following:

"The pigs in the corn-fed lot averaged slightly longer in body than did those fed peas, but this must be attributed to the individual peculiarity of the pigs comprising the different lots. In comparing the average length of the small intestines with the average length of the bodies of the pigs in the different lots, we notice that in the lot fed corn the average length of the small intestines is 18.4 times the average length of the body, and in the pea-fed lot they are 18.6 times longer than the average length of their bodies. . . .

"In the corn-fed lot we find the average percentage of intestinal fat to dressed weight to be 2.2 per cent and in the pea-fed lot it is just 2 per cent. This difference is not so pronounced as in the average percentage of kidney fat found in the two lots. . . .

"The fat from the two pigs fed peas and middlings contained a much larger percentage of water than did those fed on corn meal. What effect this may have on the curing and edible properties of the fat meat we are not prepared to say, but it would certainly add to the value of the kidney fat of the pigs from the corn-fed lot over the other for lard-rendering purposes. . . .

"In the amount of blood, weight of intestines and stomach, weight of livers and weight of kidneys the pea-fed lot has a greater average weight in every case than the corn-fed lot."

Experiments in pig feeding (*Queensland Dept. Agr. Rpt. 1899–1900, pp. 19–24*).—In a comparison of boiled mangolds and swill vs. boiled mangolds and ground barley, made with 2 lots of 4 pigs each, the average daily gain per pig in 4 weeks was 0.6 lb. on the former ration as compared with 1.65 lbs. on the latter. Cooked, i. e. boiled barley and raw ground barley were compared with 2 lots of 4 pigs each. The average daily gain in 4 weeks was 1.93 lbs. on cooked and 1.74 lbs. on ground barley; the food consumed per pound of gain was 5.43 and 5.94 lbs., respectively. Under similar experimental conditions the value of ground barley with and without cane molasses was tested. On ground barley the average daily gain per pig was 1.93 lbs. and on ground barley and cane molasses (5.7:1) it was 1.96 lbs. The food consumed per pound of gain was 5.5 and 5.08 lbs., respectively.

Whole corn compared with corn meal for fattening swine, W. A. Henry (*Wisconsin Sta. Rpt. 1900, pp. 7–11*).—In continuation of earlier work (E. S. R., 10, p. 776), whole corn and corn meal were compared for 14 weeks with 2 lots of 14 pigs each. Wheat middlings were fed with the corn and constituted one-third of the ration. A few of the pigs were Poland China Berkshire crosses; the others were pure-bred Poland Chinas. The total whole corn and wheat middlings consumed by lot 1 was 5,852 and 2,926 lbs., respectively, the total gain being 1,571 lbs. Lot 2 consumed 6,183 lbs. corn meal and 3,092 lbs. wheat middlings, the total gain being 1,938 lbs. Lot 1 required 5.59 lbs. of corn per pound of gain, while lot 2 required 4.79 lbs. The results have varied in different years, therefore the authors believe that the tests must be continued before definite conclusions can be drawn.

Feeding value of rape for growing pigs, W. L. CARLYLE (*Wisconsin Sta. Rpt. 1900, pp. 25–27*).—The feeding value of rape alone was tested with 30 pigs averaging 6 months old at the beginning of the test. For 2 weeks they were pastured on about 4 acres of rape. It was eaten readily and with no bad effects. During the time the pigs lost a total of 60 lbs.

"The results of this experiment would indicate that a ration of rape alone fed to pigs for a period of 2 weeks was not sufficient to supply the food necessary for their support. It is quite possible, however, that it may have a much higher feeding value for pigs at this age than when fed in conjunction with grain feed."

Horse breeding, A. M. SOULE (*Univ. Tennessee Record, 4 (1901), No. 1, pp. 29–36, figs. 5*).—A general discussion.

Michigan live stock; review of its present condition, R. GIBBONS (*Michigan Bd. Agr. Rpt. 1900, pp. 365–374*).—A general and statistical article.

DAIRY FARMING—DAIRYING.

On the economy of heavy grain feeding of dairy cows, F. W. WOLL and W. L. CARLYLE (*Wisconsin Sta. Rpt. 1900, pp. 37–61*).—A feeding experiment comparing medium and large quantities of grain, conducted on the same general plan as earlier work (E. S. R., 12, p. 81), is reported. The experiment included 2 lots of 8 cows each and covered 3 periods of 4 weeks each. A medium or normal grain ration, "the amount of grain which, according to careful observations and trials, was required by each animal for maintaining a good flow of milk and a constant live weight," was fed to the cows in lot A during the first and third periods and to the cows in lot B during all 3 periods. The quantity of grain in this ration averaged about 8 lbs. A heavy grain ration, which was $1\frac{1}{2}$ times the normal ration, was fed to lot A during the second period. The grain consisted of wheat bran, ground oats ground corn, and old-process oil meal. Hay and silage were fed in addition Analyses of the feeding stuffs and the nutrients of the rations are given in tables. Some of the data are summarized in the following table:

Results of feeding different amounts of grain to milch cows.

	Food consumed.			Total production.		Cost of food per pound of fat.
	Silage.	Hay.	Grain.	Milk.	Fat.	
	Lbs.	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Cents.*
Lot A:						
Period I (8 lbs. grain)	6,813	219.1	1,344	4,581.8	195.40	9.0
Period II (12 lbs. grain)	6,996	222.6	2,016	4,445.7	186.94	12.2
Period III (8 lbs. grain)	7,530	221.0	1,344	3,972.7	167.95	10.8
Average of Periods I and III	7,171.5	221.55	1,344	4,277.25	181.675	9.9
Lot B:						
Period I (8 lbs. grain)	7,372	222.3	1,344	4,416.3	189.16	9.6
Period II (8 lbs. grain)	7,700	223.4	1,344	4,076.1	173.81	10.6
Period III (8 lbs. grain)	7,602	224.0	1,344	3,735.1	159.38	11.6
Average of Periods I and III	7,487	223.15	1,344	4,075.7	174.27	10.6

The results are discussed at some length. The production of milk and butter per unit of dry matter consumed decreased during the heavy grain feeding. The after effects were unfavorable to heavy grain feeding. "The results of the experiments in this line conducted by us during the last two years lead to the general conclusion that it does not pay to feed dairy cows more than a medium amount of grain feed, which may be placed at about 8 lbs. per head daily, except in case of cows of marked dairy tendencies that respond to heavy grain feeding by an increased production of milk and fat rather than by a gain in live weight."

Record of the university dairy herd, W. L. CARLYLE (*Wisconsin Sta. Rpt. 1900, pp. 314–335, figs. 14*).—An account is given of the care and management of the dairy herd, used in a comparison of the milk and butter production of cows of the special-purpose dairy type and cows of the dual-purpose type, and the records of 12 pure-bred and grade cows for the year. The data given include the breed, age, and weight of cows; kind, amount, and cost of food eaten; number of days in milk; amount and value of products, and total profit. Variations in the production of 2 cows are noted. Illustrations are given of 10 of the cows, accompanied in each case by descriptive and historical notes and a summary of production and profit. "The records, when taken in connection with those reported last year [E. S. R., 12, p. 83], certainly contain some surprising results in favor of grade Shorthorns as profitable milkers. The cows of this breed here reported have been bought from 4 different herds in widely separated parts of the country, and have been bred from a variety of lines of breeding."

The record of the grade Guernsey cow, Dolly, summarized by periods of 8 weeks, shows "a remarkable falling off in her production between the amount produced in the best week in the first period of 8 weeks and the best week in the third period of 8 weeks. The feed received indicates that she ate as much feed during the second and third periods as she did during the first. This is a remarkable instance of the folly of condemning a cow on a single day, a single week, or even a single year's record.

"The case of Pauline, a beefy grade Shorthorn cow, is another example, but the difference is not so great in the production of the 2 years. Her record, completed in 1899, gave her credit for 4,335 lbs. of milk and 184.33 lbs. of butter fat, or 215.05 lbs. of butter. Her present yearly record gives her credit for 7,996.7 lbs. of milk and 322.1 lbs. of butter fat, or 364.56 lbs. of butter. Here we have a difference of 3,661.7 in pounds of milk, or 149.51 in pounds of butter. In her record of the present year the profit over cost of feed was $57.48, while last year it was but $20.86."

Official tests of dairy cows, 1899-1900, F. W. WOLL (*Wisconsin Sta. Rpt. 1900, pp. 62–75*).—Rules regarding the conduct of official tests of dairy cows, and directions for station representatives in conducting the tests, as adopted by the station January 1, 1900, are given. Under these rules the station, working in conjunction with the various breeders' associations, will make official tests of registered cows. The person for whom the test is made is expected to pay all expenses connected with the test, including traveling expenses and $2 a day for the station's representative, and provide him accommodations. The results of such official tests of 110 Holstein, 7 Guernsey, 2 Shorthorn, and 8 Red Polled cows are reported in detail. Data for "economical food tests" of 14 of the Holstein cows are included.

An improved cow stall, H. E. VAN NORMAN (*Indiana Sta. Rpt. 1900, pp. 95–97, figs. 6*).—The requisites of an ideal stall are given and a stall, believed to combine these requisites, which has proven very satisfactory at the station, is described.

The relation between the specific gravity, the fat, and the solids-not-fat of milk, C. GROHMANN (*Mitt. Landw. Inst. Univ. Leipzig, 1901, No. 2, pp. 55–89*).—An extended review is given of the work of Fleischmann, Veith, and others upon the composition of milk, and especially upon the determination of the amount of ash, protein, and sugar from the specific gravity and fat content. In 87 analyses of milk from various sources, the author found the difference between the calculated and the analytical results to range from −0.890 to 0.708 per cent dry matter. Not only were the differences in the percentages of ash, protein, and sugar variable, but attention is called to the fact that the specific weight of the fat varies, as the Reichert-Meissl, saponification and iodin numbers show. To determine whether a relation between the fat content of the milk and the amount of solids-not-fat may be established, the author divides his results into 3 groups. In the first group he places the milks containing less than 3 per cent of fat; in the second group those containing from 3 to 4 per cent; and in the third group those containing above 4 per cent. From an average of the 3 groups it was found that an increase in the percentage of fat shows a percentage increase in the solids-not-fat. This is brought out in the following table in which the fat and solids-not-fat of group 1 are taken as 100:

Relation of fat to solids-not-fat in milk.

Group.	Fat.	Fat-free substance.
1	100.0	100.0
2	125.7	102.5
3	171.3	103.4

The volatile products of milk, H. and G. WAUTHY (*Jour. Agricole* [*Paris*], *12* (*1901*), *No. 132, p. 48*).—Milk was distilled to dryness, the successive portions collected and examined.

Milk, A. L. WINTON and C. LANGLEY (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 122–133, pl. 1*).—Analyses of 246 samples of milk purchased from milkmen in the cities and larger villages of the State are reported. Methods of analysis are given. Eleven samples showed less than 3 per cent of fat, 54 less than 12 per cent of solids, and 17 less than 3 per cent of fat and 12 per cent of solids. Seven contained boric acid or borax and 14 formaldehyde.

Milk and cream sampled and sent by individuals, A. L. WINTON, A. W. OGDEN and C. LANGLEY (*Connecticut State Sta. Rpt. 1900, pt. 2, pp. 134–136*).—Details are reported of the examination of a number of samples of milk, cream, ice cream, and separator skim milk. None of the samples of ice cream contained added preservatives, although some of the samples of cream did.

The sanitary production of milk, A. M. SOULE (*Univ. Tennessee Record, 4* (*1901*), *No. 1, pp. 37–44, figs. 3*).—A general discussion of this subject.

Aeration of milk, J. D. DAVIDSON (*Jour. Agr. and Ind. South Australia, 4* (*1901*), *No. 7, pp. 558–560*).—It was found by experiment that the aeration of milk no only extended the time during which it remained sweet, but eliminated the anima odor and the dandelion flavor which remained in the control.

Preservation of samples of milk, P. LEENHOUTS (*Orgaan Ver. Oudleer. Rijks. Landbouwschool, 12* (*1900*), *No. 148, pp. 195–197*).—The difficulty in preserving composite samples of milk at creameries led to a study of milk preservatives, and especially of formaldehyde. The commercial 40 per cent formalin was used, and the experiments were to determine (1) whether the fat content is changed by the addition of formaldehyde, and (2) what influence the different amounts of formaldehyde exert on the duration of the preservation; also the minimum amount needed to preserve milk for a given time.

Seven flasks of milk were prepared, the fat content and souring point being determined for each lot. Then to each liter of milk was added an amount of formaldehyde varying from 1 to 6 cc. One flask was not treated and served as a check. The fat content was determined by means of Gerber's acid butyrometer and the souring point was expressed in degrees Soxhlet. The milk was tested every other day for 3½ weeks. The results are given in a table. The author concludes that formaldehyde is one of the best preservatives for milk. Throughout the experiment the fat content remained unchanged, and only when finally the milk became thick and sour did the results become untrustworthy. The tests were carried on at a temperature of 16 to 20° C., which is the temperature at which samples are usually kept in a laboratory. When samples are kept in a cool place at about 12° C., 1 cc. of formaldehyde will suffice to preserve 1 liter of milk for 30 days. Larger amounts than 3 cc. per liter are not advised.—H. M. PIETERS.

Formaldehyde as a milk preservative, A. G. YOUNG (*Med. Age, 18–19* (*1900*), *pp. 723–737*).

Milk testing at factories, G. S. Thomson (*Jour. Agr. and Ind. South Australia, 4* (*1901*), *No. 7, pp. 560–563*).—In an experiment of covering milk cans with cloth kept moistened, it was found that the milk arrived at the factory several degrees cooler and with a lower acid content by several points.

A source of error in some turbine testers, F. W. Woll (*Wisconsin Sta. Rpt. 1900, pp. 76–81*).—This has been abstracted from another source (E. S. R., 11, p. 1083).

Influence of temperature on tests of skim milk by the Babcock test, E. H. Farrington (*Wisconsin Sta. Rpt. 1900, pp. 81–86*).—The fat content of skim milk was determined by gravimetric analysis and by steam turbine testers at 140 and 200° F. in 10 comparative tests. The average results by the 3 methods were, respectively, 0.08, 0.06, and 0.03 per cent. "In every case the tests were higher when made in the tightly-closed tester and heated to about 200° F. than they were when tested in the machine having an opening in the cover and whirled at about 140° F. In some cases twice as much fat was shown in the hot test bottles as in the others. . . . Tests of skim milk made with 20 cc. of acid and whirled at a high speed in a machine heated to about 200° F. give results nearer those obtained by gravimetric analysis than are obtained by any other method."

The estimation of fat in sweetened condensed milk by the Babcock test, E. H. Farrington (*Wisconsin Sta. Rpt. 1900, pp. 86–89*).—This has been abstracted from another source (E. S. R., 12, p. 307).

Testing for pasteurized milk, A. Bernstein (*Ztschr. Fleisch u. Milchhyg., 11* (*1900*), *No. 3, pp. 80, 81*).—The following method is given for estimating the degree to which milk has been heated: To 50 cc. of the milk 4.5 cc. of a normal solution of acetic acid is added, slightly shaken until the milk has coagulated, filtered, and the clear filtrate heated. If the original milk has not been pasteurized, a heavy precipitate of albumin will form. The higher the milk has been heated, up to 90° C., the smaller will be the precipitate. Above that no precipitate will occur.

Thermal death point of tubercle bacilli under commercial conditions, H. L. Russell and E. G. Hastings (*Wisconsin Sta. Rpt. 1900, pp. 147–170*).—Standards recommended for the pasteurization of milk for the destruction of tubercle bacilli are given and discussed, and investigations conducted for the purpose of retesting some of the more recent work (E. S. R., 12, p. 1091) under commercial conditions are reported.

In 5 series of experiments milk was inoculated with pure cultures of the tubercle bacillus and heated at 60° C. in a commercial rotary pasteurizer. The time of heating in the different tests varied from 5 to 45 minutes. Control samples were unheated. The vitality of the bacilli was tested by intraperitoneal injections into guinea pigs. The results of the tests, including post-mortem notes, are given in detail. "The conclusions from these series indicate that a temperature of 10 minutes at 60° C. (140° F.) is sufficient to destroy the vitality of the tubercle organism so completely that large doses inoculated in the most susceptible portion of a very susceptible animal (guinea pig) fail to produce any development of the disease, while unheated samples of milk and those exposed to 60° C. (140° F.) for 5 minutes produced the disease without exception."

In 2 series of experiments a comparison was made of heating milk at 60° C. in the commercial pasteurizer and in open bottles placed in a water bath. In the latter case the milk remained in a quiescent condition and was exposed to the action of the air which permitted a film to form on the surface. "Where the milk was exposed in a quiescent condition, as in a glass tube or bottle, the tubercle bacilli were more resistant than where the milk was in a closed receiver and agitated. While all tubercular organisms were destroyed in the commercial pasteurizer in 10 minutes, neither an exposure for this period nor for 15 minutes sufficed to destroy the same lot of organisms when the milk was treated in a quiescent condition at the same temperature in vessels to which the air had more access. . . .

"It is recommended in order to thoroughly pasteurize milk so as to destroy any tubercle bacilli which it may contain, without in any way injuring its creaming properties or consistency, to heat the same in closed pasteurizers for a period of not less than 20 minutes at 140° F. (60° C.)."

Influence of heredity upon the percentage of butter fat in milk, W. Kirchner (*Mitt. Landw. Inst. Univ. Leipzig, 1901, No. 2, pp. 129–139*).—Observations were made during 10 years on the influence of heredity in crossing dairy cattle. From the comparison of the percentage of fat in the milk of the cows in the 2 families crossed, the conclusion is reached that the fat content is influenced by heredity.

The variation of volatile fatty acids in butter fat, P. Vieth (*Milch Ztg., 30 (1901), No. 12, pp. 177–179*).—In a series of determinations covering 2 years it was found that the Reichert-Meissl number ranged from 22.4 to 31.3. The volatile fatty acid content was highest during the spring months and lowest during the autumn months.

Moisture in butter, E. H. Farrington (*Chicago Dairy Produce, 7 (1901), No. 85, p. 18*).—A paper read before the National Butter Makers' Association at St. Paul, 1901. The results reported by various experiment station workers are given. The effect of salting has been found to reduce the moisture content. Working reduces the water content of butter, and the higher the temperature at which it is worked the greater the loss. The influence of the size of the granules upon the water content has been found to be variable. The Ontario Agricultural College reports the greater loss of moisture with butter churned to large granules. The Wisconsin Station found a greater loss with small granules.

New Zealand butter-making experiments (*Station, Farm and Dairy, 3 (1901), No. 39, p. 773*).—A report of a series of experiments carried out by the New Zealand dairy commissioner. It was found that ripened cream produced a better keeping butter than the sweet or unripened cream; that the pasteurized cream butter scored decisively over the nonpasteurized, and that the butter made from cream properly ripened with a starter had a superior flavor and kept better than that from self-ripened cream.

The "Columbia Air Churn," E. H. Farrington and F. Dewhirst (*Wisconsin Sta. Rpt. 1900, pp. 93–97*).—A description of this patent churn is given and some of the advantages claimed for it by the manufacturers are quoted. Twenty-one tests in which comparisons were made of the air churn and a barrel churn under uniform conditions are reported in tabular form. The yield of butter from 121.39 lbs. of fat in the cream was 130.19 lbs. by the air churn and 135.13 lbs. by the barrel churn, making the overrun in the two cases respectively 7.25 and 11.31 per cent. The average fat content of the buttermilk from the air churn was 0.77 per cent and from the barrel churn 0.26 per cent. The average time required for churning was 1.3 minutes less in case of the air churn. A comparison of the 2 churns as regards ease of running, economy in cost, lasting qualities, etc., was unfavorable to the air churn.

Calculating dividends for milk and for cream at the same factory, E. H. Farrington (*Wisconsin Sta. Rpt. 1900, pp. 90–92*).—This subject is briefly discussed and an illustration of the calculation of dividends is given. The fat returned to the milk patron in the skim milk is taken at 3 per cent of the fat in the whole milk. The amount of fat received from the cream patron is therefore increased by 3 per cent, and compared with the amount of fat in the whole milk received from the milk patron in calculating dividends.

Creameries and cheese factories of western Oregon, F. L. Kent (*Oregon Sta. Bul. 65, pp. 25–60, pls. 3*).—Information on this subject was collected by the author in a tour of inspection made during July and August, 1899. The bulletin contains a list of the creameries and cheese factories visited, with data as to form of organization, value of plant, number of patrons, etc., of each; estimates of the butter and cheese production in the State in 1899; an account of the more common methods of operating creameries and cheese factories; the constitution and by-laws of several of the dairy associations; a discussion of the location and cost of building and equipping creameries and cheese factories; notes on keeping accounts at factories; directions for operating the Babcock test; and miscellaneous notes on the feeding and production of cows in the State, the separators and churns in general use at factories, Babcock testers and the cleansing of test bottles, water supply and fuel of factories, and packing and marketing butter. The production of creamery butter and cheese in the State in 1899 is estimated at about 2,500,000 and 1,500,000 lbs., respectively.

Notes on some dairy troubles, H. A. Harding, L. A. Rogers, and G. A. Smith (*New York State Sta. Bul. 183, pp. 173–193*).—Flavor in milk and its products is briefly discussed, and investigations of a fishy flavor in milk, a bitter flavor in Neufchatel cheese, a sweet flavor in Cheddar cheese, and rusty spot in Cheddar cheese are reported and summarized as follows:

"Appearance of a highly-disagreeable, fishy flavor in the product of a dairy was traced to the milk of a single apparently healthy cow. On rejecting the product of this animal no further trouble was experienced. No cause for the outbreak could be found.

"An intensely bitter flavor in Neufchatel cheese was found to be connected with the activity of an acid-forming bacillus. The bitter flavor was not reproduced in liquid cultures but appeared upon draining and aerating the cheese curd.

"The causal relation of certain yeasts to the production of undesirable flavors common in Cheddar cheese appeared probable from their constant presence in cheese showing sweet flavor and their absence in all that having a clean flavor. The uniform reproduction of off-flavors, when using pure starters of these yeasts in cheese making tends still further to establish this relation.

"Rusty spot in Cheddar cheese is caused by a bacterial growth. The addition of cultures of this bacillus to the vat before adding the rennet failed to reproduce the discoloration; but adding cultures of the same organism after cutting the curd gave a very marked case of rusty spot."

Dairy disagreeables busy the bacteriologists, F. H. Hall, H. A. Harding, L. A. Rogers, and G. A. Smith (*New York State Sta. Bul. 183, popular ed., pp. 9*).—This is a popular summary of the above bulletin.

The cause of the ripening of cheese, E. von Freudenreich (*Ann. Agr. Suisse, 2 (1901), No. 1, pp. 1–5*).—In the present study it was sought to make cheese under normal conditions, but without containing certain bacteria. For this reason milk was drawn under the best aseptic conditions possible. Six lots of milk were obtained with from 62 to 316 bacteria per cubic centimeter. These lots were made into 6 cheeses. In Nos. 1 and 2, used as checks, the milk from which they were made did not contain any lactic-acid bacteria and was coagulated with artificial rennet to avoid the addition of bacteria. Two other portions (Nos. 3 and 4) were coagulated with a natural rennet that contained almost pure cultures of these lactic-acid ferments, which, according to the author, are necessary in the ripening of cheese. The fifth lot was coagulated with artificial rennet and in addition 3 kinds of lactic-acid bacteria, *Bacterium lactis acidi* and 2 others denominated α and ε, were incorporated. The sixth lot was made up as No. 5, except that only 1 kind of lactic-acid forming bacteria, ε, was added. After 10 weeks, bacteriological and chemical examinations of the cheeses were made, the chemical examination consisting in the determination of the nitrogen soluble in water, and the nitrogen of the products of decomposition, in percentages of the total nitrogen.

The following shows the chemical analyses:

Analyses of cheese ripened in different ways.

Cheese No.	Nitrogen soluble in water.	Nitrogen of the products of decomposition.	Nitrogen of decomposition in total soluble nitrogen.
	Per cent.	*Per cent.*	*Per cent.*
1 (artificial rennet)	9.31	0.75	8
2 (artificial rennet)	16.38	1.70	10
3 (natural rennet)	9.77	3.00	30
4 (natural rennet)	12.88	3.52	27
5 (artificial rennet, with 3 lactic-acid bacteria)	13.89	2.55	18
6 (artificial rennet, with 1 lactic-acid bacteria)	12.20	1.30	10

In the checks in which lactic-acid bacteria were absent, there was no evidence of ripening in the taste of the cheese. The differences in the amounts of soluble nitrogen in these cheeses appeared to depend upon the number of bacteria present which were able to decompose the casein but which did not have any favorable influence upon the ripening. The larger decomposition of No. 2 did not show an improvement in quality over No. 1. In Nos. 3 and 4, while the ripening had not progressed very far, yet the results were favorable for the production of a good cheese. The differences between No. 5 and No. 6 showed that the absence of 2 of the lactic-acid bacteria in the last lot had an unfavorable influence upon the ripening. The differences between the cheeses in the experiments are more strongly brought out in the column in the table giving the percentage of nitrogen of decomposition in the total soluble nitrogen.

The rôle of lactic acid bacteria in the ripening of cheese, R. Chodat and N. O. Hofman-Bang (*Ann. Inst. Pasteur, 15 (1901), No. 1, pp. 36–48*).—The authors made a number of culture experiments with different species of lactic-acid bacteria and the tyrothrix form of Duclaux. Casein was used as a culture medium and was prepared as follows: Fresh milk was creamed in a separator, pasteurized, coagulated, the whey removed, and the curd washed and dried. When used, the curd was treated with a small amount of water and sterilized. The small portions of the culture medium were inoculated with the various forms of bacteria tested, and the soluble and insoluble nitrogen formed are shown in tables. From the results obtained the authors conclude that the lactic-acid bacteria do not have the importance in ripening cheese that Freudenreich ascribes to them. The tyrothrix forms appeared to have the power of dissolving the casein of the culture medium while the lactic-acid bacteria did not.

The influence of the temperature of curing upon the commercial quality of cheese, G. A. Smith (*New York State Sta. Bul. 184, pp. 193–203*).—Introductory notes are given on the cheese industry in New York, and experiments reported in curing cheese at temperatures common under ordinary factory conditions and at lower temperatures. The method of making the cheese was uniform in all the experiments and is described in detail. In 1899 cheese was cured at 55, 60, 65, and 70° F., and in 1900 also at 75 and 80°. Scorings are tabulated.

"Of the cheeses made in 1899 those cured at 60° F. and below scored, on the average, almost 5 points higher on flavor and 2.5 points higher on texture, than those cured at 65° F. and above. In 1900, the average difference in favor of the lower temperatures was 5.1 points on flavor and 2.7 points on texture." The improvement of curing rooms, by making them tighter and providing some means of cooling them, as a cold-air duct, is strongly urged.

Cold-cured cheese, F. H. Hall and G. A. Smith (*New York State Sta. Bul. 184, popular ed., pp. 4*).—This is a brief review of the above bulletin.

The changes of the fat in the ripening of cheese, K. WINDISCH (*Arb. K. Gesundheitsamte, 17 (1901), pp. 1–160; abs. in Chem. Centbl., 72 (1901), I, No. 2, pp. 128–130*).—The changes in the fat in the ripening of cheese are apparent from the variations in the quality and the amount of the fat. The changes in the quality are chemical and are especially noted in the formation of soluble fatty acids. The breaking up of the glycerids with the formation of soluble fatty acids begins shortly after the manufacture of the cheese, the volatile acids being in part at least eliminated. With the changes of fatty acids, there is a gradual reduction of the Reichert-Meissl and the refractometer numbers, and in a lesser amount the saponification number. The source of the free fatty acid is in the breaking up of the fat, and it is not formed from the milk sugar or albumin. From a study of the causes of the breaking up of the fat, the author believes that bacteria play the principal rôle, the work being especially aided by certain enzym-producing species.

Influence of rennet on cheese ripening, S. M. BABCOCK, H. L. RUSSELL, and A. VIVIAN (*Wisconsin Sta. Rpt. 1900, pp. 102–122, figs. 5*).—The views of various authors on the action of rennet in cheese making are given and investigations to determine the effect of different quantities of rennet in cheese ripening are reported.

Two, four, eight, and sixteen ounces of rennet extract, respectively, were added to 1,000 lbs. of milk, and the percentage of soluble nitrogen in the cheese made in each case was determined at different intervals. An increase in the quantity of rennet extract used was accompanied in each case by an increase in the percentage of soluble nitrogenous products. The average water content of cheese made from 1,000 lbs. of milk to which 3 oz. of rennet extract had been added was 35.23 per cent, and from the same quantity of milk to which 9 oz. of rennet extract had been added was 34.37 per cent. The hypothesis advanced that an increase in the amount of rennet tends to increase the moisture of cheese and so hasten the ripening process is therefore considered untenable. To determine if other ferments than rennin in the rennet extract was the cause of increased digestion where large quantities of the extract were used, an attempt was made to inhibit the action of rennin by heat. Rennet extract heated to 152° F. for 5 minutes was compared with the unheated extract. As heating decreased the proteolytic action as well as the curdling power of the rennet extract, the results of this experiment did not permit of a definite conclusion.

Studies were made of the soluble decomposition products in cheese made with varying quantities of rennet. Four series of experiments are reported in detail. Determinations of the albumoses, peptones precipitated by tannin and by phosphotungstic acid, amids, and ammonia in cheese made with varying quantities of rennet at different stages of ripening are given. The effect of adding varying quantities of pepsin to the rennet extract was also studied, as well as the influence of acidity of curd on rate of peptic digestion. Several different brands of commercial pepsin were compared. The results of the investigations are summarized as follows:

"The increase in soluble nitrogenous products in cheese and also in milk due to an increase in amount of rennet extract used are also confined to those by-products that are peculiar to pepsin, thus indicating that the digestive action of rennet extract is attributable to the action of the pepsin incorporated with the rennet extract. The crucial test of this conclusion was made by adding purified pepsin to milk and making the same into cheese, where rennet extract was or was not added to curdle the milk. In such cheese digestion has been increased in those cases to which pepsin has been added, and this increase has been confined to those by-products that are characteristic of pepsin, and which also appear in cheese made with high quantities of rennet.

"The digestion in cheese incident to pepsin is determined mainly by the degree of acidity developed in the milk and curd. In Cheddar cheese, peptic digestion probably does not begin until the acidity of the milk is approximately 0.3 per cent lactic acid. Acid salts as phosphates, etc., favor peptic digestion in milk in a manner comparable to free acids. Free acid does not normally exist in Cheddar cheese, the apparent acidity being due to acid salts.

"Summarizing these conclusions, rennet exerts a digestive effect on the casein of cheese, due to the presence of peptic enzyms contained in rennet extracts, the action of which is intensified by development of acid in the curd. The soluble nitrogenous products formed in Cheddar cheese by rennet are the albumoses and the higher peptones that are precipitated by tannin."

A study of the action of rennet, J. J. O. de Vries and F. W. J. Boekhout (*Landw. Vers. Stat., 55 (1901), No. 3, pp. 221–239*).—The work of several authors on the influence of the organic and mineral substances of milk upon the action of rennet is reviewed. The work of Söldner upon the favorable influence of soluble lime salts on the coagulation of milk is treated at length. The effect on the action of rennet of heating, diluting, and the addition of soda solution, carbonic acid, and of calcium chlorid to the milk, are shown. From the results of the several tests the conclusion is drawn that Söldner's theory of the great influence of the soluble lime salts upon the action of rennet is not well founded, and that they do not have the importance that he ascribes to them. The solubility of lime is variable, depending upon its combination and the acidity of the milk, and does not indicate the most favorable condition for rapid coagulation. Removing carbonic acid previously added to milk will not affect the soluble lime content, but will greatly reduce the coagulating power of the rennet. It would appear, therefore, that the acidity, as well as the soluble lime content of the milk, affects the action of the rennet.

A description of the new cheese-curing rooms and the foreign cheese-making rooms, E. H. Farrington (*Wisconsin Sta. Rpt. 1900, pp. 309–313, figs. 2*).—An addition to the dairy building provides rooms for instruction in the manufacture of Swiss, brick, and Limburger cheese, and rooms for pressing and curing Cheddar cheese. The main floor of the new building, which is below the surface of the ground, is 47 by 57 ft. The ground plan and the side elevation of the building are given, and the subearth duct, method of heating, and method of roofing the cellar are described.

Officials, associations, and educational institutions connected with the dairy interests of the United States for the year 1901 (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 33, pp. 8*).—A list of each.

VETERINARY SCIENCE AND PRACTICE.

Proceedings of the American Veterinary Medical Association for 1900 (*St. Paul: Veterinary Press Co., pp. 296, pl. 1*).—The thirty-seventh meeting of the Association was held in Detroit, Mich., September 4 to 7, 1900. Some of the papers presented are briefly noted below.

Labor, rest, and confinement, *W. L. Williams* (pp. 82–92).—The author attempts to define these terms as applied to domesticated animals.

The relation of veterinary medicine to the public health, *W. H. Lowe* (pp. 92–96).—In this article the author gives a brief statement of the services which the veterinarian may render in preventing the transmission of animal diseases to man.

Sarcoptic scabies of the horse and psoroptic scabies of cattle in Montana, *M. E. Knowles* (pp. 97–104, pl. 1).—In the northern part of Montana sarcoptic scabies of the horse has prevailed to some extent since 1885. It is believed that the disease was introduced by Indian horses, perhaps during the raid of the Nez Percé Indians in 1877. During the past 3 years, about 12,000 horses have been treated for this disease, and it is now practically stamped out. Each affected horse was roped and hand treated. A brief account is given of the symptoms of the disease and of the behavior of affected horses.

The psoroptic scabies of cattle is reported as prevailing to considerable extent in Teton County, Montana. The cattle men of the State describe a similar disease which affected the buffalo, and believe that the disease was transmitted from buffaloes to domestic cattle. The disease makes its first appearance in cattle at the root of the tail or on the neck and withers, and slowly extends along the shoulders and sides of the chest. In long standing cases it comes finally to cover the entire body and head, except the part of the legs below the knees. The author estimates that of the cattle on the ranges north of the Missouri River, between the Rocky Mountains and the Dakota line, 20 per cent are affected with this disease. At first paraffine oil, to which about 3 per cent of sulphur was added, was used for hand treatment of the disease. Later extensive dipping vats were constructed, and a lime-and-sulphur dip has been employed cheaply and successfully.

The rapid diagnosis of rabies, N. P. Ravenel and D. J. McCarthy (pp. 109–111).—In all positive cases of rabies in dogs and rabbits the authors found certain constant changes in the intervertebral ganglia. The most pronounced changes were noted in the ganglia of rabbits in which the disease had been produced from subdural inoculations with material from dogs.

The relation of the lymphatics to meat inspection, T. Butler (pp. 112–123).—The author calls attention to the frequency with which the various lymphatic glands are affected in cases of infectious diseases. Detailed notes are given of changes produced in these glands by the pathogenic organisms of various diseases.

Rabies and hydrophobia, D. E. Salmon (pp. 124–144).—A controversial article concerning the nature and prevention of this disease.

Antiseptic therapeutics, J. F. Winchester (pp. 153–159).—In this article the author discusses the possibility of checking or preventing the growth of pathogenic bacteria within the animal organism by an excess of alkalies or acids and by the use of such antiseptics as potassium permanganate, benzol, and petroleum.

Obstacles to enforcing regulations requiring the tuberculin test in interstate cattle traffic, A. Peters (pp. 202–214).—The author states that the greatest obstacle to the enforcement of laws or regulations requiring a tuberculin test is dishonesty among certain cattle dealers who object to the test because it interferes with their profit, and among certain veterinarians who advance certificates without reliable tests.

Experimental tuberculosis, human and bovine, in the domestic animals, R. R. Dinwiddie (pp. 215–228).—Three pigs were inoculated with sputum cultures and another pig of the same size with bovine culture. All of these pigs soon exhibited signs of disease. The pig which received the bovine culture showed the more extensive tubercular disease. Another comparative test of sputum and bovine cultures on pigs clearly indicated the greater virulence of the bacilli of bovine origin for pigs. Comparative experiments on sheep gave similar results.

The following articles were also read during the meetings of this society: A possible cause of azoturia, A. W. Balch; The pathology of azoturia, W. A. Brinckerhoff; Practical antiseptics in surgery, G. A. Johnson; Veterinary progress in Michigan, W. Jopling; Spavin, its etiology and treatment, W. J. Martin; Snakes, snake venoms, and antivenines, E. M. Ranck; Urinary analysis in veterinary practice, P. A. Fish; Live-stock vaccines and serum therapy, W. Rushworth; Gruber's reaction in hog cholera, R. R. Dinwiddie (E. S. R., 12, p. 788); The work of the veterinary section of the experiment stations, J. J. Repp (E. S. R., 12, p. 601).

Report of cattle commissioners, I. A. WATSON and N. G. BACHELDER (*New Hampshire State Bd. Agr. Rpt. 1899–1900, pp. 353–382*).—A copy is given of the regulations of the State Board of Cattle Commissioners regarding the care and disposition of diseased animals, and regarding quarantine and inspection service. Brief notes are given on the use of tuberculin and mallein in the control of tuberculosis and glanders. It is concluded that enforcement of proper sanitary measures for preventing the development of bovine tuberculosis is as important as the destruction of diseased animals. Thorough disinfection has been insisted upon in all stables where outbreaks of the disease were found.

Phagocytosis during fatal infections, T. TCHISTOVITCH (*Ann. Inst. Pasteur, 14 (1900), No. 12, pp. 802–812*).—Rabbits were inoculated with fatal doses of streptococcus and killed for examination after $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, 2, 4, and 6 hours. These experiments showed that immediately after intravenous injection of streptococcus these organisms are found in considerable numbers in the lungs, free at first and later surrounded by polynuclear leucocytes. The leucocytes are numerous and invade the capillaries. Phagocytosis in the lungs is by no means complete, and free streptococci were found in all of the rabbits. The process of phagocytosis was more complete in the lungs than in the liver.

The bot fly (Gastrophilus equi), W. W. FROGGATT (*Agr. Gaz. New South Wales, 11 (1900), No. 11, pp. 947–951, pl. 1*).—The author gives a brief account of the life history and habits of the more common species of this family which infest the horse, ox, sheep, and camel. An experiment was conducted by T. Steel in treating mules for bot flies. After a preliminary feeding with bran mash, $1\frac{1}{2}$ drams of carbon bisulphid were given in a pint of water, and the dose was repeated 3 hours later. In the evening of the same day $\frac{1}{2}$ pt. of linseed oil was administered. The treatment had no apparent effect on the bot flies, although a large number of parasitic worms were expelled, but it was not certain that the bot flies had not left the mule when the treatment was administered. The species of bot fly which is common in Victoria is said to be *G. salutaris*.

A new process in the culture of tetanus bacillus, L. DEBRAND (*Ann. Inst. Pasteur, 14 (1900), No. 11, pp. 757–768*).—The tetanus bacillus when cultivated alone is anaerobic, and the experimenter has always the extra trouble of producing a vacuum in order to secure abundant supplies of pure cultures. In experiments conducted by the author it was found that when the tetanus bacillus was grown together with *Bacillus subtilis*, it vegetated rapidly in the presence of oxygen, and a toxin was obtained from such cultures which possessed the same properties as the toxin from the tetanus bacillus grown alone under anaerobic conditions. This gives an easy and convenient method for obtaining pure cultures of the tetanus bacillus. It was also found that other bacteria beside *B. subtilis* had the same effect on the tetanus bacillus. Among these, mention may be made of *B. mesentericus* and *B. anthracis*. When grown with the anthrax bacillus, however, the tetanus bacillus produces a very weak toxin.

On the ringworm infection in man and animals, J. L. BUNCH (*British Med. Jour., 1901, No. 2093, Epit., pp. 323–326, pls. 2, figs. 4*).—The author discusses a number of cases of ringworm which were communicated from horses and cats to man. The nature of the fungus parasite which was isolated is described in detail, together with remarks on its behavior in different culture media.

Agglutination of bacillus of Koch by tuberculous discharges, P. COURMONT (*Arch. Med. Exper. et Anat. Path., Paris, 1. ser., 12 (1900), No. 6, pp. 697–732*).—The author's experiments included series of tests with serous fluids and blood serum from man and experimental animals. When animals were inoculated with the virulent form of tuberculosis the serum reaction was almost always negative, although death followed later in every case. On the other hand, when the animals were inoculated with a less virulent form of tuberculosis the serum reaction was always positive, in the proportion of 1 to 20 in the case of the guinea pig and 1 to 600 in the case of the dog. Experiments with various serous discharges which were not tuberculous gave reactions which were always negative.

The general results obtained may be stated as follows: Nontuberculous, serous fluids do not agglutinate the tubercle bacillus under ordinary conditions in the proportion of 1 to 5. The majority of tuberculous, serous fluids show an agglutinating power in proportions of from 1 to 5 and 1 to 20. A certain proportion, however, of tuberculous, serous fluids do not give a positve reaction, even in the proportion of 1 to 5. As a rule, however, this failure of the reaction occurs in cases of advanced or generalized tuberculosis. The agglutinating power of blood is not always equal to that of the serous fluids upon the same animal. It may be more or less, or may be entirely absent, while that of the other serous fluids is quite pronounced. Under favorable conditions the agglutinating power of the blood serum and of other serums can be progressively increased. The results obtained from the study of serums of human origin and from other animals gave the same results. It is believed, therefore, that a positive reaction in the proportion of 1 to 5 constitutes a reasonably certain diagnosis of tuberculosis.

Bacillus tuberculosis piscium and the tuberculosis of frogs caused by this bacillus, Ledoux-Lebard (*Ann. Inst. Pasteur, 14* (*1900*), *No. 8, pp. 535–554, pl. 1*).—This bacillus develops in the frog under forms more varied than those of the bacillus of Koch in mammals. The cellular reactions vary in different species and to a certain extent in different organs of the same species. Each organ seems to defend itself against the invasion of the bacillus in its own way. In the liver of the frog certain special cells are recognized which differ from ordinary migratory cells and which are pigmented. These cells do not necessarily participate in the formation of tubercles, but under certain conditions they appear to be more numerous and become associated with the tubercles already formed.

Bovine tuberculosis, E. Nocard (*Jour. Agricole* [*Paris*], *12* (*1901*), *No. 130, pp. 5–10*).—The author discusses the liability to contagion from this disease and the various methods which have been proposed for preventing the spread of the disease and for controlling the sale of tuberculous meat and milk.

Outbreaks of anthrax fever traceable to tannery refuse, H. L. Russell (*Wisconsin Sta. Rpt. 1900, pp. 171–184*).—During the season of 1899 an outbreak of anthrax occurred on the Black River below Medford, Wis. Bacteriological examination of blood obtained from a horse which had died of the disease showed that the organism had all the characteristics of the anthrax bacillus. The disease prevailed for a distance of about 10 miles along the river below a tannery, and the distribution of the cases of anthrax in the affected area indicated the river water as being the carrier of the virus. The wastes of the tannery are discharged into a canal, which in turn empties into the river. The hides received by the tannery came partly from South America and partly from China. The evidence obtained pointed conclusively to these hides as the original source of infection.

Experiments were made by E. G. Hastings in testing the value of formaldehyde in destroying the anthrax bacillus. Pieces of dried hide were infected with anthrax spores and then placed in solutions of formaldehyde varying in strength from 1: 500 to 1: 10,000. The series of experiments was continued for 11 days, and at the end of this period anthrax spores capable of development were still found on the hides which had been immersed in solutions containing from 1: 10,000 to 1: 2,500 parts of formaldehyde. The formaldehyde gradually combined with the materials composing the hide, and after from 8 to 12 days its presence could not be detected in solutions of the strengths just mentioned. The formaldehyde exerted a somewhat injurious effect upon the hides, and subsequent tests showed that the hair did not "sweat off" as readily after being treated with formaldehyde as did the hide which had not been so treated. As a practical disinfection of the hides seems to be impossible, it is recommended that the waste from tanneries be disinfected, and that stock raisers should vaccinate stock on areas which are likely to become infected.

The behavior of anthrax bacillus in the body cavity of guinea pigs, J. B. Van Leent (*Centbl. Bakt. u. Par., 1. Abt., 28* (*1900*), *No. 21, pp. 737–742*).—The author's experiments were conducted on guinea pigs which weighed about 500 gm. and with anthrax bacilli from 24 to 48 hours old, which had been grown on bouillon at a temperature of 28° C. The following conclusions are drawn from the experiments: Anthrax bacilli, even when present in large quantities in the body cavity of guinea pigs, are frequently destroyed. The animal does not acquire immunity, however, during this process. In some cases, when the experimental animal succumbed to hypodermic inoculations of the anthrax bacillus, the peritoneum killed all the bacilli which were in the body cavity. If the anthrax bacillus is absorbed from the body cavity, it is fatal to the experimental animal, but the resorption of the serous fluid of the body cavity may be beneficial to the animal. The germicide action of the peritoneum is influenced to considerable extent by the presence of foreign bodies or a large quantity of fluid in the body cavity. Wandering cells seemed not to exercise any great influence on the anthrax bacillus, and no pronounced phagocytosis was observed.

Anthrax among city horses, J. McFadyean (*Jour. Comp. Path. and Ther., 13 (1900), No. 4, pp. 344–345*).—The author gives brief notes on 2 cases of anthrax in horses. The source of infection was not definitely ascertained, but it was found that the 2 animals had eaten oats from the same source, and the disease might possibly have been carried in this way.

Report on the work of the bacteriological station of the Kharkov Veterinary Institute in 1899, A. Rayevski (*Selsk. Khoz. i Lyesov., 197 (1900), June, pp. 543–552*).—During the year 1899, 238 liters of the first and 122 of the second anthrax vaccine were prepared and used in the inoculation of sheep, horses, and cattle in various parts of European Russia. The mortality from vaccination was 0.38 per cent in sheep, 0.04 per cent in cattle, and 0.29 per cent in horses.

The decomposition of peroxid of hydrogen by animal tissues and by bacterial organisms, B. Danilewsky (*Physiologiste Russe, 2 (1900), No. 21–25, pp. 12–15*).—In testing the effect of bacteria upon peroxid of hydrogen, the author made use of pure cultures of the anthrax bacillus on agar-agar. These cultures contained spores. It was found that the anthrax bacillus at ordinary temperatures decomposes peroxid of hydrogen, but loses this power to considerable degree after having been heated for from ½ to 1 hour at a temperature of 55 to 60° C. The anthrax bacillus was found to be very sensitive to alcohol, which weakened its power of decomposing peroxid of hydrogen. A number of experiments were made in determining the effect of ether, chloroform, corrosive sublimate, formaldehyde, and carbolic acid upon the anthrax bacillus.

Spore formation of the anthrax bacillus under anaerobic conditions, A. Klett (*Ztschr. Hyg. u. Infectionskrank., 35 (1900), No. 3, pp. 420–438*).—The results of the author's experiments may be summarized as follows: Spore formation in the anthrax bacillus is not dependent upon the presence of oxygen. Anthrax bacilli were found to form spores abundantly in an atmosphere of nitrogen. Spores were not formed in an atmosphere of hydrogen on account of the injurious effect of hydrogen upon the bacillus. The author believes that the term "anaerobiosis" should be more definitely characterized by reference to all the conditions which are concerned in any particular case.

A new staining method for demonstrating the so-called capsule of the anthrax bacillus, W. Raebiger (*Ztschr. Fleisch u. Milchhyg., 11 (1900), No. 3, pp. 68–70*).—The author obtained unfavorable results by fixing the bacillus upon the slide by means of the flame, and was most successful in using a 40 per cent aqueous solution of formaldehyde for fixing the bacillus. The bacillus was then stained in formalin stains—formalingentianviolet, formalinfuchsin. It was found that by this method the anthrax bacillus could be readily differentiated from other organisms, since the anthrax bacillus showed a conspicuous capsule. Even in decomposing material where numerous bacteria of other species were present, a single anthrax bacillus was readily detected.

Immunization of the anthrax bacillus against the action of rat serum, J. Danysz (*Ann. Inst. Pasteur, 14 (1900), No. 10, pp. 641–655*).—The author conducted a number of experiments for the purpose of determining the action of rat serum upon the anthrax bacillus. Small quantities of the first and second vaccine and of virulent cultures were inoculated in 20 mixtures of bouillon and rat serum, which were arranged in a series, beginning with 19 drops of bouillon to one drop of rat serum, and ending with the pure serum. The results of these experiments indicated that the action of the diastase contained in the rat serum is more noticeable in distilled than in physiological water, and more so in the latter medium than in bouillon. The first vaccine was more sensitive to the action of diastase than the second vaccine, and the latter more sensitive than the virus. Very small quantities of serum favored the active growth of the bacillus. From these experiments the author concludes that rat serum does not contain a true bacteriolytic diastase, but only a substance analogous to antiseptics, which paralyzes the functions of assimilation and growth of the bacillus, while it favors the secretion and digestive action of a diastase which is secreted by the anthrax bacillus. The bacillus protects itself against the action of rat serum by the formation of a mucilaginous sheath. The immunization of the bacillus against this substance does not render it more resistant to autodigestion, but simply permits it to produce new cultures. Rat serum deprived of its antiseptic constituent is a good culture medium for the anthrax bacillus.

By comparing the results obtained in these experiments with those indicated by experiments with solutions of arsenic, the author concludes that the digestion of the bacillus in rat serum is a phenomenon of similar nature to that of its digestion in suitable solutions of arsenic. The antipathetic substance formed by the bacillus has no direct action upon the diastase, and does not arrest the development of pathogenic symptoms.

Experimental studies on blackleg; immunization by serum, E. LECLAINCHE and H. VALLÉE (*Rev. Vét. Toulouse, 25 (1900), No. 12, pp. 745–756*).—The authors' experiments were arranged in 2 series. In the first series a goat which had been immunized by a virulent intravenous injection, received during a period of 6 months subcutaneous inoculations of muscle tissue from infected guinea pigs. The first inoculations produced rather serious local lesions. Later inoculations, however, caused no reaction. The serum of the goat acquired immunizing properties rather slowly. After 3 inoculations, at intervals of 10 days, with 5, 10, and 15 cc. of filtered material from infected guinea pigs, a serum was obtained which, in doses of from 1 to 5 cc., protected guinea pigs against inoculations of ½ cc. of virulent material. In the second series of experiments pure cultures of *Bacterium chauvæi* were used. Two horses were used in these experiments, having been immunized by intravenous injections of pure cultures. They were subsequently treated by intravenous injections of virulent serous fluid in one case and of pure culture in bouillon in the other.

The authors found that a subcutaneous injection of serum produces an immunization in organisms thus treated which permits them to endure repeated inoculations with the virulent material. Both the horses and the goat were rapidly brought to a condition where they furnished immunizing serum. A fatal dose of virus mixed with a small quantity of immunizing serum becomes neutralized. The simultaneous injection at different parts of the body of virus and serum does not produce any increased resisting power in the guinea pig. It was found that an indifferent serum obtained from horses or cattle would not bring about agglutination, even in the proportion of 1 to 12, while the serum of an immunized horse produced immediate agglutination in the proportions of from 1 to 30 to 1 to 3,000. The authors conclude that serum is endowed with preventive properties and that it confers merely a temporary immunity. Serum and virus when mixed neutralize each other without conferring a permanent immunity. From a practical standpoint the authors believe that serum therapy must be restricted in use, and that vaccination by means of pure virus is the method to be chosen, as being more simple and certain.

Preventive vaccination as a means of combating cattle plague, A. Dudukalov (*Arch. Vet. Nauk, 30 (1900), No. 11, II, pp. 447–452*).—The author discusses briefly the extent of this disease and the losses caused by it, and presents a detailed account of the method for making preventive inoculations.

The study of the organism of cattle plague, G. Garlichkov (*Arch. Vet. Nauk, 30 (1900), No. 11, II, pp. 452–461, figs. 8*).—The author discusses the methods by which these organisms may be obtained, and describes their behavior on different culture media.

Fat formation by different bacteria together with a new stain for actinomyces on sections, A. Sata (*Centbl. Allg. Path. u. Path. Anat., 11 (1900), Nos. 3–4, pp. 97–102*).—The author discusses the literature of this subject in connection with a bibliography of a number of pathogenic organisms. A method for staining actinomyces on sections is described, which depends upon the affinity of a stain known as Sudan III for fatty substances. The method includes fixation in formalin, washing in water, sectioning with the freezing microtome, staining with dilute hæmatoxylin, washing with alcohol, staining in an alcoholic solution of Sudan III for 12 to 24 hours, and embedding in glycerin.

The lesion in actinomycosis with a few new stains for the actinomyces, R. C. Rosenberger (*Jour. Appl. Micros., 3 (1900), No. 11, pp. 1051–1053*).—The author obtained good results from staining this organism with hæmatoxylin and methylene blue. The ray forms of the organism are readily distinguished, their situation being usually within an area of small round cells. A clear zone surrounds the whole mass, and beside the small round cells a number of leucocytes are usually found in the tumor.

Bacteria in milk after recovery from mammitis, J. F. Lameris and H. G. Van Harrevelt (*Ztschr. Fleisch u. Milchhyg., 11 (1900), No. 4, pp. 114, 115*).—An investigation was instituted to determine the cause of serious diarrhœa among the consumers of milk from a certain dairy. It was found that a streptococcus was present in great numbers in one quarter of the udder of the cow which had suffered from mammitis but had recovered. The streptococcus was not pathogenic for rabbits or guinea pigs. It was doubtful whether the organism was the original cause of mammitis. It persisted for several days in the apparently normal milk from the quarter of the udder which had previously been diseased.

Spotted kidney in calves, K. Kavitz (*Monatsh. Prakt. Thierh., 12 (1901), No. 4, pp. 157–192, figs. 8*).—The author made detailed studies of this disease in calves, with the following conclusions: The primary infection may be through the navel from chemical toxic substances or from infections which arise in the alimentary tract.

Diseases of sheep (*Kansas State Bd. Agr. Rpt., 12 (1899–1900), pp. 131–159, figs. 9*).—Brief accounts are given of the desirability of the practice of fall dipping. Bulletin 21 of the Bureau of Animal Industry on sheep scab is reprinted in part, and short notes are presented on ticks, lice, foot rot, stomach worms, lungworms, tapeworms, and the sheep bot fly.

Diseases of sheep, W. A. Rushworth (*The sheep. Buffalo, N. Y.: Buffalo Review Co., (1899), pp. 143–404, figs. 12*).—The greater part of this volume is devoted to a discussion of the diseases of sheep, including those of the brain and nervous system, respiratory and digestive tracts, skin diseases, and specific contagious affections. Recommendations are made with regard to the treatment of the various sheep diseases, and formulas for the approved remedies are given. A general discussion is given as to the subject of Federal and State inspection of sheep.

The micro-organism of sheep pox, F. J. Bosc (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 1, pp. 9, 10*).—The author made an investigation of cases of sheep pox for the purpose of studying the micro-organism which causes this disease. Pustules in the skin and other tissue were fixed in corrosive sublimate and acetic acid, and sectioned. In the skin pustules the micro-organism was found in epithelial cells of the epidermis and also in the sebaceous glands. In the lung the micro-organisms were found in hypertrophied epithelial cells, such as are found in catarrhal pneumonia.

The prevalence of sheep scab, A. W. Bitting (*Indiana Sta. Rpt. 1900, pp. 49–52*).—The author reports in a tabular form the results of inquiries concerning the prevalence of this disease during the years 1899 to 1900. These inquiries indicated that there are about 5,700 cases of sheep scab in the State.

Epidemics of hog cholera and swine plague, A. W. Bitting (*Indiana Sta. Rpt. 1900, pp. 37–48*).—The observations upon which this report is based cover a period of 8 years, from 1893 to 1900, inclusive. A table is given showing the number of hogs and loss from disease in Indiana for a period of years. The author studied the relation of hog diseases to the water supply, with the result that the losses were found to be much greater in the counties which border upon the Wabash and White Rivers than in the counties which were farther removed. During the same time a correspondence with breeders of pure-bred swine indicated that about 90 per cent of them lost no hogs, while their neighbors suffered severely. In most cases they had used well water, while their neighbors had used surface water. During epidemics of swine diseases the decaying carcasses are frequently thrown into rivers and other water supply, and the conditions seem to be favorable for the spread of the disease. Similar investigations, however, from 1898 to 1900, inclusive, showed no appreciable difference in the prevalence of the disease in townships bordering on the river and those which were more remote, the percentage of disease being somewhat higher in the remote townships. These results are apparently contradictory and indicate that the water supply is only one means of disseminating the contagious hog diseases. A study of the relationship between differences in elevation and the prevalence of the diseases showed that such differences had no appreciable effect. Negative results were also obtained from a study of the relation of the amount and distribution of the rainfall to the prevalence of hog cholera. In some seasons the disease was more prevalent in dry areas and in others in those having the greatest rainfall. Only slight difference in the percentage of disease was noted in townships of varying density in the swine population.

Hog cholera is present at all seasons, but is more epidemic during late summer and fall, and gradually subsides during winter and spring. Feeding with corn has not been shown to have an unfavorable effect. The author made a study of the relation of transportation to the spread of the disease. During 8 years not more than a dozen outbreaks of the disease were found which appeared independently of the shipment of stock, and the disease was not found more prevalent along railroad lines than at points more remote. Experiments were made to determine the length of time during which the hog-cholera bacillus may persist in a virulent condition in infected premises. Repeated observations showed that outbreaks of the disease occurred in from 1 to 4 years as a result of rooting out and eating the remains of former victims. Many farmers, however, allow the hogs to run on premises from which diseased hogs have just been removed, and without bad results. The carcasses of dead hogs are often fed to other hogs. In harmony with these practices is the observation that after a severe outbreak of hog cholera the premises usually remain free from the disease for a few years.

A study of the relation of the age of swine to the virulence of the infection indicated that hogs under 5 months suffered more than those which were older. Exhibitions at fairs and public sales are considered more important factors in the dissemination of disease than they are usually thought to be. Government efforts in stamping out the disease in Iowa, Minnesota, and in England have yielded favorable results, but such police measures are expensive.

Diseases of the pig, A. W. Bitting (*Special report of the Indiana State Board of Agriculture on the hog. Indianapolis: W. B. Burford, 1900, pp. 9–65*).—In this part of the report the author discusses swine diseases, including those of the alimentary tract, nervous system, and respiratory passages, those caused by parasitic worms and arthropods, and the more important infectious diseases, among which may be mentioned hog cholera, swine plague, and anthrax.

Combating swine plague and hog cholera, SCHREIBER (*Berlin. Thierärztl. Wchnschr., 1900, No. 51, pp. 61–64*).—The author conducted experiments in immunizing sheep, cattle, and horses against swine plague and hog cholera, in order to obtain from them an active serum for treatment of these diseases in hogs. A serum was obtained which in very small doses protected mice from fatal doses of the swine plague bacillus. Later this method was applied to hogs with encouraging results. The immunity thus produced, however, was only temporary. Inoculations for curative purposes in cases of swine plague were made with Septicidin. A hog which was suffering from swine plague and showed a temperature of 40.8° C. was much improved in its condition on the second day after inoculation, and on the fourth day appeared to be entirely recovered. The author conducted other experiments along this line with similar results.

A study of the constituents of corn smut, W. STUART (*Indiana Sta. Rpt. 1900, pp. 26–32*).—The author made a number of tests for alkaloid salts and total alkaloid content by technical methods which are described in detail, with the 4 reagents potassium-mercuric iodid, phosphotungstic acid, iodin in potassium iodid solution, and picric acid. Positive results were obtained from the first 2 reagents in all cases, and negative from the last 2. Tests were also made of commercial extracts of ergot and corn smut for the purpose of comparing them with extracts made in the laboratory. The results were quite uniform.

Experiments for the purpose of testing the physiological effect of alcoholic extracts of corn smut upon horses were made by Dr. R. A. Craig. In these experiments it was found that a subcutaneous injection of 25 to 30 cc. caused an increased peristaltic movement of the intestines and a slight acceleration of the pulse and breathing. An injection of 45 cc. produced in addition to these symptoms dullness and an unsteady gait. Subcutaneous injections of 15 cc. and doses of 130 cc. by way of the mouth produced little effect. Determinations were also made of the ash and moisture content of the smut spores.

Nerve diseases of horses in the sacral plexus, THOMASSEN (*Monatsh. Prakt. Thierh., 12 (1901), No. 4, pp. 145–156*).—The author gives a brief account of the symptoms and post-mortem findings in cases of diseases of the sacral plexus.

Upon the occurrence of rabies, A. W. BITTING (*Indiana Sta. Rpt. 1900, pp. 53–55*).—A report is given of 3 outbreaks of this disease which occurred within the State. During these outbreaks dogs, sheep, hogs, horses, and cows became infected with the disease.

Antirabies serum therapy, A. RODET and GALAVIELLE (*Compt. Rend. Soc. Biol. Paris, 52 (1900), No. 40, pp. 1091–1093*).—The serum employed in the author's experiments was obtained from a sheep which had been treated with rabies virus. This serum inoculated hypodermically, intravenously, or into the body cavity, during the period of incubation, proved to be without effect, except after the use of rabies virus. When injected into the brain alone, either during the period of incubation or after the appearance of rabies symptoms, it had the effect of prolonging the duration of the disease; but its influence in all cases was very slight. It did not bring about a recovery from the disease or prevent the appearance of violent symptoms. If this serum be introduced into the brain, mixed with virulent material, it exercises a marked influence on the progress of the disease and retards to a great extent the final fatal attack.

Animal parasites, I, E. P. NILES (*Virginia Sta. Bul. 108, pp. 11*).—A brief classification of the parasites of domestic animals according to the natural orders to which they belong.

Animal parasites, II, E. P. NILES (*Virginia Sta. Bul. 109, pp. 13–22, figs. 2*).—Brief popular notes on the Culicidæ with suggestions of remedies against these insects.

Destruction of offal in slaughterhouses, LAURENT (*Rec. Med. Vet., Paris, 8. ser., 7 (1900), No. 23, pp. 890–892*).—A number of disinfectant methods which have been proposed for treating offal from slaughterhouses are discussed by the author. It is contended, however, that no method is so thorough and certain as the complete incineration of all waste materials.

STATISTICS—MISCELLANEOUS.

Thirteenth Annual Report of Alabama College Station, 1900 (*Alabama College Sta. Rpt. 1900, pp. 20*).—This includes a financial statement for the fiscal year ended June 30, 1900, and reports of the director and heads of departments reviewing the different lines of station work.

Thirteenth Annual Report of Arkansas Station, 1900 (*Arkansas Sta. Rpt. 1900, pp. 7+114*).—This includes a financial statement for the fiscal year ended June 30, 1900, a brief report of the director, and reprints of Bulletins 61–65 of the station dealing with the following subjects: Some hay, forage, and pasture plants for Arkansas (E. S. R., 12, p. 634); wheat experiments (E. S. R., 12, p. 1034); the relative susceptibility of the domestic animals to the contagia of human and bovine tuberculosis (E. S. R., 12, p. 1084); notes on celery (E. S. R., 13, p. 48); and pig feeding experiments (E. S. R., 13, p. 77). A popular edition of Bulletin 63, entitled the source of tuberculosis in farm animals (E. S. R., 12, p. 1092), and a station circular on pomology and institutes are also reprinted.

Thirteenth Annual Report of Georgia Station, 1900 (*Georgia Sta. Rpt. 1900, pp. 294–371*).—This includes a report of the director on the publications and work of the station during the year, a financial statement for the fiscal year ended June 30, 1900, and a report of the biologist and horticulturist abstracted elsewhere.

Twenty-third Annual Report of North Carolina Station, 1900 (*North Carolina Sta. Rpt. 1900, pp. XXX+104*).—This includes a report of the director on the work and publications of the station during the year; reports of the agriculturist, chemist, and the horticulturist, botanist, and entomologist, giving detailed outlines of the work of their respective departments; a financial statement for the fiscal year ended June 30, 1900; and reprints of Bulletins 170–174 of the station on the following subjects: Gardening under glass (E. S. R., 12, p. 444), corn culture in North Carolina (E. S. R., 12, p. 538), the digestibility of some non-nitrogenous constituents of certain feeding stuffs (E. S. R., 12, p. 667), purification of phloroglucinol (E. S. R. 12, p. 611), another warning in regard to compost peddlers (E. S. R., 12, p. 841), and methods of determining proteid nitrogen in vegetable materials (E. S. R., 12, p. 819).

Thirteenth Annual Report of Indiana Station, 1900 (*Indiana Sta. Rpt. 1900, pp. 104*).—This includes a report of the director enumerating the different lines of station work and giving a subject list of station publications issued during the year; miscellaneous articles abstracted elsewhere; a list of periodicals received at the station; and a financial statement for the fiscal year ended June 30, 1900.

Thirteenth Annual Report of Michigan Station, 1900 (*Michigan Sta. Rpt. 1900, pp. 69–361*).—Included in these pages are reports of the director and heads of departments reviewing in some detail the work of the station during the year, a financial statement for the fiscal year ended June 30, 1900, meteorological observations noted elsewhere, and reprints of Bulletins 175–185 of the station on the following subjects: Some insects of the year 1898 (E. S. R., 11, p. 954), strawberry notes for 1899 (E. S. R., 11, p. 931), the South Haven report for 1899 (E. S. R., 12, p. 236), the production and marketing of wool (E. S. R., 12, p. 275), sugar-beet investigations (E. S. R., 12, p. 540), some insects of the year 1899 (E. S. R., 12, p. 575), cooperative soil test experiments (E. S. R., 12, p. 623), a popular discussion of pure milk supply

(E. S. R., 12, p. 986), gassy curd and cheese (E. S. R., 12, p. 984), tuberculosis and its management (E. S. R., 12, p. 987), and fertilizer analysis (E. S. R., 12, p. 933).

Thirteenth Annual Report of Tennessee Station, 1900 (*Tennessee Sta. Rpt. 1900, pp. 40*).—This includes a general outline of station work during the year; a history of the station from 1882 to 1900, with a list of publications issued during that time; reports by the agriculturist, botanist, horticulturist, chemist, and librarian reviewing the work of the different departments; a brief discussion of the object, construction, and use of daily weather charts by the meteorologist, and a financial statement for the fiscal year ended June 30, 1900.

Seventeenth Annual Report of Wisconsin Station, 1900 (*Wisconsin Sta. Rpt. 1900, pp. 352*).—A report of the director on the work and publications of the station during the year, miscellaneous articles abstracted elsewhere, lists of exchanges and acknowledgments, and a financial statement for the fiscal year ended June 30, 1900.

Organization lists of the agricultural colleges and experiment stations in the United States, with a list of agricultural experiment stations in foreign countries (*U. S. Dept. Agr., Office of Experiment Stations Bul. 88, pp. 134*).—The bulletin contains in addition to the organization lists a subject list of the publications of the experiment stations received by this Office during 1900, Federal legislation affecting agricultural colleges and experiment stations, and the rulings of the Post-Office, Treasury, and Agricultural Departments as to the construction of the act of Congress of March 2, 1887, establishing the stations.

Experiment Station Work—XVII (*U. S. Dept. Agr., Farmers' Bul. 124, pp. 32, figs. 6*).—This number contains articles on the following subjects: Distilled drinking water, soil inoculation, treatment of sandy soils, lime as a fertilizer, fertilizers for market-garden crops, pecan culture, weed destruction, maple sirup and sugar, value of cotton seed, alfalfa silage, forage crops for pigs, grazing steers, and type of the dairy cow.

Estimates of Russian crops, E. T. PETERS (*U. S. Dept. Agr., Division of Statistics Circ. 14, pp. 11, map 1*).—A report on the principal cereal crops of European Russia for 1900.

Foreign markets for American agricultural products, F. H. HITCHCOCK (*U. S. Dept. Agr. Rpt. 67, pp. 53*).—Testimony given before the Industrial Commission.

Agriculture at the Paris Exposition of 1900, F. BRETTREICH (*Vrtljschr. Bayer. Landw. Rath., 5 (1900), No. 4, pp. 511–527*).—A series of short descriptions of the agricultural exhibits of the different countries represented at the Paris Exposition.

Fourth progress report of the Victoria Royal Commission on technical education (*Melbourne: Government, 1900, pp. 210*).—A review of the progress and condition of agricultural education in Great Britain, Ireland, the continental countries of Europe, America, and the Australian colonies. Part 1 discusses the teaching of elementary agriculture in these different countries. Part 2 gives the general systems of agricultural education.

Among the patriarchs of agriculture, I. KLINGEN (*St. Petersburg: Department of Appanages, 1899, pt. 1, pp, 460, figs. 132, map 1; pt. 2, pp. VII+335, figs. 178, dgms. 4, chart 1; pt. 3, pp. 180, figs. 145; rev. in Selsk. Khoz. i Lyesor., 196 (1900), Mar., pp. 667–671*).—This large work is a report to the Department of Appanages by the chief of an expedition sent by the department for the study of subtropical agriculture in the Orient. Part 1 deals with Egypt, part 2 with India and Ceylon, and part 3 with China. These three volumes will be followed by another on Japan.—P. FIREMAN.

German agriculture at the end of the nineteenth century, L. GESCHWIND (*Ann. Agron., 26 (1900), No. 12, pp. 603–627*).—This article is a general discussion of German agriculture, treating of the nature and importance of agricultural crops, animal industry, agricultural machinery, the agricultural population, the fertilizer industry, and the causes of agricultural development in the German Empire during the nineteenth century. Much statistical matter is given in tables.

NOTES.

Iowa Station.—W. T. Shaw has recently been appointed assistant entomologist of the station.

New Mexico College and Station.—Dr. Frederic W. Sanders, who for the past two years has been president and director, has declined reelection except upon condition that the system of annual elections be abandoned or modified. The board of control having declined to change its system, Dr. Sanders will leave the institution and spend next year abroad. His successor has not yet been chosen. J. D. Tinsley has been elected vice-director for the year beginning July 1 next, with the understanding that he shall in most things act as the responsible director. For the year 1901–1902 the president of the college will retain the title of director. The department of entomology in the station has been abolished.

Oklahoma Station.—W. H. Coyle, of Guthrie, Okla., has been appointed a member of the board of regents, vice J. C. Tousley, whose term has expired. William M. Jenkins has succeeded C. M. Barnes as governor of Oklahoma and ex-officio member of the board.

Utah College and Station.—Peter A. Yoder, Ph. D., has been appointed assistant chemist in the college and station.

Experiment Farm of the Virginia State Board of Agriculture.—S. B. Heiges, formerly pomologist of this Department, has been appointed superintendent of the farm at Saxe, Charlotte County, Va., secured by the State board of agriculture for the purpose of conducting experiments with fertilizers on various crops, as required by the provisions of the State fertilizer law. It is proposed to give special attention to experiments with tobacco, but other crops will also be included. Professor Heiges will have the assistance of a tobacco expert in his work with this crop.

New Publications.—*Climat* is the name of a 16-page (32 pages octavo) semimonthly meteorological journal whose publication at St. Petersburg under the editorship of N. A. Dembchinsky is announced. The main object of this journal is stated to be the exact prediction of the weather. It will also include reports of theoretical investigations on questions of weather and climate, especial attention being given, however, to the influence of the moon on the weather, as the editor maintains that "the chief factor in the weather is the moon's attraction." All of the more important papers will be printed in Russian, French, English, and German. The predictions will cover Europe and North America, and the journal will be issued "sufficiently early to reach the most distant points (e. g., San Francisco) for which predictions are made before the fortnight to which they refer, e. g., the forecasts for the 1–15 May will come out in the beginning of April." Each number will contain 78 curves giving the weather elements at many stations in Europe and North America, and 2 maps of Europe and 2 of North America giving isobars and isotherms for each week.

A new recruit to the agricultural press, which from its title and objects is worthy of special mention, is *Agricultural Experiments*, described as "a practical review of experiment-station work, recent agricultural investigations and developments in all branches of rural industry." Its object is to present timely and readable reviews of the experiment-station and similar literature in order to aid the farmer in keeping posted in the progress along these lines and to assist him in the practical application of the results. In addition to these reviews and notes the paper contains special articles by experiment-station workers which are in a sense résumés of the work along particular lines. While the agricultural papers generally give considerable attention to the work and publications of the experiment stations, there is an opportunity for furnishing better abstracts and résumés than is usually done. The progressive farmer must depend quite largely upon the teachings of the experiment stations, and any publication which presents these observations and discoveries to him in a concise and intelligent manner serves a useful purpose.

Agricola Aridus is the title of an attractive bimonthly recently inaugurated by the agricultural department of the Colorado Agricultural College and Experiment Station. The publication is intended as a form of university-extension work, its object being educational. It differs from the popular bulletins of some stations by appearing periodically, and by being composed of short timely articles on the work of the college and the station, the object being to arouse an interest in this work and to extend its range of usefulness. The attractive and readable character of the first number bespeaks for it a useful place among publications of its class.

MISCELLANEOUS.—Notice has been sent out of the following resolution adopted by the American Veterinary Medical Association at its last annual meeting at Detroit, Mich.:

"Whereas we believe that the time has arrived in the history of our profession and in the history of our stock-breeding industry when the experiment stations of our various States and Territories should undertake the work of research in regard to the physiology and diseases of domestic animals in a more comprehensive manner than has yet been done: Therefore, be it

"*Resolved*, That this association recommend to the governing boards of the various stations that they give this branch of station work more liberal support."

NECROLOGY.—Dr. Otto Lugger, State entomologist to Minnesota and entomologist to the Minnesota College and Station, died May 21 of pneumonia. Born in Germany in 1844, he came to this country in 1865, and was engaged in the engineer service of the Great Lakes for a period of three years. At the end of this time he became assistant to C. V. Riley in Missouri, which position he held for seven years, after which he was chosen as curator of the Maryland Academy of Science in Baltimore. Professor Lugger spent two years in the Division of Entomology of this Department, and in 1888 was appointed entomologist and botanist at the Minnesota Station and professor of zoology and entomology in the college. These positions, together with that of State entomologist, he held at the time of his death. While he maintained a general interest in a variety of biological work, his main efforts were put forth in the field of entomology. In economic entomology his published contributions are recognized as being of high rank. Some of the more prominent features of his work have been his investigations on Rocky Mountain locusts and other locusts, and insects injurious to cereals, including numerous experiments in devising remedies for combating the chinch bug. During the past few years he published a number of reports on certain groups of insects, among which may be mentioned butterflies and moths injurious to fruit-producing trees, beetles injurious to fruit-producing trees, and bugs injurious to our cultivated plants. These reports contain, along with the summaries, many notes prepared from original observations on a great variety of insects during the active years of his life. In his death the Minnesota College and Station and the cause of economic entomology in general have sustained a severe loss.

The death of David Dickson, director of the practical school of agriculture at Berthonval (Pais-de-Calais), France, is reported in the *Journal d'Agriculture Pratique*. In collaboration with L. Malpeaux he had conducted a number of experiments on various agricultural topics while director of the station, notably on the use of pure and artificial milk for fattening calves, and upon the use of molasses in feeding animals.

EXPERIMENT STATION RECORD.

VOL. XIII. No. 2.

From statistics recently collated by this Office, it appears that educational institutions receiving the benefits of the acts of Congress of July 1, 1862, and August 30, 1890, are now in operation in all of the States and Territories, but not in Alaska, Hawaii, Porto Rico, and the Philippines. The total number of these institutions is 65, of which 62 maintain courses of instruction in agriculture.

The aggregate value of the permanent funds and equipment of the land-grant colleges and universities in 1900 is estimated to be as follows: Land-grant fund of 1862, $10,725,180.31; other land-grant funds, $1,528,441.37; other permanent funds, $15,017,963.80; land grant of 1862 still unsold, $3,570,907.80; farms and grounds owned by the institutions, $5,659,731.26; buildings, $16,781,968.63; apparatus, $1,456,619.19; machinery, $1,738,369.88; libraries, $1,326,889.13; miscellaneous equipment, $1,519,048.33; total, $59,325,119.70. The income of these institutions in 1900, exclusive of the funds received from the United States for agricultural experiment stations ($719,999.07), was as follows: Interest on land grant of 1862, $677,870.33; interest on other funds, $726,229.70; United States appropriation under act of 1890, $1,198,100.21; State appropriation (annual or regular), $1,889,288.34; State appropriation (occasional), $744,184.07; tuition fees, $390,334.08; incidental fees, $254,337.26; miscellaneous, $550,694.68; total, $6,431,038.67. The value of the additions to the permanent endowment and equipment of these institutions in 1900 is estimated as follows: Permanent endowment, $1,917,941.16; buildings, $948,377.94; library, $119,312.81; apparatus, $151,405.35; machinery, $141,667.15; miscellaneous, $129,288.49; total, $3,407,992.90. The number of persons in the faculties of the colleges of agriculture and mechanic arts were as follows: For preparatory classes, 333; for collegiate and special classes, 1,642; total, 2,013. In the other departments the faculties aggregated 842, making a grand total of 2,855 persons in the faculties of the land-grant institutions. The students in 1900 were as follows: (1) By classes—preparatory, 6,541; freshmen, 7,512; sophomores, 5,036; juniors, 3,648; seniors, 3,072; special, 12,964; postgraduate, 732; total, 39,505. (2) By courses—agriculture, 5,066; mechanical engineering, 3,932; civil engineering, 1,964; electrical engineering, 1,617; mining engineering, 950; architecture, 292; household economy, 1,908; veterinary science, 1,167; military tactics, 11,506. The graduates in 1900 were 3,114, and since the organization of these institutions, 41,690. The average age of graduates in 1900 was 21 years 10 months. The total number of volumes in the libraries was 1,469,318. The total number of acres of land granted to the States under the act of 1862 was 9,660,379, of which 886,889 are still unsold.

Agricultural experiment stations are now in operation under the act of Congress of March 2, 1887, in all the States and Territories. Agricultural experiments have been begun in Alaska with the aid of national funds, and two experiment stations are in operation in Hawaii; one under private auspices, the other under federal control. Steps have been taken to establish a station in Porto Rico under national auspices. In each of the States of Connecticut, New Jersey, and New York a separate station is maintained wholly or in part by State funds. In Louisiana three stations are thus maintained; and in Alabama two—the Canebrake and Tuskegee stations—are maintained wholly by State funds. Excluding the branch stations established in the several States, the total number of stations in the United States is 57. Of these, 52 received the appropriation provided for in the act of Congress above mentioned. The total income of the stations during 1900 was $1,170,857.78, of which $719,999.07 was received from the National Government, the remainder, $450,858.71, coming from the following sources: State governments, $247,281.46; individuals and communities, $2,420.51; fees for analyses of fertilizers, $70,927.31; sales of farm products, $90,088.84; miscellaneous, $40,140.59. In addition to this, the Office of Experiment Stations had an appropriation of $45,000 for the past fiscal year, including $12,000 for the Alaskan investigations. The value of additions to the equipment of the stations in 1900 is estimated as follows: Buildings, $89,416.23; libraries, $10,784.70; apparatus, $19,397.85; farm implements, $17,015.86; live stock, $22,009.10; miscellaneous, $8,850.94; total, $167,474.68.

The stations employ 693 persons in the work of administration and inquiry. The number of officers engaged in the different lines of work is as follows: Directors, 71; chemists, 143; agriculturists, 74; experts in animal husbandry, 14; horticulturists, 75; farm foremen, 24; dairymen, 30; botanists, 55; entomologists, 50; veterinarians, 29; meteorologists, 16; biologists, 6; physicists, 7; geologists, 6; mycologists and bacteriologists, 17; irrigation engineers, 7; in charge of substations, 10; secretaries and treasurers, 27; librarians, 10, and clerks, 51. There are also 30 persons classified under the head of "miscellaneous," including superintendents of gardens, grounds and buildings, apiarists, herdsmen, etc. Three hundred and twenty-seven station officers do more or less teaching in the colleges with which the stations are connected.

During 1900 the stations published 386 annual reports and bulletins. Besides regular reports and bulletins, a number of the stations issued press bulletins, which were widely reproduced in the agricultural and county papers. The mailing lists of the stations now aggregate half a million names.

In his report on the work and expenditures of the stations for the year ended June 30, 1900, the Director of this Office makes the following general statements: By far the largest part of the work of our stations has direct relation to the important agricultural interests of the communities in which they are located. The stations are, in fact, very responsive to the immediate demands of their farmer constituencies. Their greatest danger is not that they will undertake too much work of remote practical bearing, but that in the effort to meet the calls made upon them for immediate assistance they will attempt individually to cover more fields of investigation than the funds at their disposal will permit them to treat thoroughly. This temptation the stations generally are, however, resisting more successfully as their work is becoming better organized and their investigations are more carefully planned and supervised. The nature of their operations is also becoming better understood by the farmers, and the desirability of more thorough and far-reaching investigations is much more appreciated than formerly. A broader and deeper foundation of scientific inquiry is being laid each year, and there is a constant accumulation of data regarding the general agricultural conditions of the different regions of the United States. The climate, soil, water supply, native and cultivated plants, injurious insects, fungi, and bacteria are being studied in more detail and with greater thoroughness than ever before. The principles of nutrition of animals and the causes of their diseases are being subjected to more elaborate and fundamental scrutiny. Methods of investigation and the improvement of apparatus for research are being given increased attention.

Much of this work is done without public observation and in the intervals of other operations. Without doubt it should receive more definite recognition and encouragement. But it is cause for congratulation that so much patient labor of this character is being performed by station officers, who, as a rule, are seeking to advance the boundaries of knowledge for useful ends and are not deterred by a multiplicity of duties from giving attention to the more fundamental concerns of agricultural science. And this work is having its effect on the more practical operations of our stations. These are assuming a more substantial and systematic character and are being conducted with more definite relation to actual conditions. They have, therefore, a greater assurance of successful practical outcome. Questions relating to the introduction of plants or to the improvement of the live-stock industry in any region, for example, are now being investigated with a strict relation to the real requirements of the agriculture of that region which would have been impossible a few years ago. The present activity in plant breeding, as distinguished from the indiscriminate testing of varieties, is a good example of the raising of the level of experiment-station work as applied to directly practical ends. The plant breeder now sets definitely before him the kind of variety needed by the farmer in a given region or for a given purpose and applies all his scientific knowledge and practical skill to the production of such a variety. The notable success of some of the efforts in this direction already made are but a foretaste of much wider practical results as knowledge and experience in this line of endeavor increase. To do such work effectively there must be an almost ideal combination of science and practice. And the more we can learn definitely regarding the underlying principles the more surely will we be able to make successful practical applications. In such investigations science becomes more practical and art more scientific.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The heat of combustion as a factor in the analytical examination of oils and the heats of combustion of some commercial oils, H. C. SHERMAN and J. F. SNELL (*Jour. Amer. Chem. Soc., 23 (1901), No. 3, pp. 164–172*).—The accuracy and the rapidity of the determination of the heat of combustion or calorific power by the use of the bomb calorimeter, has led the authors to attempt to apply this method in the identification of oils. In the work reported the heats of combustion were determined with a bomb calorimeter of the Atwater-Blakeslee type. The results are shown in a table and are the mean of two or more determinations, the figures being reduced to combustion at constant volume. In making the determinations, the oil was absorbed by a small amount of fibrous asbestos and was ignited directly by electrically fused iron wire. The sources of the oil are given and the probable age of the sample. In each case the specific gravity, the iodin absorption, the free acid as oleic, and the heat of combustion per gram under constant volume and constant pressure are shown. Of the 40 samples reported, it was found that the sperm, rosin, and mineral oils were considerably higher in calorific value than the fatty oils. Among the fatty oils the nondrying were of slightly higher value than the drying oils. Castor oil and boiled linseed oil showed a low heat combustion. The old samples whose specific gravities were high and iodin figures low gave in all cases rather low heats of combustion. Oxidation caused by light and air seemed to lower the heat of combustion to almost the same extent that it raised the specific gravity. By dividing the heat of combustion by the specific gravity a value was obtained ranging from 10 to 10.3 in the fresh fatty oils examined. The value obtained from sperm oil was 11.2 and for mineral oils from 11.8 to 12.3. The authors conclude that from the determination of the heat of combustion, accomplished in less than one hour, it would appear that the result would be of value, considered in relation to the specific gravity, in detecting mineral or rosin oils in fatty oils or fatty oils in sperm oil.

An apparatus for the determination of the melting point of fats, F. T. SHUTT and H. W. CHARLTON (*Trans. Roy. Soc. Canada, 2. ser., 6 (1900–1901), Sec. III, pp. 21–25, fig. 1*).—An electrical method, using mercury as the medium for conveying the heat to the fat and having a bell in the circuit to note the moment of fusion. It is to some extent a modification of the method of Christomanos, but is much more rapid. The apparatus employed is figured and described. The advantages claimed for the method are that (1) there is no necessity to remelt the fat, as when drawn-out glass tubes are used, thus avoiding one source of error, (2) the factor of pressure is practically eliminated, (3) the method is rapid.

A rapid method of determining the amount of salt in butter, C. L. PITCH (*Nat. Cream. Buttermakers' Assoc. Rpt. 1901, pp. 176–181, fig. 1*).—This method, which the writer has used in 6 creameries during 1 year, is carried out as follows: The butter is sampled with a trier, and from the sample small portions are taken here and there and carefully packed in a little brass measure. The measure is suspended in a large cylinder partially filled with a known amount of hot water, and the cylinder stoppered and shaken until the butter melts; 17.6 cc. of the aqueous solution is removed with a Babcock pipette and placed in a beaker. A tablet specially prepared and containing a definite amount of nitrate of silver is dissolved in 50 cc. of cold water. The solution containing an aliquot portion of the salt of the butter is then carefully titrated with the nitrate of silver solution, using potassium bichromate as an indicator. The number of cubic centimeters of the tablet solution used to produce a permanent brick-red color indicates the number of tenths per cent of salt contained in the butter. Thus, 10 cc. of the silver nitrate solution indicates 1 per cent of salt. The author states that he is able to bring variations within $\frac{1}{4}$ of 1 per cent of the standard desired. By employing this method the amount of salt in butter can be more easily controlled and a more uniform product produced.

Determination of cocoanut oil in butter and in oleomargarine, J. Wauters (*Bul. Assoc. Belge Chim., 15 (1901), No. 1, pp. 25–28*).—A distinction is found by determining both the soluble and insoluble fatty acids by the Reichert-Meissl number.

The chemical estimation of starch, E. Gianturco (*Bol. Chim. Pharm., 39 (1900), pp. 329–335; Schweiz. Wchnschr. Pharm., 38 (1900), p. 348; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 1, pp. 40–41*).—This method is based on the tendency of carbohydrate bodies to unite with earthy bases, and is carried out in a manner somewhat similar to the method of Asboth, except an aluminum salt is used instead of barium hydroxid.

A solution of potash alum is made up, in which 1 cc. contains 0.060769 gm. alum, equal to 0.01 gm. aluminum hydroxid. Of this solution 10 cc. is used for each 0.5 to 1.5 gm. starch. With commercial starch 2.5 gm. of finely powdered, well mixed substance is put into a beaker, and 150 to 200 cc. water and 15 cc. of the alum solution added and thoroughly mixed. A small excess of ammonia is then added and the precipitate brought upon a filter, washed until no sulphate reaction is given, dried at 100°, and weighed. With meal, 3 gm. of the substance is made into a dough with a little water, and then the starch washed out into a beaker with a fine stream, and the process continued as indicated above.

Estimation of dextrose and dextrin in commercial glucose, L. Lindet (*Ann. Chim. Analyt., 6 (1901), No. 2, pp. 43–45*).—In the method proposed the total carbon is estimated by combustion with cupric oxid in the usual manner, and the rotary power of the glucose determined. From the carbon obtained by combustion the combined weight of the sugars present is calculated as $C_6H_{12}O_6$. From this figure and the rotary power of the glucose, the relative proportion of dextrose and dextrin is calculated. In making the estimation the specific rotary power of dextrose is placed at 52.5°, of dextrin at 195°.

Influence of the nature and intensity of light on the inversion of sucrose by mineral acids, H. Gillot (*Bul. Acad. Roy. Sci. Belg., 1900, pp. 863–874; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 460, I, p. 127*).—Light of all wave lengths promotes inversion of sucrose in the presence of sulphuric and hydrochloric acid. The rays in the blue, violet, and ultra violet are much more active than those in the yellow or red.

The determination of tragacanthin and dextrin in cacao and chocolate and the estimation of the dextrins by polarization, P. Welmans (*Ztschr. Oeffent. Chem., 5 (1900), pp. 478–483; abs. in Chem. Centbl., 1901, I, No. 1, pp. 65, 66*).

Method of dissolving cellulose, Thiele (*Rev. Prod. Chim., 3, p. 325; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 2, p. 119*).—Cotton wool mercerized in caustic soda, dried, and immersed in an ammoniacal solution of cupric oxid will dissolve almost immediately at ordinary temperature.

Elementary organic analysis, F. G. Benedict (*Easton, Pa.: Chemical Publishing Co., 1900, pp. VI+86, figs. 15*).—Description of apparatus and methods employed in making determinations of carbon and hydrogen in various combinations.

The determination of sugar in wine and beer in the absence of salicylic acid, F. Wirthle (*Chem. Ztg., 24 (1900), No. 95, p. 1035*).—A method for making a very delicate color test.

The cause of error in the search for salicylic acid in wines, A. Y. Ferreira da Silva (*Bul. Soc. Chim. Paris, 3. ser., 23 (1900), p. 795; Chem. News, 83 (1901), No. 2145, p. 4*).—In making this test the point is emphasized that no more than 50 cc. of the wine should be taken. In larger amounts there is danger of getting the reaction in a pure wine, as such may contain naturally enough of a substance resembling salicylic acid to respond to the test.

A new coloring matter in wine and the determination of orseille, cochineal, pokeberry, and beet coloring matter, J. Bellier (*Ann. Chim. Analyt., 5 (1900), pp. 407–413; abs. in Chem. Centbl., 1900, II, No. 26, pp. 1296, 1297; Chem. Ztg., 25 (1901), No. 2, p. 5*).

Testing for orseille in wine, R. Truchon (*Ann. Chim. Analyt., 5 (1900), No. 12, pp. 444, 445*).—Threads of wool boiled 5 minutes in a portion of the wine slightly acidulated with sulphuric acid, and then placed in ammonia water, are dyed in the presence of orseille a violet color.

Estimation of tartaric acid in presence of oxalic acid, M. Palladini (*Gaz. Chim. Ital., 30 (1900), pp. 446–453; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 460, II, p. 135*).—A solution containing tartaric, oxalic, and citric acids is neutralized with sodium hydroxid and calcium chlorid added. The oxalic acid and a part of the tartaric acid are precipitated as calcium salts. The oxalic acid is then precipitated with argentic nitrate.

International association method of tannin determination, H. R. Procter (*Jour. Soc. Chem. Ind., 20 (1901), No. 2, p. 104*).—Because of the difficulty of obtaining a clear filtrate in the analysis of certain hide powders, as quebracho extract, F. A. Blockey proposes to dilute such solutions, so that they contain approximately 0.4 gr. "tannin," instead of 0.7 gr. per 100 cc. This suggestion has been adopted by the International Association of Leather Trades Chemists, and they now direct that solutions for analysis contain not more than 0.45 and not less than 0.35 gr. of "tanning matter" per 100 cc.

The estimation of free acid in tanning decoction, B. Weiss (*Gerber, 26 (1900), pp. 269–283; abs. in Chem. Ztg., 24 (1900), No. 96, p. 355*).—A method of separation and of titration with standard alkali solution.

Estimation of tanning materials, L. Specht and F. Lorenz (*Chem. Ztg., 25 (1901), No. 1, pp. 5, 6*).—Formulas for estimating results and comparisons of results.

The estimation of organic and mineral acids in tanning solutions, F. Jean (*Ann. Chim. Analyt., 5 (1900), No. 11, pp. 413–416; abs. in Chem. Ztg., 25 (1901), No. 2, p. 4*).—A discussion of practical methods.

The quantitative estimation of malic acid, A. Hilger (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 2, pp. 49, 50*).—The application of the method with palladium chlorid in estimating the malic acid in wine.

Detection of dulcin (phenetol-carbamid) in foods and beverages, J. Bellier (*Ann. Chim. Analyt., 5 (1900), p. 333; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 1, pp. 72, 73*).

A simple gas volumetric method of estimating formaldehyde, E. Riegler (*Ztschr. Analyt. Chem., 40 (1901), No. 2, pp. 92–94*).—This method depends upon the fact that hydrazin sulphate ($N_2H_4H_2SO_4$) with a solution of iodic acid gives off free nitrogen. Hydrazin sulphate in the presence of formaldehyde forms hydrazon, and upon the addition of iodic acid the compound is broken up and free nitrogen given off. This is collected in a Knop-Wagner azotometer and the amount calculated to a zero temperature and 760 mm. pressure. One cubic centimeter of nitrogen equals 2.7 mg. formaldehyde.

The elementary analysis and calorimetric value of the muscle substance of various animals, A. Köhler (*Ztschr. Physiol. Chem., 31, pp. 479–519; abs. in Chem. Centbl., 1901, I, No. 13, p. 752*).—The carbon, hydrogen, nitrogen, sulphur, and oxygen content and the calorimetric value of the flesh of cattle, swine, sheep, dog, chicken, and horse are given.

Determination of starch in liver sausage, R. Hefelmann (*Ztschr. Oeffentl. Chem., 7, pp. 43–47; abs. in Chem. Centbl., 1901, I, No. 12, pp. 707, 708*).

Fluorescein as an indicator, H. Zellner (*Pharm. Ztg., 46 (1901), p. 100; abs. in Chem. Ztg., 25 (1901), No. 14, p. 40*).—Fluorescein is used as an indicator in estimating ammonia. It is prepared by dissolving 0.4 gm. in 50 cc. alcohol and adding 30 cc. water.

The determination of ammonia in the air of stables, A. Pagnoul (*Bul. Sta. Agron. Pas de Calais, 1900, pp. 5–8, 29–32, fig. 1*).—A description is given of an aspirator arranged to draw a definite volume (2 liters) of air through 10 cc. of acidulated ammonia-free distilled water in a Nessler tube. The ammonia is determined by means of Nessler's reagent.

Report of analyses of Paris green and other insecticides in 1900, L. L. Van Slyke and W. H. Andrews (*New York State Sta. Bul. 190, pp. 283–290*).—Analyses were made of 22 samples of Paris green and 1 sample each of Arsenoid, Paragrene, Black Death, Bug Death, and Hammond's Slugshot. In the 22 samples of Paris green the arsenic content varied from 55.83 to 60.8 per cent, and averaged 57.05 per cent. The amount of arsenious oxid soluble in water in the different samples ranged from 0.51 to 15.69 per cent and averaged 1.68 per cent. The amount of copper in the 22 samples averaged 28.97 per cent. Microscopic examination for testing the purity of Paris green was not found satisfactory. The results obtained from the study of the different samples of Paris green indicated that this substance was sold in a satisfactory condition. The chemical analysis of the other insecticides is tabulated.

Analyses of Paris green and other insecticides, C. A. Goessmann (*Massachusetts Hatch Sta. Bul. 74, pp. 7–9*).—Analyses of 14 samples of Paris green and one each of pink arsenoid (lead arsenite), green arsenoid (copper arsenite), white arsenoid (barium arsenite), Laurel green, and Bug Death are reported.

Soluble arsenious oxid in Paris green, S. Avery and H. T. Beans (*Jour. Amer. Chem. Soc., 23 (1901), No. 2, pp. 111–117*).—In this preliminary report it appears from the results of the experiments that the method of estimating the arsenious oxid in Paris green by suspending in 1,000 parts of water for 1 week is quite arbitrary. The use of a strong solution of sodium acetate seems to be a better solvent than water. The authors believe, however, that too much importance is attached to the content of "soluble arsenious oxid" in Paris green.

The iodometric estimation of arsenic acid, F. A. Gooch and Julia C. Morris (*Chem. News, 83 (1901), No. 2146, pp. 15–17*).—The authors show that an arbitrary correction of about 0.003 gm. must be deducted from the indications in Williamson's process of direct titration with thiosulphate; and a correction varying from one-half that amount to nothing, according to the amount of arsenious acid present, when determination is made by iodin after neutralization with acid potassium carbonate. In the vaporization process the application of an arbitrary correction is unnecessary.

Detection of arsenic in the presence of sulphites, J. F. Smith (*Chem. News, 83 (1901), No. 2145, pp. 2, 3*).—A modification of Marsh's test. By this method 15 parts of arsenic in 1,000,000 were detected in the presence of a large quantity of bisulphite in 5 cc. of beer without previous treatment.

The detection of arsenic in beer and brewing materials, A. C. Chapman (*Analyst, 26 (1901), No. 298, pp. 8–10*).—By this method the presence of arsenic is determined by boiling a solution in which a piece of bright copper gauze is suspended.

Potassium—microchemical detection, E. M. Chamot (*Jour. Appl. Micros., 3 (1900), No. 12, pp. 1077–1083, figs. 5*).—Methods of formation and detection of crystals of potassium salts in various materials.

Chemistry in its relation to agriculture, F. B. Guthrie (*Agr. Gaz. New South Wales, 12 (1901), No. 1, pp. 114–130, figs. 2*).—A general review of the subject with special reference to the progress of agricultural chemistry in Australia.

BOTANY.

Critical points in the relation of light to plants, D. T. MacDougal (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 252*).—The influence of light upon plants is summarized by the author as follows: "Light exercises a direct chemical effect upon the substances of which protoplasm is composed. It stimulates protoplasm to the formation of chlorophyll, although its action is not necessary to the process, and its direct chemical effect disintegrates this substance. It constitutes a source of energy which is absorbed by the chloroplasts. Absence of light constitutes a specific stimulus, calling out the various reactions of etiolation. Light acts as a directive or orienting stimulus to which the plant responds by locomotory or bending movements. Different portions of the spectrum are operative in producing these separate effects." The author states that illumination is not necessary to the motility of protoplasm, and conversely that the deprivation of light does not induce a condition of rigor, but sets up various pathological phenomena, among which is the breaking down of chlorophyll. Light does not exert a paratonic or retarding effect upon growth. Its chemical action may hinder the accumulation of somatic material. The changed development of plants in darkness is an adaptive response which has for its purpose the elevation of the chlorophyll screen and reproductive bodies.

On the development of etiolated plants when placed in sunlight, H. Ricôme (*Compt. Rend. Acad. Sci. Paris, 131 (1900), No. 26, pp. 1251–1253*).—The results of a number of experiments in which etiolated plants were placed in the sunlight and morphological changes noted are given. The effect of the change on the structure of the stem and leaves and on the weight of the plants is shown. The stems of etiolated plants were considerably longer than normal ones and the leaves were smaller when the plant had but little reserve material at its disposal. When plants having a large amount of reserve material were deprived of light for a considerable time and afterwards brought into the light, the effect of the etiolation was not as marked as in the case of those plants having a limited amount of reserve material. Transpiration was shown to play an important part in determining the effect of etiolation. It was shown that etiolated plants brought out to the light suffered a great loss of water, but this loss diminished as the dry weight of the plant increased.

Contribution to the question of the synthesis of albumin by the higher plants in the dark, R. Schröder (*Izv. Moscow Selsk. Khoz. Inst., 6 (1900), No. 3, pp. 405–428*).—The author experimented with squash, peas, potatoes, and dahlias. In the case of the etiolated squash seedlings it was found that in the first two days after the soaking of the seeds no decomposition of albumin took place, but after that the albuminous substances began to decompose as usual. No synthesis of albumin was observed. In the experiments with month-old etiolated pea seedlings, placed in a 6 per cent cane-sugar solution with other nutritive substances, no increase of albuminous nitrogen was observed, but there was a retarding of the decomposition of the proteids. In the experiments with potatoes germinated in sand cultures in the dark an increase of the albuminous nitrogen was observed. In the absence of potassium nitrate there was either no increase or it was very slow. Dahlia tubers germinated in pure quartz sand and without nutritive substances showed no increase of albuminous nitrogen. The above experiments, therefore, corroborate the statements of various authors concerning the possibility of albumin synthesis in the dark by the higher plants.—P. FIREMAN.

Rheotropism of roots, F. C. NEWCOMBE (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 250*).—Rheotropism is defined as the curvature of the root when growing in running water. In all cases so far observed the root tip curves against the stream. In the experiments upon which the report is based the author examined 32 species of plants, 15 of which have shown themselves to be rheotropic and 17 insensitive. Species of the same genius differ widely in the degree of response to this stimulus. Members of the Cruciferæ are among the most sensitive plants found, their roots often attaining an angle of 90° from the vertical. The velocity of the current was found to exercise a considerable influence upon the amount of curvature, the best response being given in a current carrying from 100 to 500 cm. per minute. A velocity of 2,000 cm. per minute in most plants produced a negative curve. The area of the root which perceives the stimulus includes the apex of the root and the elongating zone, and the roots of mature plants are as responsive as those of seedlings.

Thigmotropism of roots, F. C. NEWCOMBE (*Abs. in Science, n. ser., 13 (1901), No. 320, pp. 250, 251*).—The sensitiveness of roots to contact or pressure has been investigated and the author shows that roots are responsive to pressure on the elongating zone. Some species respond to pressure while others do not, and the response is considered of the same class of phenomena as shown by tendrils when in contact with a solid object. In the experiments outlined by the author all the roots that showed the effect of this stimulus became concave on the side receiving the stimulus.

The relation of water plants to the solid substratum, R. H. POND (*Abs. in Science, n. ser., 13 (1901), No. 320, pp. 256, 257*).—The common statement that the roots of water plants serve only as means of attachment requires, according to the author, some modification. He has found that aquatic plants rooted in soil exceeded in vegetation and dry weight plants rooted in sand or merely suspended. Plants rooted in sand or merely suspended contained an excess of starch, lime, and magnesium, while they were lacking in nitrogen, potash, and phosphoric acid. A volumetric measurement of root absorption was made showing that the rooted plants absorbed more than floating ones.

The influence of the presence of pure metals upon plants, E. B. COPELAND and L. KAHLENBERG (*Trans. Wisconsin Acad. Sci., Arts, and Letters, 12 (1900), pt. 2, pp. 454–474*).—The authors state that injury to plants grown in cultures containing pure metals will depend upon the tendency of the metal to go into solution and the specific toxicity of the metal when in solution. A series of experiments were conducted in which chemically pure metals were placed in distilled water, and the effect noted upon the growth of a number of plants. As many of the metals as were available were rolled into foil or were in the shape of wire. Some of the other metals were in the form of sticks, others in flakes, etc. The vessels containing the water cultures were glass beakers, coated internally with paraffin, so that no solution of glass would be possible. Seedlings of maize, lupines, oats, and soy beans were placed in these solutions and the effect of their growth determined by the increase in length of the radicles. In all, 30 metals were tested, the more common of which were copper, nickel, tin, silver, platinum, gold, mercury, antimony, bismuth, cobalt, iron, zinc, lead, manganese, sulphur, and carbon. The effect of these different elements is shown in tabular form. It appears that thallium, cadmium, copper, cobalt, zinc, lead, iron, antimony, magnesium, arsenic, iodin, tungsten, and tellurium were almost invariably fatal to the growth of plants. It was not always possible to demonstrate by chemical tests the presence of these substances in the roots which they had killed, but in a number of instances the appearance of the roots showed the presence of the salts of the metal that had killed it. It was found that those metals whose salts are already known to be toxic poisoned plants when present in water. It is stated as a well-recognized fact in animal physiology that the phenomena of stimulation and poisoning are very intimately related, and in the authors' experiments it was found that copper and cobalt stimulated growth very appreciably, and boron, lead, and tungsten exerted a stimulating influence in individual cases. The subject of chemical stimulants is said to be one for further study. A list of about 30 important works relating to this subject is given.

The effect of mechanical shock on longitudinal growth of plant organs, J. B. Pollock (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 251*).—Studies were made of the hyphæ of Phycomyces, hypocotyls of Brassica, radish, sunflower, lupine, and gourd, the epicotyl of beans, and the leaf sheath and first leaves of oats and wheat. Single shocks given by pressure upon the mycelium of the fungus showed that there was a retardation, followed by a recovery in from 5 to 30 minutes, after which the growth was frequently faster than at first. In the larger plants bending was followed by rapid elongation, after which growth was retarded for a short time, and upon the resumption of the functions of the plant the rate of growth was sometimes greater and sometimes less than at first. The effect of continuous shock upon plants was investigated by means of a form of apparatus which kept the plants swaying from side to side. The results obtained were decisive only in the case of experiments with gourds, which showed a decided acceleration due to the swaying. With the other plants the results were variable, but as a whole gave evidence of acceleration where the swaying was not too vigorous.

The effect of annular decortication of herbaceous plants, L. Daniel (*Compt. Rend. Acad. Sci. Paris, 131 (1900), No. 26, pp. 1253–1255*).—The effect of removing a portion of the bark from annual plants was investigated by the author, the subjects of the experiments being different species of crucifers, eggplant, and tomatoes. In the case of the crucifers experimented with, the ringing of the stems was generally followed by a wilting and final death of the lower leaves. When in a moist medium the plant was severely injured. If in a drier medium the wound was healed over to some extent. The heads produced by the different varieties of cabbage, Brussels sprouts, etc., were considerably smaller than in the check plants. In the experiments with eggplants and tomatoes there was a marked increase in the size of the fruit following the annular ringing of the plant. While there was increase in size of the solanaceous fruits, there was a corresponding decrease in their flavor. It is thought probable that the marked effect shown in these plants would probably be shown in other annual plants which furnish edible fruits.

Notes upon albinism in sweet corn, B. D. Halsted (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 247*).—The author reports a complete albinism in a cross between black Mexican and Egyptian sweet corns. The albinos were produced in about equal numbers from the white, pink, and purple grains resulting from the crosses, and in some instances about 15 per cent of the plants were white. The albino plants possessed normal vigor and in every way resembled the types, except in the lack of a capacity to produce chlorophyll. After about 2 weeks' growth the plants began to weaken, and perished within a short time. In the dark they grew like normal plants, except no etiolin was produced. The grain produced by overburdened plants seemed more liable to produce albinos than that from stalks which bore a single ear. The albinism is believed to have been due to incomplete fecundation, and the fact that the plants were close bred may have had an effect upon the progeny.

Loss of vigor in corn from inbreeding, H. J. Webber (*Abs. in Science, n. ser., 13 (1901), No. 320, pp. 257, 258*).—The effect of inbreeding corn with pollen from the same stalk is shown by a number of examples. One hundred stalks of Hickory King corn grown from seed inbred with pollen from the same stalk yielded 46 ears, weighing 9.3 lbs., while seeds of the same race produced by crossing different seedlings yielded, from the same number of stalks, 82 ears, weighing 27½ lbs. In attempting to fix hybrids of Hickory King and Cuzco, a number of ears were inbred with pollen from the stalks bearing them, while others were fertilized with pollen from other hybrid seedlings of the same parentage. The hybrids of the second generation, where the seed was inbred, showed a great loss of vigor, being small in structure and almost totally sterile. From these observations it is believed that in fixing corn hybrids it will be found desirable to cross different hybrid seedlings of the same parentage which are found to present the same characters, rather than inbreed the hybrid with its own pollen, as is frequently advocated by plant breeders.

The morphology of the fruit of Opuntia, J. W. Toumey (*Abs. in Science, n. ser., 13 (1901), No. 320, pp. 253, 254*).—While the primary function of fruits is seed production and dissemination, according to the author the Opuntia has developed special adaptations for this purpose. Under the influence of desert environment many species of plants have to a great degree lost the power of production of seed, and in *Opuntia fulgida* the fruit is mostly sterile. The reproduction of the plant largely takes place by the dissemination of the swollen, spine-covered, terminal joints. In this case the function of the fruit is not to produce seeds but to attract animals to the plant that the fragile branches may adhere to them and thus become disseminated. In many instances the author has observed clusters of spineless, short, proliferous joints which resemble fruits externally, but are entirely without evidence of even an abortive ovary. These in the economy of plants serve the same purpose as fruit clusters without the necessity of floral development.

Concerning manna produced by olive trees, Trabut (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 4, pp. 225, 226; Bul. Agr. Algérie et Tunisie, 7 (1901), No. 3, pp. 54–56, fig. 1*).—The author reports the occurrence in Algiers of a great number of olive trees which exude during the summer a form of manna which is apparently identical with that produced by the ash tree. Analysis shows it to contain 52 per cent mannite and 7.8 per cent reducing sugars. The trees producing the manna are evidently diseased. The manna exudes from the trunk and larger branches and at these points the cambium is in a state of complete liquefaction. This decomposition is caused by a bacterium. It forms large canker-like growths, exposing the naked wood. The author is led to believe that the bacteria are distributed by insects which puncture the bark, making it possible for the organism to reach the cambial layer.

The limits of variation in plants, J. W. Harshberger (*Abs. in Science, n. ser., 13 (1901), No. 320, pp. 251, 252*).—The author has made a study of the limits of variation in plants as bearing on the survival of seedlings. It was found that size and shape of leaves, weight and size of fruits varied in a mathematical ratio. The size, configuration, and persistence of early forms in the case of a number of leaves were noted, and these changes were attributed to hereditary impulse and to the direct influence of the environment, fitting the leaf to utilize the space at its disposal, thus enabling the plant to present the largest amount of leaf surface to the light.

Phenological observations in Canada in 1899, A. H. Mackay (*Proc. and Trans. Nova Scotian Inst. Sci., 10 (1899–1900), No. 2, pp. 303–318*).—An account is given of the phenomena accompanying the flowering of 10 species of plants which are distributed over a considerable portion of the country, 18 stations being reported. In addition, the first flowering and fruiting of a large number of plants, and the dates of the first appearance of migratory birds are given. The species of plants considered in the first portion of the report were mayflower (*Epigæa repens*), blue violet, red maple, dandelion, strawberry, wild red cherry, tall buttercup, service berry or shad bush, apple, and lilac.

On the nitrogenous products of the seed and the embryo of Lupinus albus, N. J. Wassilieff (*Ann. Agron., 27 (1901), No. 2, pp. 81–90*).—This is an article translated from the German[1] by E. Sellier.

The insular flora of Mississippi and Louisiana, F. E. Lloyd and S. M. Tracy (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 253*).—This paper deals with the

[1] Landw. Vers. Stat., 55 (1901), No. 1–2, p. 45.

climate, physiography, and vegetation of the islands in the vicinity of the Delta of the Mississippi, and is especially concerned with a comparison of the ecological conditions in this region and that recently reported for Ocracoke Island, North Carolina (E. S. R., 12, p. 720). The islands of the Delta region are composed of sand, muck-marsh, and what are called mud-lumps. These have distinctive strand formations which are described in some detail.

The grasses in Elliott's "Sketch of the botany of South Carolina and Georgia," F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Division of Agrostology Circ. 29, pp. 12, figs. 4*).—Notes are given, based upon a careful examination of the collection upon which the descriptions of the grasses of Elliott's Sketch of the Botany of South Carolina and Georgia, which appeared in 1817, was based. These specimens are well preserved in the herbarium of the College of Charleston, South Carolina, and furnish the basis for a critical study of some of the less known grasses of that region.

New or little known grasses, F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Division of Agrostology Circ. 30, pp. 8*).—Descriptions are given of a number of new or little known species of grasses which have been received by the Division from various sources, principally California, Mexico, and the region from the Rocky Mountains westward. A number of new species are described and new names given others.

Bermuda grass, A. S. HITCHCOCK (*U. S. Dept. Agr., Division of Agrostology Circ. 31, pp. 6, figs. 2*).—The economic distribution of Bermuda grass is given, and different forms of the grass are described. Its value as a pasture and hay grass is shown, as well as for soil binding and lawns. Means are suggested for its eradication, which may be done by proper cultivation and growing of shading crops, especially cowpeas, on the land.

Monograph of the North American Umbelliferæ, J. M. COULTER and J. N. ROSE (*U. S. Dept. Agr., Division of Botany, Contributions from the U. S. National Herbarium, vol. 7, No. 1, pp. 256, pls. 9, figs. 65*).—A revision is given of the genera and species of the North American Umbelliferæ.

Studies of American fungi: Mushrooms, edible, poisonous, etc., G. F. ATKINSON (*Ithaca, N. Y.: Andrus & Church, 1900, pp. 275, figs. 223*).—The author describes and illustrates with natural-size figures all the more important agarics found in the United States, and also genera and species of other orders of higher fungi, including many of the edible forms. An analytical key, glossary of technical terms, indexes of genera, species, and illustrations are given; and also chapters as follows: Recipes for cooking mushrooms, Sarah T. Rorer; Chemistry and toxicology of mushrooms, J. F. Clark; Structural characters of mushrooms, H. Hasselbring.

Mushrooms or toadstools, L. P. HENDERSON (*Idaho Sta. Bul. 27, pp. 27–64, pls. 12*).—Descriptions are given of a number of the more common mushrooms, and directions for their identification. Notes are given upon the value of mushrooms as food, and a number of recipes for preparing them for the table, taken from various sources, conclude the bulletin.

Edible and poisonous mushrooms and toadstools, W. TRELEASE (*Reprint from Missouri State Hort. Soc. Rpt. 1901, pp. 18, figs. 1*).

Studies on the influence of medium on the polymorphism of fungi, J. BEAUVERIE (*Études sur le polymorphisme des champignons; influence du milieu. Thesis, Lyon, 1900, pp. 269*).

FERMENTATION—BACTERIOLOGY.

Investigations on acetic-acid bacteria, E. C. HANSEN (*Compt. Rend. Travaux Lab. Carlsberg, 5 (1900), No. 1, pp. 39–46*).—Investigations are given on the limits of vitality and variations of 3 species of acetifying bacteria. The author found that *Bacterium aceti* in beer fermented at low temperature (*bière basse de garde*) remained living for 9 years, in double beer 5 or 6 years. In a saccharose solution the limit of vitality was about 2 years, and in water about 16 months. The limit of vitality of *B. pasteurianum* in the low fermented beer is about 10 years, in double beer about 6 years, in saccharose solution about 1 year, and in water from 6 to 12 months. The third species investigated, *B. kützingianum*, remains viable in the low fermented beer from 5 to 7 years, in double beer about 6 years, in the saccharose solution about 1 year, and in water 9 months. The variation of these different bacteria in different media and at different temperatures and under other conditions was determined.

Growth of bacteria in the presence of chloroform and thymol, E. F. Smith (*Abs. in Science, n. ser., 13 (1901), No. 322, p. 327*).—On account of the frequent dependence of bacteriologists upon the antiseptic property of chloroform and thymol, the author calls attention to the fact that 12 micro-organisms are known which grow readily in test-tube cultures of milk or beef bouillon to which an equal volume of chloroform has been added. Two organisms, it is stated, are known to grow readily in beef bouillon to which thymol has been added.

Duration of life of typhoid bacilli, from different sources, in ice; and the effect of intense cold on bacteria, W. H. Park (*Abs. in Science, n. ser., 13 (1901), No. 322, p. 323*).—An account is given in which 20 cultures of bacteria of typhoid fever, after having been grown for 28 hours in nutrient agar, were placed in a room the temperature of which was rather constant at about 23° F. From time to time tubes were removed and the effect of the cold, as shown in the development of bacteria, was noted. At the end of one week, only 14 per cent of the bacteria were then living, and at the end of 22 weeks all the cultures were dead. Watery suspensions of different bacteria were placed in small tubes and dropped into liquid air, exposures being from 3 minutes to 2 hours and 10 minutes. As a result of this exposure the virulence of the organisms was only slightly diminished.

The use of carbolic acid in isolating Bacillus coli communis from river water, W. B. Copeland (*Abs. in Science, n. ser., 13 (1901), No. 322, pp. 330, 331*).—A description is given of a method by which the author has been able to separate the colon bacillus by the use of solid media. The cultures were made on Würtz agar and the acid colonies were readily distinguishable by the reddening of the litmus. As numerous other bacteria are present in river water, the author has found that by adding 0.2 cc. of a 2 per cent solution of carbolic acid the number of bacteria in the water is greatly reduced, while there is apparently no effect upon the colon bacilli.

A compendium of bacteriological water investigations, W. Migula (*Compendium der bakteriologischen Wasseruntersuchung nebst vollständiger Uebersicht der Trinkwasserbakterien. Wiesbaden: Otto Nemnich, 1901, pp. VII + 440, tables 2*).

Formation of sulphureted hydrogen in town drains, and the genus Aerobacter, M. W. Beijerinck (*Centbl. Bakt. u. Par., 2. Abt., 6 (1900), No. 7, pp. 193–206*).—The formation of sulphureted hydrogen in town drains by *Spirillum desulphuricans* is mentioned. As a result of further research in this direction, the author suggests that this is due not only to the reduction of sulphate but also to free sulphur and to albuminous bodies. The decomposition of albuminous bodies is brought about either by aerobic organisms or by temporary anaerobes. These organisms were found by a special method of investigation to form sulphites. As a result of the author's investigations, the suggestion is made that these gas-forming species endowed with this temporary anaerobism should be classed together in a genus to which he gives the name Aerobacter, the species mentioned being (1) *Aerobacter aerogenes=Bacillus lactis aerogenes;* (2) *A. viscosum;* (3) *A. coli=B. coli communis*; (4) *A. coli infusionum;* and (5) *A. liquefaciens.* The different sources from which the organisms obtain their sulphur are said to be albumin, sulphur, sulphites, and sulphates.

Bacteria in the Ames, Iowa, sewage disposal plant, L. H. Pammel (*Abs. in Science, n. ser., 13 (1901), No. 322, pp. 323, 324*).—A brief description is given of a sewage plant designed for the disposal of the sewage of about 600 people. The plant consisted of the ordinary type of filter beds, the filtration amounting to about 100 gal. per day per acre. A bacteriological analysis of the filtrate showed the presence of an average of 5,127 bacteria per cc., and at no time did it rise above 11,075. An examination of the water in the tank showed, in September, 9,000,000 per cc., falling in cold weather to about 100,000. This showed the efficiency of the filter bed for removing bacteria.

The action of light upon bacteria, A. Bournaret (*Thesis, Toulouse, 1900*).

The use of paraffin to exclude oxygen in growing anaërobic bacteria, W. H. Park (*Abs. in Science, n. ser., 13* (*1901*), *No. 322, p. 323*).—The author shows that covering the nutrient solution in tubes or flasks with paraffin, whose melting point was 42° C., proved very useful in the development of cultures of anaerobic bacteria. The inoculations can be made through the paraffin before it is fully cooled, or through the paraffin film by heating in a gas flame. The accumulation of gas forces the paraffin to rise in the tube or the flask, but does not permit the entrance of oxygen.

The utility of a supply of live steam in the laboratory, H. A. Harding (*Abs. in Science, n. ser., 13* (*1901*), *No. 322, p. 331*).—On account of some of the disadvantages attending the use of gas in the bacteriological laboratory, the author has devised means by which a steam pipe is introduced into an Arnold sterilizer. By this means the sterilizer can be brought to a temperature of 99° C. within 5 minutes, and by the use of a reducing valve the temperature can be controlled at any desired degree.

Catalase, a new enzym of general occurrence, O. Loew (*U. S. Dept. Agr. Rpt. 68, pp. 47*).—In the examination of many samples of tobacco the author found that one sample from the crop of 1898 contained a very energetic enzym capable of developing oxygen by the addition of hydrogen peroxid. Tests showed that neither diastase, proteolytic enzym, emulsin, oxidase, or peroxidase were present in the sample. From further study the conclusion was reached that another enzym was present, which the author calls catalase. A résumé of previous work on the decomposing power of certain enzyms upon hydrogen peroxid, and the investigations of the author upon the enzym catalase, are given at some length. The new enzym was found to exist in both an insoluble and a soluble form, distinguished as α- and β-catalase. Quite a number of tests are reported, showing the presence of catalase in a number of plant and animal organs, and tables are given showing the amount of oxygen given off by treating the various substances with hydrogen peroxid. The method of preparing the enzym and the effect upon it of various salts, acids, bases, and other compounds, are shown. The persistence of the enzym is found to be greater than that of any other contained in vegetable organs, so far as tested. Some herbarium specimens showed its presence after a lapse of over 50 years.

From a number of tests the author concludes that catalase belongs to the oxidizing group of enzyms. Owing to its very general occurrence, its presence is not believed to be accidental, but that it plays some rôle in the physiological processes; and the energy with which it attacks hydrogen peroxid, suggests the view tentatively that its rôle in the animal and vegetable organism may be the breaking down of this product, which has been claimed by some authors to be a product of organic growth. The various views upon the formation of hydrogen peroxid in living cells are reviewed, and the author's suggestions of the probable relation of catalase to the life processes of the cells submitted.

Oxidizing ferments in phanerogams, N. Passerini (*Nuov. Gior. Bot. Ital., 6* (*1899*), *pp. 296–321; abs. in Jour. Roy. Micros. Soc.* [*London*], *1900, No. 3, p. 342*).—In examining with the guiacum test about 100 species of flowering plants belonging to 49 different families the author found evidence in all but about 20 of at least a trace of oxidase in some organ of the plant. The part in which it was most constantly present was the root. In the stem it is often stronger in the bark than in the pith. In the leaves oxidases are most commonly entirely wanting or present only in very small quantities and are then generally localized along the veins. When present in the flower these ferments are more abundant in the pistils than in the stamens. In the stamens they occur chiefly in the filaments. In fruits they are most abundant in the pericarp, disappearing in the seed before maturity. In general the reaction is strongest in those organs which change color rapidly on exposure to the air. In a number of aquatic plants examined oxidases appeared to be absent.

Upon the occurrence and function of proteolytic enzyms in germinating seeds, W. BUTKEWITSCH (*Zhur. Opuit. Agron., 1 (1900), No. 3, pp. 233–255; Ber. Deut. Bot. Gesell., 18 (1900), No. 8, pp. 358–364*).—The author reports studies on the germinated and unsprouted seeds of *Vicia faba*, *Ricinus major*, *Lupinus luteus*, and *L. angustifolius*. To ascertain the presence of proteolytic enzyms the seeds were dried and pulverized in a mortar, after which they were treated with ether for 2 or 3 days, and the extract kept in an Erlenmeyer flask in a thermostat for some time, and then examined. The treatment was considered fatal to all organisms and destructive of living protoplasm; yet in every case examined a change in the albuminoid matter had taken place, with a formation of amid compounds. The enzym present agreed closely with the trypsin of animal organisms, as has already been reported by Green. The shoots of *Lupinus luteus* and unsprouted seed of *L. angustifolius* were found to contain a body very similar to zymogen. The proteolytic enzym in the seeds, according to the author's experiments, showed sufficient activity to transform all the protein reserve material contained in the seeds. A detailed report of the author's investigations is published in *Ztschr. Physiol. Chem.*, 32 (1901), No. 1–2, pp. 1–53.

Ferment of seeds with horny endosperm, E. BOURQUELOT and H. HÉRISSEY (*Compt. Rend. Acad. Sci. Paris, 130 (1900), No. 11, pp. 731–733*).—The authors regard the seed of carob as the type of seed with a horny endosperm composed for the greater part of mannan and galactan. During germination the embryo secretes a soluble ferment which hydrolyzes the carbohydrates of the endosperm, producing mannose and galactose. Similar results are obtained with fenugreek and alfalfa. The action of these soluble ferments is comparable to that of dilute sulphuric acid. The ferment obtained from these 2 plants, which appears to be distinct from that found in the carob, is called seminase.

The presence of seminase in seeds having a horny endosperm, E. BOURQUELOT and H. HÉRISSEY (*Compt. Rend. Acad. Sci. Paris, 131 (1900), No. 22, pp. 903–905*).—Examination was made by the authors of the seed of alfalfa and indigo, with the result that they found present a small quantity of a soluble ferment, seminase, capable of liquefying the horny endosperm and transforming it to a form of sugar capable of being assimilated.

Cacao fermentation, A. PREYER (*Tropenpflanzer, 5 (1901), No. 4, pp. 157–173, figs. 4*).—The process of fermentation of cacao is described, and the author claims to have isolated an organism which is concerned in the fermentation, to which the name *Saccharomyces theobromæ* is given. It is described and the results of experiments with pure cultures stated. A modified method of cacao fermentation is described at some length.

Diastases and their uses, C. POZZI-ESCOT (*Les diastases et leurs applications. Encyclopédie-scientifique des aidemémoire. Paris: Gauthier-Villars, 1901, pp. 219*).

A proteolytic and a protein-coagulating enzym in germinating barley, F. WEIS (*Ztschr. Physiol. Chem., 31 (1900), No. 1–2, pp. 79–97*).

The formation of solanin in potatoes as a result of bacterial action, R. WEIL (*Pharm. Ztg., 1900, No. 93, p. 901*).

A diastatic enzym in the potato plant, A. MEYER (*Jour. Landw., 48 (1900), No. 1, pp. 67–70*).

On the oxydase in kaki fruit, K. Aso (*Bot. Mag. [Tokyo], 14 (1900), No. 166, pp. 285–289*).

A physiological function of oxydase in kaki fruit, K. Aso (*Bot. Mag. [Tokyo], 14 (1900), No. 166, pp. 179, 180*).

METEOROLOGY.

Report of the Chief of the Weather Bureau, 1898–99, W. L. Moore (*U. S. Dept. Agr., Weather Bureau Rpt. 1898–99, I, pp. 247*).—The first part of this report contains an account of the operations of the Weather Bureau during the year ended June 30, 1899 (E. S. R., 11, p. 621); part 2, a list of observing stations and changes therein during 1898, and hourly averages of atmospheric pressure, temperature, and wind at 28 stations; part 3, monthly and annual meteorological summaries for 159 stations; part 4, monthly and annual means and extremes of temperature and dates of first and last killing frosts; and part 5, monthly and annual precipitation.

Report of the Chief of the Weather Bureau, 1899–1900, W. L. Moore (*U. S. Dept. Agr., Weather Bureau Rpt. 1899–1900, pp. 436*).—This includes an administrative report giving a general account of the operations of the Bureau during the year,[1] and reports containing a list of observing stations and changes therein during 1899 and hourly averages of atmospheric pressure, temperature, and winds from the records of automatic instruments at 28 stations; monthly and annual meteorological summaries for 170 Weather Bureau stations; monthly and annual means and extremes of temperature and dates of first and last killing frost, 1899; monthly and annual precipitation; miscellaneous meteorological tables and reports, including data relating to sunshine and excessive precipitation in 1898 and 1899, and pressure, temperature, etc., for the West India stations; and meteorological observations of the second Wellman expedition.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 29 (1901), Nos. 1, pp. 1–48, pls. 2, figs. 3, charts 10; 2, pp. 49–98, pls. 5, figs. 10, charts 8; 3, pp. 99–144, pl. 1, charts 9*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of January, February, and March, 1901, recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 1, special contributions on The relation of rainfall to mountains, by W. H. Alexander; Climate and corn, by H. B. Wren; Methods employed in the distribution of weather forecasts, by J. Berry; Long range seasonal forecasts for the Pacific Coast States, by A. McC. Ashley; Some features of the climate of Idaho (illus.), by S. M. Blandford; Studies on the atmosphere at Trappes, France, by L. Teisserenc de Bort; Relation of the water level of Great Salt Lake to the precipitation (illus.), by L. H. Murdoch; The water level of Great Salt Lake, by G. K. Gilbert; and Fog studies on Mount Tamalpais: Number 3—photographs of fog billows, (illus.), by A. G. McAdie; and notes by the editor on the Milwaukee convention of Weather Bureau officials, station libraries, lectures and instruction by Weather Bureau men, and cumulus clouds above columns of smoke.

No. 2, Special contributions on Ice caves at Flagstaff, Ariz., by Mrs. E. Renoe; Relative length of warm and cold seasons, by H. Pennywitt; The rainfall of the Leeward and Windward islands, by M. S. W. Jefferson; The relation between the level of Great Salt Lake and the rainfall (illus.), by S. F. Mackie; Fog studies on Mount Tamalpais: Number 5—wreck of the Pacific Mail steamship Rio de Janeiro (illus.), by A. G. McAdie; Lake Ladoga from a thermic point of view (illus.), by J. de Schokalsky; and Frost fighting, by A. G. McAdie; and notes by the editor on Mr.

[1] Published also as Weather Bureau Doc. 231, and in Report of the Secretary of Agriculture, 1900.

Howard Shriver, Dr. Earl Flint, Herbertson's distribution of rainfall over the land, the storms of the Hawaiian Islands, the rainfall and evaporation of Great Salt Lake, Harvard's meteorological stations, reflection by clouds of light from a distant fire, history of meteorology in Belgium, official standard time, the work of the Meteorological Institute of Prussia, temperature of deep lakes, ice caves, Weather Bureau men as instructors, English v. metric system of measurements, the structure and formation of hail, Hann's new meteorology, the relative duration of the normal warm and cold seasons, the weather in distant regions, and new determination of vapor tension.

No. 3, special contributions on Fog studies on Mount Tamalpais: Number 4 (illus.), by A. G. McAdie; Pressure of saturated aqueous vapor at temperatures below freezing, by M. Thiesen; Auroral observations on the second Wellman expedition made in the neighborhood of Franz Josef land, by E. B. Baldwin; and Damage by hail in spite of cannonading, by J. M. Pernter; and notes by the editor on snow crystals, charts of atmosphere humidity, J. Brown Hicklin, normals for Manila, the new Philippine weather service, Weather Bureau men as instructors, dust storms and red rain, the permanence of climate, and the moon and the weather.

Report of the meteorological council for the year ending March 31, 1900, to the president and council of the Royal Society (*London: Government, 1900, pp. 158, fig. 1, charts 2*).—Gives an account, with numerous appendixes, of the operations of the weather service during the year.

The application of meteorology to agriculture, J. Vandervaeren (*Des applications de la météorologie en agriculture. Brecht: L. Braeckmans, 1900, pp. 33, pl. 1*).—The pamphlet discusses weather forecasting, briefly describing the systems followed in Belgium, France, England, Switzerland, and the United States, and explains weather signals and other means of disseminating weather predictions and storm warnings. A brief note on the importance of climatological observations is added.

Meteorological observations, 1900, L. G. Carpenter, R. E. Trimble, et al. (*Colorado Sta. Rpt. 1900, pp. 165–211, 217, 218*).—This is a tabulated daily and monthly summary of observations, during 1900, on temperature, pressure, precipitation, dew point, relative humidity, terrestrial and solar radiation, wind movement, and days of frost at Fort Collins, Colorado; monthly summaries of similar observations at Rockyford and Cheyenne Wells; and monthly summaries of observations on temperature and precipitation at the base of Long's Peak, near Estes Park, elevation about 9,000 ft.; Gleneyre, elevation 8,000 ft.; Pinkhampton, North Park, elevation 8,400 ft. Tables are also given which summarize the monthly and annual precipitation at 8 different points in the State, and show the monthly and annual rainfall at Fort Collins for the period from 1872 to 1900 with the normals for that period. The following is a summary of the principal meteorological data reported for Fort Collins: Mean temperature (½ maximum and ½ minimum), 48° F.; maximum, 94.4°, June; minimum, —23.4°, February; precipitation, 19.21 in.; snow fall, 52.1 in.; mean relative humidity, 66.3 per cent. The normals for this place are, temperature, 46.5° F., precipitation, 14.14 in.; mean relative humidity, 65.1 per cent.

Meteorological report, J. Dryden (*Utah Sta. Rpt. 1900, pp. XLV–XLVIII*).—Tables are given which show the average monthly temperature and precipitation for 12 representative points in the State, compiled from the monthly reports of the U. S. Weather Bureau. This is a continuation of the records published in a previous bulletin (E. S. R., 8, p. 963), bringing these records up to the end of 1898, except in case of Salt Lake City, for which they are brought up to the end of 1899. In case of Corinne and Ogden the figures represent averages of 29 years, for Salt Lake City 30 years, and for all other places 8 years. The mean temperature for the State, calculated from these records, is 46.8° F., the total rainfall, 12.17 in.

Barometers and the measurement of atmospheric pressure, C. F. Marvin (*U. S. Dept. Agr., Weather Bureau Doc. 241, pp. 94, figs. 23*).—This is a second edition of "a pamphlet of information respecting the theory and construction of barometers in general, with summary of instructions for the care and use of the standard Weather Bureau instruments."

The mean diurnal variation of temperature at Tacubaya, M. Moreno y Anda (*Mem. y Rev. Soc. Cient. "Antonio Alzate," 15 (1900–1901), No. 5–6, pp. 189–200*).—This is a contribution to the study of the climatology of the valley of Mexico.

Protection against hail, J. Roberts (*Grêle, 2 (1901), Nos. 4, pp. 3–5, fig. 1; 5, pp. 3–9, figs. 3*).

Agronomic charts and the agricultural situation of the Canton of Redon, G. V. Lechartier (*Cartes agronomiques et situation agricole du Canton de Redon. Rennes: Oberthur, 1900, pp. 74*).—This pamphlet explains the agricultural chart showing the composition and fertilizer requirements of the soils of Redon, based on analyses of 229 samples.

AIR—WATER—SOILS.

On the elimination of methane in the atmosphere, M. Urbain (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 6, pp. 334–336*).—Previous studies on this subject are briefly referred to and experiments are reported which indicate that the disappearance of the methane from the air is not entirely, or even largely, due to the oxidizing action of ozone, but to its absorption by plants. The latter fact was brought out by growing plants in an atmosphere containing varying amounts of methane and observing the amount of methane which had disappeared at the end of different periods.

Evaporation from water surfaces, L. G. Carpenter (*Colorado Sta. Rpt. 1900, p. 216*).—A table is given which shows the monthly and annual evaporation from a tank 3 by 3 by 3 ft. flush with the ground at Fort Collins during 14 years, 1887–1900.

Mineral-water industry (*Spec. [U. S.] Consular Rpts., 22 (1901), pt. 2, pp. 85–212*).—This is a report of consuls of the United States on the extent of trade in mineral waters in various countries of Europe, India, Japan, Siberia, Syria, Palestine, Asia Minor, New South Wales, New Zealand, Victoria, and Mexico.

The chemical composition of the soils of the southwestern districts of the Cape Colony, C. F. Juritz (*Trans. Phil. Soc. South Africa, 11 (1900), pt. 2, pp. 125–160, charts 5; Agr. Jour. Cape Good Hope, 18 (1901), Nos. 6, pp. 328–338; 7, pp. 391–401; 8, pp. 452–462*).—An account is here given of the work done to date, January 31, 1900, on the systematic soil survey of the Colony which was begun in 1892 and which has been noted from time to time (E. S. R., 12, p. 122). The results are reported in tabular form and in charts, and there is a brief discussion of the general subject of soil analysis and of the practical application of the analytical data reported, with a description of the methods used in this investigation. These methods are in brief as follows: The samples are taken to a depth not exceeding 12 in. and sufficiently below the surface to avoid top growth and accumulations. The sample is washed through a $\frac{1}{2}$ mm. mesh sieve. The part passing the sieve, together with the residue from the evaporation of the water used in washing it through, is designated fine earth and is used for the determination of lime, potash, and phosphorid acid. The portion which does not pass through the $\frac{1}{2}$ mm. mesh sieve is dried and sifted through a 1 mm. mesh sieve. The part passing through is designated coarse sand and is included with the fine earth in determining moisture, organic matter, chlorin, and nitrogen.

To prepare the solution for analysis, allow 200 gm. of the fine earth to remain in contact with 400 cc. of hydrochloric acid (sp. gr. 1.115) in a large flask for 5 days at ordinary temperature, shaking thoroughly from time to time. Filter through dry plaited filters into a dry flask, evaporate 250 cc. of the filtrate to dryness, using first a small open flame, then the water bath, and finally a sand bath or air oven at 120° C., adding during the evaporation a few cubic centimeters of strong nitric acid.

Moisten the residue with strong nitric acid and again evaporate to dryness. To expel nitric acid, moisten the residue with hydrochloric acid and evaporate nearly to dryness on the water bath, taking care to prevent the formation of crusts. Dry the residue in an air bath for an hour, treat with warm water and 20 per cent solution of hydrochloric acid, wash into a 250 cc. flask, boil for 15 minutes, and after cooling fill the flask to the mark with distilled water, and filter the solution.

For the determination of lime add to 50 cc. of this filtered solution in a 250 cc. flask 2 or 3 drops of rosolic-acid solution and ammonia from a dropping tube until a pinkish color appears. Boil until the pink color almost disappears, thus precipitating alumina and oxid of iron. After cooling, fill the flask to the mark, shake thoroughly, and filter into a 300 cc. flask, the solution being made to the mark. To 100 cc. of this filtrate add 3 to 5 drops of acetic acid and 20 cc. of a 4 per cent ammonium oxalate solution. Keep on a water bath for 6 hours and filter through double filter papers. Ignite the precipitate first over a Bunsen flame, then heat strongly in a furnace for 10 minutes. This gives the weight of lime.

To determine potash, boil 50 cc. of the original soil extract in a 250 cc. flask, add 5 cc. of a 10 per cent solution of barium chlorid and boil again for some time, add a few drops of rosolic acid and boil with ammonia, as in case of the lime determination. When partly cool add 2 or 3 gm. of crystalline ammonium carbonate and raise the temperature at once to the boiling point to separate lime and barium. After complete precipitation of the latter cool the liquid, fill the flask to the mark, and filter the solution. Evaporate 100 cc. of this filtrate to dryness in a platinum dish on a water bath, heat carefully to expel all ammonium salts, and wash the residue through a filter with boiling water into a glass dish. Add 2 cc. of a 10 per cent solution of platinum chlorid and evaporate to dryness on a water bath. After cooling add 80 to 82 per cent alcohol to the residue, allow to stand for at least half an hour, filter through a Gooch crucible, using the filter pump, and wash first with 96 per cent and then with absolute alcohol, drying the precipitate for 2 hours in a water oven. After weighing the crucible, wash the double salt through with boiling water, follow with alcohol, dry, and weigh, taking the difference between the two weighings as the amount of potassium platinum chlorid. This multiplied by 0.193 gives the quantity of potash in 10 gm. of soil.

To determine phosphoric acid, add 25 cc. of concentrated nitric acid to 25 gm. of fine earth in a 500 cc. flask and shake thoroughly. Then add 50 cc. of concentrated sulphuric acid and again shake the mixture carefully. Heat gently, shaking at frequent intervals, and if this does not secure complete oxidation add more nitric acid and continue the heating. Cool the mixture, dilute to the mark with distilled water, shake well, and filter. Nearly neutralize 200 cc. of the filtrate with strong ammonia solution, a few drops of nitric acid being used to acidulate the mixture in case the limit is exceeded. Add 200 cc. of molybdic solution prepared as follows: Dissolve 150 gm. of ammonium molybdate in a liter of water, adding 1 liter of nitric acid (sp. gr. 1.2), and heat to a temperature of 50° C. for 3 hours in a water oven. Allow to cool completely and decant the liquid through a small filter, washing the precipitate in the flask with dilute molybdic solution. Dissolve the precipitate in warm 4 per cent ammonia, acidulate slightly with hydrochloric acid, and add 20 cc. of magnesia mixture, drop by drop, at the rate of 1 cc. every 5 seconds, and then 25 cc. of 5 per cent ammonia. Shake the mixture for a short time and allow to stand for 2 hours. Filter through a Gooch crucible, wash with 5 per cent ammonia solution, dry first on an iron plate, then ignite in a furnace for 15 minutes, cool, and weigh.

Of the 212 samples of soil of which analyses are reported, only 45 contained normal amounts of lime, 167 were fairly supplied with lime, and 86 were decidedly poor in this constituent. Only 15 contained a normal amount of phosphoric acid and 124 would be classed as poor in this constituent. As regards potash, 57 samples contained normal amounts and 53 were poor. The results therefore indicate that the greatest need of the soils is phosphoric acid, the second most important requirement being lime. A comparison of hillock soils with those of the level ground showed that the former are much more fertile than the latter, although still in need of improvement.

Humus and carbon in cultivated soils, A. Pagnoul (*Bul. Sta. Agron. Pas de Calais, 1900, pp. 9–15*).—In an examination of 11 samples of soil no fixed relation was found to exist between carbon and nitrogen, but apparently the carbon, nitrogen, and humus degree varied in the same direction, although irregularly.

Investigations on the cohesiveness of soils and on mechanical and physico-chemical analysis, S. von Piedzicki (*Mitt. Landw. Inst. Univ. Leipsic, 1901, No. 2, pp. 1–54*).

Soil temperatures, L. G. Carpenter (*Colorado Sta. Rpt. 1900, pp. 212–215*).—This is a tabulated record of weekly observations on soil temperatures at different depths in irrigated and unirrigated soils.

Value of the incidental increment of plant food in soils (*Trinidad Bot. Dept. Bul. Misc. Inform., 1901, No. 27, pp. 325–327*).—It is claimed that plants derive much more plant food from soils than chemical analysis accounts for. "A large amount of incidental plant food is evidently conveyed by rain water. . . . It appears probable also that the fertility given by the deposited excreta of small animals, birds, insects, and worms and reptiles, and the decay of their bodies upon the ground, and also the decay of vegetable matter, dust deposited by wind, leaves, flowers, seeds, and branches, etc., is largely in excess of what has been previously estimated, and in fact is of as much importance as food obtained from the reserves held by the soil itself. This must be known as the 'incidental increment,' and must be taken into full account in all agricultural operations."

FERTILIZERS.

The substitution of soda for potash in plant growth, W. H. Jordan and C. G. Jenter (*New York State Sta. Bul. 192, pp. 333–350, pls. 6*).—The results of previous investigations on this subject are briefly reviewed, and an account is given of experiments at the station during the winters of 1898–99 and 1899–1900. These experiments were carried on in a forcing house, with galvanized iron pots containing 25 lbs. of ground quartz rock passing a 0.025 in. mesh sieve. Drainage was secured in the pots by a layer of 4 to 6 lbs. of quartz chips, and aeration was provided for by connecting the drainage material with glass tubes extending up the sides of the pots above the sand. One series of pots received no fertilizers. The kinds and quantities of fertilizing material used in 5 other series are shown in the following table:

Kinds and amounts of fertilizing materials added to each pot.

Order in series.	Acid phosphate.	Potassium nitrate.	Sodium nitrate.	Magnesium sulphate.	Ammonium nitrate.	Calcium carbonate.	Ferric chlorid.
	Grams.	*Grams.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*
1	7.5	5.0	5.0	2.5	....	5.0	1.0
2	7.5	5.0	....	2.5	2.35	5.0	1.0
3	7.5	....	5.0	2.5	2.00	5.0	1.0
4	7.5	....	....	2.5	4.35	5.0	1.0
5	....	....	....	....	4.35	....	....

Calcium carbonate was added in each case in sufficient quantity to neutralize any acidity which might arise. The crops grown were barley, tomatoes, and peas. The data secured and reported in the bulletin include yield and moisture, potash, and soda content of the air-dry crop. The results are summarized as follows:

"(1) A deficiency of available potash greatly depressed the growth of the plant even in the presence of an abundant supply of soda salts. A lack of soda in the presence of potash sufficient for the plant's needs seemed to have no deleterious effect whatever upon growth.

"(2) Plants to which the necessary supply of potash was not accessible took up more soda than when potash was present in abundance. Soda may be substituted for potash in quantity when the latter is lacking.

"(3) While the substitution may take place in quantity, it evidently can not do so in function, as is shown by the limited growth when the plants were deprived of potash, even though soda was appropriated in increased proportions.

"(4) The experiments incidentally suggest the view that the real need of plants for certain essential mineral constituents is not even approximately measured by the proportions of these constituents which the plant takes up."

Can plants use soda in place of potash? F. H. Hall, W. H. Jordan, and C. G. Jenter (*New York State Sta. Bul. 192, popular ed., pp. 10, figs. 4*).—This is a popular summary of the above bulletin.

The relative values of some nitrogenous fertilizers, W. A. Withers and G. S. Fraps (*North Carolina Sta. Bul. 176, pp. 15–22*).—The bulletin calls attention to the results obtained by Müntz and Girard, and Bonâme (E. S. R., 9, p. 732) in studies of the rate of nitrification of fertilizers, and also to the work of Jenkins and Britton on the availability of nitrogenous fertilizers (E. S. R., 10, p. 232), and reports experiments on the relative rate of nitrification carried out as follows:

"A sandy clay soil from a pasture was sifted through a coarse sieve (6 meshes to the inch), and a quantity of material equivalent to 0.6 gm. nitrogen was intimately mixed with 1,000 gm. of the soil. The soil was then placed in precipitating jars and kept in a dark closet, enough water being added to raise the percentage from 6.3 to 11.6. At suitable periods 3 of the jars were weighed, and the estimated loss of water was replaced in all the jars. The temperature was 28 to 30° C., and the time was 3 weeks. When calcium carbonate was added, the amount was exactly sufficient to combine with the nitrogen of the fertilizer if the entire amount were converted to nitric acid. At the end of the experiment the nitrates were leached out and the amount determined by the Tiemann-Schulze method. The amount of nitrates found in a blank experiment was deducted from the total."

The results of these experiments, as well as of tests of the solubility in pepsin-hydrochloric acid and neutral permanganate, and of vegetation tests with oats and Hungarian grass made by Jenkins and Britton, are given in the following table.

Rate of nitrification and availability of various nitrogenous fertilizers.

Fertilizer.	Rate of nitrification.				Availability.		
	Without calcium carbonate.		With calcium carbonate.		By potassium permanganate method.	By pepsin-hydrochloric acid method.	By vegetation test.
Series I:	*Per cent.*	*Rank.*	*Per cent.*	*Rank.*	*Per cent.*	*Per cent.*	*Per cent.*
Dried blood	34.8	100	54.9	100	94.4	94.7	73.3
Cotton-seed meal	33.9	97	54.8	100	91.1	91.1	64.8
Dried fish	30.3	87	46.5	85	88.7	67.3	63.9
Tankage	26.2	75	34.8	63	88.3	56.4	49.4
Bat guano	22.4	64	35.8	65	75.1	56.4	....
Bone	18.9	54	16.6	30	64.2	92.3	16.7
Bone (6 weeks)	21.7	....	17.4	....	....	....	....
Ammonium sulphate	1.3	4	31.1	55	100.0	100.0	....
Nitrate of soda	....	....	....	....	100.0	100.0	100.0
Series II:							
Cotton-seed meal	26.7	....	....	....	....	....	....
Ammonium sulphate	3.4	....	32.6	....	....	....	....

The conclusions drawn from this work are as follows:

"(1) The nitrification of blood takes place more rapidly when it is mixed with a large quantity of soil than with a small quantity.

"(2) The order of nitrification in the soil used was dried blood (most nitrified), dried fish, tankage, bat guano, bone, ammonium sulphate. Excluding the ammonium sulphate, this is the order of availability, as measured by vegetation tests, and solubility in permanganate of potash.

"(3) When calcium carbonate was added to the soil, the nitrification was greatly accelerated, and the order became dried blood, cotton-seed meal, dried fish, bat guano, tankage, ammonium sulphate, bone.

"(4) When ammonium sulphate is used as a fertilizer, in most cases it would be advisable to add calcium carbonate in some form also.

"(5) The low rate of nitrification of ammonium sulphate is probably due to the presence of organisms which nitrify organic compounds in preference to ammonium salts. The presence of the ammonium sulphate may also hinder the activity of the nitrifying organisms. The acids formed may also be a hindrance when no base is present to neutralize them. All three of these causes may be in operation at the same time."

The assimilation of free nitrogen by soil bacteria without symbiosis with leguminous plants, J. Kühn (*Fühling's Landw. Ztg., 50 (1901), No. 1, pp. 2–9*).—This article is a discussion of the results of fertilizer experiments in progress on the experiment fields of the University at Halle since 1878. The fertilizers applied annually on the different plats were barnyard manure, superphosphate and kainit, superphosphate and kainit in conjunction with ammonium sulphate and nitrate of soda, and ammonium sulphate and nitrate of soda alone. A check plat received no manure. In 1892 the results showed that where the nitrogenous and nonnitrogenous fertilizers were used together the quantity of nitrogen in the yield was greater than in the crop which had received only nonnitrogenous fertilizers, the proportion being about as 3 to 2. The author discusses the question as to where the nitrogen came from which was contained in the crop receiving no nitrogenous fertilizers. The results bearing on this subject obtained by different investigators, and indicating the increase of the available supply of nitrogen in the soil through the activity of soil bacteria without a symbiotic relation with leguminous plants, are reviewed.

Pot experiments in 1899, J. Hanamann (*Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 5, pp. 575–582*).—Experiments were conducted for three years in succession to determine the residual effects of different fertilizer combinations applied the first year the experiments were in progress. Four different kinds of soil—sand, sandy loam, loam, and clay—were used. The results for the season are recorded in detail and the observations on the action of different fertilizer substances discussed. An experiment with different reagents to test the solubility of phosphoric acids in soils is reported.

Comparative tests of fertilizing value of two new phosphates, Grimm (*Chem. Ind., 24 (1901), p. 213; abs. in Chem. Ztg., 25 (1901), No. 28, Repert., p. 106*).—Comparative tests of Wiborgh phosphate and Wolters ground phosphate on mustard, alfalfa, and barley grown in pots containing 7,000 gm. of soil are reported. The Wiborgh phosphate used contained 26.09 per cent of total phosphoric acid, 25.47 per cent of citrate-soluble phosphoric acid, 37.9 per cent of lime, 1.39 per cent of potash, and 8.76 per cent of silica. The Wolters phosphate contained 16.25 per cent of total phosphoric acid, 15.08 per cent of citrate-soluble phosphoric acid, 25.77 per cent of lime, and 28.36 per cent of silica. The latter material is prepared by fusing crude phosphates with siliceous material, sand or glass, and calcium carbonate. Its phosphoric acid was apparently more available to plants in these experiments than that of the Wiborgh phosphate.

Green manure and phosphorite as a fertilizer, A. N. ENGLEHART (*Abs. Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 6, pp. 631–648*).—This article, an abstract of a book review, treats of the use of phosphorites as fertilizers and reports the results from the use of finely ground phosphorites and barnyard manure in growing rye, the application of finely ground phosphorites alone as a fertilizer for barley, oats, potatoes, and rye, and the use of lime as compared with phosphorites. The effect of applications of phosphorites is also shown. The experiments here reported cover the period of 1885 to 1889.

Fertilizing value of steamed bone meal, F. W. DAFERT (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 2, pp. 96–98*).—In reply to the claim of Kellner and Böttcher (E. S. R., 12, p. 323) that the phosphoric acid of bone meal is very incompletely utilized on soils abundantly supplied with lime, but is very effective on those poor in this constituent, the author reports the results of experiments on both kinds of soils which seem to show that there is no definite relation between the lime content of the soil and the action of the bone meal. He therefore concludes that the action of bone meal does not depend upon the lime content of the soil, but upon other conditions.

Fish scrap fertilizers, W. H. HEILEMAN (*Washington Sta. Bul. 44, pp. 13*).—This bulletin is supplementary to a previous one (E. S. R., 12, p. 225), dealing with the sources, uses, and value of commercial fertilizers. It calls attention to the value and importance of dried fish and fish scrap fertilizers, which are very abundant in the State, but are now allowed to go to waste.

Commercial fertilizers, M. A. SCOVELL, A. M. PETER, and H. E. CURTIS (*Kentucky Sta. Bul. 90, pp. 201–230*).—This bulletin reports the results of the inspection, including analyses and valuations, of 175 samples of fertilizers examined during the last half of 1900.

Analyses of commercial fertilizers, H. B. MCDONNELL ET AL. (*Maryland Agr. College Quart., 1901, No. 11, pp. 55*).—This bulletin reports the results of analyses and valuations of 479 samples of fertilizing materials examined during the last half of 1900.

Analyses of fertilizers, C. A. GOESSMANN (*Massachusetts Hatch Sta. Bul. 74, pp. 16*).—This bulletin contains instructions regarding the sampling of fertilzers; notes on valuation of fertilizers; the Massachusetts laws relating to commercial fertilizers, with instructions to manufacturers, agents, etc.; and analyses of 64 samples of fertilizing materials, including wood ashes, ashes from jute waste, hair waste, wool waste, cotton waste, tobacco and tobacco dust, cotton-seed meal, linseed meal, hen manure, sheep manure, sewage, sizing paste, fleshings, bone, and soils (5 samples).

Registration and analyses of fertilizers, B. W. KILGORE (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 3, pp. 3–25*).—A list with guaranteed analyses of fertilizers registered during 1901, and analyses and valuations of 128 samples of fertilizers examined during the spring of 1901 are given, with explanations of terms used in analyses of fertilizers, notes on valuation, and a statement of freight rates from the seaboard to interior points of the State.

Analyses of commercial fertilizers, J. HAMILTON and W. FREAR (*Pennsylvania Dept. Agr. Bul. 72, pp. 171*).—This bulletin contains the text of the fertilizer law of Pennsylvania, notes on valuation, a discussion of the composition of raw materials and the cost of fertilizer constituents, and tabulated analyses and valuations of 716 samples of fertilizing materials examined during 1900. The average composition of the fertilizers examined during 1900 is given and their selling price and valuation are compared with similar data for fertilizers examined during previous years.

Analyses of commercial fertilizers, J. L. HILLS, C. H. JONES, and B. O. WHITE (*Vermont Sta. Bul. 86, pp. 123–144*).—This bulletin contains analyses and valuations of samples of 40 brands of fertilizers, with notes on valuation, etc., and tables showing the composition of the leading brands of fertilizers examined by the station during the past 5 years, 1896–1900.

FIELD CROPS.

Fourth report on the agricultural investigations in Alaska, 1900, C. C. GEORGESON (*U. S. Dept. Agr., Office of Experiment Stations Bul. 94, pp. 83, pls. 24*).—This report deals with experiments in growing cereals and vegetables at the Sitka and Kenai experiment stations and at numerous other points, and the steps taken to establish experiment stations at Rampart and Fort Yukon in the valley of the Yukon River.

Spring wheat, barley, rye, oats, emmer, millet, buckwheat, and corn were grown experimentally and the results obtained, together with the character and habits of growth of the different varieties, are reported. The qualities sought in cereals for the region are earliness and ability to stand up well during stormy weather. Romanow has proven the best and earliest variety of spring wheat thus far grown. Ladoga equals it in earliness, but is inferior in vigor and in yield. Among the different varieties of barley, Mansbury has given the best results and Sisolsk, an imported Russian variety, promises to stand next in value. Swedish rye, sown in May, 1899, and left undisturbed the following winter, gave a good yield. It averaged 5 ft. high in July of this year, produced heads about 6 inches long and ripened early in September. The most promising variety of oats with regard to earliness and strength of straw was Burt Extra Early, but it produced rather light yields of both grain and straw. The other varieties grown, although doing well, were either not quite early enough or did not have sufficient strength of straw. Ufa spring emmer matured early enough but was found inferior in quality to the grains already grown in that region. The best buckwheat thus far tested is Orenburg, a variety imported from Russia. A variety of early corn was grown, but it proved a failure, and the author doubts the successful culture of corn in Alaska, even for feed.

Fertilizer experiments were conducted with barley, oats, and potatoes on soil consisting largely of decayed moss and rotten and disintegrated wood. In its virgin state, this soil is almost entirely sterile. The fertilizers applied in this connection were fish guano, stable manure, and seaweed, used alone or in conjunction with lime. On unfertilized new land all the crops were failures. The best barley was grown on land fertilized at the rate of ½ ton of fish guano and a ton of lime per acre. Applications of 20 tons of seaweed with 2,000 lbs. of lime and a ton of fish guano alone per acre also gave good yields of barley. Lime when used alone was not very beneficial. Oats made very satisfactory growth on plats fertilized with fish guano alone and in conjunction with lime. Potatoes grown without manure gave very poor results, but with fish guano and lime a fair crop was produced and a still better yield was obtained from the use of seaweed as a fertilizer. These results "would indicate that the sterility of new soil is due chiefly to a lack of available plant food, and that the improvement which takes place in the land under cultivation is due to the gradual liberation of the elements of plant food, probably caused chiefly by the action of the atmosphere." The construction of brush drains was found an effective method for improving the land.

The bulletin further reviews the agricultural possibilities of different sections of Alaska, and reproduces reports on gardening operations by settlers in various parts of the coast region. The author made a tour of investigation into the interior of the territory and surveyed two proposed sites for agricultural experiment stations, one at Fort Yukon and the other at Rampart. The itinerary with full notes on the trip are given and the observations are recorded. Soil temperature and meteorological observations made at different points are shown in tables.

The influence of the water content of the soil on the development of plants, C. VON SEELHORST (*Jour. Landw., 48 (1900), No. 2, pp. 165–177, pls. 2*).—Experiments were conducted with oats and spring wheat to ascertain the influence of different quantities of water in the soil on the form and composition of the plants. Five grains were sown in each of 32 pots and the soil in all the pots received the same quantity of water to insure equal germination. When the plants had well started, the pots were divided into two series of 16 pots each. In the first series the water content was held at 47.4 per cent of the water-holding capacity of the soil, and in the second at 84.1 per cent. When the plants began to head, 4 pots of the first series were changed to the second and 4 pots of the second series to the first. The results obtained are tabulated in detail.

The tests with oats indicated that a high percentage of soil moisture during the early period of growth increases the number of internodes, and during the period of heading it increases the strength and the length of the culm. A high water content of the soil when the plants were heading considerably lengthened the two upper internodes and the rachis. The number of zigzags in the rachis, as well as the number of spikelets, was increased by a high percentage of soil moisture during early growth, while the number of blossoms developed in the spikelets was relatively much greater when the water content of the soil was high at the time of heading than when it was low. The weight of the grains responded to the same influences to which the growth of the head responded. The specific gravity of the grain was smallest in the cases of highest soil moisture at heading time. The proportion of glumes in the grain was largest in the series of high water content for the entire time of the experiments and in the 4 pots in which the water content had been decreased when the plants began to head. The nitrogen content of the grain decreased with the increase of the proportion of glumes. The author draws the general conclusions that a high percentage of soil moisture at the time of heading is highly important in increasing the yields of straw and grain.

The results with wheat were in many respects the same as with oats, but the effect of the water content during the early period of growth on the number of internodes was not so marked. It was also found that with wheat the length of the head depended upon a high water content during the early vegetative period. Increasing the amount of water in the soil at the time the wheat plants began to head did not increase the number of spikelets, but it was very effective in increasing the number of developed blossoms. The nitrogen content of the grains was influenced in the same manner as in the experiments with oats, and the specific weight of the grains agreed with their nitrogen content.

The influence of the water content of the soil and the application of fertilizers on the yield and composition of Italian rye grass and red clover, C. von Seelhorst, N. Georgs, and F. Fahrenholtz (*Jour. Landw., 48 (1900), No. 3, pp. 265, 286*).—The report on this investigation is prefaced by references to similar work by other investigators. The results obtained by Pagnoul, being to some extent opposed to those obtained by the authors, are quite fully described. The method of conducting the investigation is outlined and the results are tabulated and discussed.

The experiments were made in pots containing each 11 kg. of soil. One-half the entire number of pots received no fertilizer, while the rest of the clover pots received 1 gm. each of potash and phosphoric acid and 5 gm. of rich marl and the grass pots 1 gm. of nitrogen in the form of nitrate of soda in addition to this application. Four-tenths of a gram of clover seed and 0.6 gm. of grass seed were sown per pot. In each test 4 pots were treated alike. The different quantities of water used grouped the pots into 3 series, as shown in the table below:

Table showing the weight at which pots were held during different periods by controlling the water content of the soil.

Period.	First series.	Second series.	Third series.
	Grams.	*Grams.*	*Grams.*
May 8 to June 6	13,400	14,400	15,400
June 6 to June 22	14,400	15,400	16,400
June 22 to November 10	14,800	15,600	16,400

The results indicate that an increase in the water content of the soil within the limits of the experiment increased the yield of clover and the quantity of its most important food elements. The yield of rye grass was also increased, but owing to the dearth of nitrogen in the soil no appreciable increase in its protein content was obtained. The quality of the crops, however, suffered from an increase in the water content. The first cutting of clover showed a decrease in the percentage of protein and fat. In the rye grass the decrease in protein was greater than in the clover, which the authors again attribute to the insufficient supply of nitrogen in the soil. The percentage of dry matter in the green clover decreased with the increase of water in the soil. In general the percentage of ash in the plants increased as the water content of the soil increased. The influence of the fertilizers on the percentage of protein in the clover was very small but quite marked in the rye grass grown on the soil lowest in water content.

Agricultural, botanical, and chemical results of experiments on the mixed herbage of permanent grass lands, conducted for many years in succession on the same land; the chemical results, J. B. Lawes and J. H. Gilbert (*Phil. Trans. Roy. Soc. London, ser. B, 192 (1900), pp. 139–210*).—The topics treated in this paper are the botanical composition of the mixed herbage, chemical composition of the separated graminous, leguminous, and other herbage of the mixed produce of grass land; the state of existing knowledge as to the function of the mineral or ash constituents of vegetation; the conditions under which carbon dioxid is determined in plant ashes and the results obtained; and the dependence of the chemical composition of various crops on the character and the stage of their growth and on the fertilizers applied.

"The results show that the chemical composition of the mixed herbage is very directly dependent, not only on the supplies within the soil, and on the seasons, but also very prominently on the description of plants encouraged, and on the character of their development. . . .

"There were very characteristic differences in the composition of the ashes of different crops, according to the amounts of nitrogen they assimilated. Red clover, for example, yields large amounts of nitrogen over a given area, part of which is due to fixation, but much is certainly taken up as nitrates from the soil; and the results show that the greater the amount of nitrogen assimilated the more is the ash characterized by containing fixed base in combination with carbonic acid, presumably representing organic acid in the vegetable substance before incineration.

"The conclusion was that, independently of any specially physiological function of the bases, such as that of potash in connection with the formation of carbohydrates, for example, their office was prominently also that of carriers of nitric acid, and that when the nitrogen had been assimilated the base was left as a residue in combination with organic acid, which, according to the character of the plant, was represented more or less completely by carbonic acid in the ash.

"Further, existing knowledge—as to the condition in which nitrogen is found in soil waters, as to the action of nitrates used as manures, as to the presence of nitrates in still-growing plants, and as to the connection between the nitrogen assimilated and the composition of the ash as has been illustrated—points to the conclusion that, at any rate, a large amount of the nitrogen of the chlorophyllous vegetation on the earth's surface is derived from nitrates; while, so far as this is the case, the *raison d'être* of much of the fixed base found in the ashes of plants would seem to be clearly indicated. . . .

"When the more functionally important constituents are available in relative abundance, those which are of less importance in this respect are taken up and retained in less amount than they otherwise would be, the result being determined in great measure by the character of growth induced.

"Luxuriance or vegetative activity is intimately associated with the amount of nitrogen available and taken up. Further, chlorophyll formation to a great extent follows nitrogen assimilation. But the results relating to the increased amount of nonnitrogenous substance yielded in the mixed herbage under the influence of the various manures clearly indicate that the nitrogen being taken up and the chlorophyll formed, the carbon assimilation and the carbohydrate formation depend essentially on the amounts of potash available."

Alfalfa; methods of culture and yields per acre, E. B. VOORHEES and C. B. LANE (*New Jersey Stas. Bul. 148, pp. 3-15, pls. 4*).—This bulletin notes the growing importance of alfalfa on American farms, indicates methods of culture, and points out the usefulness and value of the plant. The yields from the different cuttings of alfalfa grown at the station, the cost of its culture per acre, the chemical composition, and the quantities of the various elements obtained per acre from the different cuttings are recorded in tabular form. The average production of green forage, dry matter, and total protein per acre of alfalfa, compared with corn, red clover, crimson clover, barnyard millet, cowpeas, and oats and peas, are also given. In 1899 and 1900 the yields of green forage were 20.21 and 26.60 tons per acre, respectively. The first cutting, made the latter part of May, was large in each year. The average cost for 3 years of growing alfalfa at the station was $29.20 an acre. On account of the permanent character of the crop, the average cost per acre was reduced as the number of crops increased. The authors recommend leaving alfalfa in the swath after cutting just long enough to become well wilted, and then to put it up into cocks to continue the curing process.

Bromus inermis, F. L. WATROUS, H. H. GRIFFIN, and J. E. PAYNE (*Colorado Sta. Bul. 61, pp. 10*).—This bulletin contains directions for the culture of *Bromus inermis*, and records the cultural tests with this grass on the college grounds and at the Arkansas Valley and the Plains substations since 1892. In summarizing the results the authors report that the growth of *B. inermis* has been very unsatisfactory. The greatest difficulty was experienced in obtaining a stand. The absence of rain after seeding, or even after the young plants had continued to grow, was sure cause of failure. It is believed that under more favorable moisture conditions the grass might succeed. On subirrigated land it made a growth of from 1 to 2 ft. high, but where flooded it became sod bound and made almost no growth.

Culture tests of cereals, EDLER (*Jahrb. Deut. Landw. Gesell., 15 (1900), pp. 221-225*).—A brief discussion on culture tests with grains.

Corn culture, J. F. DUGGAR (*Alabama College Sta. Bul. 111, pp. 95-154, fig. 1*).—This bulletin is a record of the results of experiments in corn culture, comprising variety, fertilizer, seed, and culture tests. Similar work has been previously reported (E. S. R., 9, p. 828). The results obtained during several seasons are discussed and presented in tables. Of 36 varieties of corn tested from 1 to 5 years, no single variety stood at the head in productiveness for more than one year. Mosby gave the highest average yield of varieties grown 5 years; Shaw, of those grown 4 years; Cocke of varieties tested 3 years, and Renfre and Higgins head the list in the 2-year tests. Mexican June corn made a heavy growth of stalks and leaves, but gave an unsatisfactory yield of grain. Seed corn from Virginia seemed to be more productive than seed from Illinois, Delaware, Georgia, and Alabama. As in previous experiments, the difference in the yields obtained from planting middle, butt, and tip kernels were too slight to indicate any real superiority of seed from any particular portion of the ear. Owing to a wet season, corn planted in the water furrow of bedded plats gave small yields, and the method is considered practicable only in well drained, light soils. This season corn planted May 1, in ordinary upland soil, yielded nearly 30 bu. per acre, while a number of varieties planted July 13, on good soil, proved complete failures. In a comparison of medium and thick planting of corn, Golden

Beauty, an early variety, with very small stalks, showed the largest increase in yield due to thick planting, the average increase for 3 varieties being 1.7 bu. per acre. In another series of distance experiments, conducted in 1896 and 1897, the results of both seasons favor planting so that the distance in the drill nearly equals the distance between the rows. The results of cultivation experiments indicated that the first cultivation should be deep and that frequent cultivation should be continued late into the season. Among the different methods of harvesting, the best yields of grain and forage were obtained by cutting and shocking the entire plant, as compared with harvesting the ears alone, the tops and ears, and the leaves and ears.

The fertilizer experiments comprised tests with commercial fertilizers and a number of leguminous crops. Lime was found useless on sandy upland poor in humus and unprofitable on soil containing considerable vegetable matter. Cowpea and velvet bean vines plowed under were effective fertilizers for corn. Beggar weed, as a fertilizer, also increased the yield, but to a lesser extent than velvet beans. The stubble of cowpeas and velvet beans did not produce a residual effect equal to that of the vines. A comparison of hairy vetch, hairy vetch stubble, rye, and rye stubble as manures for corn showed a yield of 8.4 bu. where the rye was plowed under and 17.5 bu. per acre where vetch was used as green manure. Vetch stubble also gave better results than rye stubble. It was found more profitable to harvest vetch for hay and turn under the stubble than to use the entire plant as a fertilizer. Applications of 200 lbs. of cotton-seed meal and 434 lbs. of cotton seed per acre, furnishing equal amounts of nitrogen, were about equally effective. Tests conducted for 2 and 3 years with acid phosphate kainit and cotton-seed meal on sandy soil showed that the use of these fertilizers was unprofitable. On "mulatto" land, cotton-seed meal increased the yield of corn 7.9 bu. while acid phosphate and kainit were ineffective.

Cooperative experiments with cotton in 1899 and 1900, J. F. Duggar (*Alabama College Sta. Bul. 113, pp. 52*).—These experiments are in continuation of work previously reported (E. S. R., 11, p. 139). Of the cooperative soil tests made in 1899 and 1900 in 37 different localities of the State, including the station, 23 gave definite results and these are given in tables and discussed. The results of the rest of the experiments were inconclusive on account of certain vitiating conditions which destroyed their value for comparison. The fertilizers employed were the same as in previous experiments. The weather conditions for both seasons were very unfavorable. The results obtained by each experiment are given, but no conclusions are drawn.

Linseed and flax (*Queensland Agr. Jour., 8 (1901), No. 1, pp. 4-6*).—An article on the possibility of profitable flax growing in Queensland.

Crop and forage notes, 1900, F. C. Burtis (*Oklahoma Sta. Bul. 48, pp. 11*).—This bulletin contains a report of the crops under test at the station in order to determine suitable varieties, the best adapted soils, and the most desirable methods of cultivation. The grass garden at the station is described, and the results with the different grasses and clovers in 1900 briefly noted. Alfalfa was sown in 1898 and 1899 on two fields, but the growth of the crop was not permanent and the second and third year there was only a poor stand left. Rape drilled in rows 30 in. apart and cultivated yielded 23.5 tons of green forage per acre, and on plats where the rape was drilled 6 in. apart or drilled with oats, the yields were 11 and 12.5 tons per acre respectively. Field peas grown with oats yielded at the rate of 15 tons of green forage per acre. The sugar beets grown at the station were too low in quality for factory purposes. For several years cowpeas grown at the station farm as a catch crop after wheat and oats have given good results. A rotation and continuous cropping experiment was begun this season with corn, Kafir corn, and castor beans and the results obtained are noted.

Reports on experiments on the manuring of rye grass and clover hay in 1899, R. P. WRIGHT (*West of Scotland Agr. Col. Rpt. 1899, pp. 17*).—These experiments were conducted on 20 farms in 5 different counties of Scotland, for the purpose of comparing different forms of fertilizers applied in various combinations. The work and its results are discussed in detail and the data given in tables. The use of commercial fertilizers for rye grass and clover gave a large and profitable increase in yield, even in an unfavorable season. In a complete fertilizer applied in spring, superphosphate was more effective than basic slag. Potash was an effective constituent, and was found to be necessary on clays and clay loams, as well as on lighter soils. It was least efficacious on soils in a high state of fertility. As a constituent of a complete fertilizer, potash, at the rate of 1 cwt. per acre, is considered the most profitable. Sulphate of potash and muriate of potash proved to be equally suitable for these crops. A mixture of nitrate of soda and of sulphate of ammonia did not give better returns than either applied separately. Barnyard manure, used in conjunction with either of these nitrogenous fertilizers, resulted in a much larger increase in the crop than when applied alone.

Influence of manures on the botanical composition of grass land, W. SOMERVILLE (*Jour. Bd. Agr.* [*London*], *7* (*1900*), *No. 2*, *pp. 145–166*).—This report on fertilizer experiments on grass land shows that nitrate of soda when used with superphosphate repressed the growth of Agrostis and increased the yield of *Cynosurus cristatus*. When applied alone or with kainit only, the herbage produced was of an inferior type. Its use was unfavorable to the development of leguminous plants and *Plantago lanceolata*. Sulphate of ammonia, as compared with nitrate of soda, produced more Agrostis, *C. cristatus*, and *P. lanceolata* and less cocksfoot (*Dactylis glomerata*) and leguminous plants. Basic slag and superphosphate affected the growth of Agrostis and cocksfoot, but had no general influence on other plants. Superphosphate generally reduced the percentage of Agrostis and cocksfoot, and as compared with basic slag it produced much more Agrostis and less cocksfoot. Kainit markedly increased the yield of leguminous plants, while it decreased the yield of Agrostis. Lime was favorable to the development of *P. lanceolata* and unfavorable to the yield of Agrostis and *Holcus lanatus*.

Culture experiments with forage plants, A. SEMPOLOWSKI (*Deut. Landw. Presse*, *28* (*1091*), *No. 13*, *p. 100*).—Brief descriptions of cultural tests with the flat pea (*Lathyrus sylvestris*), sachaline, soy bean, giant clover "colossal ladino," Hungarian clover (*Trifolium pannonicum*), Siberian vetch (*Vicia sibirica*), hedge vetch (*V. dumetorum*), and red and white lupines.

Cultivation of fodder crops (*Agr. Jour. Cape Good Hope, 18* (*1901*), *No. 1, pp. 13–15*).—A general discussion of the subject.

The present condition of Russian hop culture (*Mitt. Deut. Landw. Gesell.*, *16* (*1901*), *Sup. to No. 6, pp. 37–41*).—An article describing the culture of hops in Russia and the conditions of production.

Experiments at Rothamsted on the changes in the composition of mangels during storage, N. H. J. MILLER (*Jour. Roy. Agr. Soc. England*, *3. ser.*, *11* (*1900*), *pt. 1, pp. 57–64*).—The author reviews the investigations of others on the losses which occur in Swedish turnips, sugar beets, and mangels, and presents the results of his own work with mangels. The mangels were selected from two fields fertilized alike with barnyard manure, basic slag, and sulphate of potash, but one received in addition nitrate of soda at the rate of 550 lbs. per acre. The beets were stored in a brick shed built over a well. They were covered with straw and samples taken for analysis from time to time. The following table shows the results of these analyses as regards changes in composition of the dry matter and percentage losses of organic matter:

Composition of stored mangels.

1898–99.	In dry matter.					Loss of constituents.			
	Organic matter.	Sugar.	Pentosans.	Nitrogen.	Ash.	Dry matter.	Organic matter.	Sugar.	Pentosans.
Series I (nitrated):	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
October 31	93.62	65.65	7.65	1.256	6.38	....	....	....	....
January 6	93.24	68.43	....	1.248	6.76	8.82	9.21	4.96	....
March 28	93.83	68.82	....	1.094	6.17	3.33	3.00	1.3	....
June 20	90.55	69.01	7.84	1.579	9.45	18.47	21.17	14.17	27.4
Series II (no nitrate):									
October 31	92.01	63.04	7.46	1.652	7.99	....	....	....	....
January 6	91.40	60.29	....	1.999	8.60	4.22	4.75	8.40	....
March 28	90.48	61.72	....	2.010	9.52	14.64	16.00	16.42	....
June 20	89.81	59.64	7.24	1.890	10.19	16.03	19.08	20.56	25.8
July 4	91.36	60.11	....	2.056	8.64	15.41	16.00	19.34	....

From the table it will be seen that the nitrate of soda apparently increased the loss of sugar in the beets during storage and likewise of some other constituents. The experiment is being continued.

Variety tests and fertilizer experiments with fodder beets, A. Arnstadt (*Fühling's Landw. Ztg., 49* (*1900*), *No. 22, pp. 835–839*).—The varieties compared, Tannenkrüger, Eckendorfer, and Oliven, yielded per morgen (about 0.6 acre) 30,240, 22,680, and 17,640 kg. of beets, and 3,600, 2,700, and 3,240 kg. of leaves, respectively. The Oliven variety yielded 18 kg. of leaves and the other 2 varieties 12 kg. to each 100 kg. of beets. The Tannenkrüger variety was grown from selected seed obtained directly from the seed grower, while the seed for the other varieties was home grown, and the author believes that this circumstance has had a greater influence on the yield than the variety itself.

The results of the fertilizer experiments show that an application of 50 kg. each of nitrate of soda and superphosphate per morgen in addition to a copious dressing of barnyard manure was insufficient to obtain the largest yield. By doubling these quantities the increase in yield was also doubled. The author observed that a lack in the soil of phosphoric acid not only decreased the yield of beets but retarded their ripening and increased their water content, which was injurious to their keeping qualities.

Report on experiments on the comparative merits of varieties of oats, R. P. Wright and A. N. McAlpine (*West of Scotland Agr. Col. Rpt. 1899, pp. 40*).—These experiments were carried out on 17 farms distributed over the center and southwest of Scotland. The object of the work was to determine the most profitable varieties and to ascertain the effect of climate and soil on their relative productiveness. The experiments and the results are discussed at some length and all the data obtained are given in tables or presented graphically. The varieties tested were Providence, Potato, Sandy, Hamilton, Longhoughton, Newmarket, Tam Finlay, Tartar King, Black Tartar, Pioneer, Waverly, Banner, Improved Ligowo, Abundance, Golden Giant, Siberian, and American Beauty, the last 6 varieties mentioned being Canadian sorts. Pot experiments were made with 12 of these varieties to study their tillering powers and to compare the number of full-sized mature shoots, immature dwarf shoots, undeveloped heads, and very immature shoots not beyond the leafy stage, produced by the different varieties. The weight of produce from each pot and the percentage of kernel, husk, and moisture and the yield of meal were determined and are given in tabular form.

In these tests Banner, Longhoughton, Potato, and Black Tartarian were the best grain-producing varieties and the Potato produced rather more straw, but its grain, although the yields were about the same, was somewhat inferior in quality as compared with Longhoughton. The total yield of the Banner was equal in weight to that of the Potato, but it consisted of less straw and more grain. Black Tartarian was inferior in every respect to Potato, although in some cases it produced exceptionally high and profitable yields. The Pioneer, a black variety, was about equal in yield of straw and grain to Black Tartarian, but inferior to it in quality and milling value. The most productive varieties of straw were Sandy and Tam Finlay. Sandy produced the heaviest total yield of all the varieties but Tam Finlay, and with a very poor yield of grain was distinctly inferior to it in value of crop. Hamilton yielded almost as large a total crop as Sandy and it had a higher percentage of grain, making it the more profitable variety of the two. For combined high production of grain and straw Hamilton proved an excellent variety. These three varieties, Tam Finlay, Sandy, and Hamilton, were resistant to the attacks of tulip root disease, which destroyed other varieties with the exception of Providence which partially resisted the attack. The Providence variety was inferior to Potato on account of its yielding much less grain. Tartar King ripened about 2 weeks earlier than any of the other varieties and Tam Finlay matured about 2 weeks later than this variety and one week later than Potato. The best grain-producing varieties mentioned in the order of total value of crop were: Banner, Longhoughton, Potato, Hamilton, Black Tartarian, and Pioneer, and the best straw-producing varieties given in the same order were: Hamilton, Longhoughton, Sandy, and Tam Finlay. Longhoughton, Potato, and Hamilton were about of equal value. The results further show that the quantity of seed sown per acre is determined to a considerable extent by the variety. It was found that Tartar King and Newmarket required a much heavier seeding than Potato. The different varieties did not differ so much in yield as in the relative production of straw and grain.

The soy bean as a forage and seed crop, C. S. Phelps (*Connecticut Storrs Sta. Bul. 22, pp. 20*).—This bulletin is a popular presentation of directions for the culture of the soy bean, with brief descriptions of the various uses of the crop. The nutritive value of the soy bean is discussed and compared with that of other plants. Figures giving the proportions of total and digestible nutrients of the different crops are compiled from different sources. The bulletin treats largely of work on the soy bean at the station, the results of which have already been published in other station publications.

Hill planting of sugar beets, E. Pluchet (*Sucr. Indig. et Coloniale, 57 (1901), No. 6, pp. 168–171*).—A paper on this subject read at the International Congress of Agriculture held at the Paris Exposition of 1900.

How the beet-sugar industry is growing, R. S. Baker (*Amer. Mo. Rev. of Reviews, 23 (1901), No. 134, pp. 324–328*).—A popular article on the beet-sugar industry in the United States, but discussing principally the condition of the industry in Michigan.

The production of sugar beets in the Province of Saxony and the yields of cereal crops in Eastern and Western Germany, Schulze (*Jahrb. Deut. Landw. Gesell., 15 (1900), pp. 186–196*).—A paper calling attention to the fact that the yield of sugar beets in Saxony is the same as in other German provinces, but that the yield of grain crops is smaller. The question of increasing the yields of cereal crops by different methods of fertilizing the soil is discussed.

German beet-sugar industry, G. H. Murphy (*Sci. Amer. Sup., 51 (1901), No. 1306, pp. 20933*).—A condensed report of the discussions at the 50th annual convention of the German sugar manufacturers, held at Magdeburg May 29 to June 1, 1900.

Prospects of beet-sugar production in Siberia (*Deut. Landw. Presse, 28 (1901), No. 11, p. 84*).

Geographical distribution of the culture of sugar-cane (*Sucr. Indig. et Coloniale, 57 (1901), No. 6, pp. 197–204*).—An article discussing the climatic conditions and limits of the culture of sugar-cane and its distribution in the different parts of the world.

Can wrapper leaf tobacco of the Sumatra type be raised in Connecticut? E. H. JENKINS (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 322–329, pl. 1*).—This article is a description of an experiment conducted in 1900 to determine whether wrapper leaf tobacco of the Sumatra type could be grown in Connecticut which would compare favorably with imported Sumatra. The tobacco was grown under a frame covered with cheese cloth, and the method of covering and constructing the frame are here described. The cultivation and care given the plants is described, and the advantages accruing from growing tobacco under cover are pointed out. Samples of the tobacco produced in this test were sent to tobacco dealers and experts, and the letters containing the expert opinion concerning the quality of the leaf are reproduced. The result of the experiment demonstrated that "tobacco of the Sumatra type can be raised in Connecticut which is equal in all respects to the average imported Sumatra."

Deep culture and intensive farming in Andalusia, L. GRANDEAU (*Jour. Agr. Prat., 1901, I, No. 7, pp. 209, 210*).—A report on tests of shallow and deep plowing, sowing broadcast and in drills, and using a fertilizer application of 400 kg. superphosphate, 200 kg. potassium chlorid, and 200 kg. sodium nitrate in growing cereals.

Cooperative fertilizer experiments in Lower Austria in 1899 conducted by the Royal Agricultural Society of Vienna, F. W. DAFERT (*Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 2, pp. 81–122, pls. 2*).—This is a report on extensive cooperative experiments with fertilizers for field crops and meadows.

Tropical plants at the agricultural school at Wageningen, C. J. VAN LOOKEREN CAMPAGNE (*Orgaan Ver. Oudleer. Rijks. Landbouwschool, 13 (1901), No. 151, pp. 24–29, figs. 5*).—A description of growing sugar cane, rice, and indigo plants under glass.

HORTICULTURE.

The farmer's vegetable garden, J. W. LLOYD (*Illinois Sta. Bul. 61, pp. 16, figs. 5*).—"In order to secure data regarding the amount of labor involved in the care of a garden and the amount of produce it would yield, a 'farmer's garden' was planted . . . and was managed with a view to furnishing a continuous supply of vegetables throughout the season." A succession of vegetables was obtained by planting varieties of different degrees of earliness, and by planting the same variety at different times. The garden was well cared for throughout the season, cultivation, weeding, and hoeing being given whenever it was found necessary, and these items charged up against the garden. Vegetables were planted in rows, so that horse cultivation could be used to the greatest extent. Diagrams are given showing the shape and arrangement of the garden and the period when each vegetable was in season. Cucumber beetles were controlled by spraying with Bordeaux mixture, and cabbage worms by spraying with white hellebore.

"If nothing is charged for the use of the land nor for the manure, the total cost of the garden may be summarized as follows: Seeds and plants, $5.45; insecticides, $0.50; labor, $26.11; total, $32.06.

"In return for this expenditure the garden furnished a continuous supply of fresh vegetables throughout the growing season, with enough sweet corn for drying, tomatoes for canning, cucumbers, peppers, cabbage, string beans and green tomatoes for pickles, besides onions, beets, carrots, parsnips, salsify, winter radishes, cabbage, and celery for winter use, and parsnips, salsify, and horse-radish left in the ground for use in the spring. . . . These vegetables could not ordinarily have been bought at retail for less than $83.84. This leaves a balance of $51.78 in favor of the garden. What other half acre on the farm would pay as well?"

Horticultural department, C. P. CLOSE (*Utah Sta. Rpt. 1900, pp. XXXIII–XLI*).—The author outlines the work of the year, giving the results of some experiments in forcing radishes and the irrigation of vegetables. The radishes were planted on a number of different soil mixtures, including leaf mold, sand, and manure mixed in various proportions, and the seed planted at various depths from $\frac{1}{8}$ to $\frac{3}{4}$ in. The results, which are tabulated, seem to indicate that plantings from $\frac{3}{8}$ to $\frac{3}{4}$ in. will be most satisfactory. The bed composed of equal parts of manure and sand gave better results than any other mixture. Wherever leaf mold was used the yield was reduced. In the irrigation of vegetables, comparison was made between flooding and applying in furrows. Onions, carrots, beets, potatoes, cabbage, and beans were grown. With the exception of the beans, the largest yields in every instance were obtained on the flooded plats. With onions this gain varied from 48 to 95 per cent, carrots 6 per cent, beets 6 to 46 per cent, potatoes 53 per cent, cabbage 4 per cent. It is thought that had furrows been run on both sides of the plats, instead of only one, the results for furrow irrigation might have been better.

Profitable celery culture, W. H. Jenkins (*Agr. Epitomist, 20* (*1901*), *No. 4, p. 22*).—In setting the plants the author uses a home-made device for making the holes and watering the plants. The machine is like a 2-wheeled cart with pegs placed 2 in. apart around the wheels. These make the holes. The cart carries a tank from which two pieces of hose lead the water down over the rows of holes made by the wheels. The plants are placed in the holes and the soil pressed firmly about them. With the aid of this machine the work of planting is reduced about one-half. The rows are grown 12 and 18 in. apart. A mulch of manure is put in the 18 in. space. The blanching boards are set up so that the two rows 12 in. apart are between the boards. This is a saving of one-half the boards usually used. White Plume and Golden Self Blanching are the varieties most suited for this culture.

Cucumbers, W. Iggulden (*Jour. Hort., 53* (*1901*), *No. 2738, pp. 233, 234*).—The forcing of cucumbers is discussed, the experience of the author being drawn upon.

Melons and melon houses, A. Dean (*Garden, 59* (*1901*), *No. 1531, pp. 214, 215, fig. 1*).—Details of a successful method of forcing muskmelons.

Fertilizer experiments with onions (*Jour. Soc. Nat. Hort. France, 4. ser., 2* (*1901*), *Mar., pp. 185, 186*).—Barnyard manure supplemented by complete commercial fertilizers produced larger onions than either alone.

Sweet potatoes, D. M. Nesbit (*U. S. Dept. Agr., Farmers' Bul. 129, pp. 40*).—A popular bulletin on varieties of sweet potatoes, production in different States, culture, fertilizing, storage, shipping, and exportation of sweet potatoes, with some recipes on methods of cooking, and a brief account of the injurious fungus and insect diseases affecting them, etc.

Saving sweet potatoes for seed (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 2, p. 231*).—Seed potatoes were successfully stored by putting in a box with alternate layers of dry, fine sand.

A vegetation house arranged for pot experiments, W. E. Britton (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 306, 307, figs. 2*).—A brief illustrated description is given of a vegetation house conveniently arranged for carrying out pot experiments.

Chemical manures in the culture of greenhouse plants (*Belg. Hort. et Agr., 13* (*1901*), *No. 5, pp. 70, 71*).—Formulas are given for applying mixtures of commercial fertilizers to different kinds of greenhouse plants at different periods of growth, the mixtures to be applied dissolved in the water used for watering the plants.

On the use of commercial fertilizers for forcing-house crops, E. H. Jenkins and W. E. Britton (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 298–306*).—The results secured in plat experiments in the greenhouse with lettuce and carnations, in continuation of those previously reported (E. S. R., 12, p. 550), are given.

Lettuce (pp. 298–301).—Lettuce has been grown in rich sterilized and unsterilized compost, and in coal ashes and peat moss, with various fertilizers. The compost was sterilized by heating for 75 minutes in steam, by the same method noted in an earlier publication (E. S. R., 10, p. 265). The coal ashes used in 1898–99 were mixed with 8 per cent of peat moss, and both screened through a ¼-in. mesh. Commercial fertilizers were added to the plats made up of the coal ashes and peat moss. The same actual amount of nitrogen was given each plat, but 1 plat received it in the form of nitrate of soda, another in the form of cotton-seed meal, and the third in the form of ground bone. Muriate of potash was added to all 3 plats alike, and dissolved bone to the plats which had received nitrate of soda and cotton-seed meal.

The results secured are tabulated, and are summarized as follows: "The crops on the 2 plats of sterilized compost were uniform in quality and much larger and better than any from the 3 plats filled with coal ashes. Where nitrate was used the crop was the smallest; where cotton-seed meal was used the crop was larger by nearly one-quarter, and where bone was used the weight of crop was two and a half times as great as from the nitrate plat."

The following season (1899–1900) similar soils were used and the effect of lime studied. The best results were again obtained with sterilized compost. Of the 2 plats of unsterilized compost used, that to which lime had been added gave a greater total weight of crop and better heads than that on which no lime had been used. In the case of plats of peat and coal ashes fertilized with bone nitrogen, the addition of large amounts of lime (2,240 lbs. per acre) was of no benefit, a heavier yield and better heads being produced upon the plat limed at the rate of 650 lbs. per acre.

"In none of these plats was the lettuce of first-class marketable quality. The heads were not as compact and firm as they should have been, and we are convinced that the texture or mechanical condition, both of the compost and also of the ashes and peat moss, makes it impossible to produce the best lettuce on them, however skillful the fertilization of the soil or management of the house."

Carnations (pp. 301–306).—This experiment was planned primarily to test the effect of lime. Coal ashes were mixed with 5 per cent of peat moss, and both screened to pass a ¼-in. mesh. Six plats of this material were used, and each plat was given the same kind and quantity of commercial fertilizers. Two plats then received in addition 100 gm. each of unleached lime, two others 220 gm., and two others 340 gm. each. Five other plats were filled with compost, to which no fertilizers were added. Three, however, received 100, 220, and 340 gm., respectively, of lime. Daybreak, Portia, and Flora Hill were the varieties used. Top-dressings of nitrate of soda were added in some instances. The conclusions of the authors are as follows:

"It is evident . . . that 100 gm. of slacked lime per plat gave better results than a larger quantity when used with a soil of coal ashes and peat moss and fertilizer chemicals, and that where larger quantities were used the number of flowers was considerably decreased. This was true, both where the fertilizer was all mixed with the soil at time of setting the plants and also where doses of nitrogen were subsequently applied. In the compost soil the greatest number of flowers was harvested from plat 182, which received the maximum quantity of lime. Portia yielded better than Daybreak, averaging from 20 to 28 flowers per plant in the various plats. In no case did Daybreak yield over 18 flowers per plant.

"The chief differences noted from varying quantities of lime were in the varying number of flowers per plant rather than in any marked difference in the average size and weight of the flowers or in the length of stem. The stiffness of the stem was not noticeably affected by the lime."

Orchard notes, F. S. Earle (*Alabama College Sta. Bul. 112, pp. 157–190*).—These notes cover the season of 1900, and are similar in character to those recorded for previous years (E. S. R. 11, p. 1041). They are based on the behavior of the apples, figs, kaki or Japanese persimmons, hybrid oranges, peaches, pears, and plums, grown at the station during the season.

The station experiments show that it is possible to grow thoroughly thrifty, vigorous apple trees on the thin, droughty lands of the station if attention is given to proper cultivation and fertilizers. The station orchard is seeded to hairy vetch in the fall. The following March a strip 3 or 4 ft. wide is plowed each side of the tree rows, and kept cultivated after every rain, so as to form a dust mulch. The vetch in the middle of the rows is left until June, by which time it has ripened its seed and is able to reseed the land when plowed under. Cultivation of the whole area is then continued until the middle of July, when peas are broadcasted and cultivated in. The peas in 1900 made a good growth during the late summer and fall, and were allowed to rot on the ground. "As the peas began to die down the self-sown vetch seed began coming up, and by spring the orchard will be a solid vetch field." Under this treatment the mechanical condition of the soil is being rapidly ameliorated.

A list is given of rust-free varieties of apples, and of those attacked by the rust and the aphis. The green aphis has been controlled by the use of a commercial spray known as "Rose Leaf." Spraying the trees in winter with crude petroleum, for the purpose of destroying the aphis eggs, had no ill effects on the trees. "The effect on the lice, if any, was obscured by the general scarcity of them during the early part of the season." The following is a revised list of apples for general planting in Alabama, the varieties being given in the order of their ripening, and furnishing a succession of fruit from June until early winter: Yellow Transparent, Early Harvest, Red June, Red Astrakhan, Horse, Hackworth, Carter Blue, Thornton Seedling, Kinnard's Choice, York Imperial, Yates, Shockley, and Herschal Cox. Relative to apple growing in Alabama, the author states that—

"As a result of several years' observation and study it seems prudent to strongly urge the increased planting of apples in middle and northern Alabama. It must be fully understood, however, that apples will succeed here only with the best and most intelligent care and cultivation."

Celeste is considered by all odds the best early fig, and Green Ischia the best and most reliable late fig. Madeline is a good fig, ripening intermediate between these two. Tables are given showing the blooming period of 33 varieties of peaches and 43 varieties of plums. The various classes of plums are described and their value for the State noted. Japanese plums are considered the most important type of plums for the region. The following varieties of plums, mentioned in the order of their ripening, are given as the best varieties for general planting in Alabama: Kerr, Red June, Abundance, Burbank, and Orient. The necessity for mixing varieties in orchard planting, which bloom at about the same time, in order to secure fertilization of the blossoms, is pointed out.

The San José scale has been kept in control by spraying with a 20 per cent mechanical mixture of kerosene and water. Crude petroleum applied undiluted did not harm either apple or peach trees.

Orchard experiments, S. T. MAYNARD and G. A. DREW (*Massachusetts Hatch Sta. Bul. 73, pp. 3–9*).—Notes on the methods followed at the station in the culture, fertilizing, and spraying of apples, peaches, pears, grapes, blackberries, raspberries, currants, and strawberries are given. The yields obtained in 1900 with the different fruits are also given, together with a record of the cost of thinning, yield, and value of the fruit from Red Astrakhan, Early Harvest, Hurlbut, Baldwin, and Rhode Island Greening apple trees. In every instance the thinning was done at a financial profit. With Red Astrakhan, Baldwin, and Rhode Island Greening the yields were slightly better on the thinned than on the unthinned trees, while in the other 2 cases the yields were the same. The greatest average profit per tree ($2.05) was obtained by thinning Red Astrakhan. The profits for the other varieties ranged from 55 to 98 cts. per tree. The thinning was performed by employees unaccustomed to the work.

It is believed that with a large orchard and skilled labor the cost of thinning could be considerably reduced.

The varieties of peaches showing the greatest value were Mountain Rose, St. John, Early Crawford, Old Mixon, Champion, and Elberta. To this list Crosby and Dennis may be added for home use. Abundance and Burbank are among the most satisfactory Japanese plums grown, while the best of the American plums are Wild Goose, Hawkeye, Hammar, and Gold or Golden. Cuthbert and Loudon have given the best results with raspberries, with the King as the best early variety. Pomona is considered the best-flavored red currant, and the White Imperial the best among the white kinds. The 6 heaviest yielding strawberries were Sample, Glen Mary, Brandywine, Haverland, Clyde, and Ruby.

The chemical composition of one-year-old wood of orchard fruits according to the four cardinal points, R. OTTO (*Gartenflora, 50 (1901), No. 7, pp. 177–181*).—Branches from apples, pears, and cherries from the north, east, south, and west sides of the trees, respectively, and from the top, lower, and middle portions were taken, carefully dried, and ground into powder and analyzed with respect to dry substance, ash, and nitrogen content. The content of the ash in phosphoric acid, potash, and magnesia was also determined. The results of the analyses are tabulated and discussed. They show no regular variation whatever in the composition of the wood from the different parts of the tree as regards the cardinal points of the compass.

Apples of the Fameuse type, F. A. WAUGH (*Vermont Sta. Bul. 83, pp. 83–92, pls. 4*).—The Fameuse apple is taken as a central type of several different varieties of the Fameuse group, "all differing measurably from Fameuse, but all conforming closely enough to the Fameuse type so that their close relationship with one another and with the Fameuse may be readily recognized by the pomologist." The Shiawassee, McIntosh, etc., belong to this group.

In the opinion of the author, the Fameuse originated in Canada from seed brought from France between 1600 and 1650. It was introduced into Vermont from Canada about 1700.

The Fameuse is a favorite dessert apple almost everywhere, is a profitable commercial variety in several important apple-growing districts, the central being the island of Montreal, and has a strong tendency to reproduce itself from seed. The author states that St. Lawrence presents a closely related but separate type. Jonathan, too, is perhaps closely allied to Fameuse. Historical and descriptive notes are given of 12 varieties of apples belonging to the Fameuse group.

The Montmorency cherries, G. H. POWELL (*Amer. Gard., 22 (1901), No. 329, pp. 266, 267*).—The author considers the Montmorency cherry, Long-Stemmed Montmorency, and Montmorency Ordinaire all synonyms for the same variety, and is convinced that there is but one Montmorency in commercial orchards in America, the Montmorency called Ordinaire, by error.

The date palm for Queensland, T. M. MACKNIGHT (*Queensland Agr. Jour., 8 (1901), No. 3, pp. 197–202*).—A general article giving the habitat of the date palm, botany, methods of propagation and fecundation, treatment of fruits, food constituents, etc. It is believed that Queensland is well adapted to growing the better varieties of dates.

Figs under glass (*Jour. Hort., 53 (1901), No. 2738, p. 246*).—This article discusses the forcing-house management and best varieties of figs to grow under glass.

Analyses of the olive, F. BRACCI (*Staz. Sper. Agr. Ital., 32 (1899), p. 161; abs. in Centbl. Agr. Chem., 29 (1900), No. 10, pp. 673–675*).—Analyses of the wood, leaves, and fruit of the olive and the amounts of fertilizing ingredients removed per hectare are reported.

Pruning and training peach orchards, R. H. PRICE (*Texas Sta. Bul. 58, pp. 27–42, figs. 15*).—A series of cuts are given and explained which show proper and faulty methods of pruning the peach in Texas. The form which a tree assumes in a locality when grown out alone without pruning is believed to furnish a hint as to the correct method of pruning trees in the orchard. For Texas low-topped trees and heading back the ends of the limbs each year are advised. The purposes of pruning are thus succinctly stated by the author:

"If the ends of the limbs are not headed back the fruit will be borne farther away from the trunk of the tree each succeeding year. The limbs will become long and angling. The weight of the fruit on the ends of the long limbs will cause them to droop and frequently break or split off. If the fruit is not thinned off from them, many varieties will overbear one year and so exhaust the trees that they are not apt to bear the next year. Such orchards are liable to fruit every other year. During the heavy fruit year an overloaded tree will make but little wood growth on which to bear the following year.

"Heading back the ends of the young limbs accomplishes several important things: (1) It enables the tree to make new bearing wood for next year; (2) it thins the fruit; (3) it lessens the liability of splitting and breaking of the limbs by making them more stocky; (4) the fruit is borne near the ground, where it is easier to gather; and (5) it keeps the bearing wood nearer the main trunk by causing side branches to come out on the main limbs."

Relative to the Stringfellow method of root pruning, the author states that after careful observations with peach, plum, pear, and apple trees, grown at the station, he is convinced that the theory is not based upon sound physiological principles. The method, however, may have a local value, and wherever experience has proven this to be the case close root pruning may be followed. The principle, however, upon which the Stringfellow root system of pruning is based is not susceptible of wide application. Results secured at other experiment stations in root pruning orchard trees are quoted.

Peach growing in Maryland, H. P. GOULD (*Maryland Sta. Bul. 72, pp. 129–151, figs. 5*).—A discussion of the historical development of the peach industry in Maryland, its present status, the culture of the orchard, and the marketing of the fruit.

The first large peach orchard in Maryland was planted about 1800, in Anne Arundel County. It contained 18,000 to 20,000 seedling trees, and the product was used for making peach brandy. The canning industry came into existence about the middle of the century. At present there are about 3,000,000 trees in the State, five-sixths of which are in the 5 counties of Washington, Kent, Caroline, Anne Arundel, and Queen Anne. It is estimated that there are about 2,000,000 trees in bearing, and the product from these in 1900 was about 2,000,000 packages.

Complete directions are given for locating the orchard, preparing the soil, selection of varieties and stock, setting the trees, starting the top, intercropping, tilling, fertilizing, pruning, thinning the fruit, etc. Cowpeas have given the most general satisfaction in Maryland as a cover crop for peaches. Crimson clover has proven valuable in a few localities. It is believed that leguminous crops should be relied upon to furnish the nitrogen required in the production of the peach crop. A successful fruit grower of the State recommends that peaches for profit should be thinned to about 6 in. apart on a limb.

Relative to marketing peaches, commission men in Pittsburg, Baltimore, and New York unite in recommending the six-basket carrier for choice fruits, and larger size boxes for second-class fruit or culls. The practice of putting poor fruit in fancy packages is condemned.

Observations on the fertilization of peach orchards, E. H. JENKINS (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 352–354*).—An account is here given of the establishment, in 1894, of a peach orchard on a high hill of gravelly loam some miles from the shore of Long Island Sound. Different portions of the orchard were differently fertilized, and an account has been kept of the number of trees that have died and the number of baskets of fruit collected on the different plats. These are given in tabular form as a matter of record, but a discussion of the experiment is reserved until further results have been obtained.

Abnormal fruit branches of the peach tree, their treatment, G. BELLAIR (*Rev. Hort., 73 (1901), No. 6, pp. 136, 137, figs. 5*).—Popular article with illustrations showing proper method of pruning away abnormal fruit branches.

The sterility of fruit trees and shrubs, J. BURVENICH (*Bul. Arbor. et Flor., 1900, pp. 19–22, 51–54*).

Winter budding, H. M. STRINGFELLOW (*Nat. Nurseryman, 9 (1901), No. 4, p. 178*).—Winter budding is described and its adaptation for fall use pointed out. The author believes that success by this method is more certainly assured if a small piece of waxed cotton cloth is placed over the bud after it is put in place. Chlorosis of peaches and grapes has been overcome by the author by the addition of pulverized sulphate of iron. He believes that if several bushels of ashes and about 10 lbs. of copperas were top-dressed around a peach tree with the yellows it would probably cure it.

The chemical analysis of the coffees of the greater Comoro island, G. BERTRAND (*Compt. Rend. Acad. Sci. Paris, 132 (1901), pp. 161–164; abs. in Chem. Centbl., 1901, I, No. 9, p. 532*).—It was found that while grown upon the same island under like conditions of soil and climate *Coffea arabica* contained 1.34 per cent of caffein, while *C. humblotiana* contained none.

Coffee culture in Queensland—disbudding, H. NEWPORT (*Queensland Agr. Jour., 8 (1901), No. 2, pp. 112–114*).—Once in the life of the coffee plant, usually about the third year, it has been found advisable, in Queensland, to disbud. Only the green immature wood of the primaries need disbudding, and this should be done from 1 to 3 weeks after the blossoms appear. "Disbudding is required from the primaries whenever and only when they attempt to bear on immature or green wood. It is not necessary if the primary has secondaries upon it, and it is not necessary to disbud secondaries or any other form of branch." If, instead of disbudding, the immature wood is allowed to bear, the branches are weakened and die.

Coffee culture in Queensland—picking, H. NEWPORT (*Queensland Agr. Jour., 8 (1901), No 3, pp. 217–221, pl. 1*).—Directions are given as to when and how to pick coffee.

American tea-gardens; actual and possible, L. B. ELLIS (*Amer. Mo. Rev. of Reviews, 23 (1901), No. 134, pp. 315–320, figs. 8*).—A popular description of the tea plantation at Pinehurst, S. C., and a discussion of actual and possible results.

Bush fruits, including gooseberries, raspberries, blackberries, dewberries, C. H. POTTER (*Colorado Sta. Bul. 60, pp. 12*).—Brief cultural notes are given on these crops. Six varieties of gooseberries, 12 of currants, 23 of raspberries, and 12 of blackberries and dewberries are described, and the results secured at the station with each are given.

Brief sketch of vine growing in Russia and of measures adopted for combating the phylloxera (*Aperçu succinct sur les vignobles en Russie et sur les mesures adoptées pour y combattre le phylloxéra. St. Petersburg: Min. Agr. and Imp. Domains, Dept. Agr., 1900, 2 ed., pp. 40*).

Rupestris St. George and bench grafting, F. T. BIOLETTI (*Pacific Rural Press, 61 (1901), No. 14, p. 213*).—The unsatisfactory results obtained in the south of France on moist soils with Rupestris St. George are pointed out, and some data given on the yields obtained from bench-grafted vines and vines grafted in the vineyard for a period of 10 years. The average for the whole time was 7,340 lbs. of grapes yearly per acre for the bench-grafted vines and 4,660 lbs. for the vines grafted in the vineyard.

Flute graft applied to the vine, F. PAULSON (*Rev. Vit., 15 (1901), No. 382, pp. 409–411*).—The use of this graft in reconstructing vineyards on American stocks is coming into larger use, according to the author. Some of the advantages of the method are a longer grafting season—June to September—and a successful taking of the graft, averaging 90 to 95 per cent.

An experiment in vine topping, E. H. RAINFORD (*Queensland Agr. Jour., 8 (1901), No. 3, p. 205*).—In this experiment 20 vines were topped to about 12 in. length above the lowest bunch of grapes shortly after the berries had set, and twice afterwards when the laterals had made sufficient growth to allow it. The bunches on topped vines colored at least a week later than those on the vines not topped, and contained only 16.5 per cent of sugar, as compared with 20 per cent in the grapes grown on the normally treated vines. There was also decidedly less coloring matter in the skins. The results are believed to go some way toward proving that excessive topping is hurtful and not beneficial. The experiment will be continued the coming season.

A collection of reports on experiments in the application of fertilizers, and on the prevention of the Morell disease, C. H. CLAASSEN (*Versamel. Verslag. Rijk Gesubsidieërde Proefvelden, 1899–1900. Department Binnenlandsche Zaken (Netherlands), pp. 30*).—In each case the experiment was carried on by farmers or horticulturists under the direction of the official in charge of the work. The fertilizer experiments were conducted on an orchard, and rhododendrons, hyacinths, pole beans, roses, and grapes. Some of these experiments remain incomplete, and some for various reasons failed to give results. The fertilizer experiment in orchards planted with berry bushes showed a greater profit from the use of commercial fertilizer alone than from either stable manure alone or one-half stable manure with commercial fertilizer. The work on hyacinths was not satisfactory, though commercial fertilizer appears not to be well suited to them. The hyacinth disease appeared in some of the plats, but the figures do not show a clear relation between the fertilizer used and the disease. The disease of cherries caused by *Monilia fructigena* was kept under control by vigorous pruning. Both winter and summer pruning was practiced, with marked improvement in the health and growth of the trees.—H. M. PIETERS.

Something about nuts and nut growing, C. FORKERT (*Amer. Gard., 22 (1901), No. 329, pp. 270, 271*).—Brief notes on the propagation of pecans, with the results of a comparison of the weight of the shell and kernel of a dozen average sized nuts of pecans and English walnuts. The 12 walnuts weighed $4\frac{1}{4}$ oz., of which 2 oz. was meat, while the 12 pecans weighed 4 oz., and $1\frac{1}{8}$ oz. was meat.

Top-grafting native chestnut sprouts, W. E. BRITTON (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 307–310*).—In continuation of earlier work along this line (E. S. R., 12, p. 558), a further test has been made of the proper time for setting chestnut scions in Connecticut, and of the value of native sprouts as stocks upon which to graft the European and Japanese varieties of chestnuts. The tests were made on 3-year old chestnut sprouts, some of which had attained a height of 14 ft. and had produced burrs. Early frost and a protracted drought in midsummer severely interfered with the test.

Ridgely, Early Reliance, Coe, and McFarland were the varieties used. These were set by cleft-grafting at different times between April 20 and June 12. Two scions were usually set in each stock and the stocks were from 1 to $1\frac{1}{2}$ in. in diameter where cut off. The author states that if 1 of the 2 scions set in each cleft grew, or 50 per cent of the whole number set, it would be all that could be desired, since where both scions grow one should be cut off.

An examination of the data given shows that of the scions set, 50 per cent of Ridgely, 23 per cent of McFarland, 11 per cent of Early Reliance, and 30 per cent of Coe lived. If the percentage of stocks in which scions lived is made the basis of calculation, the percentages are as follows: Ridgely 70, McFarland 33, Early Reliance 22, and Coe 41. The good results in Ridgely are ascribed in part to its European origin, and in part to the fact that the scions were taken from young grafted trees in the vicinity of the station, and were in perfect condition, while the other scions were bruised and damaged by shipping. It is thought that better results would have been obtained with the Japanese varieties if the scions could have been cut from trees in the vicinity.

"A larger percentage of the scions of the Japanese varieties died after growth had commenced than of the European species. A few Ridgely scions were broken off by winds, but besides these only one stock lost Ridgely scions after their growth had begun, while 22 lost McFarland and 43 lost Coe scions which had already started to grow.

"The results of the work of 1900 confirm the conclusions reached in 1898, that the best time for chestnut grafting in Connecticut is about the middle of May, when the stocks are well advanced in foliage."

Of the scions set between May 11 and 25, 42 per cent lived, or stated differently, 60 per cent of the stocks carried living scions.

Pecans in Texas (*Fruitman's Guide, 10 (1900), No. 526, pp. 12, 13*).—A description is here given of the pecan industry of Texas, dealing more especially with the harvesting of the crop.

Raising Ficus elastica from the seed, P. Van Romburgh (*Teysmannia, 9 (1900), No. 7, pp. 351–353*).—Many of the seedlings used in the commercial plantings in Sumatra are obtained by keeping the ground under the trees free from weeds and collecting the seedlings that come up naturally. Seeds of *Ficus elastica* have also been known to germinate freely in the clefts of trees and on old roofs. In all cases the seedlings produced the tuberous thickening said to be characteristic of *F. elastica*. Seedlings for commercial purposes may be grown by sowing the very small seeds thickly on the surface of fine moist garden loam, in earthenware pots, which should be kept under cover. In favorable circumstances the seed will germinate in about 2 weeks, but often a much longer time is required. The young seedlings have tender, light-green leaves, and the nervation differs from that of the mature leaf. Great care is necessary to prevent damping-off. Before being planted in the place where they are to be permanently grown, the seedlings should be transplanted to the nursery and kept there for about a year.—H. M. PIETERS.

Rubber in Guatemala, J. C. McNally (*U. S. Consular Rpts., 65 (1901), No. 246, pp. 371–375*).—The culture of *Castilloa elastica* in Guatemala is popularly described, and estimates given regarding the industry. Good rubber land costs about $100 an acre. About 100,000 trees can be grown on 115 acres. The trees will bring in a return of $1 to $2 apiece, beginning with the seventh year of the plantation, and continue to produce idefinitely.

Hedges, C. L. Zimmerman (*Amer. Gard., 22 (1901), No. 330, p. 288*).—Suggestions on growing and forming hedges, and on the use of native material for the purpose.

Notes on cannas, F. K. Luke (*Rpt. Columbus Hort. Soc., 1900, pp. 150–159, pls. 3*).—Historical and botanical notes on cannas, with short descriptions of 57 varieties.

Ornamental climbers, W. R. Lazenby (*Rpt. Columbus Hort. Soc., 1900, pp. 85–88*).—Descriptive list of a number of climbing ornamentals.

A chat on daffodils, P. Barr (*Sydney: Hort. Assoc. New South Wales, 1900, pp. 18*).—Three papers on daffodils. The first gives some historical data on ancient and on modern daffodils; the second discusses the distinguishing characteristics of daffodils in their many forms and varieties; and the last discusses the production of new daffodils.

FORESTRY.

Third reunion of the International Association of Forestry Experiment Stations at Zurich, G. Hüffel (*Bul. Min. Agr. [France], 20 (1901), No. 1, pp. 148–180*).—An account is given of the meeting of the International Association of Forestry Experiment Stations, which was held at Zurich September 4–11, 1900, with representatives present from most of the continental countries of Europe. Since the previous meeting Russia and Sweden have announced their desire to officially join the association. The report gives a historical review of the association and its aims, and an account of the establishment of the Central Swiss Forestry Station and reviews some of its work. Descriptions are given of the Sihlwald forest, its sylviculture and management. The experiments recently inaugurated at Emmenthal to study the effect of forests on underground water are described briefly. These experiments have not yet progressed sufficiently far to warrant definite conclusions. Among the papers presented for general discussion were those dealing with geographic distribution of forest trees, the transmission by seed of the character of trees, diameter growth of trees, and the preservation of wood by chemical means. The next meeting of the association is to be held at Mariabrunn in 1903 or 1904.

Report of the forest experiment station in Mariabrunn for 1900, J. Friedrich (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 3, pp. 317–324*).—A brief report is given on soils and climatology, forest products, forest management, injury and diseases of forest trees, and forest technology. Notes are given upon the planting and present condition of a large number of exotic forest trees. The principal injuries reported are those due to smoke, gas, and similar causes. These are to be given special attention in a later publication.

National forestry, D. E. Hutchins (*Agr. Jour. Cape Good Hope, 18 (1901), Nos. 2, pp. 95–103; 3, pp. 163–173*).—This is a paper in which the forestry conditions of Europe and America are reviewed, and some of the advantages of governmental control of forests are pointed out.

The forest and its influence, J. G. H. Lampadius (*California Cult., 15 (1900), No. 5, pp. 65–68*).

The beech in Austrian forestry, F. Hufnagl (*Die Buchenfrage in der österreichischen Forstwirthschaft. Vienna: Wilhelm Frick, 1901, pp. 79*).

The Velani oak, Trabut (*Bul. Agr. Algérie et Tunisie, 7 (1901), No. 5, pp. 97–103, figs. 3*).—A description is given of *Quercus ægylops*, which is especially adapted to forestry conditions in Algeria. The growth of this tree presents no difficulties, and the author considers it a very valuable species for planting.

Selected trees suitable for shade, wind belts, timber, and fuel reserves, H. F. Macmillan (*Roy. Bot. Gard. Ceylon, Cir., 1. ser., 1900, No. 18, pp. 207–230*).

The world's demand for timber and the supply, R. Zon (*Forester, 7 (1901), No. 2, pp. 41–44*).—A review is given of a number of papers relative to the production, consumption, and supply of timber throughout the world. The average imports and exports of a number of countries are given, and in addition to the home production it is stated that Europe requires from 1,230,000,000 to 1,400,000,000 cu. ft. annually. This amount is secured largely from Austria-Hungary, Russia, Sweden, Norway, the United States, and Canada. As the consumption in some of these countries is almost equal to the production, the equilibrium at present is maintained almost entirely by the supplies obtained from Russia and Canada, and the supplies of these countries are estimated to last but about half a century, after which time there will be a scarcity of timber and as a consequence high prices.

Philippine forest products, F. F. Hilder (*Forester, 7 (1901), No. 2, pp. 27–33*).—A brief account is given of the forests of the Philippines, one peculiarity of them being that no single species of tree covers any great area, but in exploiting the forests in order to secure a cargo of any given kind of timber extensive regions will have to be called upon, as the species are poorly represented by individual specimens. A list of about 50 of the more important timber trees is given, their common and botanical names, together with descriptions of the characteristics of the different woods, notes on their uses, and the principal localities in which they are found. Some of the difficulties of lumbering in that country are pointed out, and as there is almost an entire absence of roads the exploitation of forests will prove expensive and difficult.

The preservation of timber by artificial means, J. H. M. HUME (*Agr. Students' Gaz., n. ser., 10 (1901), No. 3, pp. 74–79*).—The relative value of timber protected by artificial means against decay, and that receiving no special treatment, is shown. Among the various materials used for the preservation of timber, mention is made of paint, tar, varnish, sulphates of iron, zinc, and copper, chlorids of iron, zinc, and mercury, creosote, etc. The use of creosote for preservation of timber is preferred on many accounts, and the method of treating timber with this preservative is described at considerable length. Based upon the current market price of timber, the value of creosoted timber is increased fully 66 per cent for posts and 140 per cent for boards.

The harmfulness of bush fires, H. A. A. NICHOLLS (*Imp. Dept. Agr. West Indies, Pamphlet No. 4, 1901, pp. 29*).—The destructiveness of fires carelessly started or allowed to spread from intentional clearings is shown, and the author urges that severe means should be taken to prevent fires resulting from carelessness. The results of a number of fires, as shown in some of the now barren districts of Saint Dominica are cited as examples of the destructiveness of forest fires and the necessity for reforestation.

The protection of shade trees, E. H. JENKINS and W. E. BRITTON (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 330–351, pls. 9*).—This is essentially a reprint of Bulletin 131 of the station (E. S. R., 12, p. 957).

Study in Europe for American forest students, O. W. PRICE (*Forester, 7 (1901), No. 1, pp. 11–16, 38–41, figs. 4*).—The author reviews the characteristics of a number of the more prominent regions of Europe which are generally visited by students of forestry, and offers suggestions for the guidance of such students.

SEEDS—WEEDS.

Germination in distilled water, P. P. DEHÉRAIN and E. DEMOUSSY (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 9, pp. 523–527*).—The irregularities shown in the germination of seed in distilled water have been observed for a long time, and in 1875 Bœhm published a memoir upon the subject in which he held that the irregularity was due to the absence of lime in the distilled water. He maintained that in the case of beans lime was essential for their germination. His observations are said to have been largely based upon the fact that seeds placed in spring water which contained various lime salts germinated readily, while those placed in the distilled water were either wholly retarded or germinated poorly. The authors have investigated this subject and claim that lime is not necessary to the utilization of the reserve material in the cotyledons of the plant and that beans will germinate readily in pure distilled water. A report is given of their experiments in which beans, lupines, and other seeds were germinated in water which had been twice distilled in a glass still. It is claimed that the experiments of Bœhm were conducted with water which had been kept in copper vessels, and that the amount of copper dissolved by the distilled water was sufficient to prevent germination. The authors conclude that seeds may form their roots and begin their evolution in water absolutely deprived of lime, and that the development of the roots may be checked in distilled water containing very slight traces of copper.

Experiments on increasing the germination of beet seed, Z. ZIELINSKI (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 3, pp. 140–143*).—An account is given of experiments to increase the germination of beet seed. Equal lots of seed were treated in different manners, after which they were germinated and comparisons made with similar lots of untreated seed. One lot was soaked for 6 hours in water; another for 15 hours; the third for 15 hours in sodium bichromate, and then 6 hours in water; the fourth was treated with sulphuric acid for 4 hours, after which they were placed in water for 6 hours; the fifth lot was rubbed with emery paper and soaked in water for 6 hours, and the sixth lot was soaked for 15 hours in a solution of concentrated sulphuric acid and sodium bichromate, after which the seeds were placed in water for 6 hours. These experiments were repeated a number of times, and the germinations counted at the end of the sixth and fourteenth days, with the result that in every case the treated seed contained less ungerminated seed bolls at the end of the 14 days than the untreated. In 3 experiments the percentage of ungerminated seed bolls was 39, 25, and 25, respectively. The highest percentage of germination was secured in the seed treated as indicated above for the sixth lot, in which there remained ungerminated at the end of 14 days 8, 6, and 8 per cent respectively. These experiments showed the possibility of increasing the germination of seed by treating them before planting.

Report of the seed-control station of Skara, 1899-1890, S. HAMMAR (*Ber. Verks. Skara Kem. Sta. Frönkontrolanst., 1900, pp. 25–31*).—A report is given of the various seed tests conducted at the laboratory between July 1, 1899, and June 30, 1900; the maximum, minimum, and average germinations of the different kinds of seeds being shown in tabular form.

A report of the seed-control station of Vienna for the year 1900, T. VON WEINZIERL (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 3, pp. 273–316*).—A detailed report is given of the investigations conducted at the station during the past year. The number of seed tests made showed a decided increase over those of the previous season. The usual data are given, showing the results of purity, germinability, presence or absence of dodder, the origin of seeds—particularly clover seed, and studies on numerous varieties of seed.

Seed separators, L. FONTAINE (*Rev. Vit., 15 (1901), No. 376, pp. 242–245, figs. 3*).—A description is given of a form of apparatus for the separation of seeds, the principle upon which it is based being the separation by size.

The influence of soil on the distribution of mistletoe and cuscuta in Belgium, E. LAURENT (*Bul. Agr. [Brussels], 16 (1900), No. 6, pp. 457–510, pls. 5, map 1*).—The author has made an extensive study of the distribution of these 2 parasites in Belgium. The mistletoe is reported as occurring on 122 species of plants, a list of the host plants being given. The soils of Belgium are briefly described, particular attention being paid to the lime and magnesium content. While the mistletoe is not entirely confined to calcareous soils, it is found most abundant in those soils containing 1 per cent or more of lime. The same distribution is indicated for the cuscuta. Studies were made on the relation between the composition of the ash of mistletoe and the ash of its host plant, and it was found that there was no direct relation between the two. However, the mineral substances present in the ash of the mistletoe depend upon the host plant and the nature of the soil. In the course of his investigations the author was led to examine into the cause of the infrequent occurrence of the mistletoe upon pear trees, and he claims to have found that the mistletoe secretes a toxic substance which is destructive to many varieties of pear trees. Inoculation experiments were made with the juice obtained by grinding up the mistletoe in a mortar and adding distilled water to the mixture, and when a portion of the mixture was introduced through the bark of the pear tree it set up an infection that was healed with great difficulty or remained as a place for the entrance of the spores of various fungi. When the liquid was heated for 5 minutes at a temperature of 120° C., the wounds were quickly healed, just as was the case when distilled water was injected into the plant. The study of the cuscuta is not reported in the same detail as that made with the mistletoe. Its distribution seems to be governed by the same biological factors as the mistletoe, being most abundantly present upon calcareous soils.

Destruction of charlock (*Jour. Bd. Agr. [London], 7 (1900), No. 3, pp. 353, 354*).—An account is given of experiments conducted under the direction of the agricultural department of the University College of North Wales, in which 3 plats of ⅛ acre each were sprayed with copper sulphate solutions, 2, 3, and 4 per cent solutions being used. The amount of solution applied was at the rate of 50 gal. per acre. The applications, while not entirely satisfactory, destroyed about 60 per cent of the weeds without any permanent injury to the cereal crop over which it was sprayed. Grass and clover seedlings growing in the grain were unaffected by the treatment, and in one instance appeared to have been improved by the application. While not altogether favorable, the results are thought to have more than repaid the expense of the operation, and if this were persisted in for a number of years the weeds would be ultimately eradicated.

DISEASES OF PLANTS.

Notes on the life history of certain Uredineæ, M. A. Carleton (*Abs. in Science, n. ser., 13 (1901), No. 320, pp. 249, 250*).—Notes are given on some investigations of rust fungi conducted by the author. In the case of *Uromyces euphorbiæ* it was demonstrated that this rust is able to propagate itself constantly through the germinating seed of its host and in this way becomes practically a perennial species. As far as known this is the only demonstrated example of this method of propagation among the rust fungi. Culture experiments with the common sunflower rust showed that the Puccinia and Æcidium found on the sunflower are stages of the same species, and it is probable that all the species of Helianthus bear the same rust and that they have no distinction of host forms. The author reports having succeeded in germinating the peculiar thick-walled, one-celled spores of *Puccinia vexans*. These spores are shown to be neither uredospores nor teleutospores, but partake of the nature of both. They seem to be a distinct type of spore form and the author proposes for such spores the name amphispores. Experiments by the author have shown that *Æcidium tuberculatum* is a perennial species in its perennial host *Callirrhoe involucrata*, producing spores able to germinate during the coldest winter.

A tabular review of the Swedish cereal rusts, J. Eriksson (*Ztschr. Pflanzenkrank., 10 (1900), No. 3–4, pp. 142–146*).—A review is given of investigations by the author on the specialization of rust fungi, in which the hosts of the different form species are indicated. Following the classification given by the author, it appears that *Puccinia graminis secalis* occurs on rye, barley, *Triticum repens*, *T. caninum*, *T. desertorum*, *Elymus arenarius*, and *Bromus secalinus;* form *avenæ* on different species of Avena, orchard grass, meadow foxtail, millet, *Lamarkia aurea*, and *Trisetum distichophyllum;* form *tritici* on wheat; form *airæ* on *Aira cæspitosa;* form *agrostis* on various species of Agrostis; and form *poæ* on *Poa* spp. *Puccinia phlei-pratensis* is found on timothy and *Festuca elatior*. *P. glumarum* in different forms occurs on wheat, rye, barley, *Elymus arenarius*, and *Triticum repens*. *P. dispersa* is found only on rye, and *P. triticina* upon wheat. *P. bromina* occurs on a number of species of Bromus, *P. agropyrina* upon *Triticum repens*, *P. holcina* on *Holcus lanatus* and *H. mollis*. *P. triseti* is found upon *Trisetum flavescens*, and *P. simplex* upon barley only. *P. coronifera*, form *avenæ*, occurs on oats; form *alopecuri* upon *Alopecurus* spp., and form *festucæ* upon *Festuca elatior*. *P. coronata calamagrostis* attacks *Calamagrostis* spp., and form *agrostis* is reported on species of Agrostis. For many of these species the æcidial host is unknown.

Culture experiments with a rust fungi, H. Klebahn (*Jahrb. Wiss. Bot. [Pringsheim], 34 (1900), No. 3, pp. 347–404; abs. in Bot. Ztg., 2. Abt., 58 (1900), No. 9, pp. 130, 131*).—Culture experiments with a number of species of rust fungi are reported. A number of species of Melampsora occurring upon willows were studied. Formerly all these species were grouped under *M. salicis*, but a number of forms are now recognized. Four have their cæoma stage on *Larix decidua*, one on *Ribes* spp., one on *Euonymus europæa*, and one on *Orchis latifolia*, and other species of orchids.

Melampsora amygdalinæ proved to be autœcious, occurring in both forms upon *Salix* spp. The experiments with the Puccinia of Carex showed its æcidial to be passed upon species of Ribes. The complex biological group of Puccinias found on *Phalaris arundinacea* were investigated and their æcidial hosts determined. *P. phalaradis* has for its æcidial host *Arum maculatum*. *P. sessilis*, including the form *digraphidis*, has for its æcidial hosts various species of liliaceous plants, and *P. orchidearum* upon several genera and species of orchids.

Seed treatment for the prevention of bunt of wheat (*Jour. Bd. Agr.* [*London*], *7* (*1900*), *No. 3, pp. 352, 353*).—A brief account is given of experiments in which seed of wheat badly affected with smut (*Tilletia caries*) was treated with a solution of copper sulphate at the rate of 1 lb. to 1 gal. of water. This amount of solution was used upon 4 bu. of wheat, being poured over the grain and thoroughly stirred. The resulting crop was entirely free from the disease, while an adjacent plant, grown from a similar lot of untreated seed, gave 4.66 per cent of badly smutted stalks.

Potato scab and its prevention, L. R. Jones and A. W. Edson (*Vermont Sta. Bul. 85, pp. 111–120, figs. 2*).—The cause of the potato scab, its occurrence and appearance, are described in a popular manner. The development and spread of the organism through the soil is shown, and the relative resistance of a number of varieties of potatoes pointed out. Means for prevention of the potato scab are described, among them soil treatment of different kinds, such as rotation of crops, proper selection of fertilizers, use of fungicides on the soil, etc. The disinfecting of seed potatoes as a means for the prevention of the disease is described, soaking them in corrosive sublimate or formalin solutions being recommended. The effect of formaldehyde gas was investigated to a limited extent, and the authors believe that it will prove an advantageous method of treating potatoes for the prevention of scab.

Potato blight and its treatment, D. A. Brodie (*Washington Sta. Bul. 46, pp. 15, figs. 5*).—The author gives a popular description of the fungus *Phytophthora infestans*, which is a cause of considerable injury to the potato crop in his region. The results of experiments in which plants were sprayed with Bordeaux mixture are given. The average increase of the sprayed over the unsprayed areas was nearly 37 per cent. The sprayed plants remained green much longer and were not as severely injured by the ravages of cutworms, which proved very destructive. It is recommended that spraying should begin about the middle of June, and the applications be repeated every 2 weeks during the growing season. Directions are given for the preparation of the Bordeaux mixture.

Unsatisfactory growth and premature death of cane as the result of root disease, Z. Kamerling and H. Suringar (*Reprint from Arch. Java Suikerind., 1900, No. 18, pp. 24*).—A disease of sugar cane that has caused much loss and is commonly known as "dongkellanziekte" was found to consist of 2 diseases, a root rot and another root disease. The latter has its center in Djoca, while the root rot has appeared all over Java and is especially bad along the seacoast. Inquiry among sugar planters has shown that this disease is most destructive on plantations that have been in operation for more than 40 years; that on plantations opened between 1860 and 1880 there is but little root rot, and that those established since 1880 are practically free from it.

It is therefore a trouble met with only on ground that has been long used for growing sugar cane. It is claimed to be the result of soil exhaustion, which is probably dependent upon a change in the physical condition of the soil. Facts to sustain this theory will be given in a future paper.—H. M. PIETERS.

Observations on the mosaic disease of tobacco, A. F. Woods (*Abs. in Science, n. ser., 13* (*1901*), *No. 320, pp. 247, 248*).—As a result of numerous experiments conducted by the author, it is stated that the mosaic disease of tobacco can be artificially produced in a number of ways, as by cutting back plants at any stage of active growth, by repotting or transplanting a plant during active growth and thus stimulating a rapid root development, and by injecting the sterilized juice of diseased plants into a growing bud or pouring it upon the roots of a sound plant. The same disease has been produced by the author on tomatoes, potatoes, petunias, phytolacca, violets, and other plants. The disease seems to be due to a disturbance in the balance between the oxidizing enzyms and the availability of reserve foods of the plant. The introduction of the enzym present in the sterilized juice sets up a series of pathological changes in which the normal enzym of the cell is greatly increased and the availability of the reserve foods decreased. It is believed that the diseases known as peach yellows and the California vine disease are to be similarly explained, and dieback of the orange may also be due to this cause.

Spraying for asparagus rust, F. A. Sirrine (*New York State Sta. Bul. 188, pp. 233–276, pls. 12*).—Notes are given on the history and distribution of the asparagus rust (*Puccinia asparagi*), together with descriptions of the various stages of its life history. The various recommendations that have been given for the control of this disease are reviewed at some length. Burning the infested brush, which has been recommended by a number of writers, is said to be in some cases detrimental, especially if the brush is cut and burned early in the season. This tends to weaken the plants, and if continued would greatly depreciate the crop. The value of resistant varieties is considered, and while some varieties seem less subject than others, there is as yet apparently no variety which is not liable to attack. Soil conditions, as described in Massachusetts Hatch Station Bulletin 61 (E. S. R., 11, p. 159), are reviewed, and the author believes that fogs and dews probably play an important part in the spread of the disease, at least in the region covered by his investigations. Spraying for the prevention of the disease has been recommended by some writers, and the author conducted a series of experiments in which plants were sprayed with Bordeaux mixture containing resin, 3 applications being given. This fungicide was prepared by adding to a 1: 8 formula of Bordeaux mixture a resin mixture composed of 5 lbs. resin, 1 lb. potash lye, 1 lb. fish oil, and 5 gal. of water. This was thoroughly sprayed over the plants in August and September, and the effect upon the subsequent crop noted. The yield of bunches in 1899 was increased 69.5 per cent in the sprayed over the unsprayed plants, and in 1900 a gain of 48 per cent was reported. This fungicide adheres quite readily, and with a thorough application will doubtless prove valuable in combating this disease. The parasitic fungus *Darluca filum* was noticed abundantly, but it has never been observed attacking the winter spores of the rust, and there appear to be indications that this parasite will not materially check the disease where asparagus is grown in large quantities.

A form of power sprayer especially devised for spraying asparagus is described at considerable length. The apparatus is not patented, and it is described in sufficient detail so that any one desiring can manufacture a similar implement.

Protecting asparagus, F. H. Hall and F. A. Sirrine (*New York State Sta. Buls. 188 and 189, popular ed., pp. 14, figs. 5*).—This is a popular summary of bulletins 188 and 189, giving directions for spraying for the prevention of fungus and insect pests.

An investigation on damping off of seedlings, V. Peglion (*Staz. Sper. Agr. Ital., 33 (1900), No. 3, pp. 221–237*).—The fungi usually believed to cause damping off are *Phytophthora omnivora* and *Pythium debaryanum*. In addition to these, the author finds that a number of other fungi attack seedlings in the same manner. Among them are mentioned *Botrytis cinerea*, *Thielaria basicola* and *Phoma beticola*. The action of these different fungi upon the plant is described, and experiments for preventing their attacks are outlined. The author conducted a series of experiments in disinfecting soils by means of heating and by application of carbon bisulphid and formalin. Soil that was known to be infested with *Pythium debaryanum* was heated to 60 and 100° C. and was treated with various amounts of carbon bisulphid and 20 and 30 per cent solutions of formalin. The soil was afterwards seeded to Camelina, which is known to be very susceptible to attacks of this fungus. In every case the treatment had beneficial effect in reducing or totally prohibiting the action of the fungus.

On the diseases of mushrooms and their prevention, G. Delacroix (*Bul. Min. Agr.* [*France*], *19* (*1900*), *No. 5, pp. 889–899*).—A report is given on studies made by the author in the vicinity of Paris of the diseases to which mushrooms are subject. The most serious one is due to a fungus *Mycogone perniciosa*. Its method of attack is described and experiments reported in which various possible means for prevention has been investigated. Sulphate of copper, sulphate of iron, boric acid, and limewater were without effect, while thymol and lysol were found to be valuable in preventing the disease. Lysol, on account of its ready solubility in cold water, is to be preferred. A number of insects which are injurious to mushrooms in the caves are briefly described. Notes are also given on a number of other pests which are more or less troublesome in mushroom growing. One of the most serious troubles in mushroom growing is to prevent the entrance of other species of fungi which are of little or no value, such as *Clitocybe candicans* and *Pleurotus mutilus*. Attacks of *Monilia fimicola* are also mentioned, as well as that of the parasite, *Myceliophtora lutea*. For the prevention of these troubles the author recommends the thorough sterilization of the mushroom beds and spraying around them with some good fungicide, after which the spawn is planted.

A fruit disease survey of western New York in 1900, F. C. Stewart, F. M. Rolfs, and F. H. Hall (*New York State Sta. Bul. 191, pp. 291–331, pls. 4*).—The results of a survey of the western part of the State of New York, embracing 18 counties, are given. The data were obtained in the same manner as those secured for the survey of the Hudson River Valley the previous year. Circulars of inquiry and personal visits were made to different parts of the State, and the amount of damage done by the more common fruit diseases was estimated. Among the apple diseases observed were scab, leaf spot, fruit spot or Baldwin spot, fire blight, canker, crown gall, "hairy root," powdery mildew, and rust. The canker observed is attributed to 3 different organisms, and the authors believe that when more fully understood the apple canker will be found to be caused by at least three distinct organisms, which are strikingly similar in their grosser characters, and as yet have not been sufficiently differentiated to distinguish them without microscopical examination. Of these, the canker caused by *Sphæropsis malorum* is the most troublesome, and a disease hitherto unreported, caused by a species of Cytospora, is the least injurious. Investigations were made to determine the possible identity of Sphæropsis with *Macrophoma malorum*. These fungi differ principally in the character of their spores, but the authors believe that they are entirely distinct. The crown gall was found to be confined chiefly to young trees in the nursery, and it is recommended that all trees showing any trace of the disease be rejected. The "hairy root" disease was observed while examining nursery stock for crown gall. The affected trees have few if any large branch roots, the root system consisting of a multitude of small rootlets which spring from the somewhat thickened main root, giving it a bushy or hairy appearance. This disease has been known for 40 or 50 years among nurserymen, but is seldom sufficiently abundant to cause appreciable loss. Affected seedlings are usually rejected. No cause is known for this trouble.

Among apricot diseases noted are collar rot, injury of trunks and branches, brown spot, and fruit rot. The collar rot is one of the most destructive of apricot diseases. The affected trees show dead bark for a distance of 3 or 4 in. above the union or collar. On recently destroyed trees the injury never extends below the union. As a rule, affected trees wilt rather suddenly during the summer, after having put out their leaves in an apparently normal manner. This disease is not confined to any particular part of the orchard, or to any locality, and so far no satisfactory cause has been observed for it.

Of blackberry diseases observed, the rust, leaf spot, and cane knot were the most destructive. The rusts of blackberry are usually called the orange rust and the white rust, from the nature of the fungus attacking the plant. A report is given of a third which is called the yellow fall rust. This disease is due to *Uredo mülleri*. The fungus does not appear especially severe in its attack and there is no cause for alarm at its occurrence.

The fruit rot, black rot, witches' brooms, and leaf scorch of cherries are reported, and the occurrence of a new fungus on cherry branches is mentioned. This fungus (*Cryptosporium cerasinum*), while occurring rather frequently, is probably not parasitic.

The diseases of currants and gooseberries observed were cane blight, leaf spot, and powdery mildew.

The vineyards of western New York were found to be remarkably free from disease during the season. The black rot and downy mildew were destructive only in a few localities, and the powdery mildew and anthracnose were exceedingly rare. In several localities green grapes showed russet bands and blotches on their skin, which were attributed to weather conditions, probably a light frost after the fruit had set. On many of the russeted fruits one or more seeds were sometimes exposed, and this is believed to be due to the same cause as that producing the russet spots upon the fruit.

Of peach diseases the occurrence of leaf curl, yellows, little peach, brown spot, and a disease of peach trees in the nursery cellar, are among those noted. The brown spot is attributed to the fungus *Helminthosporium carpophilum*. This fungus begins its attack while the fruit is still green, but is most conspicuous on the ripe fruit, where it appears in the form of pink spots and cinnamon brown areas. The spots at first are quite small, and in time a number coalesce, forming irregular areas of cinnamon brown color, the pink discoloration almost entirely disappearing. What appears to be the same fungus was found on the branches of the peach tree, and it is believed that the fungus causing the brown spot is not only parasitic on the twigs, but occurs sometimes on the leaves and knots of the trees. Whether parasitic on leaves or not was not determined. The fungus is known also to attack the apricot fruit. The disease of peaches reported from the nursery cellar was observed in the winter of 1899–1900. The cellar contained about 10,000 peach trees trenched in sand after the usual manner. Some of the trees were wet when put in the cellar, and the sand stuck to the branches. Early in January, it was found that 15 per cent or more of the trees showed dead sections of 1 to 4 in. on the limbs to which there was adhering sand. A fungus was associated with the disease, but failure to produce mature forms made its identity uncertain.

Among the diseases of pear observed are fire blight, leaf scorch, body blight or canker, injury due to winter and drought.

Of the plum diseases, the fruit rot, sun scald, canker, and gum pockets, were the most frequently observed. Associated with the fruit rot on the mummy plum was a fungus which, it is thought, does the twig little or no harm. The species has been identified as *Coniothecium sociale*. The canker of the plum is similar to that described on the apple as due to a species of Cytospora, but the fungus on the 2 different trees seems to be distinct. The same or a similar species has also been observed on apricot and peach. Inoculation experiments were made with spores from a pure culture made from the canker on a Japan plum, in which the disease was readily communicated.

The leaf blight, canker, and powdery mildew of quinces are reported as causing considerable damage, and a number of other diseases occurring less frequently than usual.

A peculiar form of raspberry anthracnose, due to *Glœosporium venetum*, is described. Ordinarily the anthracnose rarely attacks the red raspberries, but during the season it was observed as decidedly injurious to the Cuthbert variety of red raspberry, upon which knots of various sizes were produced. These were of a rough spongy texture, often twice the diameter of the normal cane. When examined late in the summer, the knots were found to be intimately associated with the anthracnose. Similar knots are reported on the variety Thompson, and it is thought that these knots are a peculiar manifestation of the ordinary anthracnose. The raspberry rust, powdery mildew, cane blight, and leaf spot are reported as injuring the crop to some extent.

New or rare fruit diseases in western New York, F. H. Hall and F. C. Stewart (*New York State Sta. Bul. 191, popular ed., pp. 11, pls. 3*).—This is a popular summary of the above bulletin.

A rhizomorphic root rot of fruit trees, E. M. Wilcox (*Oklahoma Sta. Bul. 49, pp. 32, pls. 11*).—The results of investigations by the author on the cause of the root rot of fruit trees are given. This particular disease has been observed for some time occurring in the territory, and is due to one of the mushroom fungi. The distribution of this root rot throughout Oklahoma and the United States is traced, from which it appears to be a widely scattered disease. The most characteristic effect of the attack of the fungus is a great exudation of gum about and from the crown of diseased trees. This gum flow occurs in apple, peach, and cherry trees, according to the author's observation, and is reported in apricot and others. It sometimes happens that the amount of gum exuded is so great as to form a mass of cemented soil about the tree. The leaves are usually discolored, the yellow coloration being one of the prominent symptoms of the disease. In some cases, however, the leaves wilt rapidly during the growing season instead of becoming yellow, and this rapid wilt is the first indication of the disease. Upon examination of trees affected by the disease, typical rhizomorphic strands will be found adhering to the roots. The groups of sporophores, or—as they are commonly called—toadstools, about the base of the tree is positive evidence of the presence of the disease. The changes in the wood caused by the fungus are described, and its spread is said to be through the production of abundant spores and through the spread of the mycelial strands in the soil.

The fungus causing this disease is said to be new, and the name *Clitocybe parasitica* is given it. The technical characteristics are described and remedial and preventive measures suggested. If a single tree is found to be diseased it is recommended that a ditch be dug completely around it at a distance of about 10 ft. The ditch should be about a foot wide and 2 ft. deep, with vertical walls. This will prevent the spread of the fungus through the soil. All infested fruit trees should be removed and burned. This, together with the ditch about the place where the tree has stood, will generally prevent the further spread of the disease. The fungus has also been found to be parasitic upon various species of oak, and these should be treated in the same manner when occurring in or near orchards. Orchards should not be planted on soil known to contain old oak stumps or roots, as they may be affected and spread the disease to the trees when planted. An extensive bibliography on the subject completes the bulletin.

A root rot of fruit trees, E. M. Wilcox and O. M. Morris (*Oklahoma Sta. Bul. 49, popular ed., pp. 11, pls. 2*).—This is a popular summary of the bulletin noted above.

Preliminary report on bitter rot or ripe rot of apples, J. T. Stinson (*Missouri Fruit Sta. Bul. 1, pp. 21*).—A description is given of the ripe or bitter rot of apples, caused by *Glœosporium fructigenum*, together with the results of experiments on the prevention of the disease. The varieties used were Ben Davis and Huntsman, both of which are believed to be especially subject to the disease. Bordeaux mixture was used, from 3 to 5 applications being given the trees. The fruit on the sprayed trees was about 10 days later in ripening than upon the unsprayed trees. The leaves remained on the sprayed trees until after the fruit was gathered, and the percentage of diseased fruits was greatly reduced by the treatment. A circular was sent out by the author to fruit growers in his vicinity to ascertain the extent of the disease and what means were taken to combat it. The results of his inquiry indicate that the disease was rather widely spread and occasioned considerable loss. But little has been done for its prevention in the region covered by the inquiry. The author recommends thorough spraying with Bordeaux mixture or other good fungicide, and gives formulas for their preparation and directions for their application.

The cause and cure of canker in apple and pear trees, P. PASSY (*Gard. Illus., 22 (1900), No. 1134, p. 517*).—The canker, which is said to be a serious disease affecting the branches and stems of fruit trees, especially apple trees and sometimes pears, is due to *Nectria ditissima*, the parasitic nature of which is fully established. The author states that different varieties of apples vary in their susceptibility, some being almost entirely unaffected by the disease; others, like Reinette du Canada, are especially susceptible to it. By experimental inoculations, it was found possible to produce the disease upon a variety of pear with conidial spores taken from another pear tree. As means for the prevention of this disease, the author states the best way is to burn all diseased branches. Where this can not be done, the cankers should be cut out, removing every part attacked by the parasite, together with a portion of the sound wood, and treating the wood with a strong antiseptic, such as Bordeaux mixture, iron sulphate, etc.

The Monilia disease or twig blight of apples and pears, H. MÜLLER-THURGAU (*Centbl. Bakt. u. Par., 2. Abt., 6 (1900), No. 20, pp. 653–657*).—According to the author, during the past season, in May and June, there appeared in the orchards of various parts of Switzerland a serious disease, in which the twigs of apple trees in particular were attacked. There was observed to be some difference in the susceptibility of different varieties, a few escaping serious injury. Shortly after blooming, here and there a twig was seen to wilt. As the disease progressed, others were affected, until half or more of the newer twigs were affected. Examinations of the diseased twigs showed that they were infested with a fungus which is determined as *Monilia fructigena*. The sudden and unusual occurrence of this fungus is attributed partially to frost injuries, although the parasitism is established in a number of instances. As a means of prevention, it is recommended that all the diseased twigs be cut back into the sound wood, and during the winter all material, such as leaves, mummy fruits, etc., which carry the spores, should be collected and burned.

Peach foliage and fungicides, W. C. STURGIS (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 219–254, pls. 3*).—On account of the serious injury which frequently follows the use of fungicides on peach foliage, the author has conducted an extensive series of experiments in which Bordeaux mixture of different strengths, soda-Bordeaux mixture, ammoniacal copper carbonate solution, copper acetate, and potassium sulphid were tested. The amount of copper present in the Bordeaux mixture varied from 1 to 5 lbs. to 50 gal. of water. The copper-acetate solutions were composed of normal copper acetate as well as the subacetate. The result of spraying these different mixtures on the peach foliage are discussed at some length. Upon peach trees the use of Bordeaux mixture containing more than 2 lbs. of copper sulphate to 50 gal. of water proved injurious to the foliage and to the fruit. Similar effects were observed where the soda-Bordeaux mixture was used, some strengths of the solution proving more injurious to the fruit than where the ordinary Bordeaux mixture was used. The ammoniacal copper-carbonate solution proved injurious in the strengths employed, and the subacetate of copper caused serious defoliation of the trees. The normal copper acetate, used in the same proportion as the subacetate, had only a slightly injurious effect upon the foliage. Potassium sulphid, at the rate of 1 oz. to 3 gal. of water, had no injurious effect upon either foliage or fruit. The author states that the partial defoliation of well-grown peach trees by the application of fungicides of medium strength late in the season may not be attended with any serious or permanent injury, and in some cases a decided advantage may accrue in the earlier ripening of the fruit and its higher color, the free exposure to air and sunshine rendering it less liable to fungus attacks.

From experiments of the past season, the author believes he is justified in recommending the spraying of peach trees with Bordeaux mixture composed of 5 lbs. of copper sulphate, 5 lbs. of lime, and 50 gal. of water, before the buds begin to expand. A second application, in which the amount of copper is reduced to 2 lbs. and lime to 4, should be given the trees just before the blossoms open and once after the fruit has set. These applications are to be followed two or three times during the ripening season with potassium sulphid solution, 1 lb. to 50 gal. of water. The injury resulting from the application of Bordeaux mixture appears to be due to the direct effect of the chemical on the chlorophyll of the leaf, whereby it is disorganized and ceases to perform its normal functions of assimilation. The peculiar susceptibility of the leaves of the peach, apricot, and Japanese plum, as compared with those of the apple, pear, quince, and other fruit trees, does not appear to be connected in any way with the total thickness of the leaves or with the differences in size and distribution of the stomata. Important differences are noted in the arrangement of the spongy parenchyma of the different leaves. In those susceptible to injury it is very dense, with small, intercellular air spaces, while in the nonsusceptible ones the leaves have a loose, open texture. Whether this fact has any direct bearing upon the question of susceptibility has not been determined.

Notes on spraying peaches and plums in 1900, C. O. Townsend and H. P. Gould (*Maryland Sta. Bul. 71, pp. 115–127, figs. 2*).—The occurrence of the fruit rot (*Monilia fructigena*) upon peaches and plums is mentioned and the characteristics of the disease described. The results of experiments in which peaches and plums were sprayed with Bordeaux mixture for the prevention of this disease are given. Dilute Bordeaux mixture in which 3 lbs. of copper sulphate to a barrel of water was used greatly reduced the amount of disease without seriously injuring the foliage. No marked difference was noticed between trees which received the first application March 23 and those sprayed May 26 and June 28. The spraying should be continued well up to the time of ripening of the fruit, and, based upon the authors' experiments, can be done at an expense not to exceed 6 cts. per tree. Not only was the disease almost entirely prevented by this treatment, but the texture and size of the fruit was decidedly improved by the applications. The experiments with plums indicated that plums of the domestic varieties were apparently uninfluenced by the application of the fungicides. The Japan varieties were greatly benefited by the treatment. These are very subject to injury by the strong fungicides, and the amount of copper sulphate to a barrel of solution should not exceed 2 lbs.

Experiments in the control of fumagine of the olive, D. Vidal (*Prog. Agr. et Vit. (Ed L'Est), 22 (1901), No. 4, pp. 121–124*).—This disease of the olive is said to be quite prevalent and is characterized by the presence on the branches, leaves, fruits, and frequently on the trunks of the trees, of black, sooty-like patches. It is the growth of a number of fungi more or less well known which follow attacks of certain insects, in this case *Lecanium oleæ*. Preventive treatment must be directed against the insects upon which the fungus is dependent. The results of investigations carried out in the season of 1900 showed that the best method of treatment was to spray thoroughly with Bordeaux mixture to which turpentine was added. Two sprayings, one in June and the other in September, were found to be sufficient for the eradication of the disease.

The premature falling of fruit, J. Burvenich (*Bul. Arbor. et Flor., 1900, pp. 169–171*).

The Anaheim or California vine disease, C. P. Lounsbury (*Agr. Jour. Cape Good Hope, 18 (1901), No. 2, pp. 90–94*).—An account is given of the disease of grapes which was formerly quite prevalent in California and which has been called the "California vine disease." This disease was formerly described in a publication of this Department (E. S. R., 4, p. 498). The author believes that its spread may be prevented by the planting of resistant varieties, some of which are briefly described.

The causes of gray rot of grapes, J. Dufour (*Chron. Agr. Canton Vaud, 14 (1901), No. 2, pp. 38–42*).—The gray rot of grapes is said to have been exceedingly troublesome in parts of France during the season of 1900. In some regions it was reported to have very seriously diminished the grape crop. The disease is due to *Botrytis cinerea*. The fungus is dependent for its development upon somewhat peculiar atmospheric conditions which were present during the season. August was very dry and warm, followed in September and October by heavy rains, which produced the proper conditions for the rapid development of the fungus.

Treatment of anthracnose, with a comparison of the effects of various sprays and dressings, E. H. Rainford (*Queensland Agr. Jour., 7 (1900), No. 6, pp. 529–532*).—The author has investigated different means for the prevention of grape anthracnose. The object of his experiments was to compare the effect of different sprays and winter treatments. Winter treatments with a 10 per cent solution of sulphuric acid and a mixture of lime and sulphur were compared with sprays of eau celeste, Burgundy mixture, and Bordeaux mixture. The results obtained showed no appreciable superiority of either of the sprays over the other, but the acid dressing proved much more effective than the lime and sulphur mixture. The result of this one experiment seems to indicate that the disease may be controlled; but the experiments have not been carried sufficiently far to warrant definite recommendations regarding them.

The chrysanthemum rust, E. Jacky (*Ztschr. Pflanzenkrank., 10 (1900), No. 3–4, pp. 132–142, figs. 6*).—According to the author, the chrysanthemum rust made its appearance in England in 1895, and was reported 2 years later as occurring on the continent of Europe. The species of rust is *Puccinia chrysanthemi* and it has been claimed to be identical with *P. tanaceti*, but inoculation experiments have shown that the 2 species are not identical. Numerous experiments made by the author and others to determine the hosts of this fungus are reported, from which it appears that it is specialized on *Chrysanthemum indicum*. Inoculations by the author upon other species of Chrysanthemum, *Tanacetum vulgare*, *T. balsamita*, *Artemisia campestris*, *Hieracium aurantiacum*, and the dandelion, were unsuccessful. The fungus is described and its distribution indicated. As means for its prevention the author recommends careful attention and isolation of diseased plants, avoiding rooting any that have been attacked by the rust. The difference in susceptibility of different varieties as reported in England and in the United States is noted, but in Germany the author says no one variety seems more susceptible than the other. It is said that a great many fungicides have been unsuccessfully used for the prevention of this disease, but the author thinks the experiments were not carefully conducted, and is inclined to believe that Bordeaux mixture may be of value in preventing its spread.

A disease of carnations caused by Fusarium dianthi, G. Delacroix (*Compt. Rend. Acad. Sci. Paris, 131 (1900), No. 23, pp. 961–963*).—This disease was first described by L. Mangin (E. S. R., 11, p. 860). Later the author, associated with E. Prillieux, described the disease as due to one of the imperfect fungi, to which the name *Fusarium dianthi*, n. sp., was given. Since that time the studies have been continued and additional information gathered, which confirms them in their opinion as to the cause of this disease. The organism is in the main a soil fungus, and as a preventive treatment it is suggested that all badly diseased material should be burned, contaminated soil should not be used for growing carnations for a number of years, and in forming cuttings to be certain that they do not come from infested regions. Experiments were conducted with carbon bisulphid, sulphate of iron, formaldehyde, and naphthol, from which it was found that all, with the exception of the last, would prevent the germination of the spores and the spread of the disease.

On the parasitism of Fusarium roseum and allied species, L. MANGIN (*Compt. Rend. Acad. Sci. Paris, 131 (1900), No. 26, pp. 1244–1246*).—The author states that in cultivating carnations in a number of media he has been able to demonstrate the parasitism of a number of species of Fusarium, among them *F. roseolum*, *F. commutatum*, *F. roseum*, *F. aurantiacum*, *F. oxysporium*, and *F. pyrochroum*. The characteristics of each of these fungi upon the host are described, from which the author concludes that the parasite causing the disease upon carnations is not new and should not be given the name *F. dianthi* of Prillieux and Delacroix. Experiments conducted for the prevention of this disease have shown that lysol, corrosive sublimate, and naphthol applied to the soils are efficient in preventing the growth of the fungus.

A disease of the locust tree, H. VON SCHRENK (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 247*).—A destructive disease of the black locust (*Robinia pseudacacia*), due to *Polyporus rimosus*, is described. The fungus destroys the heart wood of the tree, leaving a soft yellow mass. The fruiting organs form on the trunk and larger branches, discharging their spores in summer and fall. The mycelium grows only in the heart wood of living trees and dies as soon as the tree is cut down. This is thought to be probably due to changed conditions of aeration, moisture, and temperature, and as a result the fungus is considered as belonging to a special class of saprophytes.

The bacterial diseases of plants, E. F. SMITH (*Abs. in Science, n. ser., 13 (1901), No. 320, p. 249*).—An account is given of diseases caused by bacteria, and the wilt of cucurbits due to *Bacillus tracheiphilus*, the brown rot of solanaceous plants due to *B. solanacearum*, and the black rot of cruciferous plants caused by *Pseudomonas campestris*, are described.

The nematodes of coffee roots, A. ZIMMERMANN (*Meded. 'S Lands Plantentuin, 37 (1900), pp. 1–23, figs. 2*).—The author gives an account of the habits and life history of *Heterodera radicicola*, *Aphelenchus coffeæ*, and *Tylenchus acutocaudatus*. The first-named species is not especially injurious to the roots of coffee in Java. The other species, however, commit serious depredations, and the number of coffee plantations which have been destroyed in Java by the attacks of these worms is estimated at over 4,000. Brief notes are given on the nature of the injuries caused by the parasitic nematodes.

Among the remedies which were tried for the purpose of destroying these worms, ferric sulphate gave promising results, while copper sulphate was used without success. Petroleum, benzin, and creolin were also used without satisfactory results. The application of carbon bisulphid was attended with good success. Experiments were also conducted in manuring the ground around infested plants, digging out and burning infested plants, quarantining infested areas, and thorough cultivation of the ground. Good results were obtained in some cases by planting other crops upon infested ground for a few years.

A considerable number of experiments were tried in grafting Java coffee upon the roots of other plants of the same family in order to determine whether such coffee might be grown upon roots which would resist the attacks of nematodes. In these experiments roots of the following plants were used: *Cinchona succirubra*, *Coffea densiflora*, *Morinda citrifolia*, *Psychotria robusta*, and *Gardenia grandiflora*. Thus far these experiments have been without promising results. The author recommends in cases of infestation by *Aphelenchus coffeæ* or *Tylenchus acutocaudatus* that areas in which the Java coffee is dying out should be thoroughly investigated, and if the nematodes are found, that such areas should not be planted to coffee. It is also suggested that further experiments in grafting coffee upon the roots of other plants might be tried on a small scale.

Literature of plant diseases, W. C. STURGIS (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 255–297*).—This is in continuation of a bibliography published in a previous report (E. S. R., 10, p. 267) in which the literature relating to plant diseases is brought down to include the years 1887–1900. The list given is not intended as a complete bibliography of the subject, but rather to enable the practical observer of plant diseases to ascertain the principal sources of information regarding the specific cause and means of prevention of various diseases, as reported in the publications of the U. S. Department of Agriculture, and the various State experiment stations.

A condensed handbook of the diseases of cultivated plants in Ohio, A. D. Selby (*Ohio Sta. Bul. 121, pp. 69, figs. 54*).—The author discusses in a popular manner some of the causes of plant diseases and the methods by which they are spread, after which popular descriptions are given of the more common diseases which have been noticed as occurring in Ohio. The diseases are arranged alphabetically under the host plants and where methods of treatment are known they are described. Directions are given for the preparation and use of fungicides and insecticides, with a spray calendar, showing briefly the method of treatment to be followed for different insect and fungus pests.

ENTOMOLOGY.

The sixteenth report of the State entomologist on injurious and other insects of the State of New York, E. P. Felt (*Bul. New York State Mus., 7 (1901), No. 36, pp. 949–1063, pls. 16, figs. 2*).—Popular accounts are given of the gypsy moth and the palmer worm, together with bibliographical references to literature concerning the latter species. A number of experiments were made with insecticides for the destruction of the San José scale. The result showed that a 20 or 25 per cent mechanical mixture of kerosene did not kill all the scales. An application of a 10 per cent mixture in summer was not injurious to the trees, but it was found that the application must be repeated every 10 days, beginning about the middle of June, in order to obtain good results. The use of pure kerosene proved unsatisfactory and is not recommended. A 20 per cent mechanical mixture of crude petroleum did not injure the trees and is reported as one of the most satisfactory remedies to be used in the early spring. Some scales escaped even when a 25 per cent mixture was used, and the latter strength is considered no more efficient than the 20 per cent mixture. A few scales were found alive after spraying with undiluted crude petroleum.

Trees were not injured by application of whale-oil soap at the rate of 2 lbs. to the gallon of water. The results were not so good as those obtained by a 20 per cent mixture of crude petroleum, 2 applications of the whale-oil soap being required to produce the effects which were obtained by 1 application of the crude petroleum. Spraying in summer with whale-oil soap at the rate of 1 lb. to 5 gal. of water was effective in killing young scales. A combination of whale-oil soap with crude petroleum gave good results, but this mixture was no more effective than the crude petroleum alone.

Hydrocyanic-acid gas proved to be very effective, practically all of the scales being killed by the use of 1 oz. of cyanid of potassium to 150 cu. ft. of space. The trees were not injured in the least. The method is highly recommended for all except very large trees, where the expense would be rather great.

Brief notes are given on the fruit-tree bark beetle, plum curculio, flea beetles, elm-leaf beetle, *Chrysochus auratus*, 12-spotted asparagus beetle, grain beetles, snake worm, forest tent caterpillar, fall army worm, elm-bark louse, harlequin cabbage bug, grasshoppers, and *Lophoderus triferana*. The forest tent caterpillar occurred in such numbers that contact insecticides were tested, with good results.

A summary is given of the reports of voluntary observers in different counties of the State. The publications of the entomologist for the year are listed, and a statement is given of the additions to the entomological collections.

Illustrated descriptive catalogue of some of the more injurious and beneficial insects of New York State, E. P. Felt (*Bul. New York State Mus., 8 (1900), No. 37, pp. 52, figs. 83*).—Brief descriptive and economic notes on the common species of insects injurious to fruit trees, small fruits, shade trees, garden crops, and grass and food products, together with brief notes on the beneficial insects and the standard insecticides.

Report of the entomologist, C. P. GILLETTE (*Colorado Sta. Rpt. 1900, pp. 123-131*).—Brief biological and economic notes are given on the codling moth, peach-twig borer, *Cacoecia argyrospila*, *C. semiferana*, leaf crumpler, climbing cutworm, *Alypia octomaculata*, *Philampelus achemon*, pear slug, woolly aphis, apple aphis, Putnam scale, *Chionaspis ortholobis*, leaf hoppers, apple-twig borer, *Lina scripta*, and wheat aphis. Cutworms are reported as occurring in great numbers on alfalfa. They belonged to the species *Carneades tessellata*. A beet army worm (*Laphygma flavimaculata*) was exceedingly injurious in 1899, but was comparatively rare during the past season. The caterpillars did the most damage to early beets and injured only late planted beets near weeds or early beets. Brief notes are also given on a number of other injurious insects, bee paralysis, black brood, and experiments with leaf hoppers, coddling moth, and grasshoppers.

Insect notes, W. E. BRITTON (*Connecticut State Sta. Rpt. 1900, pt. 3, pp. 311-322, fig. 1*).—A brief report is given on experiments with hydrocyanic-acid gas in barn and greenhouse. Treatment of hay infested with clover-hay worm was unsuccessful. The gas could not be made to penetrate very far into the mass of hay. Fumigation with this gas was tried in a greenhouse containing tomato plants which were infested with *Aleurodes vaporariorum*. The house contained 4,800 cu. ft., and 3 oz. potassium cyanid were used for each 1,000 cu. ft. The gas was generated in the afternoon, and the house was kept closed for 30 minutes. Gas was generated in vessels at each end of the greenhouse. All the insects were destroyed, but more or less injury was noted in most of the plants. A smaller quantity of cyanid than 3 oz. per 1,000 cu. ft. is recommended for fumigating tomatoes in greenhouses.

Notes are given on the banding of trees to prevent injury by the fall cankerworm. This paper was published in essentially the same form in Bulletin 26, Division of Entomology, of this Department (E. S. R., 12, p. 860). Brief notes are given in tabular form on the common and scientific names, host plants, locality, etc., of insects which are sent to the station for identification during the season. Elm scale (*Gossyparia ulmi*) occurred in considerable numbers on elm trees in different parts of the State. Spraying with whale-oil soap was found to be effective, as well as treatment with a 10 and 15 per cent mechanical mixture of kerosene and water. Cabbage plusia was successfully controlled by spraying with a 15 per cent mixture of kerosene and water. Brief biological and economic notes are given on book lice, codling moth, forest tent caterpillar, and other injurious insects.

Mechanical mixtures of kerosene and water proved very effective in the treatment of a number of insects. A 10 per cent mixture was successfully used against oyster-shell bark-louse, and apple aphis and pear psylla were destroyed by means of a 15 per cent mixture of the same substance. White flies in greenhouses and the red spider yielded readily to treatment by this insecticide.

The growth of economic entomology in Australia and its relation to agriculture, W. W. FROGGATT (*Agr. Gaz. New South Wales, 12 (1901), No. 1, pp. 131-138*).—The author discusses the economic importance of investigation of various remedies for the control of injurious insects and calls attention to exchanges of beneficial insects between government entomologists of different countries. Brief references are made to various injurious insects by way of illustration of the discussion.

Some of the internal changes which accompany ecdysis in insects, W. L. TOWER (*Proc. Amer. Assoc. Adv. Sci., 49 (1900), p. 231*).—One of the most important changes which precede ecdysis is the development of exuvial glands. These are one-celled, pear-shaped, with the smaller end prolonged into a tube which opens through a pore. The glands enlarge rapidly during the few days immediately preceding ecdysis and pour out their contents when the process of molting occurs. The glands occur on all parts of the body, but are most numerous on the pronotum.

Locusts or grasshoppers, L. Bruner (*Nebraska Sta. Bul. 70, pp. 14, figs. 13*).—An analytical table is presented for the purpose of assisting in the identification of the 10 common species of grasshoppers in the State. The 4 most important ones from an economic standpoint are *Melanoplus bivittatus*, *M. differentialis*, *M. femur-rubrum*, and *M. atlanis*. Brief notes are given on the life history of grasshoppers and on the causes for excessive increase of these insects in certain years. The author discusses the method of killing locusts with fungus diseases. Experiments with a fungus disease imported from South America were without result. Another disease very similar to the South American fungus is reported. Disking or harrowing and the use of hopperdozers are recommended in the destruction of these insects.

A preliminary report of progress of an investigation concerning the life history, habits, injuries, and methods for destroying the Mexican cotton-boll weevil (Anthonomus grandis), F. W. Mally (*Austin, Texas: Von Boeckmann, Schutz & Co., 1901, pp. 45*).—The author describes in considerable detail the life history and habits of this insect. The female eats a hole into the square, form, or young boll, and deposits 1 egg in each hole. The opening is then closed with a small drop of glue. So far as observed the eggs are deposited nowhere else. The larva upon hatching feeds upon the inside portions of the square or form in which the egg has been laid. The whole life cycle is passed in the same situation and extends through 1 month. The species hibernates in the adult stage in the cracks of bark and under rubbish of various kinds.

The adult weevil flies little, if at all, at night, and lantern traps are therefore not recommended. Good success was had in planting trap rows of cotton early in the season, using early varieties. The beetles collect upon these early plants, from which they may be jarred into pans smeared on the bottoms and sides with coal tar or other adhesive substance. This method is recommended as especially effective and economical for small areas of cotton. Since infested squares may be recognized by what is commonly called flaring and later fall to the ground, they may be collected and destroyed before the weevils have had time to mature and escape. In experiments for the purpose of determining the cost of collecting the fallen squares, it was found that during the months of May and June the squares could be gathered for from 5 cts. to 10 cts. per acre, while during July the expense reached 25 cts. an acre. This was for the work of adult negroes. When boys were used the expense was about 6 cts. per acre for the season.

As already indicated the infested squares can be recognized before falling and can be picked off and destroyed. Plowing under fallen squares gives little promise of effectiveness, since experiments indicated that the weevils could make their way to the surface after being buried to a considerable depth. For the purpose of securing early trap plants, it is recommended that the seed of early fruiting varieties be planted or seed grown in a northern latitude. Infested cotton seed may be fumigated with carbon bisulphid at the rate of 1 lb. to from 25 to 50 bu. of seed.

It is well known that squares which do not bloom within 6 weeks of frost very seldom come to maturity. Such squares, therefore, serve chiefly as food and places for egg laying of the weevils. By turning stock into cotton fields late in the summer the young squares containing weevils will be grazed off. The stalks and other portions which are left by cattle may be cut down and piled up so as to serve as attractive hibernating quarters for the weevils. Such piles of refuse may then be burned.

Since the boll weevil is protected against ordinary insecticides during its whole life, special methods of spraying are recommended. The best results were secured by the use of poisoned molasses. A formula for use on trap plants is 2 gal. cane molasses, 2 oz. arsenic boiled in water until dissolved, 4 oz. arsenate of lead, and 46 gal. of water. On the main crop of cotton for use in midsummer the following mixture was found effective: 1 gal. cane molasses, 1 oz. arsenic, 6 oz. arsenate of lead, and 47 gal. of water. The author insists upon the desirability of beginning all lines of treatment as early as possible in the spring.

A supplementary report of investigation of the Mexican boll weevil is appended, in which the author calls attention to the work which has already been done, and the appropriations which will be necessary for continuing the work.

The Mexican cotton-boll weevil, F. W. Mally (*U. S. Dept. Agr., Farmers' Bul. 130, pp. 30, figs. 4*).—The essential facts contained in this bulletin have been noted above from another source.

The root louse of grain and means of combating it, G. del Guercio (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 87–94, figs. 4*).—The author describes *Pentaphis trivialis* in all its stages and gives brief notes on its habits and life history. Mention is made of a remedy previously recommended, which consists in mixing double sulpho-carbonate of potash and lime in the soil. The fumes of carbon bisulphid are given off from this compound, which destroy a certain proportion of the lice. The author recommends also the destruction by means of carbon bisulphid of the ants which attend this species of plant louse.

Caterpillar plagues, with an account of the potato pests at Windsor, W. W. Froggatt (*Agr. Gaz. New South Wales, 12 (1901), No. 2, pp. 237–243, pls. 2*).—The author gives an account of an unusually extensive outbreak of injurious caterpillars. The larvæ of *Plusia verticillata* appeared in such numbers as to threaten the utter destruction of potato fields. As many as 200 caterpillars were shaken from a single plant. The caterpillars remained on the underside of uninjured leaves or clung close to the leaf stalk after the leaves had been eaten. Notes are given on the life history of this insect and on its other food plants. The larvæ of *Mamestra ewingii* attacked potato plants in a different manner, gnawing into the main stalk, so that it soon broke off. This species appeared to prefer alfalfa when this plant could be obtained as food.

Considerable damage was also done by the bollworm, and especially by *Nysius vinitor*, which occurred in great numbers and injured the potato stems by sucking out the juices. Spraying with Paris green gave fairly satisfactory results in combating the caterpillars, but better results were obtained by fastening 2 boards together inclined to one another at right angles, and hauling this apparatus between the rows immediately behind men who knocked off the caterpillars by means of brushes. A crude sort of hopperdozer was also constructed, containing tar or kerosene, and the caterpillars were brushed into this apparatus as it was drawn along. These machines proved very effective.

On the origin and distribution of Leptinotarsa decem-lineata, and the part that some of the climatic factors have played in its dissemination, W. L. Tower (*Proc. Amer. Assoc. Adv. Sci., 49 (1900), pp. 225–227*).—An abstract of an article read by the author at this meeting. The parent form of the Colorado potato beetle is considered to be *L. undecem-lineata*, which seems to have originated in South America. The distribution of the beetle in North America was confined to Mexico and the Rocky Mountains until about 1850. In 1859 the beetle was reported as occurring in injurious numbers as far east as the 98th meridian, and during the next 20 years it traveled eastward to the Atlantic Coast and covered the whole country to latitudes 37 to 47° north. The species is double brooded, but it is the second brood which flies most and which consequently is the most concerned in increasing the distribution of the species. The beetle is not a strong flyer, and is unable to make much progress against a strong wind. Its flight is therefore controlled largely by the wind. During August and September there are certain well-defined wind tracks, and the beetle has progressed most rapidly along these lines. The most rapid advance has been made in the track of the westerly winds along the Lakes and down the St. Lawrence Valley. At present the potato beetle is distributed throughout all that portion of North America which lies east of the Rocky Mountains and between latitudes 32 and 55° north. A related species, *L. juncta*, has retreated before the advance of the Colorado potato beetle, and is now confined to a more southern distribution. A number of geographical forms of the potato beetle are apparently being developed, but these forms are not easily determined without accurate and detailed measurements.

The pea weevil and means of combating it, G. Staes (*Tijdschr. Plantenziekten, 6 (1900), No. 3-4, pp. 105-123*).—The author presents a brief account of the insects which most commonly prove injurious to peas. The life history of *Bruchus pisi* is described in detail, and notes are given on the literature of the subject. In combating the attacks of this insect the author recommends planting seed which is free from weevils. This may be accomplished by securing uninfested seed or by treatment of infested seed for the destruction of the weevil. It is recommended that peas be heated in an oven to a temperature of from 50 to 60° C. for a short time, during which they are constantly stirred. Seed peas may be held over a year for the purpose of allowing the weevils to escape, so that they may be destroyed. It is advisable also to destroy any pea pods which may be left in the field. Weevils should be prevented from escaping from infested peas into the fields before planting time.

The cane borer in Louisiana and Hawaii (*Hawaiian Planters' Mo., 20 (1901), No. 1, pp. 22-26*).—Notes on the habits, life history, and most efficient means of combating *Sphenophorus obscurus*.

A little-known asparagus pest (Agromyza simplex), F. A. Sirrine (*New York Sta. Bul. 189, pp. 277-282, figs. 5*).—The adult is a metallic black fly 3 to 4 mm. long, usually found resting on the flowers and branches of asparagus plants. The pupal condition resembles the flaxseed stage of the Hessian fly. The puparia appear as raised spots under the epidermis near the base of the asparagus stems. The process of laying eggs was not observed, but from the fact that mines made by the maggots first start beneath the leaf scale, it is suspected that the eggs are occasionally deposited under or near the leaf scale. The species mines beneath the outer bark, and eats the green portion of the plant between the epidermis and the wood. When several maggots are present they completely girdle the stem. Although the species has been under observation for 4 years, it has not been observed as injurious to cutting beds. During 1900 it did considerable damage to seedling and newly set beds. Infested plants turn yellow and finally die much earlier than they naturally should do.

From the habits of the pest it is apparent that there is little opportunity of applying insecticides. Since eggs for the first brood are deposited early in June, it is recommended that small shoots should not be allowed to grow on cutting beds during the cutting season. It is also advised that old stalks be pulled and burned after they are dead, preferably late in the fall. There are 2 broods of the insect per year.

Natural enemies and artificial remedies for Pieris brassicæ, G. del Guercio (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 95-108, figs. 3*).—Among mechanical means for fighting this species destruction of the eggs is recommended as of prime importance, and the destruction of the caterpillars as second in importance. Egg destruction is more practicable in this species than in *P. rapæ* or *P. napi*, since in the case of the first species they are laid in groups of considerable size and have a bright yellow color. Experiments were made with a number of chemicals, such as superphosphate of lime, solutions of potash and soda soaps, soap emulsions with petroleum, benzene and bisulphid of carbon, soap emulsions with heavy oil of tar, and solutions of alkaline tar. The superphosphate of lime had no apparent effect upon the caterpillars. Solutions of potash soap in strengths of from 1½ to 2½ per cent destroyed the caterpillars quickly and did not leave any bad odor upon the plants. The author states that the caterpillars of the cabbage butterfly may be destroyed by much weaker solutions of insecticides than are usually employed. Brief notes are given on the various insect parasites of the species and on the extent and economic importance of this parasitism.

Suggestions about combating the San José scale, H. P. GOULD (*Maryland Sta. Bul. 73, pp. 153-166, figs. 2*).—A number of experiments were conducted for the purpose of determining the effect of different percentages of kerosene on peach trees and on the San José scale. During these experiments it was found that considerable damage was done to peach trees by spraying them with a 20 per cent kerosene mixture during a dormant period, while the same mixture applied during the period between March and the blossoming period gave more satisfactory results. It was found that tobacco whale-oil soap solutions caused some injury to the foliage if they were used of strength sufficient to destroy the adult San José scale. A 5 per cent solution of kerosene had little effect on the scale, while the 20 per cent solution destroyed practically all of the scales. The 5 per cent solution did not injure the foliage, and the 20 per cent solution was only slightly more injurious to the foliage than the 10 per cent solution. The trees should not be sprayed at a time when the solution will freeze, since considerable damage to peaches results from this process. No differences were noted in results whether the kerosene was applied on cloudy or clear days.

A brief popular discussion is given of the comparative value of crude petroleum as an insecticide and regarding whale-oil soap and fumigation with hydrocyanic-acid gas as remedies for the San José scale.

Observations on a new species of scale injurious to citrus fruits in Italy, G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 3-26, pl. 1*).—The author describes the scale insect in all its stages under the name *Ceroplastes sinensis.* The food plants of this scale are *Citrus aurantium, C. limonum, C. deliciosa,* and *Muhlenbeckia platyclados.* The life history and habits of this scale are described in some detail. For preventing the larvæ from attaching themselves to the woody parts of the plants, the author had good success in using a mixture containing oil of tar, 10 to 15 liters; neutral carbonate of soda, 7 to 10 kg.; water, 80 to 90 liters. Tar soaps also proved effective. For the first treatment concentrated tar soap is recommended, containing soft soap, 1 kg.; water, 3 liters; oil tar, 1 liter. For the second treatment the mixture should contain about 2 per cent oil tar, and the third 1½ per cent. Branches which were painted with the insecticide showed upon examination that all the insects had been destroyed. The scales of other species of scale insects were thoroughly penetrated. In combating this scale it is also recommended that *Muhlenbeckia platyclados* in the vicinity of citrus orchards should be destroyed.

Brief notes are given on the life history, habits, and means of combating *C. rusci* and species of Aspidiotus, Mytilaspis, Diaspis, etc.

Means of infestation by the olive fly and methods of checking its further spread, G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 27-86, pl. 1, figs. 2*).—The author discusses in a critical manner the literature relating to *Dacus oleæ.* The insect is described in all its stages, including the varieties *funesta* and *flaviventris.* The life history, habits, and metamorphosis of the fly are described in detail, and notes are given on the relative severity of infestation of different varieties of olives. From this study it appears that the fly passes successively from one variety to another of olive from its first appearance in July and August to the time of its greatest prevalence in November and December. Experiments were conducted for the purpose of testing the efficiency of plowing and cultivating the soil in destroying the pupæ of the fly. From these experiments it was found that burying the pupæ in loose soils and rolling and drenching the soil with water had no effect in preventing the flies from emerging. In loose soils inundation did not destroy the pupæ. In compact soils, on the other hand, whether with or without rolling and the use of water, the insects were unable to escape after being buried deeply.

The author gives notes on experiments to determine the influence of temperature on the olive fly. It was found that larvæ exposed to a temperature of from 0 to −6° R. were destroyed in large numbers. The author determined by experiments with bisulphid of carbon that the insects were destroyed when 800 cc. of this substance was used per cubic meter of space.

A number of birds are known to feed upon the olive fly, and among the predaceous and parasitic insects which keep the insect in check the author mentions *Eurytoma rosæ*, *Tricomalus spiracularis*, *Eulophus pectinicornis*, and *Cremastogaster scutellaris*.

A discussion is given of the beneficial effects of the parasitism of the olive fly, the injuries caused by this fly, the remedies in common use against its ravages, remedies which are adapted to deterring the adult insect from depositing its eggs, and remedies devised for the destruction of the egg, larva, and pupa. Among the latter the author mentions hyposulphite of potash and soda, burning over the ground, and injection of cyanid of potash into the plant tissues. Experiments with the last-named remedy gave negative results.

Two strawberry pests, J. B. Smith (*New Jersey Stas. Bul. 149, pp. 17, pls. 2*).—The author has worked out certain hitherto unknown details in the life history of strawberry-leaf roller (*Phoxopteris comptana*). The eggs are laid on the underside of the leaf, and are of a green color and difficult of detection. The larvæ hatch in from 5 to 7 days, crawl upon the upper side of the leaf, and begin the formation of webs. The first full-grown larvæ were obtained on June 8, and the author believes that the larval life occupies about 4 weeks. From these larvæ moths emerged on June 19 and began egg laying on June 22. The complete life cycle is therefore from 42 to 50 days. There are 3 annual broods, of which only the first and second are especially injurious.

The author describes the insect in its various stages, and makes brief mention of parasitic insects which are its natural enemies. As a remedial measure the author recommends spraying with arsenical poisons as soon as the moths are seen flying in considerable numbers, a second time one week later, and a third time after another week.

The strawberry-root louse (*Aphis forbesi*) is reported as causing considerable damage to strawberries. The insect is described in its various stages, and brief popular notes are given on its life history and the remedies which have proved most effective in combating it.

Two new enemies of grapes, G. del Guercio (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 410–416, figs. 4*).—*Drepanothrips reuteri* is described in detail, and brief notes are given concerning its life history and injurious habits. Experiments with insecticides in controlling the species showed that the larvæ were killed almost instantly when sprayed with a 2 to $2\frac{1}{2}$ per cent solution of soft soap, and that the same solution was equally effective against the pronymphs and adult insects. A carbolized extract of tobacco was tried in 1, $1\frac{1}{2}$, 2, $2\frac{1}{2}$, and 3 per cent solutions. The weaker strengths stupified the insects but did not kill them. The stronger solutions were very effective.

Another enemy of grapes is found in *Schizoneura ampelorhiza*, which feeds upon the roots of grapevines. The author describes the species in detail. This root louse was found in large numbers in an active form on grapevine roots, but does not produce tubercles such as are caused by the puncture of phylloxera. Infested roots, on the contrary, shrivel up and die. Fortunately the species so far as known has a limited distribution.

Animal parasites—III, E. P. Niles (*Virginia Sta. Bul. 110, pp. 13, figs. 5*).—This bulletin contains brief popular notes on *Gastrophilus equi*, *G. hæmorrhoidalis*, *G. nasalis*, ox bot fly, ox warble fly, and sheep bot fly.

Spraying crops, S. T. MAYNARD and G. A. DREW (*Massachusetts Hatch Sta. Bul. 73, pp. 9-15*).—The chief insecticides used during the year were Paris green, arsenate of lead, arsenic and lime, and kerosene emulsions. The principal fungicides were Bordeaux mixture and a simple solution of copper sulphate. Insecticides were in most instances combined with Bordeaux mixture. For spraying apple trees to combat insect and fungus pests, Paris green was used at the rate of ¼ lb. to 50 gal. of Bordeaux mixture. Arsenate of lead was found to be a better insecticide for use upon the plum. Experiments for testing possible injury to the foliage of peaches, cherries, and Japanese plums showed that the foliage of these trees was injured somewhat by green arsenoid and insect green, but not by arsenate of lead. Brief notes are given on desirable pumps and nozzles.

The poisonous property of a solution of nicotin and its use in the destruction of insects, G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 124-134*).—The observations reported in this paper were made on experiments with the larvæ of the silkworm. Preliminary experiments in spraying these larvæ with distilled water showed that they were not disturbed by such treatment. Spraying with solutions of various strengths of nicotin caused convulsive movements of the larvæ within a short time, which caused them to fall from the plants, with death as a result in the majority of cases. The author believes that solutions of nicotin act poisonously upon insects by means of vapors, and that these vapors, even in minute quantity, cause irritation, convulsive movements, and ultimate falling of the larvæ from infested plants. Brief notes are given on the comparative effects of pure nicotin, nicotin rendered alkaline and acidulated, and nicotin mixed with soap solution. The treatment with a mixture of 1 part nicotin, 15 to 25 parts soap, and 2,000 parts of water, caused complete paralysis of the caterpillars, which lasted for 24 hours.

The use of carbon bisulphid in horticulture, V. VERMOREL (*Emploi du sulfure de carbone en horticulture. Villefranche (Rhône): Librairie du Progrès agricole et viticole, 1901, pp. 39, figs. 4*).—The author experimented with bisulphid of carbon in the destruction of white grubs (*Melolontha vulgaris*). It was found that 300 kg. per hectare or 30 gm. per square meter gave very satisfactory results in combating these insects. It is necessary to apply the remedy in May soon after the eggs are deposited and while the larvæ are in the younger stages.

Similar results were obtained in using bisulphid of carbon in combating the mole cricket (*Gryllotalpa vulgaris*). The insecticide was applied in the same proportions and was found to be the only remedy which would effectively destroy these insects in the soil. Good results were obtained in fighting rats, moles, and various injurious insects by means of carbon bisulphid. The author discusses in considerable detail the nature and action of bisulphid of carbon, and the apparatus by means of which it can most conveniently be applied.

Tree fumigation in California, C. P. LOUNSBURY (*Agr. Jour. Cape Good Hope, 18 (1901), No. 1, pp. 210-223, figs. 4*).—This article contains a general description of the apparatus and formulæ used in fumigating trees with hydrocyanic-acid gas.

Report of the inspector of fumigation appliances, W. LOCHHEAD (*Toronto: L. K. Cameron, 1901, pp. 15, figs. 7*).—An act requiring fumigation of nursery stock was put into force in the spring of 1899. Fumigation houses and boxes were made and tested, and such as were too hurriedly constructed showed a leakage of gas and had to be repaired. Copies are given of the regulations and instructions for the fumigation of nursery stock, and a detailed account is presented of the equipment necessary for fumigation and the formulas used. A brief discussion is given of the effect of gas treatment on nursery stock. The tender terminals of peach stock were not affected until nearly double the normal dose of cyanid of potash was used for a 1-hour exposure. Apple trees withstood exposure to 6 times the normal dose, plums 3 times, and pears 3 to 4 times. Detailed directions are given for making boxes suitable for fumigating small lots of nursery stock and for the construction of fumigation houses.

Important insecticides, directions for their preparation and use, C. L. MARLATT (*U. S. Dept. Agr., Farmers' Bul. 127, pp. 42, figs. 6*).—This is a revision of Farmers' Bulletin 19 (E. S. R., 6, p. 315). The bulletin has been in part rewritten and revised, in order to include a discussion of some of the more recent insecticide treatments. The chief additions are concerned with an account of the use of pure kerosene and crude oil, the mechanical mixtures of these oils with water, and the distillate emulsion, which is an emulsion of crude oil and soap recommended by the California State Board of Horticulture.

A contribution to the study of the insect fauna of human excrement, L. O. HOWARD (*Proc. Washington Acad. Sci., 2 (1900), pp. 541–604, pls. 2, figs. 22*).—A shorter popular account of these investigations was published in *Pop. Sci. Mo.*, 58 (1901), No. 3, pp. 249–256. The author made extended observations for the purpose of determining the species of flies and other insects which, from their coprophagous habits, may be considered liable to carry the typhoid fever organism from place to place. Many species of insects were bred from human excrement, including 44 species of beetles, a number of Hymenopterous parasites, and 36 species of Diptera, while 41 other species were captured upon excrement. These species are listed and detailed notes are given concerning the habits and life history of the more important Diptera, including *Compsomyia macellaria*, *Sarcophaga sarraceniæ*, *S. trivialis*, *Stomoxys calcitrans*, *Homalomyia canicularis*, *Muscina stabulans*, *Phora femorata*, *Lucilia cæsar*, *Drosophila ampelophila*, *Calliphora erythrocephala*, and other species. The 77 species of Diptera belonged to 21 different families. Extensive collections were made of flies which visit dining rooms or kitchens, and which might, therefore, come in contact with human food. These collections included 23,087 flies in different stages. Of this number, 22,808, or 98.8 per cent, were the common house fly (*Musca domestica*). The remaining 1.2 per cent comprised a number of species, some of which have already been mentioned. The conclusions may be stated as follows: Of the 77 species of flies whose feeding habits might bring them into contact with typhoid organisms only 8 are likely to come in contact with human food. Of these 8 the common house fly is by far the most important and is to be considered a constant source of danger wherever care is not exercised in the disposal or disinfection of excrement from typhoid patients.

The renewing of queens, U. GUBLER (*Rev. Internat. Apicult., 23 (1901), No. 2, pp. 26–28*).—The author concludes from his observations that bees may produce fertile queens from April until October, but that the most favorable time is at the end of the period for collecting honey.

The conditions of sericulture in Italy, E. VERSON (*Ann. R. Staz. Bacol. Padova, 28 (1900), pp. 22–33*).—Brief notes on the statistics of silk culture in Italy from 1880 to 1889.

The possibility of prolonging the life of silkworm chrysalids, E. QUAJAT (*Ann. R. Staz. Bacol. Padova, 28 (1900), pp. 15–21*).—The author conducted experiments to determine the question of whether the life of the silkworm could be prolonged in the chrysalis stage by means of lowering the temperature. While considerable influence was exercised upon the silkworms by the low temperature to which they were subjected, it was found that many of the moths which issued from chrysalids thus treated were in poor condition and laid infertile eggs.

Glandular tissues in the circulatory system of the silkworm, E. VERSON (*Ann. R. Staz. Bacol. Padova, 28 (1900), pp. 69–84, pl. 1*).—The author discusses the literature of the subject and describes in detail hypostigmatic, peritracheal, pericardial, and epigastric glands of the silkworm.

The relation between the weight of the eggs of the pure races and of crossed races of silkworms, E. QUAJAT (*Ann. R. Staz. Bacol. Padova, 28 (1900), pp. 34–39*).—This is a controversial article. The author believes from his own observations that the weight of the eggs of crossed races is not greater than that of a pure race.

Publications relating to sericulture during the year 1900 (*Ann. R. Staz. Bacol. Padova, 28 (1900), pp. 107-116*).—An extensive bibliography of the subject.

FOODS—NUTRITION.

First report on the inspection and analyses of food products under the pure-food law for 1900, B. W. KILGORE, W. M. ALLEN, ET AL. (*North Carolina State Bd. Agr. Bul., 21 (1900), No. 12, pp. 61*).—Details are reported of the examination of a large number of samples of foods and beverages in accordance with the State pure-food law. Fifty-three commercial stock foods were also examined. The following table shows the extent of adulteration of foods and beverages:

Summary of results of the examination of food products.

Food products.	Total number samples.	Percentage of adulteration.
Beers and other alcoholic drinks	35	77.14
Breakfast foods	24	4.17
Butter	11	....
Canned goods:		
Asparagus	9	77.77
Boston baked beans	1	100
Celery	2	100
Corn	70	60
Corn and tomatoes	4	100
Garden peas	37	81
Lima beans	8	62.50
Okra	2	50
Okra and tomatoes	8	100
Pumpkins	8	50
Snap beans	9	77.77
Succotash	14	7.14
Tomatoes	55	63.63
Catsups	36	97.22
Flour	37	....
Lard	11	9
Nonalcoholic summer drinks	33	72.72
Oil	11	18.18
Sauces	7	86
Vinegar	22	59
Total	454	56.04

Gluten contents of Hungarian wheat and flour, T. KOSUTÁNY (*Kisérlet. Közlem., 3 (1900), No. 4 pp. 227-268*).—This article contains detailed comparative analyses of Hungarian and foreign wheats and wheat products. The primary object was to show the relative values of Hungarian flours as compared with those of other countries. Incidentally the theory is advanced that flours possessing the same amount of gluten may possess entirely different food values, since they manifest different physical properties. Comparative tests were made of the tenacity of dough made of flour and water in definite proportions. If 50 gm. of dough could be extended to cover an area of ½ square meter without breaking, the flour was rated as first quality. With poorer grades the same area could not be covered with 75 gm. of dough. The author considers this a more exact method of grading than by the separation of the gluten or the aleurometer or farinometer tests. With the best Hungarian flours tested, a dough tissue of 100 sq. cm. weighed about 0.4 gm., and 33 sheets superimposed upon each other measured less than 1 mm. in thickness. A number of tables are given to show that total nitrogen constituents and gluten are not identical in amount in wheat flours or wheat and do not vary in equal ratio. The article includes the results of the analysis of 178 samples of Hungarian and 16 samples of foreign wheat.—P. FIREMAN.

The chemical composition and nutritive value of barley and its products: V, Bread, A. NIKITIN (*Vestnik. Obsh. Hig. Sudeb. i. Prakt. Med., 1899, p. 1526; abs. in Chem. Ztg., 24 (1901), Repert., pp. 73, 74; Ztschr. Untersuch. Nahr. u. Genussmtl., 3 (1900), No. 10, p. 694*).—The composition of two sorts of rye bread is reported.

The chemical composition and nutritive value of barley and its products. V, Bread, A. NIKITIN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 1, p. 36*).—The author furnishes corrections for the data given in the article noted above.

Concerning a new method of bread making, G. LEBBIN (*Hyg. Rundschau, 10 (1900), pp. 409–415; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 1, pp. 41, 42*).—A process of making bread without previous grinding of the grain is described.

An abnormal fermentation of bread, C. H. ECKLES (*Reprint from Rpt. Iowa Acad. Sci. 1899, pp. 165–173*).—Sticky or slimy bread and the bacteria which cause it were studied, as well as the viscid material formed, the heat of baking, methods of preventing slimy bread, etc. The author noted the rise of temperature in the interior of the loaf after newly baked bread was removed from the oven.

"It is evident that the bacteria causing the [abnormal] fermentation are able to survive the heat of baking. In this connection 2 experiments were made to determine what the temperature inside a loaf of bread is during baking. A thermometer was inserted in the top of a loaf of bread with the bulb in the center. Just as the bread was ready for removal from the oven the temperature was taken at intervals until the reading sank to 150° F. It was observed in both trials that the temperature of the bread raised several degrees within 5 minutes after being removed from the oven, then slowly declined. . . . In the first trial the temperature at the end of 1 hour's baking was 196° F. Five minutes later it reached 206°, then gradually declined to 150° within 2 hours. In the second trial the temperature recorded at the end of baking was 197°, which raised to 208° within 5 minutes, and within 15 minutes sank to 200° F. and reached 150° in about the same time as in the first trial."

Preparation of flour products for microscopical examination, R. WOY (*Ztschr. Oeffentl. Chem., 6 (1900), pp. 213, 214; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 1, p. 42*).

Concerning the carbohydrates of caragheen moss, J. ŠEBOR (*Oesterr. Chem. Ztg., 3 (1900), No. 18, pp. 441–444*).—From an extended chemical study, the author concludes that the carbohydrates in caragheen or Irish moss (*Chondrus crispus*) consist of a complex of galactose, glucose, and fructose, with a little pentosan (possibly xylan) present as an impurity. These bodies are not present in the same proportion as in raffinose. It is regarded as uncertain whether the carbohydrates are present as a mixture or in the form of a complicated molecule. The author inclines to the latter opinion on account of the solubility of the matter in water, its presence in the plant cells in grain-like masses, and its ability to form colloid solutions with water. He believes further that such a complex molecule is built up like starch as a reserve material.

The manufacture of starch, sugar, dextrin, maltose preparation, sugar colors, and invert sugar, W. BERSCH (*Die Fabrication von Stärkezucker, Dextrin, Maltosepräparaten, Zuckercouleur und Invertzucker. Vienna, Pest, Leipsic: A. Hartleben, 1900, figs. 58; rev. in Oesterr. Chem. Ztg., 4 (1901), No. 1, p. 11*).—A handbook.

A process for preparing starch and sugars from horse chestnuts, C. F. CROSS and J. S. REMINGTON (*Deut. Zuckerind., 25 (1900), No. 43, Sup. 1, p. 1632*).—A patented process is described.

The chemical composition and nutritive value of different sorts of meat, A. BEYTHIEN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 1, pp. 1–9*).—Analyses are reported of the muscular tissue and fatty tissue of a number of different cuts of beef, pork (fresh and smoked), and mutton.

The red color of salt meat, J. HALDANE (*Jour. Hyg.* [*Cambridge*], *1* (*1901*), *No. 1, pp. 115–122, fig. 1*).—From a number of experiments the following deductions were drawn: "The red color of cooked salt meat is due to the presence of NO-hemochromogen. The NO-hemochromogen is produced by the decomposition by the the meat of NO-hemoglobin to which the red color of salt meat is due. NO-hemoglobin is formed by the action of nitrite on the NO-hemochromogen, in the absence of oxygen and in the presence of reducing agents.

"The nitrite is formed by reduction within the raw meat of the niter used in salting. The nitrite is distributed by long cooking."

The handling and preserving of raw meat, R. EMMERICH (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, *4* (*1901*), *No. 1, pp. 17, 18*).—The author insists on the need of cleanliness in slaughtering and handling meat.

On the occurrence of tin in preserved meat, together with some observations on the estimation of and the compounds of tin in preserved meat, F. WIRTHLE (*Chem. Ztg.*, *24* (*1900*), *p. 263; Chem. News*, *82* (*1900*), *No. 2144, pp. 308, 309*).

The manufacture and exportation of tasajo, or jerked beef, by River Plata countries (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 399–404*).—The preparation of this sun-dried and salted beef is described and statistics of the amount exported are given.

Eggs and their uses as food, C. F. LANGWORTHY (*U. S. Dept. Agr., Farmers' Bul. 128, pp. 31*).—Eggs and their uses are described and the flavor of eggs, digestibility, marketing and preservation, desiccated eggs, egg powders and egg substitutes, and similar topics are discussed. The bulletin summarizes a considerable amount of the work of the experiment stations and American and foreign investigators, on the subjects treated of.

Lard oil, M. DUYK (*Bul. Assoc. Belge Chim.*, *15* (*1901*), *No. 1, pp. 18, 19*).—Analysis and description of lard oil—"prime steam lard" or neutral—imported into France to be used in the manufacture of oleomargarin.

The soy bean and its products from a chemical and dietetic standpoint, A. NIKITIN (*Vestnik. Obsh. Hig. Subed. i. Prakt. Med.*, *1900, No. 4, pp. 453–469; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, *4* (*1901*), *No. 1, pp. 39, 40*).—The author summarizes the literature of soy bean products with especial reference to food value, quoting many analyses made by himself and other Russian investigators.

Manufacture of cocoanut butter in Mannheim (*Sci. Amer.*, *84* (*1901*), *No. 18, p. 282; U. S. Consular Rpts.*, *66* (*1901*), *No. 248, pp. 63, 64*).—A descriptive article.

Coffee substitutes (*Proc. Agr. Hort. Soc. Madras, 1901, Apr.–June, p. 5*).—A note quoted from G. Watt, on the composition and use as coffee substitute of the seeds of *Spermacoce hispida*.

Studies of theobromin and caffein and the salts they form, T. PAUL (*Archiv. Pharm. 239* (*1901*), *Nos. 1, pp. 48–80; 2, pp. 81–90*).—Studies by methods of physical chemistry.

Acetic acid in foreign countries (*Spec.* [*U. S.*] *Consular Rpts.*, *22* (*1900*), *pt. 1, pp. 83*).—A summary of information received from American consuls in foreign countries on the consumption, price, and importation of acetic acid as well as the form in which it is demanded locally.

The preservation of food, R. C. T. EVANS (*British Food Jour.*, *2* (*1900*), *Nos. 19, pp. 178, 179; 20, pp. 214, 215; 21, p. 245; 22, p. 278*).—A general discussion.

Nutrition investigations at the University of Illinois, H. S. GRINDLEY and J. L. SAMMIS (*U. S. Dept. Agr., Office of Experiment Stations Bul. 91, pp. 7–20*).—The composition of a number of food materials is reported together with dietary studies of a teacher's family and a boarding club of mechanics. The total food consumed per man per day by the former was: Protein, 106 fat 11, and carbohydrates 445 gm. and the fuel value 3,290 calories. Similar values for the latter study were: Protein 118, fat 145, carbohydrates 378 gm., and fuel value 3,382 calories. The average daily cost, including waste, was 28 and 23 cts., respectively. The results are discussed at some length.

Nutrition investigations at the North Dakota Agricultural College, E. F. LADD (*U. S. Dept. Agr., Office of Experiment Stations Bul. 91, pp. 21–26*).—It was found that on an average a club of women students consumed 64 gm. protein, 99 gm. fat, 360 gm. carbohydrates per woman per day, the fuel value being 2,660 calories. The average daily cost of food including waste was 13.8 cts.

Nutrition investigations at Lake Erie College, Ohio, ISABEL BEVIER and ELIZABETH C. SPRAGUE (*U. S. Dept. Agr., Office of Experiment Stations Bul. 91, pp. 27–42*).—As shown by a dietary study, a club which was made up almost entirely of women students and teachers, consumed on an average: Protein 68, fat 115, and carbohydrates 321 gm. per woman per day, the fuel value being 2,665 calories. The cost including waste was 18.3 cts. per day. The results are discussed and compared with those obtained in similar studies elsewhere.

The digestion of various food substances, C. TURLE (*British Food Jour., 2 (1900), Nos. 21, pp. 246, 247; 22, pp. 278, 279*).—A general discussion.

Contribution to the physiology of digestion; function of the spleen in the formation of trypsin, A. HERZEN (*Arch Physiol.* [*Pflüger*], *84 (1901), No. 3–4, pp. 115–229*).—The author cites a number of experiments conducted by himself and his students which lead him to the conclusion that the spleen secretes some substance which possesses the power of changing protrypsin into trypsin.

Contribution to the physiology of digestion: I, Influence of several foods upon the quantity and quality of the gastric juice, A. HERZEN (*Arch. Physiol.* [*Pflüger*], *84 (1901), No. 3–4, pp. 101–114*).—On the basis of experiments made in the author's laboratory, which are not yet reported in full, the effect of a number of foods, including, among others, raw meat, meat juices, and meat broth, on the secretion of gastric juice and its composition, is discussed. The experiments were made with dogs having suitable fistulæ. The experiments are discussed with special reference to the theories advanced by J. P. Pawlow.[1]

Feeding tests with a dog given different nitrogenous materials, K. KORNAUTH (*Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), Nos. 1, pp. 1–25; 2, pp. 133–162*).—In a study of the comparative value of a number of vegetable and animal proteids, the digestibility ot aleuronat, conglutin (from lupines), casein, gelatin, hide powder, and nuclein was determined, as well as the balance of income and outgo of nitrogen and phosphorus. With the exception of the nuclein preparation, which was unpleasantly acid, the nitrogenous substances were as well or better digested than meat meal. Although definite conclusions are not drawn, the experiments, in the author's opinion, do not indicate that the phosphorus of casein was more thoroughly assimilated than that of other foods. On casein gains of nitrogen were accompanied by corresponding gains of phosphorus.

The assimilation of fats, DESGREZ (*Rev. Gen. Sci. Pures et Appl., 1900, July 6; abs. in Ztschr. Untersuch Nahr. u. Genussmtl., 4 (1901), No. 5, p. 206*).—According to the author his experiments demonstrate that fat is converted in the body into glycogen, and not into sugar. In experiments with dogs the amount of glycogen in the muscles was much increased when fat was consumed, while the glycogen in the liver was not increased. The conclusion is therefore drawn that fat is not converted into carbohydrates in the liver, but that the conversion takes place under the influence of the leucocytes.

Concerning lipase, the fat-splitting enzym, and the reversibility of its action, J. H. KASTLE and A. S. LOWENHART (*Amer. Chem. Jour., 24 (1900), No. 6, pp. 491–525*).—Lipase was found in largest amount in the liver, next in the pancreas, kidney, and submaxillary gland. The enzym was tested as to its hydrolizing power

[1] Die Arbeit der Verdauungsdrüsen. Bergmann, Wiesbaden, 1898.

in forming ethyl butyrate. In the experiments a glycerin extract of lipase from the pancreas, prepared by macerating portions of the organ and straining through cloth, was used. Filtering through filter paper almost completely removed the enzym. The enzym was found to be more stable than usually supposed and its action was strongest at 40° C., while it was destroyed at 65 to 70° C.

In studying the effect of lipase on ethereal salts of a homologous series, it was found that the stability of the latter decreases with the increase of the molecular weight of the combined acid.

With concentrated amounts of the enzym or with small amounts of ethereal salts hydrolysis was complete. The authors believe that under other conditions the hydrolizing action of the enzym stops and its action under favorable circumstances is reversed. Experiments are described, wherein ethyl butyrate was formed from butyric acid and alcohol by the action of lipase. The trials were carried on with control experiments and the presence of the butyrate detected by its odor. About 5 per cent of the butyric acid was changed into ethyl butyrate. The bearing of this result on fat absorption, storing, and translocation in the plant is discussed.

The question of the resorption of fat, I. MUNK (*Centbl. Physiol.*, *14* (*1900*), *pp. 121–125, 153–156; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, *4* (*1901*), *No. 5, p. 205*).—A controversial article.

Concerning the influence of butter on the secretion of gastric juice, W. A. WIRSCHILLO (*Vrach* [*St. Petersburg*], *21* (*1900*), *pp. 423, 424; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, *4* (*1901*), *No. 5, p. 206*).—The principal conclusions, which were drawn from experiments made with man in which the stomach contents were examined, follow: Butter diminishes the hydrochloric acid and pepsin of the gastric juice, and hinders the secretion of the gastric juice less when first taken than after a time. The peptonizing power is greater under the influence of butter than without it. Butter diminishes the activity of the glands secreting gastric juice, and the secretion does not continue longer than when no butter is consumed. According to the observer butter should be given an important place in the diet of invalids on account of its nutritive value, pleasant taste, and easy digestibility.

Concerning the quantitative determinations of easily digested carbohydrates (starch and nearly related bodies) in the human feces, J. STRASBURGER (*Arch. Physiol.* [*Pflüger*], *84* (*1901*), *No. 3–4, pp. 173–189*).—As the result of investigations, the author concludes that the small amount of starch present in the feces can be determined quantitatively with the Volhard-Pflüger sugar method.

The silica content of human and animal tissues, H. SCHULZ (*Arch. Physiol.*, [*Pflüger*], *84* (*1900*), *No. 1–2, pp. 67–100; abs. in Chem. Centbl.*, *72* (*1901*), *I, No. 11, p. 636*).—Details of chemical investigations are reported.

ANIMAL PRODUCTION.

Rye as a concentrated feed, W. VON KNIERIEM (*Landw. Jahrb.*, *29* (*1900*), *No. 3, pp. 483–523*).—Tests made at the Peterhof Experimental Farm on the value of rye grain as a concentrated feed are reported and discussed. The investigations include a test with milch cows, a feeding test with pigs, digestion experiments with horses, sheep, rabbits and hens, and chemical and physiological studies of the fat of rye and other feeding stuffs.

Tests with cows (pp. 484–491).—The first test reported was made by A. von Villon. Two cows were fed during 3 periods from November 13 to February 12. The coarse food was 30 lbs. of clover hay daily. During the second period 1 cow was fed in addition 5 lbs. of malt dust, and another cow 5 lbs. of crushed rye daily. But little change was produced by the addition of grain to a ration of such nutritious coarse feed as clover hay. The ration containing the malt dust appeared to have a more favorable influence upon the production of milk than the ration with rye.

A more extended test was made by J. Plohman in a comparison of rye and oats with milch cows. The tests were carried on during different periods of lactation, the cows being given the 2 feeds alternately in order to eliminate the factor of individuality. The coarse feed was 15 lbs. of clover hay, 12 lbs. of straw, and 2 lbs. of cocoanut cake daily. The concentrated feed was 6 lbs. of ground rye or ground oats. The day's rations contained practically the same amounts of protein, the fat being larger in the case of the oatmeal ration.

The test extended from November 25 to January 8, and was divided into 3 periods of 10 days each, with 5 days interval between. In every case it was found that the oatmeal ration gave a larger production of milk than the rye meal ration. The fat content of the dry substance of the milk was higher in every case with the oatmeal ration. The following table shows the result by periods:

Fat in the dry substance of the milk.

	Cow No. 1.		Cow No. 2.	
	Ration.	Fat in total solids.	Ration.	Fat in total solids.
		Per cent.		*Per cent.*
Period 1	Oats	28.77	Rye	26.41
Period 2	Rye	26.24	Oats	26.98
Period 3	Oats	28.67	Rye	24.48

The specific gravity of the milk was in every case lower on the oat ration than on the rye ration. Of the butter made during the different feeding periods, no difference was noticed in the grain or taste, but that made on the rye ration was harder, while that made on the oat ration had a deeper yellow color. No bad effects on the animals were noticed in feeding the rye ration.

As analysis shows, rye grain is poor in fat, and hence it is recommended to feed it with coarse food rich in fat or in connection with oil cake.

Tests with sheep (pp. 491–500).—Tests made by P. Kasimirsky, on the comparative digestibility of rye and oats by two sheep and the effects of these grains on the digestibility of hay, are reported. The ration consisted of 700 gm. of hay and 300 gm. of grain per day. The usual experimental methods were followed, the coefficients of digestibility of the rye and oats alone being calculated from the digestibility of the whole ration, as described in a previous publication (E. S. R., 10, p. 1083). The average results follow:

Coefficients of digestibility of hay, oats, and rye; average of two sheep.

	Protein.	Fat.	Crude fiber.	Nitrogen-free extract.	Ash.
Hay and oats:	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Calculated digestibility of hay alone	68.83	64.08	44.22	48.43	41.57
Calculated digestibility of oats alone	81.61	93.72	71.98	82.35	45.79
Hay and rye:					
Calculated digestibility of hay alone	44.22	67.75	41.08	58.72	....
Calculated digestibility of rye alone	68.00	30.83	7.00	77.20	....

The author calls attention to the fact that when rye formed part of the ration the digestibility of protein and crude fiber of the hay was diminished, while that of the nitrogen-free extract was increased; furthermore, the fat of rye was much less thoroughly digested than the fat of oats.

Tests with pigs (pp. 500–504).—On the basis of tests carried on by Schukowski, the comparative value of rye, barley and milk for pigs, is discussed. Two pigs were fed rye with whole milk for 17 days. Barley was then substituted for rye until the end of the feeding period, which covered 142 days. Two similar pigs were fed barley for 68 days and then rye alone or rye and barley for the remainder of the test. The total gain of the first lot was 127.98 lbs.; of the second, 132.32 lbs. The author states that rye, as distinguished from barley, was not eaten readily when fed in large amounts and that sometimes it was refused altogether. The conclusion was drawn that although large amounts of rye can be successfully fed such rations can not long be continued. To compare whole milk and skim milk, a ration of whole milk and barley was continued with one of the pigs for some 7 months. After a short time on whole milk and barley, a similar pig was fed at the close of the test on skim milk and barley. The author calculates that skim milk made a return of 0.38 ct. per kg.

Tests with horses, rabbits and hens (pp. 504–523).—The author reports and discusses a number of experiments made with horses, rabbits and hens. The comparative digestibility of rye and oats was tested with horses by W. Groot. The grains were fed with clover hay, the daily ration consisting of 4,914 gm. of the former and 8,190 gm. of the latter. The usual experimental methods were followed. The average coefficients of digestibility of the two rations follow:

Coefficients of digestibility of hay and oats, and hay and rye; average for two horses.

	Dry substance.	Protein.	Fat.	Crude fiber.	Nitrogen-free extract.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Hay and oats	51.46	62.80	59.81	35.60	60.26
Hay and rye	52.24	55.84	8.89	31.23	66.11

As pointed out by the author, when oats constituted part of a ration, the fat was much more thoroughly digested than when rye was fed. He believes that the chief reason why oats are such superior feed for horses is that almost no vegetable fat is so easily digested as that of oats. In the tests noted above, the time spent in work was recorded as well as the weight of the horses. The losses in weight were greater on the rye ration than on the oat ration. The fact that variations in weight can serve for judging the value of feeding stuffs is insisted on. The author believes that although oats are much better feed for horses than rye, yet the latter can be fed to advantage in rather large quantities. He recommends that the grain be soaked before feeding and that the horses be gradually accustomed to it. Since rye is deficient in fat, this constituent should be supplied by other feeding stuffs. The low coefficients of digestibility of fat observed when rye was fed is discussed and tests bearing on this subject by Roschnowski, Redych, and R. Slawinski, are briefly reported. Roschnowski found that as an average of two tests, the coefficients of digestibility of rye by rabbits was as follows: Dry matter, 85.95; protein, 68.45; fat, 72.70; nitrogen-free extract, 93.59; crude fiber, 65.97; and ash, 36.15 per cent. According to Redych's results, rabbits digested 98.3 per cent of the fat of cocoanut cake, 94.8 per cent of the fat of oats, and 76 per cent of the fat of rye. Slawinski found that rabbits digested 96.3 per cent of the fat of cocoanut cake; 65.5 per cent of the fat of oat straw, and 55 per cent of the fat of rye straw.

Further studies of the comparative digestibility of rye, oats and barley, and especially of the fat are reported by the author, which were made by W. Grost. Three hens were used, and the daily ration consisted of 70 gm. of the grains tested. The coefficients of digestibility follow:

Coefficients of digestibility of rye, oats, and barley; experiments with hens.

	Dry matter.	Protein.	Fat.	Nitrogen free extract.	Crude fiber.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Rye	76.96	70.72	16.59	87.8	2.4
Oats	49.88	62.34	84.01	60.82	.5
Barley	69.41	75.41	67.43	81.11	.2

In this case also the coefficients of digestibility of the fat of barley was lower than that of the other grains. As the author points out, digestion experiments with poultry present this difficulty, viz, the urine and feces are excreted together; therefore, in determining the coefficients of digestibility of protein, the amount of uric acid and ammonia excreted was determined and the sum deducted from the total nitrogen. The remainder was assumed to represent the nitrogen of the undigested protein.

In discussing these experiments and those reported above (see milch cows, sheep, and pigs), the author draws general deductions concerning rye as a concentrated feed, some of which follow: Rye may be profitably used as a feeding stuff, but some precautions are necessary in the method of feeding, and in the selection of other constituents of the ration. Rye should be soaked or coarsely ground. On account of the low content of the crude fiber and the low coefficients of digestibility of the fat, this grain can not be recommended as a concentrated feed for horses or young cattle. When, on account of its comparatively low cost, rye must be used, the other feeding stuffs should be chosen so that the necessary fat is supplied. No injury to health was observed when rye was fed except in the case of pigs fed this grain alone. Such injury the author believed due to ergot and other impurities.

As bearing upon the low coefficients of digestibility of the fat of rye, the author reports a number of determinations by P. Kotow of the chemical character of the fat from the grain and straw of rye and oats. The results follow:

Comparison of the fat of rye, oats, rye straw, and oat straw.

	Specific gravity.	Melting point.	Unsaponifiable material.	Acid number.	Saponification number.	Ether number.	Insoluble fat.	Iodin number.
		°C.	*Per cent.*				*Per cent.*	
Rye fat	0.9284	29	8.5	12.2	360	347.8	80.2	117.2
Oat fat	.9324	26	7.8	14.8	204	189.2	77.1	98.4
Rye-straw fat	.8278	58	10.2	27.5	110.5	83	55.4	82.2
Oat-straw fat	.8507	57	8.6	18.2	190.8	172.8	56.1	66.5

The differences observed in these fats are discussed, and it is stated that further studies will be reported on the relation between the chemical constituents of fat to its digestibility.

Vetch as concentrated feed, W. VON KNIERIEM (*Landw. Jahrb., 29 (1900), No. 3, pp. 524–540*).—The value of vetch seed (*Vicia sativa*) is discussed, many investigations previously reported b ing cited. The author reports experiments made at the Peterhof Experimental Farm with cows by Schaposchnikoff and A. Buschmann and with pigs by M. von Wichert. The digestibility of vetch seed was tested with rabbits and compared with that of pea meal.

It is stated that because of its cheapness vetch-seed meal has been fed to the dairy herd at the Peterhof Experimental Farm for several years. Increasing amounts were fed, aggregating in one year 1,421 lbs. per head, or a daily average of almost 4 lbs. It favorably influenced the milk yield, the cows ate the vetch-seed meal readily, and it was not detrimental to the health of a single individual.

In an experiment by Schaposchnikoff a cow was feed during 3 periods with 35 lbs. of clover hay. During the second period 5 lbs. of vetch-seed meal was added to the daily ration. With the vetch ration there was a large increase in the yield of milk and in the percentage of protein and a decrease of the percentage of butter fat. The cow ate the vetch with relish, and no unfavorable results were apparent.

In another experiment by A. Buschman, a comparison was made between vetch-seed meal and cocoanut meal. These 2 concentrated feeds were fed in connection with 15 lbs. of trefoil clover and 10 lbs. of oat straw daily. This amount of vetch-seed meal had no bad effect upon the health of the cow, while the yield of milk was 8 per cent higher than with the cocoanut-meal feed. The fat content of the milk was 4.24 per cent during the first cocoanut-meal period, 3.58 during the vetch-seed-meal period, and 4.38 during the concluding cocoanut-meal period.

The test with pigs covered 70 days. Two of the pigs were fed vetch seed alone, vetch and milk, or vetch and barley. For a few days barley alone was given. Two similar pigs were fed barley alone at first, and later barley and milk. The grains were coarsely ground. On the first ration the total gain was 18.265 kg. and on the second 21.726 kg. One pig in each lot was then slaughtered and the feeding continued with the other, hay meal being added to the rations. In 18 days the pig fed the vetch ration gained 10.249 kg. and the pig fed barley 15.579 kg. In this test it was observed that the pigs did not eat the vetch with great relish, and sometimes it was refused. The author believes, however, that vetch seed may be profitably used as a feeding stuff for pigs, although some caution must be observed. On the other hand, vetch was found to be a very satisfactory feeding stuff for milch cows, and at the same time, according to the author, it is very cheap.

Concentrated feed stuffs; condimental stock and poultry foods, J. B. Lindsey (*Massachusetts Hatch Sta. Bul. 71, pp. 40*).—A large number of analyses of feeding stuffs are shown in tables, giving the brand, manufacturer, source, and the protein and fat guaranteed and found. The various feeds are divided into 4 classes, with reference to their protein content. For New England conditions, the most economical concentrated feeds in the author's opinion are cotton-seed meal, corn-gluten meal, gluten feed, dry brewers' grains, malt sprouts, and fine flour middlings. Expensive feeds are wheat bran, linseed meal, and so-called mixed feeds. The latter especially are undesirable, on account of being so often adulterated. Therefore it is usually more economical for the feeder to make his own mixtures. For this purpose tables of desirable mixtures are given. Of the 11 samples of cotton-seed meal not guaranteed, 8 were found to be largely adulterated. Farmers are therefore urged to purchase only guaranteed meals. The gluten meals and feeds were free from adulteration and usually of excellent quality. A large number of the so-called oat feeds were of very inferior quality, and, while costing nearly as much as corn, are only $\frac{1}{2}$ to $\frac{2}{3}$ as valuable.

A large number of analyses of condimental stock foods and condition powders are reported and the substances found in them discussed. They were found to consist principally of cereals, oil meals, and by-products. In some, condiments as fenugreek and gentian were found, as well as various other products, as salt, sulphate of magnesium, soda, charcoal, sulphur, and, in poultry foods especially, ground oyster shells, charcoal, and pepper. The condition powders varied very much in composition, but in general the author believes were of very little value, and in no way merited the strong claims made for them by the manufacturers. Their cost is excessive, and in no case are they necessary to the health of the animal.

Commercial feeding stuffs in the Connecticut market (*Connecticut State Sta. Bul. 133, pp. 29*).—Agents of the station collected in the 25 towns and villages of the State 186 samples of commercial feeding stuffs. The results of analysis are shown, giving the chemical composition, the digestible nutrients, and the cost per ton. A list showing the average weight of 1 qt. of each of the feeds named is also given. With the exception of cotton-seed meal, old-process linseed meal, and hominy chops, the percentages of fat in these feeds was not very unlike, ranging between 2.4 and 5.5 per cent. As the protein is the nutrient which the feeder is chiefly concerned in getting, a comparison is shown of the cost of that ingredient in each of the classes of foods. If 20 lbs. of protein in cotton-seed meal cost \$0.64, then 20 lbs. of protein in gluten meals cost about \$0.85, in gluten feeds \$0.88, in wheat feeds \$1.20, in oats, corn, provender, corn chop, etc., \$1.77, and in oat feeds and other trash \$2.10. This is a rough but practically just statement of the comparative cost of protein in the feeding stuffs analyzed. Cheap and low-grade oat feeds are considered to be of very little value. Corn meal should be produced by the feeder, and he is advised not to buy anything containing less protein than wheat feeds, and especially to avoid purchasing the condimental and medicinal foods, put up usually under proprietary names.

The composition of commercial feeding stuffs sold in Connecticut (*Connecticut State Sta. Rpt. 1900, pp. 361–387*).—A reprint of the above bulletin.

Condimental and medicinal cattle and poultry foods (*Connecticut State Sta. Rpt. 1900, pp. 355–360*).—Reprint of Bulletin 132 of the station (E. S. R., 13, p. 75).

Analyses of commercial feeding stuffs, J. L. HILLS, C. H. JONES, and B. O. WHITE (*Vermont Sta. Bul. 84, pp. 95–107*).—In accordance with the State law regulating the sale of commercial feeding stuffs, 230 samples were analyzed. These included cotton-seed meals, linseed meals, Cleveland flax meal, gluten meals and feeds, oat feeds, corn-and-oat feeds, corn and oats, wheat bran, wheat middlings, mixed wheat feeds, ground oats, corn and bran, hominy chop feed, calf meal, poultry foods, and animal meal.

"A general survey of the analyses discloses no considerable amount of adulteration. There is still some sale of goods containing more or less plentiful proportions of oat hulls, but buyers are coming to understand this better and to purchase accordingly. This is not an adulteration in the eye of the law, provided the composition of the goods is stated and maintained. There are still some sales being made of goods carrying oat hulls, where the guaranty is lacking. Pressure is being brought to bear upon the makers of such mixtures to comply with the law. . . .

"Guaranties were not upheld as well with the gluten feeds samples as with the meals, unless refuge is taken behind the 'dry basis' claim. . . .

"Germ oil meal is a new material on the Vermont market. It is made largely from the germs of the corn kernel, is lower in its protein content than the other glucose by-products, and is very high in fat. The four samples analyzed were uniformly below guaranty. . . .

"Oat feeds and corn and oat feeds are largely made up of the residues from the manufacture of oatmeal and other breakfast foods. They form the outlet for oat hulls and light oats, and contain, as a rule, much more woody fiber (oat hulls) than is found in a good quality of oats or provender. Certain of these goods are fortified with more or less of some highly nitrogenous concentrate like cotton seed or linseed meal. Others are very lacking in protein and are hardly more than oat hulls."

Experiments on the utilization of gorse, A. C. GIRARD (*Ann. Agron., 27 (1901), No. 1, pp. 5–44*).—The composition of gorse was studied, and also its digestibility by a horse and a sheep. The culture of gorse is described and the plant compared with alfalfa.

Contribution to the subject of aspartic acid and asparagin, A. JOLLES (*Arch. Physiol. [Pflüger], 84 (1901), No. 7–10, pp. 446–450*).—From his experiments the author concludes that when aspartic acid is oxidized with permanganate of potash, the nitrogen is obtained in the form of ammonia. When asparagin is oxidized, more than one-half of the nitrogen is obtained as urea, the remainder as ammonia. The experiments are discussed in relation to their bearing upon the oxidation of asparagin by animals.

Rational stock feeding, W. J. SPILLMAN (*Washington Sta. Bul. 48, pp. 48*).—A popular discussion of the principles of stock feeding. This is a revision of an earlier bulletin (E. S. R., 10, p. 583).

Notes on the animal industry of Porto Rico, O. F. COOK (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 663–667, pls. 10*).—Brief notes on feeding stuffs, breeds of cattle, poultry, etc., are given.

Steer-feeding experiments, L. FOSTER and L. A. MERRILL (*Utah Sta. Rpt. 1900, pp. LV–LXIII*).—The cost of raising steers from birth until they were two years old was tested with 4 grade Jerseys. At first they were fed whole milk and later skim milk and grain. The calves were pastured during the summer, and in the winter were fed alfalfa, corn stover, grain, and roots. At the beginning of the test calves 1 and 2 each weighed 58 pounds. They gained on an average of 1.35 and 1.12 lbs. per day, respectively. Calf number 3 weighed 94 lbs. at the beginning of the test and gained on an average of 1.39 lbs. per day. Number 4 weighed 76 lbs. at birth and gained 1.15 lbs. on an average per day. The profit on the calves was $12.78, $8.59, $9.38, and $6.82, respectively. The total cost of raising calves 1 and 2 was $23.30 and $22.05, respectively, while numbers 3 and 4 each cost $19.98.

"It should be remembered that these steers were grade Jerseys, which accounts for their light weights. Grades of any good beef breed would no doubt have given much better returns, but this experiment was intended to show what may be done with grade Jersey steers by those who seek to improve their dairy herds by the use of a Jersey bull. The quality of the meat was excellent, the very best sold at the local markets during the year."

Report on experiments on the winter feeding of cattle, 1898-99, J. W. Paterson (*West of Scotland Agr. Col. Rpt. 1899, pp. 22*).—Tests with 4 lots of steers from December 24, 1898, to April 8, 1899, on the comparative value of the following rations are reported: Linseed cake, decorticated cotton-seed cake and maize meal, bruised oats and decorticated cotton-seed cake, and decorticated cotton-seed cake. In every case Swedish turnips, hay, and straw were fed in addition. The greatest profits were realized on the first ration and the lowest on the second, while the third and fourth ranked between these two. Linseed cake produced more gain than the decorticated cotton-seed cake, but the increase did not compensate for the extra expense. When compared with cotton-seed cake and maize, linseed cake alone was still more unprofitable.

Feeding skim milk to calves, A. L. Haecker (*Nebraska Sta. Bul. 68, pp. 22-29*).—Six grade calves were used. Three calves (lot 1) were taken from their dams a day or two after birth and fed whole milk for about 10 days. Skim milk, to which flaxseed meal was added, was then gradually substituted for whole milk. At the end of 8 weeks the calves were weaned. They were then pastured and later fed in the barn. The average weight of the calves in lot 1 at the beginning of the trial was 90 lbs.; at the end of 5 months, 333 lbs.; and when a year old, 798 lbs. The three calves in lot 2 were allowed to run with their dams for 5 months. The average weight of the calves at birth was 78 lbs.; at the end of 5 months, 347 lbs.; and when a year old, 792 lbs. Record was kept of the milk and butter fat produced by the dams of the calves in lot 1 and the data used in computing the cost of feeding. Among the conclusions were the following:

"As to the quality of the calves in the two lots, it was quite easy at the end of the fifth and sixth periods (of 4 weeks each) to pick out the sucking calves, as they were rounder in body and had better coats, but at one year old this difference could not be detected. . . .

"In conclusion it may be safely said that by careful feeding good steers can be raised on skim milk by using ground feed to replace the lost butter fat.

"The cost of feed for a skim-milk calf raised to six months old was about nine dollars. Where a market for butter is accessible, even cows with a beefy tendency can be milked with profit and their calves raised with little cost and work."

Milk and artificial foods for calves, L. Malpeaux (*Bul. Soc. Vaud. Agr. et Vit.* [*Lausanne*], *1900, No. 143, pp. 774-780*).—A résumé of experiments reported earlier (E. S. R., 12, p. 978).

Sheep-feeding experiments, L. Foster and L. A. Merrill (*Utah Sta. Rpt. 1900, pp. LXIII-LXVIII*).—The comparative value of good wheat, frosted wheat, No. 1 wheat screenings and No. 2 wheat screenings was tested with 4 lots of 24 lambs each. In every case alfalfa was fed with the grains. The authors state that No. 1 wheat screenings consist of alfalfa seeds, clover seeds, and various weed seeds; while screenings No. 2 was made up mostly of cracked, broken and shrunken wheat. At the beginning of the test, which covered 14 weeks, the average weight of the lambs was about 47 lbs. each. On good wheat the average daily gain was 0.19 lb., and on frosted wheat 0.21 lb.; on No. 1 screenings, 0.21 lb., and on No. 2 screenings 0.24 lb., while 4.54, 4.19, 5.32, and 4.38 lbs. of the grains were required per pound of gain, respectively, in addition to about 6½ lbs. of alfalfa. The cost of food eaten per pound of gain in the 4 lots was 4.88, 4.18, 3.24, and 3.95 cts., respectively.

"Taking into account both the rate and the cost of the gains, the results of this experiment indicate that it is more profitable to feed screenings than either good or frosted wheat."

The composition of the different grains fed is reported and the work of the Canadian stations in feeding frozen wheat cited in some detail.

The influence of manures on mutton, W. SOMERVILLE and T. H. MIDDLETON (*Jour. Bd. Agr.* [*London*], *7* (*1900*), *No. 3, pp. 311–331*).—Continuing previous work (E. S. R., 12, p. 75), a test on the effect of different fertilizers on pasture land, as shown by gains in weight made by sheep and by the hay crop, is reported. As in previous years, the fertilizers consisted of cotton-seed cake, lime, and ammonia. One plat, No. 6, served for the purpose of comparison and was not fertilized. Some of the results obtained in the test in 1900, as well as the results obtained in the four years during which the investigation has been continued, are shown in the following table:

Results of different methods of manuring pasturage as shown by production of mutton.

Plats.	Treatment.	Total gains made by sheep in 1900.	Gains in weight of sheep in 4 years in excess of plat 6.	Gain (+) or loss (−) per acre in 4 years. *a*	Total cost of fertilizers per acre in 4 years.
		Pounds.	*Pounds.*		
1	Cotton-seed cake	80	228	+$9.42	$7.90
2	Lime	60	21	−11.04	12.64
3	Basic slag	131	408	+25.64	5.75
4	....do	139	227	+11.89	5.35
5	Superphosphate	137	218	+ 7.72	8.83
6	Untreated throughout	44			
7	Superphosphate and potash	137	255	+ 6.80	12.55
8	Superphosphate and lime	159	279	+ 7.49	13.69
9	Superphosphate and ammonia	128	228	+ 2.98	14.31
10	Dissolved bones	134	234	+ 2.90	14.86
11	Basic slag	89			8.02

a Based on the weight of the sheep.

The hay produced on the different plats in 1900 is reported and the amount compared with the crop of previous years. In discussing the tests the author says:

"Without attempting to draw general conclusions, it may be said that the third and fourth seasons of the Tree Field experiment clearly indicate that manures may modify the value of pasture by affecting the season of growth, as well as by increasing the weight of produce. Under the influence of different manures a late pasture may be made earlier, or a short-lived pasture may be induced to persist far into the autumn. There is nothing new in this assertion; most farmers who have had experience in the manuring of pastures will have remarked it as certainly as they have noted that increased production of meat follows manuring. But just as the Tree Field experiment has afforded an exact means of determining the live-weight increase due to the action of manures, so it promises to throw light on the specific effects of certain fertilizers on the quality, the earliness, and the persistence of pastures. Exact information on these points is much wanted, and the future development of the Tree Field plats promise to be instructive."

Our horse-raising industry (*Landw. Jahrb. Schweiz, 15 (1901), No. 1, pp. 55, tables 3*).—An extended account of horses and horse breeding in Switzerland.

Concerning the shelter and care of draft animals and poultry in winter, E. S. Zürn (*Fühling's Landw. Ztg., 49 (1900), Nos. 22, pp. 839–842; 23, pp. 882–886; 24, pp. 913–915*).—A general discussion.

Breeding thoroughbred poultry, J. J. McCue (*Agr. Gaz. New South Wales, 11 (1900), No. 12, pp. 1075–1087, dgm. 1*).—Selection, reversion, inheritance, the sexes and their power, and line breeding are discussed with relation to poultry.

Ducks and duck breeding, E. Brown (*Jour. Bd. Agr. [London], 7 (1900), No. 3, pp. 300–310, figs. 4*).—A general discussion.

Foreign markets for eggs and poultry, H. E. Alvord, N. B. Ashby, and S. Lowe (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 321–345*).—This includes a number of short articles by the authors mentioned on such subjects as "The report on poultry and egg trade in foreign markets," etc.

The British egg supply, E. Brown (*Jour. Roy. Agr. Soc. England, 3. ser., 11 (1900), pt. 4, pp. 605–645, figs. 11*).—The article contains many statistics and other information regarding the egg industry as well as information on poultry raising and kindred topics.

DAIRY FARMING—DAIRYING.

Alfalfa protein vs. purchased protein in rations for dairy cows, E. B. Voorhees and C. B. Lane (*New Jersey Stas. Bul. 148, pp. 15–22*).—Alfalfa hay was compared with wheat bran and dried brewers' grains in quantities furnishing practically the same amounts of protein. The test included 4 cows and lasted 60 days. The record of each cow is given in detail and the data are summarized and briefly discussed. "The experiment showed that the protein in alfalfa hay could be successfully and profitably substituted in a ration for dairy cows for that contained in wheat bran and dried brewers' grains, and for this purpose is worth \$11.16 per ton, when compared with the wheat bran and dried brewers' grain at \$17 per ton."

Some forage plants for summer feed, T. L. Lyon and A. L. Haecker (*Nebraska Sta. Bul. 69, pp. 30–42*).—This bulletin is a report on experiments with forage plants for the purpose of determining their relative value for pasturage and for soiling and comparing the value of certain of these crops for milk and butter fat production under the two systems of feeding. Similar work has been previously noted (E. S. R., 11, p. 279) and the results are here again briefly reported. The method of conducting the experiments was the same as described in the abstract of the previous work. Rye and sorghum gave the largest amounts of pasturage and corn and millet the smallest amounts among the annual forage plants. Alfalfa and awnless brome grass representing the perennial crops afforded the least pasturage. The brome grass furnished only a little more than half during the same part of the summer. The largest increase in the yield of milk and butter fat was obtained from cowpeas and alfalfa, followed by rye, oats and peas, sorghum, Kafir corn, and awnless brome grass, in the order given. Cowpeas produced the greatest quantity of milk and butter fat from a given area of land. A comparison of alfalfa, sorghum, and corn when used for pasturage and for soiling showed that in the case of each crop from two to three times as much feed was produced from a given area when the crop was used for soiling as when it was pastured. The average daily production of milk and butter fat for the same amount of forage was 1.17 times greater when the cow was pastured on the crop than when it was fed as soiling.

Summer forage crops, J. B. Lindsey (*Massachusetts Hatch Sta. Bul. 72, pp. 16, pls. 4*).—This bulletin gives a concise description of a number of forage crops which have been grown at the station for soiling purposes. The relative advantages of pasturage and soiling, desirable forage crops and crop mixtures, and suitable fertilizers for their culture are discussed. A system of soiling crops for 10 cows is suggested, with the times for seeding and cutting, and the area of each. Several grain mixtures for feeding to cows in connection with the soiling crops are given; and the composition and digestibility of grasses, cereals, legumes, and various fodder mixtures, as well as the number of pounds of digestible dry matter, protein, and carbohydrates in different weights of the several fodder groups are tabulated.

Studies on the rational use of the prickly pear (Opuntia ficus indica) for feeding milch cows, G. Stogia (*Staz. Sper. Agr. Ital., 1900, p. 113; abs. in Centbl. Agr. Chem., 1900, No. 12, pp. 803, 804*).—An experiment was made with 5 cows in feeding cut stems of prickly pear in combination with bran and hay. The prickly pear contained: Protein 0.54 per cent, fat 0.128, carbohydrates 2.6. It was found that 25 kg. prickly pear and 14 kg. good hay made a very desirable ration. The milk secretion was increased by feeding prickly pear in the ration, the water content remaining constant or becoming a little less. It is advisable to expose the prickly pear to the sun for 5 days before feeding. If the plant is young, less than 3 years, it is apt to cause a slight diarrhea; if too old the plant will be somewhat woody.

Report of the Hvilan Control Association, 1899–1900, N. Hansson (*Landtmannen, 11 (1900), No. 29, pp. 457–467*).—This association was formed in 1898 for the purpose of controlling and improving the production of the dairy herds of the members who reside in the district of Hvilan, Sweden. The work described in the present report covers the period from May 1, 1899, to May 1, 1900. Eighteen dairy herds, containing in all about 300 cows, were regularly tested every 21 days during the year by the assistant in charge of the work. The system of feeding practiced on the different farms, as well as the production of the individual cows, was determined, and the economy of the production in each case and for the different herds. The latter is calculated on the basis of so-called "food units," 1 kg. of grain feed being assumed equivalent to 2.5 kg. of hay, 4 kg. of straw, 10 kg. of roots, etc. Some of the average results for the year for 235 cows that finished a whole year's work are as follows: Milk produced per head, 3,327.4 kg.; average fat content, 3.19 per cent; butter fat produced, 106 kg., equivalent to 116.71 kg. butter; cost of producing 1 kg. milk, 1.7 cts., and 1 kg. butter, 44.6 cts. (about 20 cts. a pound). The rations of the cows consisted (per 100 food units) of 38.4 per cent concentrated foods (11.1 per cent oil cakes) and 61.6 per cent of coarse fodder.

The educational value of the work of these control associations, which during the last decade have been formed in large numbers in the Scandinavian countries, and especially in Denmark, can hardly be overestimated. A gradual improvement in the production of the herds and in their economy of production has been wrought, due first of all to the weeding out of the poorest cows in the different herds, and also to the adoption of a better system of feeding and caring for the animals, and to the use of superior pure-bred bulls.—F. W. WOLL.

Report of the Control Association of Vejen and Vicinity, 1899–1900, C. Nyegaard (*Mälkeritid., 13 (1900), No. 37b, pp. 591–638*).—The report gives detailed information concerning the individual production and food consumption of 598 cows in 25 different herds, for the winter and the summer periods, as well as for the whole year, and average annual data for 13 herds for a period of 5 years, 1895–1900. A detailed account is also given of the cost of rearing and keeping young cattle, bulls, and swine on the farms belonging to this Danish control association.—F. W. WOLL.

The dairy herd, H. J. Waters (*Missouri State Bd. Agr. Bul., 1 (1901), No. 1, pp. 64–76*).—A popular article on the selection, breeding, and feeding of dairy cattle.

The influence of the amount of water consumed on the milk secretion, B. Koch (*Jour. Landw., 49 (1901), No. 1, pp. 61–88*).—The object of the experiment was to study the influence of the water consumed upon both the yield and the composition of the milk. Previous work along this line is reviewed at some length. In the present experiment 2 cows were fed similar rations during 4 periods. In the first period of 20 days the cows were given in addition 30 gm. of salt each daily, during the second period of 20 days 80 gm. of salt, during the third period of 10 days 120 gm. of salt, and during the fourth period of 20 days the same as in the first period. The amount of water consumed by each animal was carefully determined. The milkings were made twice daily, at 5 a. m. and 5 p. m. The average daily results are shown in the following table:

Average daily yield and composition of milk.

	Water consumed.	Milk yield.	Dry matter.	Fat.	Nitrogen.
	Kg.	*Kg.*	*Per ct.*	*Per ct.*	*Per ct.*
Cow No. 66:					
Period I	31.5	10.315	12.773	3.895	0.528
Period II	41.2	10.259	12.907	3.934	.527
Period III	36.0	9.935	12.675	3.908	.536
Period IV	30.5	9.561	12.791	3.863	.534
Cow No. 67:					
Period I	41.4	18.695	10.999	3.134	.454
Period II	48.8	16.892	10.860	3.105	.458
Period III	53.5	15.075	10.732	3.046	.468
Period IV	51.9	15.132	10.878	3.010	.460

Bacillus lactis viscosus, a cause of ropiness in milk and cream, A. R. WARD (*Science, n. ser., 13 (1901), No. 322, pp. 324, 325*).—From the examination of creameries in the State of New York, it was found that ropiness in milk from 3 different localities was due to *Bacillus lactis viscosus*. This organism, found in water, multiplies at a temperature as low as 8° C. In the cases coming under the author's observation, the milk was cooled in long open-topped cans in ice water, and the water was found in each instance to contain the organism. By adding to the water potassium bichromate 1 part to 1,000, the trouble was obviated. Although scrupulous care had been observed in sterilizing vessels, the trouble persisted in its appearance, the milk doubtless being inoculated each time from the water in which the cans were cooled.

The changes in milk caused by heating, J. SEBELIEN (*Chem. Ztg., 25 (1901), Nos. 27, pp. 293, 294; 28, pp. 307, 308*).—A compilation of the work of various authorities.

Calcium and sodium citrates in the coagulation of the blood, lymph, and milk, L. SABBATANI (*Atti. R. Accad. Sci. Torino, 36 (1901), pp. 27–53; abs. in Jour. Chem. Soc. [London], 80 (1901), II, No. 461, p. 175*).—The results shown support Vaudin's hypothesis that the citric acid normally in milk assists in keeping the calcium salts in solution. They also tend to confirm the view that calcium in a chemically active condition is necessary to the coagulation of milk.

The bacterial condition of city milk, and the need of health authorities to prevent the sale of milk containing excessive numbers of bacteria, H. W. PARK (*Science, n. ser., 13 (1901), No. 322, pp. 322, 323*).—It was found that during the coldest weather the milk sold in New York City averages about 250,000 bacteria per cubic centimeter, during the cold weather about 2,000,000, and during hot weather about 5,000,000. Investigation showed that the milk sold in other large cities is in about the same condition. Attention is called to the fact that children in cities sicken on the milk supplied in summer, and that where they are put on milk that is sterile, or that contains few bacteria, they as a rule improve rapidly. Any intelligent farmer with sufficient cleanliness and a low temperature can supply milk averaging not over 100,000 bacteria per cubic centimeter; and the author suggests that the sale of milk should be so regulated that that containing more than this number per cubic centimeter should be excluded from the market.

A report upon the examination of milk, E. A. DE SCHWEINITZ (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 147–153*).—The results of the examination of a number of samples of milk obtained from various sources in the city of Washington. The average number of bacteria per cubic centimeter found in the samples of sanitary milk examined between January 1, 1898, and February 1, 1899, was 5,971. The average number of bacteria per cubic centimeter in the samples of pasteurized milk examined during the same time was 266. The total number of bacteria per cubic centimeter in samples obtained from various dairies furnishing milk for the city was found to average over 61,886.

Butter making, C. L. Willoughby (*Missouri State Bd. Agr. Bul., 1 (1901), No. 1, pp. 27–63, fig. 1*).—A popular article on butter making, relating especially to the conditions within the State.

Starters and flavors, G. L. McKay (*Nat. Cream. Buttermakers' Assoc. Rpt. 1901, pp. 133–140*).—A popular article describing the use of starters for ripening cream at the Iowa Agricultural College, Ames.

Moisture in butter, E. H. Farrington (*Nat. Cream. Buttermakers' Assoc. Rpt. 1901, pp. 140–147*).—A résumé of the work of various experiment stations upon the water content of butter and the conditions affecting the same.

A comparison of the yield of salted and unsalted butter and the influence of the aeration of the milk upon the quality of the butter, Sebelien (*Molk. Ztg., 15 (1901), No. 15, pp. 253, 254*).—This is a report of work done by H. P. Lunde, E. Helm, and P. O. Petersen, under the direction of V. Storch, Copenhagen. The experiments covered a period of several months, and the investigations were carried on in 5 different dairies. Butter was made from milk under like conditions. After churning, a portion was washed, worked twice, and salted in the usual manner. Another portion was thoroughly washed and worked once, but not salted. The yield of the unsalted butter averaged 2.4 per cent less than the yield of the salted butter. The lesser yield of the unsalted butter ranged from 1.2 to 3.7 per cent. The loss in washing was 0.26 per cent with the salted and 0.47 per cent with the unsalted butter. The water content of the salted butter was 16.49 per cent, of the unsalted 17.12. The substances other than water and fat were 4.75 per cent in salted and 1.57 per cent in unsalted butter. This difference was largely made up of salt, the salted butter containing 2.45 per cent of that substance. The casein content of the salted butter was 0.97 per cent, of the unsalted 0.80 per cent; milk sugar, salted butter 1.01 per cent, unsalted butter 0.76 per cent.

The results of the aeration of milk upon the quality of the butter were variable. In 19 per cent of the trials the product was improved, in 25 per cent there was no difference, while in 56 per cent of the trials the butter produced by aeration was inferior to the control.

Fishy flavor of butter, the cause and remedy, M. A. O'Callaghan (*Agr. Gaz. New South Wales, 12 (1901), No. 3, pp. 341–346, figs. 8*).—Later work, it is said, corroborates the previous views of the author, that the fishy flavor of butter is caused by the bacterium *Oidium lactis*. By inoculating a portion of milk with this bacterium, fishy flavored butter was produced, while the control portion of the milk produced butter of good flavor. Also by pasteurizing a portion of milk containing this germ the pasteurized milk produced butter of good flavor, while the control transmitted the fishy flavor. As a remedy pasteurization of infected milk is recommended, the bacilli causing the fishy flavor being readily destroyed at 168° F. Cleanliness in and about the dairy is also urged, to prevent the inoculation of the butter during the manipulation of the milk.

Report upon experimental exports of butter, 1898–99, H. E. Alvord (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 154–243*).—This is a statement of the results of the efforts of the United States Department of Agriculture in promoting the exportation of American dairy products. The results of the trial shipments are given in full with the scores of the different shipments and the style of packages. The requirements of European markets, especially those in England, are discussed at some length.

Cooperation in Denmark, A. Vind (*Creamery Jour., 11 (1901), No. 138, p. 3*).—Method of organizing and managing cooperative creameries.

Report of the ninth annual meeting of the National Creamery Buttermakers' Association, St. Paul, Minn., February 18–22, 1901, E. Sudendorf (*Nat. Cream. Buttermakers' Assoc. Rpt. 1901, pp. 184*).

Improvement of cheese-curing rooms, J. W. Robertson and J. A. Ruddick (*Ontario Dept. Agr., Dairy Division Bul. 1, n. ser., 1901, pp. 13, figs. 9*).—An experiment is reported of curing cheese in a room connected with a subearth air duct and with provision for using ice to keep the temperature below 65° F., in comparison with an ordinary first-class curing room with no special means of regulating the temperature, and in a curing room of poor construction. During June and July and part of August, cheeses made under like conditions were taken from the press and distributed in equal numbers in the 3 rooms. When the cheeses were from 3 to 5 weeks old they were placed in cold storage, and at the end of the season were divided into 3 lots, according to the rooms in which they were cured, and were scored by a committee of the Montreal Butter and Cheese Association. It was found that those cheeses cured at a temperature not exceeding 65° F. were very much superior in quality. They were better bodied, more silky in texture, and much milder in flavor, while retaining their moisture better than those cured in the ordinary way. They were rated fully ½ ct. per pound higher in price. The cheeses in the room under control lost 2.53 per cent of moisture, those in the good ordinary room 3.95 per cent, while those in the poor curing room lost 4.45 per cent. Counting the depreciation in value and the loss of moisture, it is estimated that a 50-ton factory would loose in a season $313.90 by not having a curing room in which the temperature could be controlled. This is an amount considerably in excess of the cost of making a curing room. The methods for improving curing rooms with cement floors and walls, the construction of subearth ducts, and the use of ice in racks are figured and discussed. The cost of a subearth duct for a space of 5,000 cu. ft. is estimated at $169.55. An ice rack for use in a curing room may be constructed at a very small cost, the expense of using ice depending almost entirely upon the cost of the ice.

Testing Cheddar cheese, G. S. Thomson (*Jour. Agr. and Ind., South Australia, 4 (1901), No. 8, pp. 632–634*).—Tests were made to determine the value of the acidity apparatus in Cheddar cheese making. In the examination of 14 cheeses it was found that in only 3 instances did the acidity exceed 0.8 per cent at the time of pressing. This shows careful manipulation, by the use of the hot-iron test combined with the burette. At the time of renneting the acid ranged from 0.18 to 0.25 per cent. In general the cheeses made from the milk with the higher percentages of acid scored highest.

In the case of cheese having "holey" and gassy curd, it is suggested that all utensils and cloths used in the manufacture be thoroughly sterilized and the sanitary conditions in and about the factory perfected. Should the trouble persist, the individual milks received should be investigated and the source of the infection located.

Statistics of oleomargarine, oleo oil, and filled cheese, R. A. Pearson (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 287–320*).—Statistics of the production and distribution of oleomargarine, oleo oil, and filled cheese from 1876 to the end of the fiscal year 1899.

VETERINARY SCIENCE AND PRACTICE.

A preliminary report of poison parsnip in western Washington, D. A. Brodie (*Washington Sta. Bul. 45, pp. 12, fig. 1*).—In a herd of dairy cows 16 were taken sick and 6 died within a short time. It was suspected that the cause of death was the presence of *Cicuta vagans* in the hay. In order to determine whether the hay was poisonous, 2 feeding experiments were undertaken. A yearling steer was allowed to eat freely of the hay for 4 days without any bad results. Another yearling was fed about 3 lbs. of *Œnanthe sarmentosa*, which was picked out of the hay. The result was the same as in the first experiment.

It was thought well to try experiments in feeding fresh plants of *C. vagans*. The stem and leaves of 8 plants, collected on May 5, when the plants were about a foot high, were fed to a yearling steer without producing any symptoms of poisoning beyond a slight twitching of the muscles of the nose. A small quantity of roots was fed at the same time to 2 yearlings, with the same results. The plant was tested in the same way July 26 to 31, when in bloom, the roots, stems, and flowers being fed together. Again, August 12 to 15, plants were fed, when the seed was ripe, without causing any bad effects. On November 23, when the new roots had developed sufficiently to be tested, a quantity of the new roots was cut into small pieces and fed to an 8-months-old heifer. The animal died after about 3 hours with violent symptoms. On November 4, 3 roots, which had been cut into small pieces on the previous day, were fed to a heifer without producing any poisonous effects. Two days later the same animal was fed fresh roots and manifested serious symptoms of poisoning, although recovery ultimately resulted. Two other experiments resulted in the death of the animals in from 3 to 3½ hours.

Feeding experiments with *O. sarmentosa*, *Angelica genuflexa*, *A. hendersoni*, *Sium cicutæfolium*, *Heracleum lanatum*, *Conioselinum gmelini* indicated that these plants were not poisonous.

Contagious diseases of animals in foreign countries (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 479–495*).—An account is given of the distribution, virulence, and means of combating the more important contagious diseases in Great Britain, France, Switzerland, German Empire, Hungary, Italy, Sweden, Denmark, Belgium, Netherlands, Norway, and New Zealand.

Report of the chief inspector of stock and registrar of brands for the year 1899, P. R. GORDON (*Queensland Dept. Agr. Rpt. 1899–1900, pp. 79–87*).—This report contains statistical notes on the diseases of sheep and cattle. Fewer cases of contagious pleuro-pneumonia have been reported than during the previous year. The injuries from tick infestation are also being reduced. Inoculation against Texas fever has been largely practiced, and a great proportion of the cattle have become immune to the disease. A number of experiments were tried in dipping cattle to destroy the ticks. The following formula was used with fairly good success: Arsenic 10 lbs., soap 5 lbs., soda wash 28 lbs., Stockholm tar 7½ gal., water 400 gal. It is suggested that certain birds, known as the magpie lark (*Grallina picata*) and the wagtail (*Sauloprocta motasilloides*), which continually hover around tick-infested cattle and frequently perch on their backs, may be instrumental in destroying the ticks. A brief statement is given of the number of marsupials and dingoes destroyed and bounties paid upon them.

Division of veterinary science, J. A. GILRUTH (*New Zealand Dept. Agr. Rpt. 1900, pp. 145–227, pls. 7*).—The author reports four serious outbreaks of anthrax in different localities (pp. 147–154), and gives details of the symptoms and post-mortem findings in these cases. It is believed that the introduction of the disease was due to the importation of infected bones. The evidence for this belief consisted in the fact that the outbreaks occurred on turnip paddocks, and that these paddocks had been recently dressed with manure containing a proportion of bones. In 3 out of the 4 outbreaks the disease was further disseminated by feeding dead carcasses to pigs with disastrous results. The methods which were adopted for preventing the spread of the disease include burying in lime or burning of all anthrax carcasses.

Detailed descriptions are given of 2 outbreaks of swine plague (pp. 154–159). After experiments in serum diagnosis, the author adopted the dilution of 1 part serum to 20 parts of a 24-hour broth culture. In this way a decided agglutination was produced within a few minutes. The location of the chief lesions of the disease differed strikingly from that of previous outbreaks. In other epizootic outbreaks of this disease pneumonia and inflammation of the serous membranes were the chief symptoms, whereas in the outbreak under consideration the lesions were chiefly confined to the alimentary tract. The pathogenic bacillus was isolated in all cases and believed to be the same.

Quite extensive studies were made on tuberculosis of cattle (pp. 159–162). Herds were tested with tuberculin, and a large number of animals were subjected to careful clinical examination for the purpose of determining more accurately the physical symptoms of the disease. The post-mortem findings of 200 cattle condemned for tuberculosis and destroyed are summarized in tabular form.

The author discusses the results of the inspection of meat in slaughterhouses, the subject of compensation for condemned animals, the inspection of dairy cattle on the premises, veterinary education, bacteriological examination of dairy products, and malignant cancerous growths in domestic animals.

The nature and cause of the "bush" disease of cattle and sheep is considered (pp. 186–189). The post-mortem examination of animals dead of this disease indicated a condition of anæmia, with a fatty degeneration of the liver, but no other organic lesion. In some cases in sheep the animals became much emaciated and dropsical. A few specimens of *Strongylus contortus* were found in the stomach of sheep, but not enough to have been responsible for the symptoms. The author believes that the best treatment for this disease consists in a radical change of feed. The exact nature of the trouble remains doubtful.

Brief notes are given on *Strongylus cervicornus* in calves, on red water of cows, strangles in horses, hepatic cirrhosis in horses and cattle, and *S. tentracanthus* in horses.

A number of outbreaks of malignant œdema in sheep and lambs are reported (pp. 194–197). This disease occurs chiefly after shearing sheep and docking lambs. Experiments were made for the purpose of determining the means whereby infection is spread. A small quantity of soil was taken from an infected locality and about ½ gm. was dissolved in 5 cc. sterilized water. After a sediment had formed, the muddy colored liquid was used for inoculating a 3-months-old lamb. The lamb became stiff in the inoculated leg after 24 hours; later the flank was swollen and sensitive to the touch. Death occurred 56 hours after inoculation. Three species of bacilli were isolated from the blood of this animal, 2 being aërobic and 1 anaërobic. Inoculations of pure cultures of the anaërobic bacillus produced marked cases of malignant œdema. For preventing the spread of this disease the author recommends the removal of surface soil of infected yards, which should be placed in a heap where it can thoroughly be mixed with quicklime. The fresh surface should then be treated with strong and cheap antiseptics. In shearing sheep or docking lambs it is imperative that all wounds should be immediately treated with some antiseptic such as carbolized oil.

The author investigated a disease of sheep called suppurative pleurisy and pneumonia (pp. 197–200). An extensive outbreak of this disease occurred in lambs soon after dipping. Post-mortem examination of dead animals showed marked changes in the pericardium. It was distended by the accumulation of a large quantity of serous fluid, and the whole surface was covered by a fibrinous deposit ½ in. in thickness. Affected animals held the head extended and slightly to one side, and the gate was unsteady, with a distinct tendency to fall upon the left side. A detailed description is given of a micro-organism which was found in the fibrinous pus. Pure cultures were made and the disease was reproduced by means of inoculation of lambs.

Brief notes are given on acute facial eczema in sheep, which is believed to be due to eating rape in excessive quantities. A disease among quail recently imported from California was studied with the result that a hemorrhagic condition was found, with a microorganism similar, if not identical, with that of fowl cholera.

The Seventh International Veterinary Congress, B. A. NÖRGAARD (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 534–557*).—The author gives a general account of the work of this congress, which was held at Baden-Baden, Germany, August 7–12, 1899. The paper by Professor Bang, on preventive measures against tuberculosis, is reprinted in full, and brief accounts are given of other discussions on tuberculosis, foot-and-mouth disease, milk inspection, the prevention of swine epizootics, etc.

Researches on the treatment of tuberculous animals according to the method of Landerer, and on the virulence of tubercle bacilli, E. KROMPECHER (*Ann. Inst. Pasteur, 14 (1900), No. 11, pp. 723–749*).—For the purpose of determining the action of cinnamic acid in curing and preventing tuberculosis and of determining the reaction of animals to tubercle bacilli of varying degrees of virulence, the author conducted a large number of experiments, of which the principal results are herein stated. Landerer in work along the same line claimed both curative and preventive power toward tuberculosis for cinnamon. The author employed slightly alkaline, sterilized cinnamate of soda in a 4 per cent solution. Rabbits were inoculated with this substance in the vein of the ear and guinea pigs in the peritoneum or hypodermically. For tubercular material with which to inoculate these animals after a preliminary treatment with cinnamate of soda the author used pure cultures of tubercle bacillus of human origin 3 weeks of age. During some weeks and months the author treated the experimental animals with cinnamate of soda and later inoculated them with the tubercular bacilli. Treatment with cinnamate of soda was given once or twice per week. Rabbits received intravenously each time from 0.1 to 0.4 gm., doses of 0.6 to 0.8 gm. having proved harmful. Guinea pigs received from 0.1 to 0.2 gm. of a 2 per cent solution. These experiments demonstrated that a treatment for a period of $2\frac{1}{2}$ to 4 months, during which the experimental animals received from 1.9 to 3.15 gm. of cinnamate of soda, had no tendency in any case to produce immunity or to retard the course of the disease. The animals which were treated succumbed to generalized tuberculosis in from 1 to 2 months after inoculation, as did also the check animals.

In order to test the supposed therapeutic action of cinnamate of soda, the author inoculated rabbits and guinea pigs with the tubercle bacillus and began a treatment with the cinnamate from 2 to 28 days afterwards. The cinnamate was given regularly twice a week in doses of from 0.10 to 0.15 gm. Animals which were thus treated succumbed to tuberculosis within from 1 to 3 months, as did also the check animals. During these experiments it was noted that intravenous injections of cinnamate of soda produced a marked leucocytosis and hyperæmia of the bone marrow. The animals increased somewhat in size. The conclusion is drawn that cinnamate of soda has no effect in producing immunity against tuberculosis or in curing cases which already exist.

In order to study in detail the virulence of different tubercle bacilli, the author made further studies of 7 cultures, 3 of which were taken from tuberculosis of mammals, 3 from birds, and one from fishes. The results from inoculating guinea pigs with tubercle bacilli from these three sources may be briefly compared. Virulent tubercle bacilli produced a rapidly progressing tuberculosis, with the development of tubercles in which caseous material was formed. Nonvirulent tubercle bacilli, as well as tubercle bacilli from fish, did not cause any apparent disturbances in the health of the animal, although slight microscopic changes were produced, which were characterized by the appearance of giant cells surrounded by other spherical cells.

The author tried experiments to determine the action of tubercle bacilli subjected to a temperature of 120° C. Virulent bacilli subjected to this temperature, when inoculated into rabbits in quantities varying from 1 to 8 cc., produced within 15 days typical caseous processes with giant cells and with stainable tubercle bacilli. All animals inoculated in this manner showed a pronounced decrease in weight. Nonvirulent tubercle bacilli which had been subjected to the same temperature and later inoculated into the body cavity or hypodermically produced no changes in the experimental animals. Inoculations with the tubercle bacilli from fish in quantities of from 2 to 4 cc. had no effect, the health of the animals remaining good, and no changes were revealed by a microscopic study. From these experiments the author concludes that virulent tubercle bacilli are not killed by subjection to a temperature of 120° C.

The author studied the problem of variation in reaction to tuberculin on the part of animals which had been inoculated with tubercle bacilli of different degrees of virulence. It was found that animals inoculated with from 0.1 to 0.25 mg. of virulent tubercle bacilli, after a period of from 2 to 4 weeks, reacted by a rise in temperature of from 1 to $1\frac{1}{2}$°. Animals inoculated with the same amount of nonvirulent tubercle bacilli usually showed an elevation of only a fraction of a degree when tested with tuberculin. Animals which were inoculated with tubercle bacilli from fish did not react to the tuberculin test.

In order to determine the reaction of tuberculous guinea pigs to tuberculins prepared from tubercle bacilli of different degrees of virulence, the author made a number of inoculation experiments. During this study it was found that tuberculous guinea pigs which received from 0.1 to 3 mg. of tuberculin, prepared from virulent tubercle bacilli, showed an elevation of temperature which constantly exceeded 1°. Tuberculous guinea pigs when tested with from 0.2 to 3 mg. of tuberculin from nonvirulent tubercle bacilli of human origin, from fishes, or from tubercle bacilli which had been subjected to a high temperature, reacted with a rise of temperature which never reached 1°.

The period of incubation of tuberculosis in cattle and the age of tubercular lesions, NOCARD (*Rec. Méd. Vét., Paris, 8. ser., 7 (1900), No. 23, pp. 811-815*).—The results of the author's experiments may be stated as follows: Ingestion of tuberculous material rarely causes tuberculosis, while inhalation is believed to be the ordinary method by which the disease is acquired. Enormous quantities of tuberculous material were fed to 4 cows, with the result that 1 resisted infection entirely and no lesions could be found in the other 3, although they responded slightly to the tuberculin test. Experiments indicated that tuberculous material could be inhaled in a state of dry, impalpable dust or in fine particles held in suspension.

The period of incubation of tuberculosis in experimental animals varied from 19 to 32 days. Direct inoculation into the trachea did not give uniform results. The lungs entirely escaped infection. Even in cases infected by inhalations of dry tubercular material the pulmonary alveoli were not attacked, the tubercular lesions being confined to the pleura or periphery of the pulmonary lobes. The mucous layer of the bronchial tubes and active mammary glands showed very slight resistance to infection, and were nearly always centers of tubercular lesions. The author believes that the mammary glands may occasionally be the primary focus of tuberculosis. Intravenous inoculations with virulent tubercle bacilli uniformly gave the most malignant and rapid form of tuberculosis; but since this method of infection can hardly be realized under natural conditions, it is of no great practical importance. The interesting fact was noted in connection with experimental tuberculosis that the tubercles in no case became caseous or calcified.

The growth of tubercle bacilli on acid media, G. JOCHMANN (*Hyg. Rundschau, 11 (1900), No. 1, pp. 1, 2*).—During culture experiments it was found that a medium with an acid reaction had a favorable effect upon the growth of the tubercle bacillus. The author continued his experiments along this line, in order to determine the conditions most suitable for producing a rapid growth of the bacillus.

The most vigorous development was obtained from the use of blood serum of sheep, cattle, and man, to which lactic acid had been added in the proportion of 10 drops of a 1 per cent solution to 50 cc. of blood serum. The blood serum should give a neutral reaction with litmus paper before the lactic acid is added. The most rapid growth was obtained by the use of human blood serum, treated as just described. The author concludes from his experiments that for the culture of the tubercle bacillus a slightly acid medium has a beneficial influence. In media prepared from meat juices the normal acid condition of such juice is very suitable. In the case of media which are naturally alkaline or neutral, good results are obtained by the addition of lactic acid.

Danger from tuberculous animals, E. NOCARD (*Bul. Agr. Algérie et Tunisie, 6 (1900), No. 24, pp. 671–681*).—The author discusses the general problems of the danger of transmission of tuberculosis from animals to man through close association and eating meat and milk products. It is stated that none of the meat of tuberculous animals should be offered for sale without being properly labeled. It is recommended that the various milk products from tuberculous animals should be offered for sale only after pasteurization at a temperature of at least 85° C. It is also suggested that tuberculosis of pigs and goats should be added to the lists of contagious diseases under the supervision of sanitary officers. The danger from the use of milk from tuberculous animals is believed by the author to be much overestimated.

On the seizure and condemnation of tuberculous meat, J. M. WILSON, J. W. MASON, and F. W. MARTIN (*Public Health, 13 (1901), No. 5, pp. 351–358*).—The authors present a discussion concerning the attitude which should be adopted by sanitary officers with respect to the condemnation of tuberculous meat, especially that of animals in which the disease existed in its earlier stages. The authors suggest the practical difficulties of convincing the owners of such animals of the danger of eating the meat, provided the disease was apparently confined to the lungs, liver, or other internal organs.

Legislation with reference to bovine tuberculosis, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 28, pp. 173*).—This bulletin contains a compilation of the laws, rules, and regulations of the different States and Territories with reference to the control of tuberculosis in cattle. It is designed to furnish information to breeders and shippers of cattle.

International congress for the consideration of the best methods for checking or curing tuberculosis, E. A. DE SCHWEINITZ (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 126–133*.—This article contains an account of the delegates and the work of the congress, and brief abstracts of the more important papers read during the sessions.

Anthrax produced in animals by mixing anthrax spores with their regular feed, NIKOLSKY (*Ann. Inst. Pasteur, 14 (1900), No. 12, pp. 794–801*).—The author began his experiments on 5 white rats by feeding bread which had been sprinkled with an emulsion containing anthrax spores grown on gelatin without peptone, at a temperature of 37° C. The rats resisted infection for a considerable time. At the end of 16 days 2 died, 1 on the following day, and 2 on the twenty-first day. An autopsy showed that these animals died of anthrax. In all cases the liver and spleen were enlarged, and a microscopical examination showed the presence of anthrax bacillus in the blood. Similar experiments on gray rats gave negative results, as these animals were not infected after feeding with the spores for over a month. The author conducted similar experiments upon rabbits, which were killed at varying periods after feeding with anthrax spores. The conclusions drawn from these experiments are that animals which receive ordinary fodder infected with anthrax spores develop anthrax as certainly as by any other method of infection. The spores develop in the contents of the intestines in spite of the antagonism of other micro-organisms, and penetrate the walls of the intestines and the lymphatic vessels, and finally enter the blood.

Changes in the anthrax bacillus in decomposing ox blood outside of the body, E. BERNDT (*Centbl. Bakt. u. Par., 1. Abt., 28 (1900), No. 19, pp. 648–651, pl. 1*).—The author presents a brief critical discussion of the literature of this subject. A sample of blood was received from an animal which had died of anthrax, and was subjected to culture for the purpose of making a positive diagnosis. The blood sample was kept under observation for a number of days, and examinations were made each day for the purpose of determining the conditions of the anthrax bacillus. From these investigations it was demonstrated that clearly differentiated anthrax bacilli were to be found in anthrax blood kept in a flask in the dark, at normal temperature, for 13 days. Disintegration of the anthrax bacilli began in the central portions. The segments which were stained blue gradually became less receptive to the coloring matter and exhibited a granular disintegration. The so-called plasma capsule took the stain much longer. Anthrax bacilli with a sharp contour, but without color differentiation, were to be observed 14 days after the blood had been drawn.

The susceptibility of crosses of Algerian merinos to anthrax, MARTINET (*Rec. Méd. Vét., Paris, 8. ser., 7 (1900), No. 23, pp. 108–111*).—In order to determine any possible variation in the susceptibility of different races of sheep to anthrax, the author selected for his experiments a pure-bred merino, a lamb of which both parents were merino crosses, and 2 lambs from crosses of the second generation. The 4 animals were inoculated with anthrax virus which had undergone 2 passages through rabbits. Three of the animals died of anthrax, but the time of resistance varied and indicated that the resistant power toward the anthrax was in inverse proportion to the amount of merino blood present in the animal. The first animal died within 36 hours, the second within 74 hours, the third within 92 hours, while the fourth remained without infection. Other experiments and observations were made along the same line, with similar results. The author recommends crossing of the pure merinos where anthrax is liable to cause losses.

The origin of lingual actinomycosis in cattle, A. BREUER (*Ztschr. Fleisch u. Milchhyg., 11 (1900), No. 4, pp. 103–111*).—The author describes in detail the anatomical structure of the tongues of cattle as related to the development of actinomycosis in this organ. During this study it was observed that the frequency of cases stood in a rather constant relation to the age of the animal. Actinomycosis of the tongue was never observed in animals under 2 years of age, while the number of cases increased rapidly after 3 years, and in cattle of from 8 to 10 or more years of age the tongue was almost always affected in cases of this disease. The author believes that the cause of frequent actinomycosis of the tongue in cattle is to be found in the anatomical structure of this organ. Numerous changes take place, especially during old age, in the dorsal ridge of the tongue, and the author states that the disease invades this organ in consequence of these changes.

Experiments with Texas fever and southern cattle ticks, E. C. SCHROEDER and W. E. COTTON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 33–52*).—*Growing noninfected ticks and afterwards infecting them* (pp. 33–41).—An attempt was made to grow ticks on animals immune to Texas fever. Horses, mules, dogs, sheep, goats, rabbits, pigeons, and guinea pigs were used without success. Ticks which were taken from a permanently infested field containing cattle recently recovered or sick with Texas fever were placed on a young calf without causing a development of the disease. The second generation of ticks were grown on the same calf with the same result. The third, fourth, and fifth generations were grown on adult cattle without producing Texas fever; while another portion of the fifth generation from adult ticks which were grown on cows from North Carolina, when placed on 2 northern cows, produced Texas fever, with death in one case. Further experiments were conducted along the same line, from which it is concluded that it is possible to obtain a supply of southern cattle ticks which can be grown on susceptible cattle without causing disease, and that noninfectious cattle ticks, after having lived for several successive generations on susceptible cattle without causing disease, may produce fatal cases of Texas fever after having lived for a single generation on an animal from infested territory. The virulence of the infection is in no way influenced by the length of time which has elapsed since the southern animals were removed from the Texas fever area.

A note on the vitality of the southern cattle tick (pp. 41, 42).—Ticks were collected from a cow of the experiment station of the Bureau and placed in cotton-stoppered flasks. Eggs were soon laid, and on March 11 they had nearly all hatched. The young ticks remained without food, except the empty egg shells and dead bodies of the adults, and without water until July 21, when they were placed on a cow. The majority of them were still alive and developed into full-sized adults by August 13. They produced fertilized eggs which subsequently hatched. The possibility is suggested of cattle ticks outliving an infection of Texas fever and becoming annually reinfected in the spring.

A note on the persistence of the Texas fever organism in the blood of cattle (pp. 42, 43).—On October 4, 1895, 2 calves about 5 months old received hypodermic injections of blood from a southern cow. The calves suffered a very mild attack of Texas fever. In August of the following year the blood of these calves was used for inoculating 2 northern cows. Acute cases of Texas fever developed, and one of the animals died. The experiment shows that infectious blood when injected into young cattle in the fall of the year, although producing a very mild attack in them, may render the blood of the young cattle sufficiently virulent to cause fatal cases of Texas fever in adult cattle 10 months later.

An experiment in blood and serum injections in connection with Texas fever investigations (pp. 43–52).—Experiments in inoculation with blood and serum from recovered cattle indicated that large doses of blood or serum may produce a milder form of the disease than small doses. In experiments along this line on 8 cattle; the amount of blood used for inoculation ranged from 10 cc. to 400 cc., and inoculations were made subcutaneously or intravenously. The injections were given on August 1. The first attack of Texas fever began about August 10. The cattle recovered and suffered a second attack about the middle of September. At this time one of the animals died. The results obtained from these experiments showed that the quantity of blood from an immune cow used for inoculation has no influence upon the severity of the inoculation disease, and that no difference is noted in the effects of intravenous and subcutaneous injections. A dose of 10 cc. of blood is recommended as most satisfactory for inoculation purposes. The experiments indicated that the antitoxin which is present in the blood of immune cattle can not be introduced into susceptible cattle in quantities which will serve as a protective agent.

Hemorrhagic septicæmia in cattle, S. D. Brimhall and L. B. Wilson (*Jour. Comp. Med. and Vet. Arch., 21 (1900), No. 12, pp. 722–731*).—Three outbreaks of this disease occurred in Minnesota during the fall of 1900. In 3 herds, containing 67 animals, 37 were affected and all died. The chief symptoms were loss of appetite, fever, lameness, swelling of the legs and submaxillary region, and black or bloody discharges. Death usually occurred in from 6 to 24 hours. The lesions found on post-mortem examination were chiefly hemorrhagic areas in the subcutaneous connective tissue, muscles, lymph glands, and external organs. The cervical lymph glands, heart, spleen, and intestines were most affected. Post-mortem examination was made on 9 animals, and a bacillus was obtained from all cases apparently identical with that of hemorrhagic septicæmia described by other authors. Inoculations of rabbits, guinea pigs, and calves produced the characteristic symptoms of the disease. Experiments in immunizing animals by inoculation with filtered cultures yielded fairly satisfactory results, although the number of experiments was too small to determine the degree of immunity thus produced.

Protective inoculation against foot-and-mouth disease of sheep, as practiced in the immunization of sheep and pigs, LOEFFLER and UHLENHUTH (*Berlin. Thierärztl. Wchnschr., 1900, No. 52, pp. 613–616*).—As previously reported, the authors have produced a serum which rendered young pigs quite immune to this disease. In doses of 0.1 cc. per kg., an immunity was produced which lasted for 3 weeks. In doses of 0.2 to 0.5 cc. per kg., immunity persisted for 8 weeks. The same serum was used successfully in rendering cattle immune from foot-and-mouth disease. Immunity in cattle, however, was only of short duration. In an outbreak of the disease in a herd of 416 sheep, 28 sheep received an injection of serum 2 days after the first appearance of the disease. The sheep were apparently well at the time, but 4 were sick on the day after vaccination. These 4 were probably infected at the time they were vaccinated. All the other vaccinated animals remained healthy. Foot-and-mouth disease broke out in a large herd of swine. A number of the pigs were vaccinated, and all the vaccinated animals showed a perfect immunity to the disease. The authors describe in detail the methods for obtaining the immunizing serum in a rapid and convenient manner.

The nature, cause, and economic importance of ovine caseous lymphadenitis, V. A. NÖRGAARD (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 638–662, pls. 7*).—The first cases of this disease in the United States were reported by Dr. O. B. Hess, from Los Angeles, Cal. Later it was reported from Chicago, Omaha, and Kansas City by inspectors stationed at those places. Usually no characteristic symptoms are observed in affected animals during life. The disease is chronic and the pathological changes develop so slowly as to cause no striking interference with the health of the affected sheep. This is especially true of lambs and sheep which are raised for mutton and which are marketed before they are 2 years old. A careful examination of an affected sheep will disclose an enlargement of one or more of the superficial glands, the precrural and prescapular glands being most frequently attacked. By metastasis the disease may attack the principal organs of the body, causing a chronic broncho-pneumonia, with symptoms of coughing. Several thousand cases are observed annually in slaughterhouses of the United States, and the progress of the pathological changes usually correspond to the age of the animal.

When first infected by the micro-organism of the disease the gland tissue enlarges to several times its original size. Later an abscess is formed with caseous contents of greenish yellow color. In the liver pathological changes are most frequently in the form of large nodules. The kidneys are seldom affected.

The micro-organism of this disease is a short bacillus, with rounded ends. It is aërobic and develops well upon glycerine agar or in peptonized beef bouillon, but most readily on blood serum. Bouillon containing 1 per cent of dextrose in fermentation tubes indicates a fermentation in the bulb with an acid reaction. The organism develops most rapidly at a temperature of 37° C., and is destroyed by exposure for 10 minutes to a temperature of 65° C., or 6 minutes of 70° C. An exposure of 5 days to direct sunlight does not destroy the vitality of the organism. Culture tubes kept at a temperature of 6 to 8° C. for a period of several weeks showed an active development when subsequently incubated at a temperature of 37° C.

In guinea pigs intravenous inoculations of from 3 drops to 0.3 cc. caused death in from 4 to 10 days. Intra-abdominal inoculations of from 0.3 to 0.75 cc. proved fatal in from 8 to 15 days; while subcutaneous injections of from 0.25 to 0.75 cc. caused death in from 15 to 28 days. Guinea pigs fed with oats infected with bouillon cultures of the organism died after from 5 to 8 weeks. In rabbits intra-abdominal inoculation in doses of from 0.25 to 0.75 cc. caused death in from 20 to 32 days; while rabbits inoculated by the subcutaneous method did not die until from the 25th to the 38th day. Experiments on pigeons and fowls indicated that these animals are immune to the disease. Inoculation experiments with sheep produced a chronic form of the disease with apparent recovery of external abscesses in some cases. Feeding experiments with sheep gave negative results. The author believes that the disease has existed in this country for many years. Of 16,000,000 sheep slaughtered in Chicago, Kansas City, and South Omaha during the years 1897–1900, inclusive, only 3,236 were condemned for this disease.

The disease is infectious and due to the bacillus of Preisz, which is pathological to mice, guinea pigs, rabbits, and sheep, but not to pigeons and chickens. It prevails in certain districts in the western part of the United States, and all classes of sheep, whether pure blood, breeded, or common stock, are susceptible. A bibliography of the subject is added.

The organism of sheep pox, E. Nocard (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 3, pp. 50, 51*).—The author's investigations on this disease indicated that the blood of animals affected with sheep pox is not virulent at any period of the disease. Experiments were tried on 3 sheep, in inoculating them with the blood from affected animals. All 3 sheep remained without infection, and a subsequent inoculation with fresh virus demonstrated that the injections of blood had had no effect in producing an immunity against sheep pox.

Staggers in sheep, J. D. Stewart (*Agr. Gaz. New South Wales, 11 (1900), No. 12, pp. 1112–1117*).—Outbreaks of a disease in sheep commonly known as "staggers" were reported from Narrabri. The disease was ascribed to several causes, such as micro-organisms and improper feeding, and the poisonous effects of marsh mallow. Various tissues of affected sheep were subjected to microscopical and bacteriological investigations with the result that no micro-organisms were found. A chemical analysis was made of marsh mallow, since this plant constituted one of the chief elements of the feed of the affected sheep. The protein contents of the plant were found to be rather high, and it is suggested that this is due to the presence of an alkaloid. The disease has been known for some time, and has been especially prevalent during the past 2 years. It affects sheep of all ages. The symptoms of shivering or staggering become especially pronounced when the animals are driven hurriedly. Under such circumstances a high temperature and rapid pulse and respiration are noted. Post-mortem examinations failed to determine with certainty the cause of the disease.

Experiments with lime-and-sulphur dip (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 506–508*).—Experiments were made by W. R. Southey to ascertain whether the fleece of sheep was injured by dipping in this mixture. Samples of wool were submitted to experts, who reported that the wool was uninjured, although slight traces of the dip were to be detected.

A comparative study of the biological characters and pathogenesis of Bacillus X, B. icteroides, and the hog-cholera bacillus, W. Reed and J. Carroll (*Jour. Expt. Med., 5 (1900), No. 3, pp. 215–270, pl. 1, figs. 4*).—The authors previously called attention to the resemblance of these bacilli and the similarity of the lesions produced in guinea pigs, rabbits, and dogs by *B. icteroides* to those caused by the hog-cholera bacillus. As a result of this work *B. icteroides* was considered a variety of the hog-cholera bacillus. The present paper contains details of observations upon which these conclusions are based. *B. X* is considered as belonging to the colon group. It is most pathogenic for guinea pigs when injected into the peritoneal cavity. The bacillus is pathogenic for rabbits in quantities of from 1 to 5 cc., whether injected into the body cavity or subcutaneously or intravenously. Rabbits died in from 16 to 43 days after inoculation.

B. icteroides and the hog-cholera bacillus are facultative, anaërobic organisms, which are decolorized by Gram's method, and do not liquefy gelatine. Details are given of the morphology of these bacilli and of their behavior in different culture media. Both bacilli possess a considerable range of pathogenesis for animals. The hog-cholera bacillus is pathogenic, in some degree, for mice, guinea pigs, rabbits, pigeons, dogs, and hogs. The lesions produced by the hog-cholera bacillus are compared with those produced in the same animals by *B. icteroides*, and found to be in general very similar. Details are given of the macroscopical and microscopical pathogenical lesions on animals artificially infected with the bacilli.

The close affinity of *B. icteroides* and the hog-cholera bacillus is indicated by the following facts: Sterilized cultures of *B. icteroides* protected guinea pigs against a fatal dose of the hog-cholera bacillus. Sterilized cultures of the hog-cholera bacillus protected these animals against a fatal dose of *B. icteroides*. Rabbits may be immunized against a virulent culture of the hog-cholera bacillus by repeated doses of a living culture of *B. icteroides* of weak virulence. The bacilli possess, therefore, the power of reciprocal immunization. An equally pronounced reciprocal agglutinative reaction is also obtained from the blood of animals artificially inoculated with *B. icteroides* and the hog-cholera bacillus.

The authors conclude that *B. X* belongs to the colon group, while *B. icteroides* is a member of the hog-cholera group. The channel of infection, the duration of the disease, and the lesions in mice, guinea pigs, and rabbits are the same for *B. icteroides* and the hog-cholera bacillus. *B. icteroides*, when fed to pigs, causes fatal infection, accompanied by diphtheritic and ulcerative lesions in the digestive tract, such as are seen in hogs when infected with the hog-cholera bacillus. The disease may be acquired by exposing hogs in pens already infected with *B. icteroides*, or by feeding them the organisms. While the blood of yellow fever does not exercise a pronounced agglutinative action upon *B. icteroides*, the blood of hog-cholera agglutinates this bacillus in a marked degree.

Hog-cholera and swine-plague investigations in Iowa (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 501, 502*).—The supervision of the work of the Bureau on swine diseases in Iowa is in the hands of Dr. McBirney. Altogether 21,000 animals were treated during the season of 1899. Of the total number of animals treated, about 70.5 per cent survived, while in nontreated herds during the years 1896–1899 only about 31 per cent of the hogs survived.

Our present knowledge of the kidney worm (Sclerostoma pinguicola) of swine, LOUISE TAYLER (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 612–637, figs. 16*).—The author gives an elaborate account of the synonymy of this species, a description of the internal and external anatomy, and a review of the literature relating to this subject. On account of the habits of hogs, any practical measures for preventing infection will meet with difficulty. Feeding from clean troughs and supplying an abundance of pure drinking water will diminish the infestation of the kidney worm, but will probably not entirely prevent the disease. The kidney worms are not transmissible to man in either the egg or adult condition, and ordinary methods of packing or curing kill all the worms. A bibliography of the kidney worm is appended to the article.

Diphtheria in horses, L. COBBETT (*Centbl. Bakt. u. Par., 1. Abt., 28 (1900), No. 19, pp. 631–634*).—A case of diphtheria in a child was traced to a horse which showed a discharge from the nose containing diphtheria bacilli. The animal was killed and cultures made of the bacilli obtained immediately after death. The bacillus thus obtained was not to be distinguished from the diphtheria bacillus, and produced the same pathological lesions when inoculated into guinea pigs. The author believes that the observation is of great practical value as showing the possibility of the presence of diphtheria in the nasal passages and larynx of horses, and also the possibility of human infection from this source. It is suggested also that this may help to explain the observed fact that the blood of normal horses often contains active diphtheria antitoxin.

Experiments with serum and defibrinated blood of animals which had recovered from horse sickness, A. EDINGTON (*Jour. Comp. Path. and Ther., 13 (1900), No. 4, pp. 281–300*).—During these experiments it was found that neither the serum from recovered animals, nor that from animals which had been subjected to a series of inoculations with constantly increasing doses of virulent blood, possessed any appreciative curative action or antitoxic quality. Strengthened serum, when mixed with a fatal dose of virulent blood, deprives the latter of its virulence; and it appears from this experiment that such serum exerts a definite action on the virus. The results were not, however, entirely uniform. While 100 cc. of strengthened serum in most cases prevented 1 cc. of virulent blood from producing any marked elevation of temperature in the susceptible animal, 1 case was observed in which this result was not obtained.

The study of the attenuation of rabies virus by means of heat, W. G. Ouchakoff (*Arch. Sci. Biol. [St. Petersburg], 8 (1900), No. 2, pp. 131–135*).—The author prepared an emulsion from the cerebro-spinal material of a rabbit which had died of rabies. Water was then added, and the whole was passed through a sterile filter. In the preliminary experiments the emulsion was separated into quantities of 3 cc. and placed in test tubes 1 cm. in diameter. These were then subjected for 15 minutes to temperatures of 40, 50, and 60° C. Inoculation experiments with the virus thus treated showed that this virus was destroyed at a temperature between 50 and 60° C. Further experiments showed that when the virus was subjected to a temperature of 52° for a half hour it was only slightly attenuated. A temperature of 53°, however, for 10 minutes greatly attenuated or completely destroyed the virus.

A new form of infectious lung disease in guinea pigs, F. Strada and R. Traina (*Centbl. Bakt. u. Par., 1. Abt., 28 (1900), No. 19, pp. 635–648*).—An extended outbreak of a very fatal lung disease was observed in guinea pigs, and since these animals are of great importance in all pathological laboratories for experimental purposes, the authors undertook an investigation of the nature and cause of the disease. Affected guinea pigs were attacked by fits of coughing, accompanied with asthmatic breathing. Post-mortem examinations showed that the lungs were unusually distended and of a dark brownish-red color, with a peculiar spotted appearance. In some cases large yellowish-colored spots were observed on the surface of the lungs. The lungs in nearly all cases were strongly hepatized. The spleen was normal and kidneys congested. A micro-organism was isolated from the diseased animals and described as new under the name *Bacterium pneumoniæ caviarum.* Detailed descriptions are given of the appearance of this organism and of its behavior on different culture media. A number of inoculation experiments were conducted, with the result that the disease was reproduced with the same symptoms which were observed in cases of natural infection.

Second outbreak of maladie du coït in Nebraska (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 134–144*).—A report is made by Dr. C. M. Day on 24 cases of this disease.

Culture media for biochemic investigations, E. A. de Schweinitz (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 145, 146*).—This article was previously published in the *New York Medical Journal* for March, 1893. A culture medium was used containing for every 1,000 cc. distilled water 0.2 gm. magnesium sulphate, 1 gm. acid potassium sulphate, 10 gm. ammonium sulphate, and 45 gm. glycerine. This liquid was substituted for beef broth in the preparation of agar, or solid nutrient media. For the tubercle bacillus the solution of salts was used containing 7 per cent of glycerine and 1 per cent of peptone, while for the glanders bacillus the media were prepared in the same way, except that 5 per cent of glycerine was used. Later asparagin was substituted for peptone.

Artificial modifications of toxins, with special reference to immunity, J. Ritchie (*Jour. Hyg. (Cambridge), 1 (1901), No. 1, pp. 125–144*).—Extensive experiments on the effects of hydrochloric acid and alkalis.

Disposition of dead animals in foreign cities (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 346–361*).—This article contains information obtained through the Department of State relative to the disposal of bodies of animals, the use of such flesh for cat and dog meat, fat for soap making, hoofs for glue making, bones for fertilizer, hides for leather, etc., and in the case of animals dead of contagious diseases their complete incineration, as practiced in various European cities.

Notes on parasites, 50–52, C. W. STILES and A. HASSALL (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 558–611, pls. 2, figs. 7*).—The muscle fluke belonging to the genus Agamodistomum was found by the trichina inspectors of the Bureau. It is possible that the species is identical with *A. suis* of Europe. It has been reported from Buffalo, New York, by Mr. C. Bullard. It is unlikely that the parasite is transmissible to man, and there is no indication that infested tissue is rendered unfit for food.

The lung fluke (*Paragonimus westermanii*) has been found in tigers, cats, dogs, hogs, and man. The authors give an elaborate bibliography of the species and describe its life history. The occurrence and pathological lesions caused by the worm in different species of hosts are discussed in detail. In 1898 Dr. A. J. Payne forwarded portions of a hog's lung containing specimens of this worm. In all, 52 cases of infestation by this species were reported. In the majority of cysts which were examined 2 specimens of the worm occurred. They were of a pinkish color, nearly or quite round on cross section, and the largest specimens attained a length of 14 mm. and a diameter of 4 mm. The cysts in the lungs were from 12 to 37 mm. in diameter and contained a chocolate-colored semifluid material, in which many eggs were found. These worms have not been diagnosed in hogs, except on post-mortem examination, and the symptoms are therefore not noted. It is probable that the fluke requires an invertebrate intermediate host, probably mollusk, after leaving swine, and that infection could, therefore, not be transmitted directly from hogs to man.

The conical fluke (*Amphistoma cervi*) has been reported from Europe, Asia, Africa, Australia, Canada, and the United States. Specimens of this species in the United States were repeatedly collected from steers during meat inspection at Sioux City, Iowa.

Note on the chicken tick (Argas americanus), A. HASSALL (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 496–500, pl. 1, figs. 7*).—This species is native to tropical America, and is gradually extending its distribution northward. It has been reported from various parts of Texas as causing loss to poultry raisers. For combating the tick the author recommends thorough application of whitewash in a hot condition. The whitewash may be made more effective by adding one quarter of a pound of carbolic acid to each $1\frac{1}{2}$ lbs. of lime. The mixture is then thoroughly applied, so as to fill the cracks of the walls and floors.

AGRICULTURAL ENGINEERING.

Irrigation investigations in California, E. MEAD (*U. S. Senate, 56. Cong., 2. Session, Doc. 108, pp. 73*).—A preliminary report on irrigation investigations conducted in California during 1900 by this Office in cooperation with the California Water and Forest Association. It contains a brief statement of the plan, organization, and outcome of these investigations, with extracts from the reports of the agents and experts in charge of the work in different localities in California.

Irrigation farming in the Southwest, D. A. WILLEY (*Sci. Amer., 84 (1901), No. 4, pp. 53, 54, figs. 4; Tradesman, 44 (1901), No. 12, pp. 51, 52, figs. 3*).—This is an account of the methods followed in the irrigation of rice on the great southern prairie which extends along the coast from the parish of Saint Mary in Louisiana to the Texas line, with notes on the harvesting and thrashing of rice and on the extent of the rice interests of Louisiana and Texas. Originally diversion of water from streams was depended upon exclusively for irrigation of rice fields. In time, however, it was found necessary, in order to insure a reliable supply of water in time of drought, to construct pumping plants for raising water from streams and from wells.

Irrigation studies, E. Mead (*Trans. Amer. Soc. Civ. Engin., 44 (1900), No. 882, pp. 149–180, pl. 1, figs. 10*).—An explanation of the investigations being carried on by the author under the direction of this Office, with descriptions of apparatus and methods.

Irrigation in Hawaii, W. Maxwell (*U. S. Dept. Agr., Office of Experiment Stations Bul. 90, pp. 48, pls. 6, figs. 3*).—This bulletin discusses the climatic, soil, and other conditions as affecting irrigation in Hawaii, and gives the results of irrigation experiments, especially with sugar cane, carried on in the islands by the author for a number of years. It deals with evaporation of moisture from water surfaces and soils, transpiration of moisture by vegetation, power of soils to absorb and retain moisture, salts in Hawaiian soils and waters, duty of water, irrigation practice on the Hawaiian Islands, and study of irrigation at the Hawaiian Experiment Station, including observations on distribution of water and results of overirrigation.

Irrigation in the Hawaiian Islands (*Sci. Amer., 84 (1901), No. 2, p. 20, figs. 3*).—A brief account of a canal dug along the slopes of the great crater of Haleakala, island of Maui, by which a stream of water flowing 50,000,000 gal. daily is brought 22 miles for distribution over a sugar plantation.

Irrigation in the Philippines, G. D. Rice (*Irrig. Age, 15 (1901), No. 6, pp. 186–191*).—This is a brief account of observations on the present status and future prospects of irrigation development in these islands as applied to the culture of coffee, tobacco, chocolate, peanuts, oranges, lemons, and mangoes. Irrigation is now practiced to only a limited extent, but the need and opportunities for its development are very great. "There are very large plantations of rice, tobacco, sugar cane, chocolate, coffee, peanuts, and other products in these islands awaiting proper development by irrigation. At present many of the plantations are in a state of idleness, owing to the continuance of dryness, which might be overcome if the water supplies of the country were properly utilized."

Biennial report of the State Engineer of Idaho, D. W. Ross (*Idaho State Engin. Rpt. 1899–1900, pp. 101, pls. 8, maps 3*).—The subjects treated in this report are the arid and irrigable portions of Idaho; increase of population and irrigation since 1890; irrigation surveys; projects under the Carey Act; irrigation districts; duty and distribution of water, including accounts of investigations carried on in cooperation with this Office; water rights and their adjudication; plans for dams and embankments, and selections of desert lands by the State.

The reservoir system of the Cache la Poudre Valley, E. S. Nettleton (*U. S. Dept. Agr., Office of Experiment Stations Bul. 92, pp. 48, pls. 14*).—This is an account of the experience of the Cache la Poudre Valley in the construction and use of storage reservoirs. The bulletin describes the Cache la Poudre River and Valley, reviews the history of the settlement and development of the valley and the systems of cropping practiced there, and gives detailed accounts of the reservoir systems established by local and individual enterprise in the valley, including their location, construction, filling, and use. It is shown that by means of the water saved from waste by these reservoirs and by the system of rotation in the use of water practiced in the valley, the area capable of being irrigated has been doubled and the irrigation has been more effective and thorough than is usual without the aid of storage reservoirs. The author's general conclusions are as follows:

"(1) Reservoirs in the Cache la Poudre Valley are a paying investment.

"(2) Storage of water in this valley is capable of extension.

"(3) There is a necessity for increasing the carrying capacity of reservoir feeders.

"(4) Reservoir embankments should be better protected from damage by wave action.

"(5) Reservoir outlets should be inspected annually.

"(6) Exchange of water facilitates its distribution and amplifies its use.

"(7) Accurate measurement is essential in the exchange of water.

"(8) The concert of action in the exchange of water appears to have lessened the number of legal conflicts.

"(9) Laws based on the outcome of customs are usually well founded.

"(10) Greater economy in the application of water is attained by alternating rather than prorating in times of scarcity, both among canals and among users from canals."

Seepage gains and losses, L. G. Carpenter (*Colorado Sta. Rpt. 1900, pp. 135–140*).—This is a continuation of previous observations (E. S. R., 11, p. 394) on the Cache la Poudre, Rio Grande, Conejos, and Uncompahgre rivers, and Big Thompson, Little Thompson, St. Vrain, Left Hand, Boulder, South Boulder, Clear, and Bear creeks.

Conveyance of water in irrigation canals, flumes, and pipes, S. Fortier (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 43, pp. 86, pls. 15, figs. 27*).—The experience of the author in the construction of irrigation canals and related hydraulic works used in the reclamation of the arid lands is given under the following heads: Irrigation canals, including location, standard cross sections, grades, operating canals in winter, aquatic plants in canals, and flow of water; wooden flumes, including flume lining, framework, protection of ends, carrying capacities, and semicircular flumes; stave pipe, including lumber for staves, steel for bands, construction, location of pipe line, durability, use, and cost; riveted-steel pipe; and cast-iron pipe, including history, manufacture, dimensions and weights, testing and inspecting, laying, durability, and cost.

The Austin dam, T. U. Taylor (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 40, pp. 52, pls. 16, figs. 12*).—"In this paper the author describes the preliminary projects, the construction of the dam, the difficulties encountered, the silting up of the storage reservoir, and, finally, the failure of the structure and the probable causes which led to the catastrophe. The attempt is made to present these facts from the engineering standpoint."

Inter or sub irrigation, H. P. Stiles (*California Cult., 16 (1901), No. 4, pp. 49, 52, 53, figs. 3*).—This is a discussion of Woodbridge's system of inter-irrigation, with a description of a subsoil plow devised by the author for breaking up hardpan and preparing the soil of orchards for irrigation.

The organization of irrigation farming, W. Toussaint (*Deut. Landw. Presse, 28 (1901), No. 17, p. 135*).

Reservoirs for irrigation, water power, and domestic supply, J. D. Schuyler (*New York: John Wiley & Sons, 1901, pp. XVIII+414, pls. 80, plans 25, figs. 130*).—This is "an account of various types of dams and the methods and plans of their construction, together with a discussion of the available water supply for irrigation in various sections of arid America; the distribution, application, and use of water; the rainfall and run-off, the evaporation from reservoirs; the effect of silt upon reservoirs, etc." It contains chapters on rock fill, hydraulic fill, masonry, and earthen dams, natural reservoirs, and projected reservoirs.

Irrigation laws of the Northwest Territories of Canada and of Wyoming, J. S. Dennis, F. Bond, and J. M. Wilson (*U. S. Dept. Agr., Office of Experiment Stations Bul. 96, pp. 90, pls. 6*).—This bulletin "gives the texts of the irrigation laws of the Northwest Territories of Canada and of Wyoming, with the regulations, forms, and methods of procedure adopted in their administration and discussions of the principles underlying the laws, and the methods followed in their enforcement."

The windmill, its efficiency and economic use, E. C. MURPHY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, Nos. 41 and 42, pp. 147, pls. 16, figs. 70*).—This is a revision of a previous paper of this series printed in 1897 (E. S. R., 9, p. 796), embodying additional data obtained by recent investigations.

Test of a manure spreader, W. STRECKER (*Mitt. Landw. Inst. Univ. Leipsic, 1901, No. 2, pp. 91–128, figs. 19*).

Practical suggestions for farm buildings, G. G. HILL (*U. S. Dept. Agr., Farmers' Bul. 126, pp. 48, figs. 28*).—This "contains plans and specifications for inexpensive farm buildings, both dwellings and barns, and several suggestions relating thereto."

House drainage and sanitary fitments, G. J. G. JENSEN (*London: Sanitary Publishing Co., 1900, pp. XX+257, pl. 1, figs. 347*).—In this book the attempt is made to present the subject in an untechnical manner and so concisely and simply that it may be readily comprehended by those having no previous knowledge of the subject.

STATISTICS—MISCELLANEOUS.

Thirteenth Annual Report of Colorado Station, 1900 (*Colorado Sta. Rpt. 1900, pp. 77–225*).—This includes a financial statement for the fiscal year ended June 30, 1900; a report of the director giving the regulations of the State board of agriculture governing the operations of the station and detailed plans of station work for 1900, notes on the station staff, list of publications issued during the year, and a general review of the work of the station and substations; an inventory of station equipment; list of exchanges; departmental reports giving detailed accounts of the different lines of station work; a report of the superintendent of the Arkansas Valley Substation giving notes on experiments with cantaloupes, sugar beets, tomatoes, grasses and leguminous plants, potatoes, wheat, and apples; and a report of the superintendent of the Plains Substation, including notes on the fruits, vegetables, and field crops under cultivation, notes on the forest trees planted as wind breaks, observations on soil moisture, and notes on the agricultural conditions of eastern Colorado.

Thirteenth Annual Report of Illinois Station, 1900 (*Illinois Sta. Rpt. 1900, pp. 15*).—A brief statement of the principal lines of station work, a subject list of the bulletins issued since the organization of the station, a detailed financial statement for the fiscal year ended June 30, 1900, and the organization list of the station.

Ninth and Tenth Annual Reports of New Mexico Station, 1899 and 1900 (*New Mexico Sta. Rpts. 1899 and 1900, pp. 15–32, 59–87*).—Reports of the director and heads of departments reviewing the different lines of station work and financial statements for the fiscal years ended June 30, 1899 and 1900. The chemist notes the discovery of a deposit of bat guano in the Territory and gives the composition of the material. Lists of publications of the entomologist each year are given. Reports of the superintendents of the San Juan and Las Vegas substations outlining work in progress are included, the latter containing notes on weather conditions during the calendar year 1899.

Eleventh Annual Report of Utah Station, 1900 (*Utah Sta. Rpt. 1900, pp. LXVIII*).—This contains a report of the director reviewing at some length the history, organization, equipment, work, and publications of the station; a subject list of Bulletins 1–70 of the station; a financial statement for the fiscal year ended June 30, 1900; list of exchanges; and departmental reports giving outlines of investigations in horticulture, irrigation, poultry raising, chemistry, dairying, and stock feeding, together with meteorological observations and some of the results of work along different lines noted elsewhere.

Ninth Annual Report of Washington Station, 1899 (*Washington Sta. Rpt. 1899, pp. 8*).—This contains a report of the director reviewing briefly the different lines of station work and giving a financial statement for the fiscal year ended June 30, 1899.

Tenth Annual Report of Washington Station, 1900 (*Washington Sta. Rpt. 1900, pp. 8*).—This contains a report of the director reviewing briefly the different lines of station work, and giving a financial statement for the fiscal year ended June 30, 1900.

A report on the work and expenditures of the agricultural experiment stations for the year ended June 30, 1900, A. C. True (*U. S. Dept. Agr., Office of Experiment Stations Bul. 93, pp. 181, pls. 8*).—This includes a critical review of the conduct and general management of the stations, with brief abstracts of all station publications received during the fiscal year ended June 30, 1900, and general statistics relative to organization, publications, principal lines of work, revenue, expenditures, etc.

Report on the agricultural resources and capabilities of Hawaii, W. C. Stubbs (*U. S. Dept. Agr., Office of Experiment Stations Bul. 95, pp. 100, pls. 23*).—This bulletin deals with the agricultural conditions and capabilities of the Hawaiian Islands, with special reference to the establishment of an agricultural experiment station. The author visited the islands as special agent of this Department, and the collected information here set forth pertains to subjects of direct agricultural interest. A suitable location for an experiment station was selected, and recommendations regarding its equipment and suggestions as to its lines of work are presented. The physical, geographical, and geological features of the islands, including the soils and the origin of the Hawaiian people, are discussed, and the climate and rainfall are briefly noted. The greater part of the bulletin is devoted to a consideration of the flora of the islands, the production of coffee and sugar, and the growing of fruits and vegetables. Many native and introduced plants are briefly described, and some of the fruit trees and the palms growing on the islands, together with plants bearing seeds in the neighborhood of Honolulu, are enumerated. Stock raising, irrigation, forestry, labor, and land matters, including the history of land titles and land ownership, are each given separate consideration.

Agricultural resources and capabilities of Porto Rico (*U. S. House of Representatives, 56. Cong., 2. Session, Doc. 171, pp. 32, pls. 7*).—This is a report by S. A. Knapp, special agent of the Department of Agriculture, on investigations of the agricultural resources and capabilities of Porto Rico, with special reference to the establishment of an agricultural experiment station in the island. In the discussion of these subjects, climate, soil, water supply, forestry, public roads, the cane-sugar, coffee, and tobacco industries, the culture of corn, rice, fruits, nuts, and vegetables, stock raising, and, in general, the economic conditions of the island are considered and improvements in different lines are suggested. A list of fruits and nuts, including those produced in Porto Rico and others that may safely be introduced, is given. The report concludes with a discussion on the establishment of an experiment station near San Juan.

Crop Reporter (*U. S. Dept. Agr., Division of Statistics Crop Reporter, Vol. II, Nos. 10–12, pp. 8 each*).—Among the articles of a statistical nature included in these numbers are the following: Report of the statistician for the fiscal year 1900, the trans-Atlantic cattle trade, the world's flax crop, interstate commerce, trade opportunities in Southern republics, United States commerce with Japan, crop report for March, agricultural exports, production of wheat in Russia since 1883, the winter grain crops of France, estimates of world's wheat crop, manufacture of beet sugar, crop conditions on April 1, 1901, Bureau of Animal Industry, production of rye in Russia since 1883, Russian wheat crop of 1900, and exports of butter, cheese, and eggs from the United States and Canada.

Sixteenth Annual Report of the Bureau of Animal Industry, 1899 (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1899, pp. 790, pls. 41, figs. 45*).—This contains the report of the chief, reviewing the work of the Bureau during the year; a number of articles noted elsewhere; reprints from the Yearbook of the Department for 1899 of articles entitled Some examples of the development of knowledge concerning animal diseases (E. S. R., 12, p. 488), Administrative work of the Federal Government in relation to the animal industry (E. S. R., 12, p. 488), and Dairy development in the United States (E. S. R., 12, p. 484); reprint of Bulletin 24 of the Bureau entitled Notes upon dairying in California and the export of California butter to the Orient (E. S. R., 12, p. 89); reprint of Farmers' Bulletin 100 entitled Hog raising in the South (E. S. R., 11, p. 381); abstracts of 10 station bulletins reporting investigations along lines embraced in animal industry; brief miscellaneous articles taken in part from correspondence and consular reports, dealing with hog cholera and swine plague investigations in Iowa, a correction to an article appearing in the report of the Bureau for 1898 on the cattle tick and tuberculosis in New South Wales, sale of American thoroughbred horses in England, the exhibit of the Bureau at the Trans-Mississippi and International Exposition at Omaha in 1898, experiments with lime-and-sulphur dip, disinfection of hides of cattle shipped to the United States, injury to hides by branding, successful treatment of lumpy jaw, cattle notes of southwestern Texas, a report concerning the cattle of Porto Rico, Texas cattle, some statistics of cattle and cattle products of the Argentine Republic, decrease in Canadian-British cattle trade, shipments of Venezuelan cattle to Cuba, trade of Liverpool with the United States, United States sausages in Gibraltar, Germany's wool import, Silesian wool, American boots and shoes in Denmark, leather manufactures in Germany, leather industry in Japan, leather industry in Russia, exports and imports of animal products of Cape of Good Hope, Siberian dairy notes, potato bread for horses in Germany, and the distribution of tuburculin, mallein, and blackleg vaccine by the Bureau; a list of sanitary officers for the control of animal diseases in the various States; statistics for 1899 of the number and value of farm animals, the world's wool clip, and the receipts and shipments of farm animals at leading cities; rules and regulations of the Bureau of Animal Industry issued in 1899; and laws for the control of contagious diseases of animals in the different States. The report also contains several statistical articles dealing with the trade of Porto Rico in animals and animal products, imports of animals and animal products into the United Kingdom, imports and exports of animals and animal products, and the number of live stock in foreign countries.

Investigation of the great plains—field notes from trips in eastern Colorado, J. E. Payne (*Colorado Sta. Bul. 59, pp. 16, pls. 2, map 1*).—The author traveled over 1,300 miles, mainly in Kit Carson and Arapahoe counties, interviewing settlers and obtaining information as to the methods employed and results obtained in tree planting, fruit growing, and stock raising. Notes are also given on methods of irrigation, the results obtained with different field crops, character of the soil, weeds, insects, etc.

Farm and dairy industries of America, C. Sealey (*Queensland Agr. Jour., 8 (1901), No. 1, pp. 12–18*).—A report on an extended tour through Canada and the United States.

Perfume farm in Western Australia (*Queensland Agr. Jour., 8 (1901), No. 3, pp. 215, 216, fig. 1*).—A description of a perfume farm lately started in Western Australia. Wild verbena is the plant principally grown at the present time. An illustrated description is given of a box successfully used in extracting scent from flowers.

The plant breeding station at Svalöf in Sweden (*Mitt. Deut. Landw. Gesell., 16 (1901), No. 9, pp. 49–51*).—An article giving the history and describing the management and purpose of the institution.

NOTES.

ALABAMA COLLEGE AND STATION.—F. S. Earle has resigned his position in this institution to accept a position in connection with the botanic gardens at Bronx Park, N. Y.

COLORADO COLLEGE AND STATION.—W. R. Thomas has succeeded P. A. Amiss as principal of the State board of agriculture. Bids are to be called for for the construction of the foundation of a building for the department of irrigation engineering and the offices of the experiment station. This building will cost about $40,000. E. S. G. Titus, who has been acting assistant entomologist of the station for the past year, has accepted the position of assistant to S. A. Forbes, of the Illinois Station and Bureau of Natural History. The board of control has authorized the completion of the sale of what has been called the Divide Substation and transferred the property to the purchaser.

CONNECTICUT STATE STATION.—S. W. Johnson has resigned his position as a member of the station staff. W. E. Britton has been appointed State entomologist under the recent act of the general assembly providing for the inspection of nurseries and for experiments in combating insect pests. The act provides that the State entomologist is to be a member of the station staff and is to receive no other salary than that paid by the station. An annual appropriation of $3,000 is made for carrying on the work. Walter Mulford has been appointed State forester under an act of the general assembly concerning the reclamation of barren lands by tree planting.

IDAHO COLLEGE AND STATION.—John Henry Dye, C. E., a graduate of the University of Michigan, has been elected professor of civil engineering in the college and irrigation engineer of the station.

IOWA COLLEGE AND STATION.—John A. Craig, of the department of animal husbandry of the college and station, has resigned to accept a position as editor in Des Moines, Iowa, his resignation to take effect September 1. W. J. Kennedy, of the University of Illinois, has been elected to succeed Professor Craig. C. H. Eckles, dairy bacteriologist and assistant in the dairy department, has resigned to accept an assistant professorship in charge of dairying at the University of Missouri.

KANSAS COLLEGE AND STATION.—R. W. Clothier, assistant chemist of the station, has resigned to accept the professorship of agriculture and chemistry in the Normal School at Cape Girardeau, Mo. The station has recently completed experiments in the feeding of 130 calves for the production of "baby beef" and is undertaking investigations in pasture and range improvement, and with forage plants in connection with the Bureau of Plant Industry of this Department. At a recent meeting of the board of regents the two departments of chemistry in the college were combined, J. T. Willard being made professor of chemistry and George F. Weida assistant. E. A. Popenoe was relieved of horticultural work, the latter being left for the present in charge of A. Dickens.

MARYLAND STATION.—A. L. Quaintance, M. S., of the Georgia Station, has been appointed associate horticulturist and entomologist. E. P. Sandsten, M. S., a graduate of the Minnesota University, has been appointed general assistant in horticultural work, succeeding H. P. Gould, resigned. F. P. Veitch has resigned as assistant in soil work to accept a position as assistant soil chemist in this Department. The soil investigations which the station has carried on for several years will be discontinued. H. C. Whitford has been appointed to the position vacated by R. H. Pond, assistant plant pathologist. The board of trustees at their annual meeting made provisions for building a house to furnish quarters for the herdsmen and for the dairy and horticultural apprentices at the station.

MAINE STATION.—H. W. Britcher has been appointed assistant zoologist to the station.

MISSOURI STATION.—J. F. Gmelich, of Boonville, has succeeded N. M. Givan as a member of the governing board of the station.

NEBRASKA UNIVERSITY AND STATION.—E. A. Burnett has been made director of the station, *vice* Chancellor E. Benjamin Andrews, who retires from the work of the station. R. W. Thatcher, assistant chemist of the station, has resigned to accept a position as assistant chemist of the Washington Station. H. R. Smith, B. Sc., a graduate of the Michigan Agricultural College, recently acting professor of agriculture in the University of Missouri, has been elected assistant professor of animal husbandry in the university and assistant in animal husbandry at the station, to take effect September 1. W. H. Tuck, laboratory assistant in the department of animal pathology, has resigned to accept a position with a large disinfecting company. J. H. Gain, a graduate of Chicago Veterinary College, has been elected assistant in the department of animal pathology of the station.

NEW MEXICO STATION.—The offices of second assistant chemist and assistant botanist have been discontinued.

NORTH CAROLINA COLLEGE AND STATION.—The college and station passed June 1, 1901, under the control of the State board of agriculture, composed of the following members: S. L. Patterson, chairman of the board of agriculture, Raleigh; J. B. Coffield, Everetts, N. C.; E. L. Daughtridge, Rocky Mount, N. C.; W. M. Dunn, Newbern, N. C.; C. N. Allen, Auburn, N. C.; J. S. Cunningham, Cunningham, N. C.; A. T. McCallum, Red Springs, N. C.; J. P. McRae, Laurinburg, N. C.; L. G. Waugh, Dobson, N. C.; W. A. Graham, Machpelah, N. C.; A. Cannon, Horseshoe, N. C.; Howard Browning, Littleton, N. C.; J. R. Joyce, Reidsville, N. C.; G. E. Flow, Monroe, N. C.; and J. C. Ray, Boone, N. C. The office of professor of agriculture in the college and agriculturist at the station was vacated. A professorship of veterinary science and animal industry and the office of State veterinarian were established. An instructorship in biology in the college and biologist of the station was also established. President G. T. Winston, of the college, resigned as director of the station, and B. W. Kilgore, chemist of the State board of agriculture, was appointed as his successor in the directorship.

NORTH DAKOTA COLLEGE AND STATION.—Two barns, one for horses and the other for cattle, the combined cost of which will be about $18,000, are being constructed to replace the large station barn burned January 5. Experimental work has been undertaken at Edgeley, a little over 100 miles southwest of Fargo, under a small State appropriation made for the establishment of a substation at that place. A $12,000 addition is being made to Mechanical Hall, and the contract has been let for the construction of one wing of a science building.

PENNSYLVANIA STATION.—Enos H. Hess has severed his connection with the station as assistant to the director to assume the management of a large farm at Casanova, Va.

SOUTH CAROLINA COLLEGE AND STATION.—The capacity of the chemical building has been doubled by recent additions. A. P. Anderson, entomologist, has tendered his resignation, to take effect September 1. P. H. Rolfs has resigned to accept a position in the Division of Plant Industry in this Department. He will be pathologist in charge of the Tropical Laboratory at Miami, Fla.

South Dakota Station.—President John W. Heston has been elected acting director of the station.

Utah Station.—W. W. McLaughlin, B. S., has been appointed assistant chemist of the station.

Vermont Station.—A. W. Edson, A. B., assistant botanist of the station, has become student aid in the Bureau of Plant Industry of this Department, and W. J. Morse, B. S., has been appointed to succeed him.

Virginia Station.—John Spencer, V. S., has been appointed assistant veterinarian, *vice* C. McCulloch.

Necrology.—Dr. Charles Mohr, the well-known botanist of the Southern United States, died at Asheville, N. C., July 17, in his seventy-seventh year. Dr. Mohr was born December 28, 1824, at Esslingen-on-the-Neckar, Germany. He was educated as an apothecary, but his natural inclination was in the line of botany. In 1846 he made a trip to South America, returning to Europe early in 1848, soon after which he came to the United States, settling in Mobile, Ala., in 1857, making that his home thereafter. He has long been considered an authority on the forest, medicinal, and other economic plants of the South. In 1885 he prepared and had charge of the collection of medicinal and other useful plants of the South at the New Orleans Exposition. He contributed the information regarding Southern forests to the report on the forests of the United States in the Tenth Census Report and Bulletin 13 of the Division of Forestry. The Timber Pines of the Southern United States was written by him. He also contributed extensively to botanical and pharmaceutical journals, usually treating of economic considerations. At the time of his death there was in course of publication for the Botanical Division of this Department a report on the flora of Alabama, which gives results of forty years of his observations.

EXPERIMENT STATION RECORD.

Vol. XIII. No. 3.

The address of J. Cossar Ewart, M. D., F. R. S., at the recent meeting of the British Association at Glasgow will be of interest to persons who appreciate the frail foundation upon which our knowledge of the science of breeding animals rests and the desirability of systematic experiments directed along that line. Dr. Ewart, who is professor of natural history in the University of Edinburgh, is well known for his investigations in this line, which have extended over a number of years, although the results have been published only in part in zoological and veterinary journals. A number of his papers on the subject of telegony and reversion and the results of breeding zebra hybrids were published in book form in 1899 under the title of The Penycuik Experiments, named for the place where these experiments have been conducted. In that volume he presented the views held by biologists, breeders, and others interested in the question of telegony or "germ infection," a term which he defined as a convenient explanation of many of the obscure phenomena which come under the notice of breeders and fanciers. He there outlined a series of experiments which might be undertaken on that subject and signified his desire to correspond with anyone interested in undertaking some of these experiments.

In the meantime his own experiments have been continued. This year, as president of the zoological section of the British Association, he delivered the opening address, taking for his subject "The experimental study of variation." In this he reviewed the theories of variation and cited many experiments with different kinds of animals. He gave special attention to the subject of the cause of variation—the possible effect of age, ripeness of the germ cells, condition of the soma, change of habitat, environment and use-inheritance, and telegony—and discussed the effects of intercrossing and interbreeding on variation and the swamping effect of intercrossing on new varieties. In regard to the subject of telegony, after carefully considering all the more striking supposed cases of "infection," Dr. Ewart stated very positively that "there is no satisfactory evidence that there has ever been, either in the human family or amongst domestic animals, a single instance of infection." He indicates that the true cause of variation is not likely to be found either in maternal impressions, the direct action of environment, use-inheritance, or telegony. Instead of simply stating that variation is due to the constant recurrence of slight inequalities of the nutrition of the germ cells, he believes that we may assert with some confidence that differences in age, vigor, and health of the parents and differences in the ripeness of the germ cells are potent causes of variation. He holds that intercrossing, though a direct cause of retrogressive variation, is only an indirect cause of progressive variation, while in-and-in breeding at the right moment is a cause of progressive variation. He discusses at some length the "swamping" effects of intercrossing, showing that "progress in a single direction is probably often due to new varieties swamping old—it may be long established—varieties, and that several varieties may be sufficiently exclusive to flourish side by side in the same area and eventually (partly owing to their aloofness, i. e., to differential mating) give rise to several species."

In conclusion Dr. Ewart states his belief that the time has come when a well-equipped institute for biological and other experiments bearing upon these questions should be provided.

The need of such experiments must be patent to all who are familiar with the theories and traditions of stock breeding. Considering the very great progress which has been made in recent years in agricultural science, it is rather remarkable that our knowledge of the laws upon which the breeding of animals for different purposes rests has remained practically at a standstill. While attention has been given to nearly every other line of animal husbandry, this interesting and important field has been passed over, probably on account of the difficulties and the time-consuming nature of such experiments. These, however, should not present themselves as barriers to institutions whose permanence is assured and which can safely lay plans for a long term of years. Stock breeding suggests itself as a most inviting field for experiment station work, and one in which very important, if not epoch making, results are quite within the range of possibility.

In this day of specializing, the field would seem to be sufficiently inviting to attract men who should prepare themselves for it by the very best means possible, and be content to make the subject a life study. What has long been needed is a master mind to work over and digest the theories and traditions on which our so-called principles of breeding rest. They rest too largely at present on experience, rather than on systematic experiments, which affords instances in support of almost any theory. The information needs to be classified and graded, and the wheat separated from the chaff that has been passed down to us through successive manuals on the subject. It would seem that some few of the experiment stations in this country might be in position to enter upon some phase of this work, under the advice of such a competent guide as Dr. Ewart, which, if carried on systematically and in a cooperative way, might be productive of noteworthy results.

The rapid evolution of the soil work of this Department from a subordinate division of the Weather Bureau to a Bureau organization of its own within a period of six years from its inception, and with an appropriation the year of its elevation to a Bureau of over $109,000, gives this line of investigation a prominent position in the activities of the Department. The reorganization of the division into a Bureau of Soils went into effect July 1, and involves the extension of its work along a number of lines of practical utility as well as the strengthening of those developed in the past. The Bureau is charged with the study of soil problems in their relation to practical agriculture; the investigation of the physical and chemical properties of soils, the classification and mapping of soils, to show the distribution of the various soil types, with a view to determining their adaptability to certain crops and their management and treatment; the investigation of alkali problems and their relations to irrigation and to seepage waters; and the investigation of tobacco soils, methods of cultivation and curing of tobacco, introduction of improved varieties, and the marketing of tobacco in foreign countries.

The interest which has been aroused by the investigation of tobacco soils, and especially the successful growth of Sumatra tobacco in Connecticut, has given rise to demand for investigation of tobacco soils in other localities and for soil studies on the adaptability of other crops, notably the sugar beet and certain varieties of fruits at present grown to perfection only on quite restricted areas. During the present year an area of nearly six million acres has already been surveyed and mapped, which has included field work in about a dozen different States, and other sections of the country are being taken up this fall. In several of the Western States this work has included studies of alkali problems, and plans were laid for making a practical demonstration in Utah of the efficiency of drainage in the reclamation of alkali lands. The appointment of Mr. F. D. Gardner, who had this work in hand, to the management of the Porto Rico experiment station, prevented carrying out these plans; but much interest has been expressed in the undertaking, and it is hoped that such a demonstration may be made later.

Following the success in growing Sumatra tobacco under shade on soils of certain definite character in Connecticut, cooperative experiments were undertaken with a number of farmers in Connecticut and Massachusetts on areas as widely separated as possible, on typical soils which were thought adapted to this crop. In this way nearly 43 acres of Sumatra tobacco were grown during the past season under the supervision of the Bureau. While it will naturally be some time before the actual results of this experiment are known, the present indications are that the crop will yield at least double the cost of production, nearly three-fourths of which is due to the erection of the shade and hence is in the nature of a permanent improvement.

Another successful line of work in the tobacco investigations has been the fermenting in bulk of the type of leaf grown in Lancaster County, Pa., instead of in tightly packed cases. The first experiment was made on an old crop which had not fermented by the usual case method, but had developed a considerable amount of black rot. Bulk fermentation proved perfectly successful, the quality of the leaf being improved and the black rot checked entirely. Subsequently over 4,000,000 pounds of tobacco was fermented in bulk under the direction of the Bureau by several of the leading packers, with a total loss of only 35 pounds from black rot and all other causes. The success of this method of fermenting the tobacco, both in improving the quality of the leaf and in controlling the dreaded black rot, appears to be assured, and it is confidently predicted by the packers themselves that the new method will entirely supersede the old, especially where large crops are handled.

A distinctly new line of the soil investigations will be developed under Prof. F. H. King, who has recently been added to the personnel of the Bureau. This will consist of investigations directly related to problems in soil climatology and soil management. The Division of Soils was orignally organized in the Weather Bureau "to investigate the relations of soils to climate and organic life." This feature of its work has not been lost sight of, although it has in large measure been crowded out by the development of the work in other directions. The establishment of this line of research as a permanent feature of the work of the Bureau is in conformity with the general plan of reorganization, and is looked upon as an important step in strengthening and extending its activities.

As at present organized the Bureau embraces the following branches: Administrative, in charge of Milton Whitney; soil chemistry, F. K. Cameron; soil physics, Lyman J. Briggs; soil surveys—eastern division, C. W. Dorsey, western division, T. H. Means; tobacco investigations, M. L. Floyd, and soil climatology, F. H. King. This completes the organization of the Bureau for the present. The plan will be to develop the branches of field and laboratory investigations already provided for and to extend the soil survey as rapidly as possible, establishing new branches only as they may be called for in the development of the present lines.

Several of the colleges in the West are deriving some income from the lands granted them under the Morrill Act by leasing them for grazing purposes. While the rental for such lands is very low, in a number of cases it nets a considerable sum in the aggregate. A decision recently rendered by the supreme court of Montana on the disposition of such funds is of interest in this connection. The leases on lands of the College of Agriculture and Mechanic Arts yield at present about $6,500 a year, and about $16,000 of this money had accumulated in the State treasury. The State attorney-general held that it was not available to the college until it had been specifically appropriated by the legislature. The college authorities thought differently and carried the matter to the supreme court of the State on a mandamus proceeding. The court decided that this money was in the nature of an income from the land scrip, for the expenditure of which provision had been made in the Morrill Act and subscribed to by the State in its acceptance, and hence that it was not subject to further legislative action. This decision places the funds in the hands of the State board of education, which has charge of all the State institutions. The funds may now be appropriated by this board for specific purposes the same as any other funds of the college.

In Wyoming, where about $15,000 has accumulated from the leasing of portions of the land scrip, the legislature has already taken action upon this matter, but of such a nature as practically to withhold the funds from the university. The contention has been made that this money is subject to the same restrictions as prescribed by the Morrill Act for the proceeds from the sale of the land scrip, and that therefore none of the principal can be used. A bill passed the last session of the legislature directing that the principal be invested in 5 per cent par bonds, and the interest applied to the university. Up to the present time such an investment has not been made, and the university, which holds that the money derived from leases is itself in the nature of interest on the land endowment, as the principal has not been encroached upon, is compelled to await the action of the next legislature. Unless this law is repealed it will prevent the university deriving any material benefit from its land grant for a long period, as the constitution of the State prohibits the sale of any of its public lands for less than $10 an acre.

Preliminary plans for a new agricultural building for the use of this Department have recently been accepted by the commission of award appointed for that purpose. Some months since this commission invited architects to submit plans for such a building, outlining the general requirements and some considerations to be taken into account. In compliance with this invitation ten architects submitted plans, which have been passed upon by the commission, resulting in the acceptance of those of Lord & Hewlett, of New York. These plans contemplate a magnificent marble structure of classic design and imposing proportions. The features are a main building or front something over 300 feet in length, with wings at either end extending to the rear for the accommodation of the various laboratories. The front and wings are four stories in height, with a well-lighted basement under the whole, and provide 158,400 square feet of space.

The estimated cost is a little over $2,000,000. It is understood that these plans are of necessity only preliminary, and that a considerable number of changes will be required to adapt them to the needs of the Department. The exterior and the general arrangement, however, have been made to conform to the general plans of the commission now considering the improvement of the parks and public buildings of Washington. It is planned to locate the new building approximately on the present site of the main building, facing the contemplated parkway from the Capitol to the Washington Monument.

It is with deep regret that we chronicle the death of Dr. M. Maercker, of Halle, which occurred on October 19, at the age of 59 years. Dr. Maercker and his services to agriculture and agricultural chemistry are too generally known in this country to need more than passing notice. The agricultural experiment station at Halle, which is the largest and one of the oldest of the German stations, in its present proportions is a monument to his indomitable energy and the confidence which his work inspired. As director of this station for over 30 years, he so systematized the enormous amount of control work which it was called upon to do that he was able, in addition, to carry on a creditable amount of research and a large amount of experimentation of a more practical nature in the field and vegetation house. Remarkably progressive in his ideas, he was impressed with the importance of investigations for practice's sake as well as for science's sake, and probably few of the German stations have had a more direct influence in improving the methods and practice of their constituents than the Halle station. The dominant spirit of the American stations appealed strongly to Dr. Maercker, and their example was, as he declared, an inspiration to him in bringing agricultural experimentation more closely into touch with agricultural practice. As a teacher he was vigorous and inspiring, and as a writer and a speaker his influence was felt far and wide. One of the foremost figures in agriculture of his day, his death will be keenly felt in all the varied lines of activity in which he had been prominent.

THE ASH CONSTITUENTS OF PLANTS; THEIR ESTIMATION AND THEIR IMPORTANCE TO AGRICULTURAL CHEMISTRY AND AGRICULTURE.

B. Tollens, Ph. D.,

Director of the Agricultural-Chemical Laboratory, University of Göttingen.

Part I.—The Ash of Plants, its Preparation and Analysis.

Regarding the origin and importance of the residue remaining after the burning of plants, i. e., the ash elements or "the salts," strange theories were held in the first part of the nineteenth century, even among many of the learned men of that time. At the close of the eighteenth century Theodore de Saussure had demonstrated the soil in which the plants grow to be the source from which the ash elements are derived, and clearly showed these elements to be indispensable to the life of plants. Although his theory received the support of the chemists of that day, as Davy and Berzelius, it was not until after 1840 that its truth became generally accepted. About that time Boussingault[1] in France and Liebig[2] in Germany based their celebrated writings upon those of de Saussure[3] and the fundamental researches of Wiegmann and Polstorff.[4] The importance of the ash constituents of plants and their study was soon very generally conceded by agriculturists as well as by others, and now the matter is accepted beyond any doubt.

De Saussure attempted the most careful estimation of the ash elements of plants, not only the total amount of ash, but also the quantities of the individual constituents; and these determinations by improved methods have been made extensively ever since. When regard is had to absolute accuracy, ash analysis is not as simple as might at first appear, or as some chemists who have given little attention to the subject are inclined to regard it. On the contrary, it requires the exercise of special precautions, as Strecker,[5] among

others, has pointed out. This is recognized by handbooks of analytical chemistry, such as Fresenius's, for example, which treat the subject of ash analysis at considerable length.

PREPARATION OF THE ASH.

The principle of ash determination is very simple, and while in the case of some materials the incineration is easily made, in the case of many others great difficulties are presented which may cause quite large errors. The following points should be especially noted: (1) The incineration must be complete or nearly so, and no carbon should remain. (2) None of the ash elements should be volatilized, this precaution applying especially to potash and soda, phosphoric acid, sulphuric acid, and chlorin. (3) Further, it should be remembered that elements which occur only in part as highly oxidized inorganic acids but in other forms as well, as, for example, sulphur in proteids or phosphorus as glycerine-phosphoric acid in lecithin, are only present in the completely incinerated ash in the form of acids (sulphuric and phosphoric acids).

In case it is desirable to know how much sulphuric acid, as such, is in the original substance before incinerating, it is extracted with dilute hydrochloric or nitric acid in the cold or with slight heat, and the sulphuric acid precipitated with barium chlorid.[1]

For the combustion of the organic matter various methods have been described since the time of de Saussure, some simple and others more complicated, only a few of which can be noted. De Saussure[2] wrote: "The . . . plants are burned on a large sheet of iron, and the residue incinerated in a crucible at a dark red heat until the carbon particles can not be burned further." He first burned the substance in large quantity on an iron plate to reduce the volume, and then completed the incineration in a crucible (probably of clay). This method is practiced at the present day when a large quantity of ash is desired, and when a sufficiently large platinum crucible is not available one of fire clay is used, the charred mass being transferred to a smaller platinum crucible for completing the operation.

The ordinary platinum vessels, both crucibles and dishes, permit the free access of a current of air. The crucible was formerly heated over a charcoal fire or an alcohol lamp. In the incineration over a coal-gas flame or oven, as is now commonly done, there is the danger that some of the sulphur of the gas may be oxidized and unite with the bases of the ash, thereby causing an error in the sulphuric-acid content. There-

fore, it has been recommended by Baumert, Counceler,[1] and von Schröder and Reuss[2] to employ an alcohol lamp in exact determinations of the sulphur content of plants, as, for example, in studying the injury to forest trees caused by the sulphur in the gases given off by smelters. In such cases the Berzelius alcohol lamp or one of similar construction should be employed.

When the incineration is carried on in a platinum dish care should be taken to bring the glowing substance into contact with the air, either by frequent stirring, or by suspending a glass tube, for example an ordinary lamp chimney, above the dish to increase the draft.[3] There is always a danger, too, that the substance in the bottom of the dish may be heated too high, while the top portion will not be heated enough, and thus the incineration be uneven. In order that the upper portions of the substance may be properly incinerated the heat must be applied from above, and this is accomplished most simply by laying a platinum cover loosely over the dish, which holds the heat in and reflects it upon the substance.[4] This is accomplished in the method of the Association of Official Agricultural Chemists[5] by the use of a muffle.

If care is not exercised and a too high degree of heat is applied, inaccuracies may follow, due to the volatilization of the alkalis as well as some of the phosphoric[6] and sulphuric acids, or other errors, as the fusing together of the ash inclosing carbon and the formation of silicates which are difficult to decompose.

To avoid the volatilization of sulphuric acid or sulphur in other forms various methods have been employed. For example, W. Mayer[7] found 0.464 per cent of SO_3 in wheat when incinerated with potash and saltpeter, and only 0.04 to 0.06 per cent when incinerated in the ordinary manner. Ulbricht[8] treated clover leaves by heating in nitric acid and drying and then incinerating with saltpeter and potassium carbonate. With this treatment 1.476 per cent of SO_3 was found, while a portion

[6] Erdmann (Ann. Chem. u. Pharm., 54 (1845), p. 353) and Strecker (Ann. Chem. u. Pharm., 73 (1850), p. 346) have called attention to this point; while according to Lechartier (Compt. Rend. Acad. Sci. Paris, 109 (1889), p. 727) scarcely any phosphoric acid volatilizes, though some sulphuric acid may be driven off. See also Weber (Ann. Phys. u. Chem. [Poggendorff], 81 (1850), p. 402).

[7] Ann. Chem. u. Pharm., 101 (1857), pp. 129–154.

[8] Landw. Vers. Stat., 3 (1861), p. 249.

of the substance burned without the addition of alkalis, etc., yielded only 0.417 per cent.

Many chemists in preparing the ash in platinum dishes, whether over a flame or in the muffle, first extract the fusible salts from the charred substance with water, then dry and incinerate the residue completely, afterwards adding the extract, evaporating, and gently glowing.

SPECIAL INCINERATING APPARATUS.

In order to regulate the admission of air to the substance and at the same time to retain the volatile substances, several forms of apparatus have been proposed in which the substance is burned in a current of air or oxygen, and the volatile portion or fine particles collected. König used simply a glass tube drawn out to a point for discharging a small current of oxygen into the faintly glowing substance.

Mitscherlich[1] and Schloesing[2] heated the substances in a platinum or silver boat placed in a wide glass or porcelain tube, through which a current of carbon dioxid was first passed, until the charring was complete and combustible gases ceased to be given off, and then a current of oxygen, and the incineration completed. By this means there should hardly be any volatilization of substance and no inclosing of carbon by the fusing of the salts. A similar apparatus has been recommended by Reese.[3]

Hlasiwetz[4] employed a double-necked flask, in one opening of which a porcelain tube was placed in a perpendicular position, wide above and narrow below, with a sieve of platinum in the bottom upon which the substance was placed. The substance was ignited and air was drawn through the tube and the bottle by means of an aspirator until the combustion was complete. The products of combustion were passed through the water in the flask, which held any particles carried along mechanically, as alkaline chlorids, etc. The incineration was completed in a platinum dish.

Shuttleworth[5] and Tucker,[6] working in the Agricultural-Chemical Laboratory of the University of Göttingen, have recently made use of another principle. They employed a specially constructed platinum crucible of large size, with a platinum cover carrying a tube reaching to the bottom of the crucible, through which a current of air was con-

ducted, and with an arrangement for retaining any particles of volatilized substance. The construction of the two forms of apparatus is shown in the accompanying figures.

A weighed amount of the substance is placed in the crucible without the cover, and charred on a sand bath until no more gases are given off. The cover with the tube for conducting air is then put in place and the crucible heated over a naked flame. The air is forced into the Shuttleworth apparatus (see fig. 1), while in the Tucker apparatus

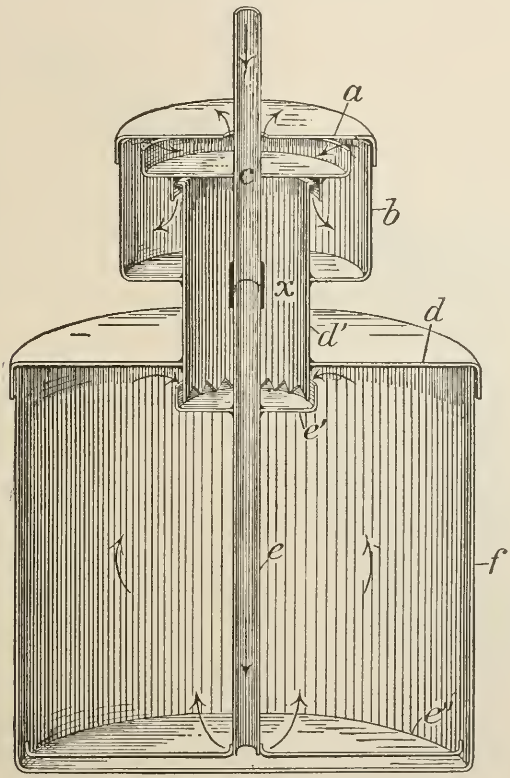

FIG. 1.—Shuttleworth apparatus for ash determination.

(fig. 2) it is drawn through by means of an aspirator, the tube conducting the current of air to the bottom of the crucible carrying a stirrer in both cases. In the Shuttleworth apparatus the loss of light particles of matter is avoided by an attachment to the cover (*d′*, *b*.) containing water (*c*). In the Tucker apparatus the air drawn off is passed through a small flask (*g*) containing water, in which the volatilized chlorids, etc., are collected.

During the combustion the substance is stirred by a platinum stirrer, which in the Shuttleworth apparatus is attached to the tube introducing air into the crucible, and in the Tucker apparatus extends down through the inlet tube.

The Tucker apparatus has the advantage over the Shuttleworth apparatus of simplicity of construction and ease of operation. Again, the cover of the Shuttleworth apparatus is complicated, and forcing the air through is less satisfactory than drawing it through, as in Tucker's apparatus. The conical form of the crucible of Tucker's apparatus is also preferable, permitting the heat to be applied more uniformly.

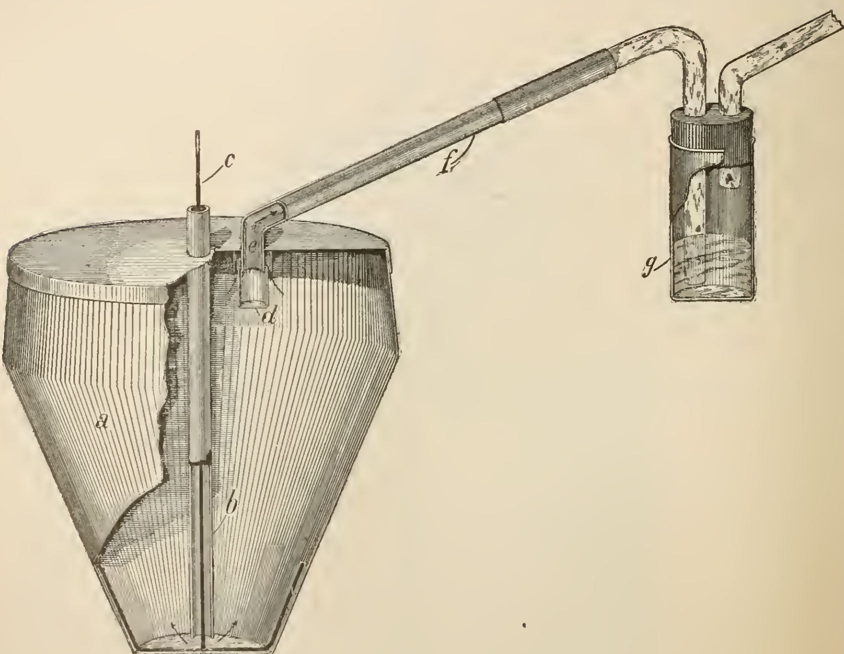

FIG. 2.—Tucker apparatus for ash determination.

With this apparatus, straw, leaves, and potatoes are incinerated in the course of two hours, the charring occupying about 1½ hours, and the completion of the incineration in a current of air requiring not more than a half hour.

H. Wislicenus[1] has recently described an apparatus which embodies the principle of the Tucker apparatus, but consists only of a platinum cover which may be adapted to dishes and crucibles ordinarily found in laboratories, thus doing away with the special crucible.

Another form of incinerating apparatus is the Berthelot bomb, in which the substance is burned, by means of an electrically heated wire, in oxygen under 25 atmospheres pressure. This apparatus has the advantage of excluding every possible loss, and is absolutely closed

[1] Ztschr. Analyt. Chem., 40 (1901), No. 7, p. 441.

during the operation; but the manipulation of it is somewhat difficult, special care being necessary in collecting the products of combustion, and, as Berthelot[1] states, it burns only small amounts at a time. Furthermore, the apparatus is quite expensive, and necessitates a supply of compressed oxygen. The same applies to the modified apparatus constructed by Mahler and by von Hempel and Atwater.[2]

Grouven[3] destroyed organic matter by combustion in superheated steam in iron tubes. In this method the sulphur occurring in plants in such compounds as protein, etc., is not oxidized to sulphuric acid, as in the usual process of burning, but is obtained as sulphuretted hydrogen.

It sometimes happens that the incineration occupies a long time, even in the Shuttleworth and Tucker forms of apparatus exceeding the 2 hours which is usually sufficient; for example, when large quantities of fusible salts and especially alkaline phosphates are present. In such cases the carbon particles are occluded from the action of oxygen of the air; but in burning in an open platinum dish this occurs to a much greater extent, so that the incineration may sometimes require 10 or 12 hours and even longer. In such cases the danger from loss of alkaline salts is naturally great, increasing as the temperature is raised.

In order to prevent the enveloping of particles of carbon, due to the fusing of salts, these salts may be removed prior to the combustion. In the method of Fresenius,[4] mentioned above, the charred substance is extracted with water or acetic acid,[5] the insoluble portion collected on a filter, dried, and incinerated, and the soluble portion then added, evaporated, and gently incinerated. (See also Reichardt.[6]) This operation requires both time and pains.

The fusing of the salts may also result in the formation of silicates which are difficult to decompose with hydroclorie acid, as in the case of straw which contains much silicic acid, and is an important point to be observed, as Shuttleworth[7] has pointed out. In such case the portion of the ash insoluble in hydrochloric acid must be treated with hydrofluoric acid, and the bases contained in that portion estimated separately.

ADMIXTURES TO FACILITATE INCINERATION.

To overcome the difficulties of incineration, attempts have been made for many years to discover some substance to be added to the mass

which would prevent the fusing of the salts and unite with the volatile substances, like chlorin, sulphuric acid, and phosphoric acid, so as to avoid their loss.

As an oxygen-furnishing material and to facilitate the incineration Verdeil[1] employed ammonium nitrate, and Keller nitric acid, for animal substances. Platinum sponge was first employed by H. Rose.[2] This material, however, is somewhat expensive. Platinum chlorid, employed by Rose and Fleitman,[3] is similar in its action, but naturally the volatilization of an indeterminable amount of chlorin from the platinum chlorid renders it impossible to accurately determine the chlorin in the ash. Admixtures of iron oxid, as recommended by Gräger,[4] and of ferric nitrate, employed by A. Müller,[5] likewise accelerate the combustion and may be useful in some cases. In employing mercuric oxid, as practiced by Will, the analyst must guard against the mercury vapor given off. The addition of sand likewise facilitates the burning, and Alberti and Hempel[6] recommend in incinerating sugar products, molasses, etc., adding a weighed amount of quartz sand, which is afterwards subtracted from the total weight of the ash. However, by the use of sand chlorin, sulphuric acid, and phosphoric acid are at least partially driven off.

Kassner[7] mixed calcium plumbate (Ca_2PbO_4) with the substance, thereby facilitating the burning, but interfering with the later analysis of the ash. The same objection applies to bismuth nitrate, which Bechamp[8] recommended. Among other admixtures suggested may be mentioned pumice stone, copper oxid, clay, and magnesia, employed by Donath.[9] According to Donath, these are inferior (at least with sugar products) to incineration at first in dilute and later in pure oxygen. Recently H. Wislicenus[10] has suggested moistening the greyish ash with pure hydrogen peroxid, which facilitates the complete combustion of the carbon.

Most frequently, however, admixtures of an alkaline character are employed, and these, while facilitating the combustion, are also of real value in preventing the volatilization of chlorin and sulphuric acid, which otherwise are in danger of being lost. Strecker[11] has employed the addition of baryta, Way and Ogstone[12] barium nitrate,

Slater[1] barium superoxid, Wackenroder[2] lime, calcium carbonate, and calcium acetate, all with good results. Von Schröder and Reuss[3] in the analysis of forest products impregnated the substance with a solution of sodium carbonate previous to charring, to prevent the loss of chlorin and sulphuric acid. Councler[4] added to each gram of substance to be burned 1 cc. of a 10 per cent soda solution, dried, charred, and incinerated over an alcohol lamp. Behaghel von Adlerscron and Bunge[5] earlier showed that in incinerating animal substances correct figures for the chlorin content were obtained only with the addition of sodium carbonate.

Shuttleworth[6] found the addition of a measured quantity of calcium acetate of known calcium content very advantageous, the lime resulting from the higher heating retaining the chlorin and preventing the fusing together of the salts, so that the mass remained porous and difficultly decomposed silicates were not formed. This admixture is especially to be recommended in case of substances like straw, which are rich in silicic acid, with leaves, and with seeds rich in phosphoric acid. With potatoes it is not necessary, as von Daszewski[7] has found, because they are easily and completely incinerated without such addition.

A further advantage of the addition of alkaline substances in the incineration is the avoidance of the formation of pyro-phosphate in the ash and incomplete precipitation of the phosphoric acid, which may result in case of insufficient treatment of the ash solution with nitric acid.[8]

Addition of sulphuric acid in incineration.—In the analysis of molasses and other sugar products, the incineration is now generally carried on with the aid of sulphuric acid, as proposed by Scheibler.[9] This addition simplifies the operation very materially, but the bases are naturally all recovered in the ash as sulphates. As this increases the weight over the bases themselves or their carbonates, a correction must be made in the weight of the sulphate ash, which according to Scheibler should be about one-tenth of the ash. Although this factor is now commonly used for the correction, it is only a conventional factor and by no means accurate under all circumstances. Hence, others, as Biard,[10] Sidersky, von Lippmann, and Wiechmann,[11] have

preferred to deduct one-fifth of the ash; and, because of this uncertainty, Alberti and Hempel advocate their method of combustion with a known amount of quartz sand, as mentioned above. Hehner[1] has also proposed the addition of sulphuric acid in the combustion of glycerine, using the factor 0.8.

It is apparent that ash prepared with the addition of sulphuric acid can not be employed for the later estimation of that acid, or for chlorin, and probably not for phosphoric acid.

CRUDE ASH—PURE ASH.

The substance secured by the described methods, whether or not with the addition of some material to assist the incineration, is not the true or pure ash, but is regarded as crude ash. This crude ash is of variable composition, but may contain any residue of carbon which escaped combustion, particles of "sand" from the soil which adhered to the substance, and more or less carbon dioxid, combined with the alkali bases when other acids, especially phosphoric, are not present in sufficient quantity. Carbonic acid is driven off from calcium carbonate by intense heating, and also from alkali carbonates when fused with silicic acid. To obtain an ash free from carbonic acid Stutzer and Isbert[2] moistened the ash with nitric acid and then glowed again. This is not always applicable, as the chlorin is also partly or wholly volatilized. As the carbonic acid in the ash is a variable and uncertain quantity, it is best to estimate the amount present and deduct it from the crude ash.

The pure ash may be stated to be the crude ash, less the carbon dioxid, unconsumed carbon, and sand.

DETERMINATION OF CARBON DIOXID.

The carbon dioxid is usually determined by collecting the liberated gas in a weighed potash bulb. The very complete and satisfactory apparatus described by Fresenius is familiar to all. As this is somewhat complicated the writer employs in his laboratory an apparatus similar in part to one described by Vogel,[3] and which has proved to be very efficient. Shuttleworth avoided transferring the ash from the crucible of his apparatus (p. 211) to a special carbonic acid apparatus by using the crucible itself as a generator, with the stirrer (*e*) and upper part of the lid (*a* and *c*) removed. For this purpose he made the joint between the lid and the crucible tight by one or two wide rubber bands, and placed a rubber stopper carrying the acid funnel and the evolution tube in the larger opening (*b*) of the cover. Tucker also

[1] Ztschr. Analyt. Chem., 28 (1889), p. 363; Jour. Soc. Chem. Ind., 8 (1889), No. 1.
[2] Ztschr. Physiol. Chem., 12 (1888), p. 78; Ztschr. Analyt. Chem., 29 (1890), p. 433.
[3] Die Versuchsstation der deutschen Landwirtschaftsgesellschaft. Berlin, 1896, p. 17.

made the determination directly in the crucible, but employed the wash bottle (*g*) of his apparatus (p. 212) in collecting the carbonic acid.

ESTIMATION OF SILICIC ACID.

After driving off the carbonic acid the contents of the generating flask are transferred to a porcelain dish, evaporated to dryness on a water bath with aqua regia, dried at 105 to 110°, as in analysis of silicates, moistened with concentrated hydrochloric acid, and after a half hour heated with warm water. The silicic acid and any unconsumed carbon are filtered out with a Gooch crucible,[1] and the filtrate made up to a definite volume (250 to 500 cc.). The contents of the crucible are dried at 120° and weighed for silicic acid and carbon. After incineration the usually very small amount of carbon is determined by difference.

When silicates not decomposed by hydrochloric acid are formed, the precipitate must be dried at 120° and collected on a filter previously dried at that temperature, and weighed for silicic acid and carbon, after which it should be incinerated, weighed, and the residue subtracted from the previous weight to determine the carbon. The residue from the above, containing silicates, is evaporated with sulphuric acid and hydrofluoric acid or ammonium fluorid to free the silicic acid, and then weighed as sulphate. The sulphuric acid must be determined in the latter and subtracted, in order to determine the bases of the silicates to be deducted from the weight of crude silicic acid, giving the pure silicic acid.

All this is a complicated operation and requires much time and care. It is important, therefore, to avoid the formation of difficultly decomposable silicates. This is accomplished by employing the lowest possible temperature for incineration, and by mixing sodium carbonate, lime, or baryta with the substance. In the writer's laboratory the formation of silicates is avoided by the use of the Shuttleworth or Tucker apparatus and by the addition of calcium acetate.

SEPARATION OF SAND AND SILICIC ACID.

The silicic acid which is obtained by the above-described methods is that which is present in the substance as amorphous silicic acid. Crystallized silicic acid and silicates may also be present in the substance examined, especially with roots, in the form of sand or earth adhering to them.

For the separation of this "sand" from the true silicic acid of the plant, various means have been suggested. Prominent among these is

[1] In the methods of analysis adopted by the Association of Official Agricultural Chemists, November, 1898, p. 77, there is described a hardened filter of Schleicher and Schüll. The silicic acid, sand, and carbon are washed from this into a platinum dish and before incinerating are boiled with a saturated solution of sodium carbonate, sodium hydroxid added, and the silicic acid and sand separated.

boiling the silicic-acid mixture with a solution of sodium carbonate or of sodium hydroxid, neither of which attack the sand but dissolve the amorphous silicic acid derived from the substance itself. To this end the silicic-acid residue after weighing is boiled with a concentrated solution of sodium carbonate, or, according to Fittbogen,[1] with a 5 to 6 per cent solution of sodium hydroxid, in a platinum dish with continuous stirring (to avoid bumping), filtered, washed, and the residue ("sand") weighed. The latter is subtracted from the crude ash in order to obtain the pure ash.

The results of this troublesome operation, however, are not always satisfactory. The difficulties of separating quartz and sand from amorphous silicic acid have been well illustrated in mineral analysis.[2] It is consequently preferable to free the materials to be incinerated from sand and earth as far as possible, in order that the determination and deduction of sand may be avoided.

ANALYSIS OF PURE ASH.

So much has been written upon the determination of the several ash elements that it will be impossible to review the entire subject here. Only brief mention can be made regarding the shortest means for estimating the principal constituents.

While the whole series of mineral elements which occur in plants may be present in the ash, in most cases only the more important ones are considered, and among these the phosphoric acid in particular gives rise to some analytical difficulties.

It is convenient to use 3 aliquots for the analysis, made up as described above, determining the iron and alumina, lime and magnesia in the first, the sulphuric acid in the second, and the potash and soda in the third; a separate solution for the phosphoric acid and chlorin being made up with nitric acid.

In the first aliquot the iron and alumina are precipitated with ammonia and acetic acid, the precipitate being mainly neutral iron phosphate, as aluminum phosphate occurs but rarely in important amounts. If the above is not satisfactory, the precipitate may be dissolved and the constituents determined separately—the phosphoric acid with molybdic acid, the iron by titration with potassium permanganate, and the aluminum by difference or by the method of Berthelot and André[3] of precipitating alumina as phosphate with sodium hyposulphite. The lime is determined in the filtrate from the iron phosphate precipitate by means of ammonium oxalate, and the magnesia in the

[1] Landw. Vers. Stat., 13 (1871), p. 114.

[2] Michaelis, Ber. Deut. Chem. Gesell., 28 (1895), Ref. p. 1020; 29 (1896), Ref. p. 562; Lunge, Ibid., 28 (1895), Ref. p. 1020; 29 (1896), Ref. p. 188.

[3] Ztschr. Analyt. Chem., 35 (1896), p. 630; Ann. Chim. et Phys., 7. ser., 5 (1895), p. 429.

filtrate from the latter with ammonia and sodium phosphate or ammonium phosphate.

In the second aliquot the sulphuric acid is precipitated with barium chlorid, the precipitate being boiled once with dilute hydrochloric acid. The third aliquot is treated with recrystallized barium hydrate to remove the ferric oxid, magnesia, and sulphuric and phosphoric acids, and then with ammonium carbonate to remove the barium and lime. The filtrate is neutralized with hydrochloric acid, evaporated to dryness, and the ammonia driven off, after which the residue is purified by taking up in water, filtering, and evaporating, and the combined weight of the potassium and sodium chlorids obtained. The potash in this residue is determined with platinic chlorid as usual, and the soda found by difference.

The phosphoric acid is precipitated from the nitric acid solution first with molybdic acid and then with magnesia mixture; and the chlorin is precipitated in another portion with silver nitrate.

To avoid contamination of the solutions it is advisable to employ only dishes of platinum or of Berlin or Meissen porcelain, and Jena glass beakers. The calculations are made by means of the atomic weights of Clarke or of the Berlin atomic weight commission. The results must of course be corrected for the chlorin in combination, deducting its equivalent of oxygen from the total.

DEFECTS OF THE DESCRIBED METHOD.

The above described method may possibly be regarded as open to criticism, as it does not take account of all the elements occurring in ash, and does not make an altogether sharp separation of phosphoric acid, lime, and magnesia. It possesses the advantage, however, of being applicable to analysis on a large scale, which can not be said of the theoretically exact methods, as they require too much time, and except in the hands of very expert analysts are liable to lead to error.

Among the limitations of the method it will be noticed that no notice is taken of manganese, although this element is frequently found in plant ash. Pichard[1] found it in considerable amount, especially in fungi, leaves, and grain. It may be estimated in the filtrate from the iron-phosphate precipitate with bromin, the manganese being precipitated as MnO_2. If no manganese is separated it is mixed with other precipitates.

The lime precipitate derived by the above method may contain some phosphoric acid and also some magnesia; and, on the other hand, the lime is not wholly insoluble in the acid solution. These errors may counterbalance each other, but some lime may be thrown down later with the magnesium phosphate.[2] In very exact analysis, either the

[1] Compt. Rend. Acad. Sci. Paris, 126 (1898), p. 550.

[2] Among others see Hornberger, Ztschr. Analyt. Chem., 18 (1879), p. 361; Richardson, Ztschr. Analyt. Chem., 23 (1884), p. 409; Amer. Chem. Jour., 3 (1881), p. 422.

phosphoric acid must be removed before the precipitation of the lime and magnesia, or the precipitates obtained as above must be purified by reprecipitation, the filtrates being added to the principal solutions of lime, magnesia, etc., respectively, and in this way absolute accuracy approximated. This operation, however, is so troublesome, time consuming, and questionable in the hands of any except very skilled analysts that where a number of ash analyses are to be made it becomes wholly impracticable. In most cases the above method or a similar one will suffice, giving results approximately accurate and at all events comparable with each other.

Among those who have sought to remove the difficulties due to phosphoric acid, König[1] attempted to separate it before the precipitation of the lime and magnesia by combining it either with stannic oxid, or with a ferric salt as iron phosphate. He gave the preference to the latter, which is carried out as follows: Sufficient ferric chlorid solution of known strength is added to the solution to unite with the phosphoric acid as $FePO_4$. The solution is made alkaline with soda or ammonia, then slightly acid with acetic acid, some ammonium acetate added, boiled and filtered. In the solution thus freed from phosphoric acid, lime and magnesia may be estimated without difficulty. Hornberger[2] and Ulbricht[3] have employed a similar method.

The above method is not the one which König[4] describes in his manual of agricultural analysis, but a simpler one similar to it. The methods of analysis of the Association of Official Agricultural Chemists adopted in 1898 (p. 78) prescribe the use of ferric chlorid.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Methods of chemical soil investigation, G. Berju (*Landw. Vers. Stat., 55 (1901), No. 1–2, pp. 19–31; abs. in Chem. Centbl., 1901, I, No. 14, p. 795*).—Treatment with hydrochloric acid is claimed to give no indication of the available plant food in soil. Dyer's method using 1 liter of 1 per cent citric acid for 100 gm. of soil is considered preferable to using ½ liter of 2 per cent acid for the same amount of soil, because absorption by the soil is less from the weaker solution than from the stronger. In experiments on the length of digestion required, it was found that shaking in a rotary apparatus making 48 revolutions per minute for 6 hours one day and 2 hours the following day was sufficient to extract the soluble potash and lime in every case and the phosphoric acid in most cases. In these experiments 750 cc. of 1 per cent citric acid at a temperature of 18 to 20° C. was used to 75 gm. of soil. Somewhat less was dissolved by 8 hours continuous shaking than by the above method. Longer shaking dissolved a little more phosphoric acid, but the slowly soluble phosphoric acid is not considered practically important. Samples of sandy and loam soils were shaken with 0.1 per cent solutions of potassium nitrate and ammonium chlorid, with and without the addition of 1 per cent citric acid solution. The absorptive power of the soils for potash and ammonia was only very slightly affected by the citric acid. The influence of the absorptive power of soils on the results of chemical analysis is to be further studied.

On the methods of chemical investigation of soils, B. Sjollema (*Chem. Ztg., 25 (1901), No. 29, pp. 311, 312*).—Experiments are reported in which samples of soil of different character were subjected to successive extractions with 1 per cent citric acid. The results show that ordinary methods, such as that of Dyer, do not remove all of the phosphoric acid soluble in 1 per cent citric acid, but that on subsequent treatment with this solvent further amounts of this constituent go into solution, the amounts so dissolved being quite large, but varying with the character of the soil.

On the determination of the potash content of soils, A. Rümpler (*Landw. Vers. Stat., 55 (1901), p. 149; abs. in Chem. Ztg., 25 (1901), No. 18, Repert., p. 62*).—A preliminary note on the determination of the potash extracted from soils by treatment with limewater or solutions of potassium chlorid. There seems to be a definite limit to the extraction of the potash by this method, beyond which further treatment with the solvent fails to remove any more of this constituent. The author believes that the potash removed by the proposed treatment is that occurring in zeolitic silicates and is especially available to plants. Vegetation experiments to further study this subject are to be undertaken.

Analysis of soils, J. A. Murray (*Analyst, 26 (1901), No. 301, pp. 92–96; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 463, II, p. 350*).—A criticism of the method proposed by Hall and others (E. S. R., 12, p. 905). The principal suggestions offered are that (1) the constituents should be reported in ounces per cubic foot; (2) a determination should be made of organic carbon; (3) that undried soils yield a larger proportion of available phosphoric acid than dried; and (4) the stones in the soil should be tested for available plant food.

On a serious error in the method of Kubel-Tiemann for the determination of organic matter in drinking waters, DUYK (*Ann. Chim. Analyt., 6* (*1901*), *pp. 121–124; abs. in Chem. Centbl., 1901, I, No. 20, p. 1113*).—The author finds that sodium chlorid in acid solutions interferes to a marked extent with the oxidation of organic substances dissolved in water. It is therefore necessary before applying such methods to remove the chlorin. For this purpose the author uses silver oxid (Ag_2O).

Determination of nitric nitrogen in water by means of stannous chlorid, H. HENRIET (*Compt. Rend. Acad. Sci. Paris, 132* (*1901*), *No. 16, pp. 966–968*).—At the boiling temperature stannous chlorid in presence of hydrochloric acid converts nitric nitrogen into hydroxylamine hydrochlorid as follows: $3\ SnCl_2+KNO_3+8\ HCl=3\ SnCl_4+NH_2\ OH\ HCl+KCl+2\ H_2O$. This reaction may be used in determining nitrates by adding an excess of stannous chlorid of known strength and titrating the excess with iodin. The stannous chlorid used is prepared by dissolving 14 gm. pure tin in 1 liter of pure hydrochloric acid. The solution is kept in a flask from which air is excluded. The iodin solution is prepared by dissolving 8 or 9 gm. of iodin and 20 gm. of potassium iodid in 1 liter of distilled water. Its strength is determined by titration with sodium hyposulphite, or with a solution of potassium nitrate of known strength.

Apparatus for the determination of nitrogen in nitrates by the Schulze-Tiemann method (*Böhm. Ztschr. Zuckerind., 25* (*1900*), *pp. 356–358; abs. in Chem. Centbl., 1901, I, No. 22, p. 1216, fig. 1*).

On the determination of chlorin in natural waters, its accuracy and significance, E. G. SMITH (*Trans. Wisconsin Acad. Sci., Arts, and Letters, 13* (*1901*), *pt. 1, pp. 359–365*).—This is a brief discussion based upon the author's experience in examination of waters of the accuracy of three methods commonly used for determining chlorin, namely, the gravimetric method, and the volumetric methods of Mohrs and Volhard. Of these the author has found Mohrs' method most reliable, and the modifications of it which he has found necessary for the greatest accuracy are given in detail.

Detection of bicarbonates in waters, E. POZZI-ESCOT (*Ann. Chim. Analyt., 6* (*1901*), *pp. 135, 136; abs. in Chem. Centbl., 1901, I, No. 20, p. 1113*).—For this purpose the author adds to 250 cc. of the water a few drops of a solution of 0.5 gm. of pyrogallol in 5 to 6 cc. of water, to which 2 drops of officinal iron chlorid solution has been added. If carbonates or bicarbonates are present a violet or amethyst color appears. Ammonia interferes with the reaction.

Determination of sulphids, hydrosulphids, and thiosulphates coexisting in solution especially in sulphurous mineral waters, A. GAUTIER (*Compt. Rend. Acad. Sci. Paris, 132* (*1901*), *No. 9, pp. 518–523*).

Notes on recent work of the German Sugar Commission appointed for fixing normal standards, A. HERZFELD (*Ztschr. Ver. Deut. Zuckerind., 1900, pp. 1126–1128; abs. in Jour. Soc. Chem. Ind., 20* (*1901*), *No. 3, p. 268*).—The Brix tables in use at present are based on determinations made by Balling in 1839. The new tables, worked out by the German Sugar Commission, are somewhat higher than the old tables.

Volumetric estimation of invert sugar, F. STOLLE (*Ztschr. Ver. Deut. Zuckerind., 1901, No. 541, II, pp. 111–117; abs. in Jour. Chem. Soc.* [*London*], *80* (*1901*), *No. 462, II, pp. 286, 287*).—By the proposed method a portion of the solution of the invert sugar is added to a known volume of Fehling's solution, the excess of the latter being estimated by titrating with an ammoniacal solution of potassium cyanid. In titrating the color is destroyed by the formation of potassium cuprous cyanid.

The determination of mannose in sugar-cane products, H. PELLET (*Bul. Assoc. Chim. Sucr. et Distill., 18* (*1901*), *No. 10, pp. 758–769*).—Methods of analysis.

A multiple fat extractor, C. L. Penny (*Delaware Sta. Rpt. 1900, pp. 85–93, figs. 2*).—The author describes a device and method the chief object of which is "so to expedite the determination of fat in milk and its products as to make accurate gravimetric determinations economically possible in competition with the speedy volumetric methods now in use. . . . The apparatus devised to this end differs in its principle of action little, if at all, from the well-known Soxhlet extractor. Its chief peculiarity is such an arrangement of parts as admits any number of samples at the same time and under a single operation to the action of the same extracting liquid. This is attained by the use of a single common chamber for all of the samples, in which they are held in shallow capsules placed parallel and close together." Tin-foil capsules containing an absorbent such as sand or asbestus are used. The solvent is that portion of gasoline distilled off at 100° C. The fat is determined by difference. It was found that extraction was approximately complete in 4 and practically complete in 12 hours. The time required for drying the sample at steam heat when a determination of total solids was to be made was from 12 to 14 hours, and for drying the extracted sample from 2 to 4 hours. The method is considered as accurate as the ether extraction method.

A comparison of the Reichert-Meissl numbers obtained in the analysis of butter, M. Siegfeld (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 10, pp. 433–446*).—A compilation of the results obtained by different chemists under different conditions from 1879 up to the present time.

Halpen's reaction for cotton-seed oil and the behavior of some American lards toward the same, P. Soltsien (*Ztschr. Oeffentl. Chem., 7 (1901), pp. 25–27; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 462, II, p. 292*).—The author advocates the use of amyl alcohol in the Halpen test, and heats the oil to be tested with 20 per cent of a 1 per cent solution of sulphur in carbon disulphid. The light is not excluded during the heating in boiling water. Several samples of genuine American lard which responded to this test are supposed to be derived from pigs fed on cotton-seed meal.

The optical method of examining fats and waxes, G. Marpmann (*Chem. Rev. Fett u. Harzind., 8 (1901), pp. 65–68; abs. in Chem. Centbl., 1901, I, No. 18, pp. 1015–1017*).—A description is given of the methods and results of determining fats and waxes singly and in combination. A table of fats and waxes is included showing the refraction number obtained with the Zeiss-Wollny apparatus.

The detection of archil in wine, R. Truchon (*Ann. Chim. Analyt., 5 (1900), pp. 444, 445; abs. in Analyst, 26 (1901), No. 302, p. 129*).—Fifty cc. of the wine is acidified with 1 cc. of 10 per cent sulphuric acid and boiled 5 minutes with a little wool which is then washed and immersed in ammonia water. With uncolored wines the wool will assume a green tint; in the presence of archil it turns violet, the intensity indicating the quantity of coloring matter.

The valuation of commercial solutions of lactic acid, F. Jean (*Ann. Chim. Analyt., 5 (1900), pp. 285, 286; abs. in Analyst, 26 (1901), No. 302, p. 132*).

Notes on the proximate analysis of cloves, A. McGill (*Analyst, 26 (1901), No. 302, pp. 123–126*).

The chemical action of Bacillus coli communis and similar organisms on carbohydrates and allied compounds, A. Harden (*Jour. Chem. Soc. [London], 79 (1901), No. 462, pp. 610–628*).—The author found in the fermentation of glucose by *Bacillus coli communis*, that the lactic acid produced while sometimes less, never exceeded one-half of the amount of sugar fermented. Alcohol and acetic acid were produced in about equal amounts. The products of *Bacillus typhosus* were similar except that formic acid was produced instead of a mixture of carbon dioxid and hydrogen. Other bacteria were found to decompose glucose with a different result.

Micro-chemical analysis, H. BEHRENS (*Anleitung zur mikrochemischen analyse. Hamburg: Leopold Voss, 1899, 2. ed. enl., pp. XI + 242, figs. 96*).

Proceedings of the seventeenth annual convention of the Association of Official Agricultural Chemists (*U. S. Dept. Agr., Division of Chemistry Bul. 62, pp. 153*).—This is an account, edited by the secretary, H. W. Wiley, of the meeting held in Washington, D. C., November 16 to 19, 1900, and which has been previously reported (E. S. R., 12, pp. 503–509). The papers read before the meeting and the discussions thereon are reported in full.

BOTANY.

Grasses—I, L. H. PAMMEL, J. B. WEEMS, and F. LAMSON-SCRIBNER (*Iowa Sta. Bul. 54, pp. 71–344, figs. 137*).—Original observations and compiled notes are given relating to the general description of grasses; the growth and minute structure of their roots, stems, leaves, and flowers; a discussion of fertilization and hybrids; and the various phenomena attending germination. Chapters are devoted to cereals in which the more important ones are described, and their production, climatology, and uses as medicines are indicated. Various sugar-producing grasses are enumerated and other economic uses described. The poisonous and injurious effects of certain grasses are mentioned, and notes given on the fungus diseases to which grasses in general are subject.

Our native pasture plants, F. LAMSON-SCRIBNER (*U. S. Dept. Agr. Yearbook 1900, pp. 581–598, pls. 4, figs. 11*).—Descriptions are given of many of our more important native pasture grasses, the author having grouped them under the heads of grasses of wooded regions, mountain meadows, and deer parks, treeless regions, and pasture plants of alkali soils.

Some Arizona grasses, E. D. MERRILL (*U. S. Dept. Agr., Division of Agrostology Circ. 32, pp. 10*).—Critical notes and descriptions of new species and varieties of grasses collected by D. Griffiths and R. H. Forbes, of the Arizona Station, are given.

Aristida purpurea and its allies, E. D. MERRILL (*U. S. Dept. Agr., Division of Agrostology Circ. 34, pp. 8*).—Critical notes and technical descriptions are given of *Aristida purpurea* and the allied species which occur in North America.

Oil-yielding plants cultivated in Egypt, G. BONAPARTE (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 1, pp. 14–19*).—The plants cultivated in Egypt for the production of oil are said to be flax, sesame, cotton, safflower, and lettuce. The methods of extraction and character and uses of the oils, as well as the use of the by-products, are described.

The geology and botany of the Upper Peninsula Experiment Station, C. F. WHEELER (*Michigan Sta. Bul. 186, pp. 17–27*).—Notes are given upon the geology of the substation located at Chatham in the northern peninsula of Michigan, and lists and critical notes are given upon the trees, shrubs, and herbaceous plants growing at the station grounds. A list is also given of a number of fungi which were observed causing diseases of cultivated plants at the substation.

Descriptions and illustrations of new species of Micromycetes, F. TASSI (*Bul. Lab. Orto Bot. R. Univ. Siena, 3 (1900), No. 3–4, pp. 117–132, pls. 4*).—Descriptions are given of about 50 species of Micromycetes which have not hitherto been described. Many of them occur on dead or decaying plants, although a few were found to be parasitic on the leaves of living plants. Among the latter class may be mentioned *Phyllosticta yulan*, which is found parasitic on the leaves of *Magnolia yulan; P. edwardsiæ*, on the *Edwardsia microphylla; P. salisburiæ*, parasitic on the leaves of the common *Gingko biloba; Phoma bulbicola*, on bulbs of Freesia; *Ascochyta catalpæ*, on the leaves of *Catalpa speciosa; Bartalinia nervisequa*, on the leaves of *Magnolia grandiflora; Glœosporium coffeicolum*, on the leaves of *Coffea arabica;* and *Pestalozzina celestri*, parasitic on the leaves of *Celastrus buxifolia*.

Edible mushrooms of North Carolina, C. W. Hyams (*North Carolina Sta. Bul. 177, pp. 27–58*).—Notes are given on the food value of mushrooms, directions for their collection, and descriptions of a number of the more important mushrooms occuring in the State.

The sexual reproduction of fungi, P. A. Dangeard (*Botaniste, 7. ser., 1900, No. 3–4, pp. 89–130*).—A critical review is given of some of the recent literature relating to the reproduction of fungi.

On the evaporation of water by plants, F. Yanovchik (*Selsk. Khoz. i Lyesor., 197 (1900), June, pp. 487–508*).—Three series of experiments are described which were carried out at the Kherson Experiment Field in 1898 and 1899. The amount of water evaporated was determined by the aid of a special apparatus which is fully described. In the series of experiments made in 1898 with spring wheat, the humidity of the soil was kept in 3 vessels at 50 per cent, in 1 at 40 per cent, and in 2 at 30 per cent of saturation, which corresponds to 16, 12.8 and 9.6 per cent of water, respectively, in the soil. The evaporation per gram of dry matter from the vessels with 50 per cent humidity was 512, 532, and 555 gm., respectively; from the vessel with 40 per cent humidity, 484 gm.; and from the 2 vessels with 30 per cent humidity, 591 and 578 gm., respectively. In 1899, 2 series of experiments were carried out. In the first series the soil contained 18.7 per cent water and was kept in 6 vessels at this optimum of humidity and in 2 at 14 per cent. In 2 vessels barley was grown, in 2 oats, and in 4 spring wheat. In 2 of the vessels with wheat, the soil was maintained at 14 per cent of humidity. The evaporation per gram of dry matter was as follows: From barley, 471.8 and 470.6 gm.; from oats, 666 and 615.3 gm.; from wheat (with optimum humidity), 542.9 and 518.2 gm.; and from wheat (with 14 per cent humidity), 452.2 and 466.4 gm. of water. In the second half of the summer another series of experiments was carried out with barley, but not so much with a view of establishing the normal amounts of water evaporated (the season being too much advanced), as for a comparison of the amounts of water evaporated by different varieties of barley. The soil was kept at the optimum humidity. There evaporation per gram of dry matter from two-rowed barley, 456.7 and 404.7 gm.; square head barley, 378.9 and 400.4 gm.; Guymalaye barley, 329.6 and 335 gm.; and Trifurcate barley, 314.5 gm. of water.—P. FIREMAN.

On the presence of invertin or sucrose in grapes, V. Martinand (*Compt. Rend. Acad. Sci. Paris, 131 (1900), No. 20, pp. 808–810*).—The author states that he has found invertin present in the juice of the grapes of all varieties that he has been able to obtain. A method of separation is described, as well as some of the properties of the substance. Invertin acts upon sucrose best at a temperature of 54 to 56° C. The quantity of acetic acid, which limits its maximum action, lies between 5 and 13 parts per thousand. It does not pass through a porcelain filter, and is partially arrested by the filter paper ordinarily employed in laboratories. Its properties in general are very similar to those of the diastase secreted by *Aspergillus niger*. The quantity of sucrose found in the grapes is comparatively large, as shown by the amount of sugar which it is able to invert. It is also found present in the leaves of the grape, 2.5 gm. of fresh leaves furnishing a unit of sucrose. Its action in fermenting must is stated, and it is further said that it is never found in wine that has been well oxidized, nor in wines which are attacked by bacterial diseases.

Concerning a diastase which inverts saccharose in white wines, B. Fallot and L. Michon (*Rev. Vit., 1900, Nos. 347, pp. 141–144; 348, pp. 179–181; 349, pp. 197–201*).

On the exosmosis of diastases of plants, J. Laurent (*Compt. Rend. Acad. Sci. Paris, 131 (1900), No. 21, pp. 848–851*).—From cultures with sterile media, the author has shown that starch may be utilized by young maize plantlets, their roots not only absorbing a small quantity of soluble starch which is formed during the sterilization of the liquid at 120° C., but starch paste was liquefied and served as a nutrient to the plant. Similar experiments were conducted with wheat, peas, and buckwheat, together with another series with maize, in which the radicle after attaining a length of from 1 to 5 cm. was immersed in starch paste. It was found upon germination that a part of the amylase formed in the seed was transferred from the plant by exosmosis, the seeds rejecting it to their advantage. At the same time the starch material was acted upon by the ferment and converted into a form capable of being utilized by the young plants. This phenomenon occurs only during the process of germination, older plants being unable to utilize starch through the exosmosis of amylase.

Experiments on the question of the formation of albuminoids by plants in darkness, M. IWANOFF (*Landw. Vers. Stat., 55 (1901), No. 1–2, pp. 78–94*).—A brief review is given of some of the literature relating to the formation of proteids by plants in darkness, and results of the author's experiments with kohl-rabi, carrots, and potatoes. These roots and tubers were divided, and analyses made of a portion, the other part being planted in pots and kept in darkness. After an interval of 2 or 3 months, analyses were made of the portions planted and it was found that the albuminoids had increased in an appreciable amount.

On the influence of various inoculating materials on tubercle formation and yield of leguminous plants, F. NOBBE and L. HILTNER (*Landw. Vers. Stat., 55 (1901), No. 1–2, pp. 141–148, fig. 1*).—A report is given of experiments in which various dilutions and concentrations of inoculation material were tested to ascertain the effect of such material upon the development of tubercles upon the roots of leguminous plants, as well as upon the total product. The experiments covered a number of years. The results obtained showed that there was a comparatively slight difference in the dry matter and nitrogen content of plants which had received the different strengths of inoculating material, the weakest and strongest solutions giving almost identical results. In the experiments the authors employed a normal strength of Nitragin, and it was used in strengths varying from 0.01 normal to 100 times the normal bacterial content.

Physiological and anatomical investigations of the cuscutas, M. MIRANDE (*Extr. Bul. Sci. France et Belg., 25 (1900), pp. 284, pls. 16*).

A guide to botanical investigations and vegetable physiological experiments, F. SCHLEICHERT (*Anleitung zu botanischen Beobachtungen und pflanzenphysiologischen Experimenten. Langensalza: Hermann Beyer & Sons, 1901, pp. VIII + 182, figs. 64*).

List of publications of the Division of Botany, F. V. COVILLE (*U. S. Dept. Agr., Division of Botany Circ. 30, pp. 10*).—A classified list of the publications of the Division of Botany from its establishment in 1869 to date is given.

ZOOLOGY.

Birds useful to agriculture, E. H. FORBUSH (*Massachusetts State Bd. Agr. Rpt. 1900, pp. 36–61, pls. 4*).—The author discusses the various ways in which birds are beneficial to the farmer. The subjects considered include the use of guano and special notes on the feeding habits of hawks, owls, cuckoos, woodpeckers, goatsuckers, flycatchers, crows, blackbirds, sparrows, swallows, wrens, creepers, and warblers.

Birds as protectors of woodlands, E. H. FORBUSH (*Massachusetts State Bd. Agr. Rpt. 1900, pp. 300–321, figs. 3*).—A discussion is given of the feeding habits of birds with special reference to their beneficial action in destroying caterpillars and other insects which are injurious to trees. Lists are given of the birds which feed on the gypsy moth, brown tail moth, forest tent caterpillar, apple-tree tent caterpillar, cankerworms, white-marked tussock moth, May beetles, and plant lice. Observations are given on the birds which are especially useful in the destruction of the eggs of injurious insects on trees during winter. Brief notes are given on the injuries to trees which may be done by certain birds in eating off the buds or in boring into the bark of sound trees.

How birds affect the orchard, F. E. L. Beal (*U. S. Dept. Agr. Yearbook 1900, pp. 291–304, figs. 5*).—A brief discussion of the economic relationship of woodpeckers, titmice, nuthatches, cuckoos, warblers, birds of prey, shrikes, catbirds, etc., with especial reference to their harmful and beneficial actions in cultivated orchards.

The food of nestling birds, S. D. Judd (*U. S. Dept. Agr. Yearbook 1900, pp. 411–436, pls. 5, figs. 9*).—The author investigated the food materials of nestling birds as compared with those of adults of the same species. A large number of species were studied, and it is concluded that the young of all birds excepting doves and pigeons are fed at first almost exclusively on an animal diet and that later the diet is gradually changed so as to include vegetable materials. The parent birds frequently carry insect food to the young while their own diet is chiefly vegetable.

The relationship of crows to agriculture, J. Jablonowski (*Kisérlet. Közlem., 4 (1901), No. 2, pp. 143–182, figs. 3*).—An elaborate discussion is given of the feeding habits and economic relation of *Corvus frugilegus* and *C. cornix*.

Protection of birds and game. Directory of state officials and organizations for 1901, T. S. Palmer (*U. S. Dept. Agr., Division of Biological Survey Circ. 33, pp. 10*).—The present circular contains a corrected directory of officials, and organizations concerned with the protection of birds and game in the United States and Canada.

Directions for the destruction of prairie dogs, C. H. Merriam (*U. S. Dept. Agr., Division of Biological Survey Circ. 32, pp. 2*).—The use of poisoned grain as a bait and of carbon bisulphid in burrows is recommended.

Rabbit destruction (*Jour. Agr. and Ind. South Australia, 4 (1901), No. 8, pp. 639, 640*).—Formulas are given for preparing poisoned water containing arsenic, strychnin, or cyanid of potash, and for making poisoned baits, such as phosphorized pollard, phosphorized wheat, and baits poisoned with arsenic and strychnin. For destroying the rabbits in burrows, the use of bisulphid of carbon is recommended and also the use of pieces of absorbent cloth saturated with kerosene and sprinkled with sulphur. These rags are to be lighted and pushed well into the burrow.

METEOROLOGY.

Amplification of weather forecasts, A. J. Henry (*U. S. Dept. Agr. Yearbook 1900, pp. 107–114, pls. 3, fig. 1*).—This paper explains the Government system of weather forecasting with a view to encouraging "the making of local predictions by persons whose working hours are spent for the most part in the open air." The generalizations given apply to all parts of the country east of the Rocky Mountains, but it is believed that they will be found most useful in the middle and upper Mississippi and Ohio valleys, the Lake region, and the Middle States.

Hot waves: Conditions which produce them, and their effect on agriculture, A. T. Burrows (*U. S. Dept. Agr. Yearbook 1900, pp. 325–336, pls. 3*).—This article discusses the extent and character of injury caused by hot waves, periods of occurrence, sections affected, and meteorological conditions producing hot waves. "With the present fragmentary knowledge of the basic cause of meteorological changes, we are confined to the statement that during a hot wave the eastward circulation of the atmosphere, both upper and lower, is for the time being almost totally suspended, and that radiation is at the same time at a minimum. A careful study of the weather charts covering such periods leads to the belief that it is quite practicable to forecast high temperatures for a period of from 4 to 5 days, but predictions for a longer time are, for the present at least, the merest guesswork and not entitled to credence."

Meteorological observations, W. T. ELLIS, R. ROBERTSON, S. A. BEDFORD, A. MACKAY, and T. A. SHARPE (*Canada Expt. Farms Rpts. 1900, pp. 43, 44, 280, 281, 389, 434, 475*).—This includes monthly summaries of observations during 1900 on temperature and precipitation, total snowfall and rainfall during 11 years, 1890–1900, and a monthly record of sunshine during 1898, 1899, and 1900, at the Central Experimental Farm at Ottawa; notes on the weather and a monthly summary of maximum and minimum temperatures during the year ended November 30, 1900, at Nappan, Nova Scotia; a monthly record of maximum and minimum temperatures, rainfall, snowfall, and sunshine during the year ended November 30, 1900, at Brandon, Manitoba; similar observations for the same period at experimental farm, Indian Head, Northwest Territories; and a record of highest and lowest temperatures, rainfall, snowfall, and sunshine during the year ended November 30, 1900, and during 4 preceding years, 1896–1899, at Agassiz, British Columbia.

Report of the meteorologist, W. H. BISHOP (*Delaware Sta. Rpt. 1900, pp. 239–249*).—Monthly summaries of observations at 6 different places in Delaware on temperature, pressure, precipitation, relative humidity, and prevailing winds during the year ended June 30, 1900, and a summary of observations on temperature and precipitation during the calendar year 1899 are given.

The summary for 1899 is as follows:

Annual summary of meteorological observations in Delaware, 1899.

Locality.	Temperature.			Total rainfall.	Number of days on which 0.01 in. or more of rain fell.
	Highest.	Lowest.	Mean.		
	Deg. F.	*Deg. F.*	*Deg. F.*	*Inches.*	
Newark	95 (June and July)	−11.5 (Feb.)	51.1	38.33	89
Middletown	99 (June)	−11 (Feb.)	52.7	40.15	75
Dover	95 (June)	−14 (Feb.)	53.3	40.80	77
Milford	97 (June)	−12 (Feb.)	55.7	34.62	79
Seaford	99 (June)	−11 (Feb.)	54.5	43.77	81
Millsboro	100 (June)	−10 (Feb.)	54	43.86	88

Meteorological observations (*Maine Sta. Bul. 69, pp. 196, 197*).—This is a monthly summary of observations at Orono during 1900 on atmospheric pressure, temperature, precipitation, cloudiness, and wind movement. The mean temperature for the year was 43.46° F. (mean for 32 years 42.54°), mean pressure 29.79 in., precipitation 53.80 in. (mean for 32 years 45.33), and number of cloudy days 153.

Annual report of the central station for meteorology and terrestrial magnetism, Vienna (*Jahrb. K. K. Central-Anst. Met. u. Erdmagnet., Vienna, 1900, pp. 192*).—This is mainly a collection of tables giving (1) daily observations on atmospheric pressure, temperature, moisture, direction, and force of the wind, and precipitation at 20 stations in Austria during 1899; (2) hourly and daily observations on pressure, temperature, wind, rain, sunshine, and soil temperatures at Vienna and at a few of the other stations of the first class during 1899; and (3) observations on temperature fluctuations in Lower Austria in the winter of 1898–99.

Agricultural meteorology (*Météorologie agricole. Paris: Paul Dupont, 1900, pp. 51, figs. 4*).—This pamphlet, prepared for use at the Exposition at Paris in 1900, gives a brief history of the Russian weather service and an account of the organization of special service for agricultural meteorology in 1897; and a descriptive list of the apparatus, reports, charts, etc., illustrating methods and results, exhibited at the exposition. There is also included an account of work on forest meteorology, and of the charts exhibited at the exposition showing results of such observations.

Meteorological observations in 1899, R. GUERIN (*Observaciones meteorológicas correspondientes al año de 1899; observaciones meteorológicas practicadas en varios lugares de la República. Guatemala: Tipografía Nacional, 1900, pp. 57*).—Daily and monthly summaries are given of observations on temperature, pressure, humidity, rainfall, etc., at the central laboratory at Guatemala and by cooperating observers in different parts of the republic.

Formation of hail and surfusion, Rosenstiehl (*Grêle, 2 (1901), No. 6, pp. 3–8*).—A discussion of the theories of the formation of hail.

Cannonading against hail in Belgium, J. Vandervaeren (*Rev. Gén. Agron. [Louvain], 10 (1901), Nos. 4, pp. 145–163, figs. 8; 5, pp. 201–216, pl. 1*).—The extent and results of this method of protection against hail in Belgium are reported, the conclusion being that it has been decidedly profitable in protecting glass houses and crops.

Protection against hail, J. Roberto (*Grêle, 2 (1901), Nos. 6, pp. 9–15; 7, pp. 11–16, figs. 2; 8, pp. 6–10*).

An easily constructed barometer, G. W. Russell (*Amer. Chem. Jour., 25 (1901), No. 6, pp. 508–510, fig. 1*).

WATER—SOILS.

Development and distribution of nitrates and other soluble salts in cultivated soils, F. H. King and A. R. Whitson (*Wisconsin Sta. Bul. 85, pp. 48, figs. 11*).—This is in large part a reprint, with more detailed data, of an account of investigations already noted from another publication of the station (E. S. R., 13, p. 24), but contains also accounts not previously reported of investigations on the limit of nitric nitrogen in field soil at which the leaves of corn and oats turn yellow, difference between the amounts of nitric nitrogen under growing crops and in cultivated fallow ground at the same time, distribution of nitrates and other soluble salts in soil under growing corn as it comes into full tassel, the strength of soil solutions under field crops, results of Warington's nitric nitrogen studies at Rothamsted, method of determining soluble salts and nitric nitrogen in field soils, sensitiveness of the methods used in the study of nitric nitrogen and soluble salts, and possible error in results due to the methods.

The investigations reported in this bulletin were made on 9 plats of soil aggregating 10 acres, and covered the first, second, third, and fourth feet of soil separately in each case. The objects were to study the variations in the amount of nitric nitrogen and soluble salts in the soil under different conditions of cropping and culture, to determine the amounts of nitric nitrogen in the soil required for the healthy growth of crops, to trace the relations, if any, between the amount of nitric nitrogen and total soluble salts in the soil water and that of the deeper ground water wells, and to devise an accurate, rapid, and sensitive method for the determination of nitric nitrogen in soils. The conclusions drawn from the work are as follows:

"(1) The nitrates and total soluble salts in the surface foot start in the spring comparatively small in amount, then increase somewhat rapidly until June 1 on clover and oat ground, and until July 1 on corn and potato ground; from these dates they fall more or less rapidly until August 1, when crops are growing most vigorously. After this date they remain nearly constant with a general tendency to rise slightly until September. In the third and fourth feet the seasonal changes are comparatively small and show but little progression, and they are not marked in the second foot.

"(2) The amounts of nitrates and of soluble salts in the soil under the clover and oat crops were much smaller than in the soil under corn and potato crops through the entire season, the greatest differences occurring during the month of June.

"(3) There has been no strong concordance between the yields of dry matter per acre and the amounts of nitrates found in the soils during the season, but where the yields have been relatively quite small, there too has been found a marked deficiency of both nitrates and total soluble salts. In the case of the 3 corn crops the largest yields of dry matter are associated with the largest total soluble salts.

"(4) The relation between the amount of nitrates in a soil and the total soluble salts varies between wide limits, when the salts are measured by the electrical method. It occasionally happens that there may be as much or even more nitrates than the total salts indicated. This may be due to the destruction of bicarbonates by the nitric acid when it is forming.

"(5) The amount of nitrates and soluble salts under growing crops and in fallow ground at the same time is very different. Our observations show a relation for nitrates of 10.88 lbs. in the surface foot per acre as a mean, to 473.65 lbs. for immediately adjacent fallow ground at the same time.

"(6) It was found that stirring the soil once per week, as compared with the stirring of it once in two weeks, left the soil after 91 days with 98.16 as compared with 53.01 lbs. of nitric nitrogen per million of dry soil. In the second series of experiments, which covered 258 days, the soil stirred once per week had acquired a mean of 225.41 parts, and that once in two weeks 158.79 parts per million of dry soil, showing the largest gains with the more frequent cultivation.

"(7) It was found that stirring the soil to depths of 1 in., 2 in., 3 in., and 4 in. during an interval of 258 days resulted in an increasing amount of nitric nitrogen until the 3 in. depth was passed, but that cultivation 4 in. deep gave a smaller nitrification than the 3 in. depth did.

"(8) In the plant house cylinders nitrification appears to have taken place to a depth of 3 ft., but was most rapid in the surface foot.

"(9) There was 22 per cent more nitric nitrogen developed in soil upon which clover had grown than from that after corn, and 13 per cent more than from that after oats, during the same time, under like conditions.

"(10) Virgin soil which had grown corn continuously the same number of years that like soil had grown clover contained, at the beginning of the cultivation experiment, nearly three times as much nitric nitrogen as that upon which the clover had grown, and it closed the cultivation period with 17 per cent more.

"(11) Virgin soil growing oats began the cultivation experiment, after the same number of years of cropping as the soil bearing clover, with 2.6 times as much nitric nitrogen, and closed the 91 days with 13.8 per cent more.

"(12) Clover and alfalfa appear to hold the nitric nitrogen in the soil down to a lower limit than corn, oats, and potatoes do, but when the crop is removed from the ground nitrification appears to go on faster in the clover and alfalfa soil.

"(13) The amount of nitric nitrogen left in the surface foot of soil before crops begin to turn yellow for lack of available nitrogen becomes very small, the amount found being 0.213 parts per million where oats were yet green, and 0.025 parts per million where they were turning yellow. In corn it was found as low as 0.95 parts where corn was green, and 0.10 parts per million where it was strongly yellow.

"(14) The amounts of nitric nitrogen and of soluble salts were found greatest between the rows of corn, as they were coming into tassel, and least, directly beneath hills, except in the surface 6 in., and in the fourth foot where the relations were slightly reversed.

"(15) The amounts of nitric nitrogen and of total soluble salts are less in the deeper ground water of wells of this vicinity than in the soil moisture of the fourth foot, the nitric nitrogen being only about one-third of the amount.

"(16) Observations indicate that when the textural equilibrium of soils is destroyed in the presence of salts in solution the reflocculation and regranulation of the soil may take out of solution a portion of the salts, leaving a smaller percentage present after establishing the new equilibrium."

The soil solution for the determination of nitric nitrogen was prepared by kneading for 2 or 3 minutes in a mortar 50 gm. of the soil in a close muslin sack with 250 cc. of a 0.1 per cent solution of formaldehyde containing 5.36 cc. of a saturated solution of potash alum. The solution was then wrung from the sack and allowed to settle. Fifty cubic centimeters of the clear solution was evaporated to dryness on a water bath, 12 to 20 drops of disulphonic acid were added, and after standing at least 10 minutes with thorough stirring 20 cc. of distilled water and enough ammonia to make the solution alkaline were added. The nitric nitrogen was determined by the colorimetric method, using standard solutions of potassium nitrate. Total soluble salts were determined by electrical resistance, according to Whitney's method. A table is given showing the amount of soluble salts for different readings of the instrument calculated from a solution curve determined for these investigations. Duplicate determinations of nitric nitrogen by the method described showed quite satisfactory agreement, but it was found necessary to protect the solutions from denitrification by the use of formalin and to make the determinations as promptly as possible. It was found "that solutions to which formalin had been added lost none of their nitrates in 4 days, while duplicate solutions to which no formalin had been added lost from 12.2 to 71.6 per cent of their nitrates in that time. . . . This protection of the formalin against denitrification is not permanent and in some cases samples rich in nitrates have lost the whole on standing 5 weeks. In other cases we have observed notable losses on standing 2 to 3 days, this being greater than 50 per cent as a mean of 5 cases."

As stated above, the electrical method for total soluble salts seemed to be subject to an error due to the absorptive power of soils for soluble salts. In 2 series of experiments in which soil was made into a paste (1) with distilled water containing 100 parts per million of potassium nitrate, and (2) with drain water containing 195 parts of soluble salts per million, the results were as follows:

Amounts of soluble salts actually present and found by electrical method.

	Amount in soil.	Amount added.	Total.	Amount found.	Amount absorbed.
Series 1	44.172	17.2	61.172	46.10	15.072
Series 2	44.172	38.82	82.992	69.72	13.272

"These results indicate that the making of the soil paste with dilute soil solutions resulted in fixing some of those salts in an insoluble form. Another set of observations in clearing turbid solutions gave similar results both with nitrates and with other salts, which makes it appear that breaking down the soil texture will throw out of solution soluble salts already contained in them."

Nitrification in northwest soils, F. T. Shutt (*Canada Expt. Farms Rpts. 1900, pp. 159–161*).—The progress of nitrification was studied in the soils used in the observations on soil moisture referred to on page 233. "The method adopted was to weigh out 100 gm. of the fresh soil and add thereto 1,000 cc. of ammonia-free distilled water and shake the mixture well for 1 hour. It was then allowed to settle for 1 hour and the free ammonia in an aliquot part at once determined. A further quantity was at the same time set aside in contact with a zinc-copper couple (by means of which nitrates are reduced to ammonia) and at the expiration of 24 hours distilled. From the free ammonia in the distillate the amount previously found deducted and the remainder calculated to nitrogen, and recorded as nitrogen in nitrates in one million parts of the water-free soil." The results are set forth in the subjoined table:

Nitrates and nitrites in soils at different dates.

[Parts per million of water-free soil.]

Date.	Brandon soil.		Date.	Indian Head soil.	
	In fallow, 1900. In crop, 1899.	In crop, 1900. In fallow, 1899.		In fallow, 1900. In crop, 1899.	In crop, 1900. In fallow, 1899.

"It is to be confessed that the present investigation gives support to the view that the nitrates are largely lost to the surface soil during the late autumn months, but whether this occurs in normal seasons to the extent here indicated is very doubtful."

The origin of nitrates in caverns earth, W. H. Hess (*Jour. Geol., 8 (1900), pp. 129–134; abs. in Tech. Quart., 14 (1901), No. 1, Rev. Chem., p. 45*).—Analyses and other data are cited to show that "the nitrates are not derived from the excrement of bats, as popularly supposed, but have their origin in the oxidation or nitrification of organic matter in the surface soil through the agency of bacteria, and the subsequent leaching of the nitrates so formed downward into caverns, where they slowly accumulate with other salts as the water escapes by evaporation."

Nitrates in cave earths, H. W. Nichols (*Jour. Geol., 9 (1901), No. 3, pp. 236–243*).—An argument to disprove Hess's hypothesis above referred to.

Soil solutions: Their nature and functions, and the classification of alkali lands, F. K. Cameron (*U. S. Dept. Agr., Division of Soils Bul. 17, pp. 39*).—This bulletin[1] discusses the nature and function of soil solutions, including the mutual effect of electrolytes, hydrolysis, rôle of iron, calcium, carbon dioxid, and organic matter in the soil, some possible functions of hydrous silicates, acidity of soils, supposed poisonous action of heavy metals, soil analyses, and absorption by soils; the classification of alkali lands, including the formation of alkali, methods of analysis, limitations of the classification, and descriptions of Pecos, Fresno, Salt Lake, Billings, and modified types of alkali; and occasional occurrence of alkali in humid regions—in Maryland, Florida, and various other localities.

As regards the nature and functions of soil solutions, the following general conclusions are drawn:

"(1) The mineral, and to a large extent the organic, components of the soil are electrolytes, and soil solutions are mainly solutions of electrolytes.

"(2) The hypotheses of electrolytic dissociation and hydrolysis in aqueous solution give rational explanations for many phenomena hitherto regarded as inexplicable or exceedingly obscure.

"(3) The rational procedure in the chemical investigation of the soil, from the point of view of its relation to crop culture, is to study the soil solution and in what manner it is modified by contact with the solid and gaseous components of the soil."

The classification of alkali as "black" or "white," depending upon the presence or absence of sodium carbonate, is condemned as "inadequate in view of our present knowledge of alkali phenomena." A classification based "on chemical grounds, considering alkali conditions or the result of the action of aqueous solutions of certain soluble salts" is tentatively proposed. Four classes of alkali are considered, the predominating features in the formation of which are, (1) the action of the sodium chlorid on gypsum, resulting in the formation of sodium sulphate and calcium chlorid, typified in alkali soils of the Pecos Valley, New Mexico; (2) the action of sodium chlorid on calcium carbonate resulting in the formation of sodium carbonate and calcium chlorid as occurring typically about Fresno, Cal.; (3) the simultaneous action of sodium chlorid upon gypsum and calcium carbonate resulting in the formation of only small quantities of soluble carbonates, a very common form typified in the alkali of the Salt Lake Valley, Utah; and (4) the interaction almost exclusively of soluble sulphates, not a common class, occurring typically about Billings, Mont. Modifications of the types described are more or less frequently found.

A number of cases of the occurrence of soluble salts in the soils of a humid region are cited as evidence "that the essential differences between conditions obtaining in the soils of humid and arid regions are rather those of degree than of kind; that the fundamental forces at work are in reality the same, and that the study of the phenomena presented in one area can and should be of the greatest value in interpreting those of another area."

---

[1] See U. S. Dept. Agr. Rpt. No. 64 (E. S. R., 12, p. 522).

Objects and methods of investigating certain physical properties of soils, L. J. Briggs (*U. S. Dept. Agr. Yearbook 1900, pp. 397–410, pls. 2, figs. 2*).—This article explains the importance of certain of the physical properties of soil—texture, structure, relation to water and salts in solution, temperature, flocculation, etc.—and describes briefly methods for mechanical analysis of soils and for the determination of structure, water content, temperature, and soluble salts; the methods given being in the main those which have been worked out in the Division of Soils of the Department.

Conservation of soil moisture, F. T. Shutt (*Canada Expt. Farms Rpts. 1900, pp. 154–159*).—Observations on soil moisture at Brandon, Manitoba, and Indian Head, Northwest Territories, are reported. The plan of the investigation was as follows:

"Early in the spring on each of the farms two areas having as far as possible soil of a similar character were selected, the one intended to be fallowed during the present season, and which had been cropped in 1899; the second area to be cropped, but which had been fallowed in 1899. Samples from each of these areas were taken, month by month, from May to November, inclusive, to 2 depths—the first representing the upper 8 in.; the second the depth from 8 to 16 in. These samples, taken in special canisters, were immediately on collection forwarded to the laboratory. On their arrival each canister of soil was at once weighed and its contents thoroughly mixed, sampled, and the moisture determined in duplicate. From the average weight of the canister of water-free soil (obtained from the 7 monthly determinations) and the percentage of moisture, the amounts of water in tons and pounds per acre were calculated. The canisters ($2\frac{1}{2}$ in. by 8 in.) used were very stout and open at both ends. In taking the samples they were thrust into the ground until level with the surface and then removed with the aid of a sharp spade, and covered with deep and close-fitting caps. To prevent any possible evaporation en route, 'electric' tape was used to cover the edge of the cap or lid where it fitted over the canister."

The season of 1899 was characterized by a plentiful but normal precipitation; that of 1900 was exceedingly dry during the earlier months of the summer and unusually wet during the middle and later months of the summer. Under these conditions it was found that the soils which had been in fallow the previous year contained during May, June, and July more moisture than those which had been cropped the preceding year, but "there was a constant tendency for the soil moisture in both fallowed and cropped soil during the latter months of the experiment to approximate."

Canadian soils, F. T. Shutt (*Canada Expt. Farms Rpts. 1900, pp. 148–154*).—Chemical analyses of a surface soil and 2 samples of hardpan (at depths of 2 and 5 ft.) from British Columbia, 4 samples of soil from Northwest Territories, and 1 from Nova Scotia are reported, with a discussion of their fertilizer requirements and suggestions as to their treatment.

Soils of the Upper Peninsula, A. C. Lane (*Michigan Sta. Bul. 186, pp. 43–45*).—A brief discussion of the characteristics of the soils of the Upper Peninsula of Michigan.

Soils of Mississippi—plant food and productiveness, W. L. Hutchinson (*Mississippi Sta. Bul. 66, pp. 23, figs. 5*).—Tables based on analyses previously reported (E. S. R., 12, p. 1022) are given which show the phosphoric acid, potash, nitrogen, and lime per acre to a depth of 4 in. in 76 samples of prairie soils, 8 of Yazoo-Mississippi delta soils, and 46 of sandy and sandy-loam soils.

"The results show that the prairie soils, and also most of the soils in the northeastern prairie region, contain relatively large amounts of the ingredients reported in the tables, which are the important ones. The amount of phosphoric acid in the sandy, sandy-loam, basin, and brown silt-loam soils is relatively small, and it is on these lands that commercial fertilizers are constantly used under all crops. These lands should also have the benefit of stable manure and cowpeas, with superphosphates under crops following the cowpeas.

"Soils containing 1,000 lbs., or over, of phosphoric acid per acre, in the upper 4 in. of soil, have enough of this ingredient for large crops. . . . As the amount of this ingredient, in the surface soil, falls materially below 1,000 lbs. per acre, the demand for phosphates is apparent in proportion to the deficiency, provided all other essential conditions for large yields are present.

"The supply of potash seems to be ample everywhere in the State and we have no evidence that any of our soils require the use of fertilizers containing potash to increase the yields. The results do not indicate the minimum amount of potash in the soil that is adequate for good crops.

"Nitrogenous fertilizers increase the yields of most of the soils in the State, and where nitrogen is added by growing cowpeas, velvet beans, vetch, and melilotus, which also add organic matter to a soil and improve its texture, results of the most satisfactory kind are obtained.

"Some of our soil work also indicates that, where the amount of phosphoric acid in a soil is abnormally high, the cotton plant will use several times as much of this ingredient as it needs for normal development. This is probably true of other substances as well. . . .

"Lime, in large amounts, undoubtedly influences the texture of a soil; it may also have to do with the solubility of the plant food in a soil, but, with good texture, soils will produce well even though the amount of lime present is small. The brown loam soils do not contain much lime, and yet, in proportion to the amount of plant food present, they are probably the most productive lands we have. The texture of these soils is good."

The construction and use of graded and level embankments and terraces to prevent washing of soils is explained. The reclaiming of washed lands, the value and use of stable manure and restorative crops, and the use of commercial fertilizers are also discussed.

Bacteriological studies of drinking water, F. D. Chester (*Delaware Sta. Rpt. 1900, pp. 66–76, figs. 2*).—On account of a serious outbreak of typhoid fever in the city of Wilmington attention was directed to a spring from which many people obtained drinking water, and water from this source was analyzed and tested for the presence of pathogenic bacteria. Two organisms were isolated, one a variety of coli bacillus, and another belonging to the hemorrhagic septicæmia or swine-plague group. Details are given concerning the cultural and morphological characters of these 2 organisms. Since the organism of the hog-cholera group is closely related to the typhus bacillus, its presence in the water is considered as indicating a fæcal contamination.

Water from farm homesteads, F. T. Shutt (*Canada Expt. Farms Rpts. 1900, pp. 191–194*).—Tabulated analyses are given of 41 samples of well waters examined during the year.

FERTILIZERS.

Basic superphosphate, its preparation and use as a manure, J. Hughes (*Jour. Soc. Chem. Ind., 20 (1901), No. 4, pp. 325–332*).—The history of the manufacture and use of superphosphates is briefly reviewed; tests of the solubility of various phosphates in weak citric acid (1 part to 1,000 parts of water) are reported; and the preparation of basic superphosphate by mixing slaked lime (15 parts) with ordinary superphosphate (85 parts) is described. The results of tests of the solubility of the product in water, weak citric acid, and ammonium citrate (2.5 per cent solution) are given. None of the phosphoric acid was soluble in water, but from 12 to 13 per cent was soluble in the weak citric acid (1:1,000) and about 10 per cent in ammonium citrate, being more soluble in these reagents than basic slag. The basic superphosphate is claimed to be especially suited to acid soils or those deficient in lime.

Twelve years' experiment with Thomas slag, A. ANDOUARD (*L'Engrais, 16 (1901), No. 19, pp. 447, 448*).—A brief summary of the results obtained by Wagner, Maercker, the author, and others.

Statistics of the manufacture and use of Thomas slag (*Deut. Landw. Presse, 28 (1901), No. 31, pp. 270, 271*).

A fertilizer experiment with crude phosphate, F. W. DAFERT (*Ztschr. Landw. Versuchw. Oesterr., 4 (1901), No. 5, pp. 627–629*).—Previous experiments by the author (E. S. R., 12, p. 839) showed that Algerian phosphate was quite effective as a source of phosphoric acid for summer barley and oats. The experiments here reported show that it is also very effective as a fertilizer for clover.

Report of the agricultural chemical laboratory of the Ministry of Agriculture and Imperial Domains in St. Petersburg for 1898, P. S. KOSSOVICH (*St. Petersburg: Department of Agriculture, 1900, pp. 242; rev. in Selsk. Khoz. i Lyesov., 199 (1900), Oct., pp. 237, 238*).—This report contains two articles which may be mentioned here: (1) Availability for plants of the phosphoric acid of the Russian phosphorites, and (2) ability of plants to utilize the phosphoric acid of phosphorites. According to experiments reported, plants may be divided with regard to their ability to avail themselves of the phosphoric acid of the phosphorites into 4 groups: (1) Plants with high capacity—mustard, buckwheat, hemp, winter rye; (2) plants with medium capacity—peas, barley, summer rye, beets; (3) plants with a low capacity—potatoes, oats, vetches; and, lastly, (4) plants almost devoid of this capacity—millet, flax, and clover.—P. FIREMAN.

Nitrate of soda and sulphate of ammonia, H. BACHMANN (*Fühling's Landw. Ztg., 50 (1901), No. 11, pp. 386, 387*).—The results of comparative tests of nitrate of soda (8 cwt. per hectare) and sulphate of ammonia (6 cwt. per hectare) on potatoes, fodder beets, and kohl-rabi are briefly reported. In these experiments the sulphate of ammonia was apparently more effective than nitrate of soda.

The regulation of the trade in nitrate of soda, M. ULLMANN (*Die Regelung des Verkehrs mit Chilisalpeter. Melle: F. E. Haag, 1901, pp. 25, pls. 4*).—This pamphlet includes an account of the action of a commission of the Society for the Protection of the Chemical Industry in Germany regarding the regulation of trade in nitrate of soda, a discussion of the basis of guarantees of purity, and a brief review of experiments regarding the poisonous property of nitrate containing perchlorate.

Experiments at the Bavarian moor culture station on the action of potash fertilizers on upland moors, A. BAUMANN (*Vrtljschr. Bayer. Landw. Rath., 6 1901), No. 1, pp. 20–35*).—Comparative tests of kainit and concentrated and basic potash salts are reported.

The consumption of potash salts in 1900, MAIZIÈRES (*L'Engrais, 16 (1901), No. 23, pp. 542–544*).—Statistics for various countries.

Fertilizing with lime refuse from gas works (*Deut. Landw. Presse, 28 (1901), No. 34, p. 297*).—The handling and the fertilizing value of this material is briefly discussed. Three weeks' exposure to the air is claimed to be sufficient to decompose poisonous sulphur compounds.

An analysis of the Leeds gas liquor, A. W. COOKE (*Jour. Soc. Chem. Ind., 20 (1901), No. 3, pp. 225, 226*).—A complete analysis.

Fish fertilizers, MAIZIÈRES (*L'Engrais, 16 (1901), No. 17, pp. 398, 399*).—Mainly statistics of the industry in the United States.

Manuring the soil, J. FIELDS (*Oklahoma Sta. Bul. 50, p. 11*).—A popular discussion of this subject.

A report on the demonstration experiments with fertilizers carried out by the Agricultural Society of Vienna in lower Austria during the year 1900 (*Ztschr. Landw. Versuchw. Oesterr., 4 (1901), No. 5, pp. 596–626, pl. 1*).—A detailed account is given of 72 cooperative experiments with oats, 49 with barley, 38 with wheat, 2 with meadow grasses, 2 with potatoes, 1 with flax, and 1 with clover.

The organization and results of cooperative fertilizer experiments in Bavaria, H. Dubbers (*Vrtljschr. Bayer. Landw. Rath., 6 (1901), No. 1, pp. 35–43*).—The results of cooperative experiments with fertilizers on grains, potatoes, beets, alfalfa, and meadows are briefly reported.

Organization of fertilizer experiments (*Deut. Landw. Presse, 28 (1901), No. 37, pp. 326, 327*).—The plan of cooperative experiments which have been undertaken in Bavaria for the purpose of making a systematic study of fertilizer requirements is described, and some of the results with barley, oats, potatoes, roots, hay, and alfalfa are reported.

Commercial fertilizers and humus, K. de Vrieze (*Deut. Landw. Presse, 28 (1901), No. 34, pp. 296, 297*).—An argument to prove that the continued use of commercial fertilizers does not necessarily result in a decline in the humus content of soils.

Fertilizers, F. T. Shutt (*Canada Expt. Farms Rpts. 1900, pp. 161–166*).—Analyses of 6 samples of marl, 3 samples of gypsum, 2 of wood ashes, and 1 of wool waste are reported, with discussion of their value as fertilizers.

Fertilizer inspection, C. D. Woods (*Maine Sta. Bul. 72, pp. 42–48*).—This bulletin contains analyses of 136 brands of fertilizers (manufacturers' samples) licensed before March 9, 1901, with a summary of the chief provisions of the State fertilizer law.

Fertilizer inspection in North Carolina, B. W. Kilgore (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 4, pp. 3–30, 36*).—The names and guaranteed composition of fertilizers registered for 1901, and analyses and valuations of 201 samples of fertilizers examined during the spring of 1901, with the usual explanations regarding freight rates, valuation, etc., and a note on the increased trade in fertilizers in the State during the year.

Official report on commercial fertilizers inspected, analyzed, and licensed to be sold in the State of Ohio during 1900 (*Ohio State Board of Agriculture, 1901, pp. 85*).

Commercial fertilizers, J. H. Stewart and B. H. Hite (*West Virginia Sta. Bul. 72, pp. 32*).—This bulletin gives the results of analyses and valuations of 287 samples of fertilizing materials examined during the year 1900.

Analyses of licensed commercial fertilizers, 1901, R. H. Shaw and A. Vivian (*Wisconsin Sta. Bul. 86, pp. 10*).—This bulletin contains the text of the Wisconsin fertilizer law, notes on the sources of fertilizing ingredients in fertilizers and on valuation of fertilizers, and analyses of 5 samples of fertilizers sold in the State during the year.

Draft bill to regulate the sale of agricultural fertilizers and feeding stuffs (*Jour. Jamaica Agr. Soc., 5 (1901), No. 3, pp. 120–122*).—The text of an act passed in 1901, providing for the inspection of fertilizers and feeding stuffs sold in Jamaica.

Recent contributions to knowledge relating to the fertilizer industry, von Grueber (*Chem. Ztg., 25 (1901), No. 35, pp. 373–377*).—A general summary.

FIELD CROPS.

Field experiments, J. Atkinson (*Iowa Sta. Bul. 55, pp. 362–384, figs. 7*).—These experiments comprised variety and culture tests with corn, oats, barley, spring wheat, spelt, sorghum, rape, kohl-rabi, soy beans, and sugar beets. Nineteen varieties of corn selected out of 50 varieties grown in 1898 and 1899 were given a further test in 1900. The best yielding varieties were of selected stock. The varieties giving the best returns, mentioned in the order of their productiveness, were: Reid Yellow Dent, Legal Tender, Snow Flake White, Seckler Perfection, and Champion White Pearl, yielding from 90.9 to 100.3 bu. per acre. Wisconsin Earliest Dent, with a yield of 52.5 bu. per acre, was the least productive. The other varieties, given in the order of their yields, were: Golden Beauty, Mammoth Cuban, Western Yellow Dent, Nebraska White Prize, Lenocher Homestead, Star Leaming, Iowa Silver Mine, Western White Dent, Iowa Gold Mine, Pride of the North, and Goddard King of Earlies, all yielding over 67 bu. per acre. The average results for two years show yields of 71.9 bu. per acre with deep cultivation, and 82.4 bu. when shallow cultivation was given. Several of the most important varieties tested are described, and a number of typical and imperfect ears are figured, and the selection of corn is discussed. A score card for judging ears is presented.

Of 35 varieties of oats tested for 2 years in succession 12 gave an average yield of over 50 bu. per acre. New Salt Lake gave the best yield, 58.8 bu. per acre, followed by Silver Mine with 58.7 bu., Nebraska Gold Mine with 58.2, and Green Mountain with 57.5 bu. per acre. The earliest variety, Early Champion, ripening July 6, gave an average yield per acre of 55.2 bu. White Russian, the latest variety, ripened July 25, and gave the lowest average yield per acre, 39.3 bu. Early Champion and Early Dawson are recommended as being little apt to rust and well suited as nurse crops for clover and grasses.

Of 19 varieties of barley grown for three years in succession, Mansbury, Common 6-rowed, Success, Champion Beardless, and Black Hulless, with average yields of 74.4, 70.4, 56.9, 53.8, and 44.4 bu. per acre, respectively, were best suited to Iowa conditions.

The yields for the season of 1900 of a number of cross-bred wheats grown since 1898 are reported. Of 24 varieties, the best yielding were Minnesota No. 71, Early Java, Minnesota No. 185, White Russian, Preston, Minnesota No. 188, and Minnesota No. 66, giving a yield of 33, 30.5, 27.5, 27.5, 26.8, 26.7, and 25.7 bu. per acre, respectively. All varieties yielded over 19 bu. per acre. Early Java, a promising variety obtained from southern Nebraska, ripened July 20. Growing wheat and oats in a mixture of different proportions gave better yields than growing either alone. A mixture of 4 pecks of oats and 4 of wheat yielded 1,860 lbs. per acre, a better yield than any other proportion of oats and wheat for seed. Spelt yielded 2,200 lbs. of thrashed grain per acre in 1899 and 1,960 lbs. in 1900. Sorghum sown May 21 and cut August 27 yielded 29 tons of green fodder or 12 tons of sorghum hay per acre. The use of 40, 80, or 120 lbs. of seed per acre gave practically the same results as to yield, but the thicker-sown crop grew better and contained more water and less saccharine matter than the crop from thinner sowings. Sorghum, sown after barley had been harvested in July, was about 7 feet high and in full head by September 20. It was cut September 29 and gave 21 tons of green sorghum per acre, which cured into 7 tons of hay.

Rape sown May 24 and harvested on September 10 yielded 21 tons per acre in 1898, and in 1899 60 bu. of oats and 18 tons of rape were grown on an acre when 6 pecks of oats and 1 lb. of rape were sown together in the spring. In 1900 rape and oats sown together were successful only on the higher and poorer land. On bottom land the rape completely smothered the oats, even when sown 10 days later. Successful culture tests of kohl-rabi and soy beans are reported. Owing to a wet season the work with sugar beets did not give satisfactory results.

Field experiments with farm crops, W. Saunders, J. H. Grisdale, W. T. Macoun, R. Robertson, S. A. Bedford, A. Mackay, and T. A. Sharpe (*Canada Expt. Farms Rpts. 1900, pp. 7–42, 82–95, 127–132, 137, 138, 177–184, 281–300, 334, 338–362, 391–409, 437–456, pls. 3*).—As in preceding years, variety, culture, and fertilizer tests with cereals, root and forage crops were carried on at the experimental farms in Ottawa, the Maritime Provinces, Manitoba, British Columbia, and the Northwest Territories (E. S. R., 12, p. 535). The results of the variety tests with the different crops in 1900 have been previously reported (E. S. R., 13, p. 34). The plan and scope of the experiments this season were practically the same as described in preceding abstracts, and the results are reported in the usual form. Owing to the prevalence of drought the results were not uniformly satisfactory. The cultural experiments consisted of early and late sowings of turnips, carrots, sugar beets, mangels, potatoes, and flax; distance experiments with corn, soy beans, horse beans, and potatoes; early and late harvesting of root crops; rotation tests; thick and thin seeding of flax; sowing selected seed of barley; growing mixed-grain crops; sowing wheat, oats, and barley; and planting potatoes at different depths, etc. The fertilizer experiments included tests of barnyard manure and different commercial fertilizers and of clover as a green manure for cereal crops. At Ottawa, turnips and carrots sown May 16 and pulled November 6 gave better returns than when sown May 30 and harvested October 16. Mangels showed only a small advantage from early sowing this season. In previous tests the results of planting potatoes at different dates have indicated that planting after June 24 would not give a fair crop, but in 1900 a good crop was obtained from a planting on July 7. At the station in the Maritime Provinces, turnips, mangels, and carrots were planted on May 28 and June 12, and the yields in every case were in favor of the earlier planting. A similar test was made at the other stations, but owing to an unfavorable season the results were quite irregular, although in general they favored planting on the earlier date. Experiments in sowing flax at the rate of 40 and 80 lbs. per acre on different dates at 4 of the stations gave varying results, due to some extent to the season. The differences in yield were small in many cases. At the station in the Maritime Provinces the yield of flaxseed was in favor of the heavier and early seeding, while the yield of straw was irregular. The best yields of flax straw at the Manitoba Station were obtained from the heavy seeding made in either of the first three weeks of May, but the yield of seed in this case was not much affected by either the date of seeding or quantity sown. The results at the Experimental Farm of the Northwest Territories showed the best yield of seed from the light sowing made May 29, and the best yield of straw from the light sowing made May 22. At the British Columbia Station the yields of straw were all in favor of light seeding, while the yields of seed were in favor of the heavy seeding, and the results on the whole favored sowing at an early date. Sugar beets planted June 2 at the Manitoba Station gave better results than beets planted May 19.

In the distance experiments corn was grown in rows 21, 28, 35, and 42 in. apart, respectively. The best yields in the Maritime Provinces, Manitoba, and Northwest Territories were obtained from rows 21 in. apart, while at Ottawa the results seemed to be in favor of 35 and 42 in. when cut in the early milk stage. Much the best single yield, however, 30 tons and 536 lbs. per acre, when cut in the early milk stage, was obtained from selected Leaming corn sown in rows 21 in. apart. In British Columbia corn was grown in hills and drills at these different distances, in the one case the plants being thinned to 6 in. apart in the row, and in the other to 3 or 4 in a hill. In general, the results in both cases favored planting 21 in. apart. Soy beans and horse beans were grown in rows 21, 28, and 35 in. apart at several of the stations. At the Maritime Provinces farm 21 in. was found best for soy beans and 35 in. for horse beans, while at Ottawa the results with horse beans were the same, but with soy beans were best at 28 in. In Manitoba and the Northwest Territories rows 35 in. apart gave the best yields for both crops, while in British Columbia 28 in. for soy beans and 35 in. for horse beans were found the best distances. Potatoes planted 10, 12, 14, 16, and 18 in. apart in rows 2½ ft. distant at Ottawa for 5 successive years have given an average yield in favor of planting 12 in. apart in the row.

A test of various cuttings for potato planting, including seed ends and whole potatoes and cuttings of 1, 2, 3, and 4 eyes, was conducted at the Manitoba farm, the best average results being from the cuttings with 2 eyes, and a good yield from the seed ends. The whole tuber used as a set gave the largest yield, but the product was very irregular.

Of 10 varieties of barley grown from selected seed at Ottawa, all gave an increasing yield except Danish Chevalier, a two-rowed variety, which gave a crop of 2 bu. and 24 lbs. per acre less from selected than from unselected seed. The increase in yield ranged from 40 lbs. to 8 bu. and 40 lbs. per acre. At the same station in a similar test with spring wheat 6 varieties gave a larger yield from selected seed as compared with unselected seed, while 2 varieties gave the same yield from both kinds of seed. The same test with wheat and barley at the Manitoba Station resulted in yields sometimes in favor of selected and sometimes in favor of unselected seeds.

At Ottawa a test of growing oats after different crops resulted in the best yields after horse beans. The smallest crops were obtained after millet, flax, and soy beans. Trials were also made of plowing under green clover for oats, corn, and potatoes, and in every case an advantage was apparent in the yield. Spring wheat grown after different crops in Manitoba gave much larger yields when preceded by leguminous crops than by cereals.

One series of fertilizer experiments at Ottawa was made with fresh and rotted barnyard manure, fresh slaked lime, superphosphate and Thomas slag, all applied singly to spring wheat and oats. The results did not differ much, and it is concluded that the land contained all the available plant food the crops could utilize. In a second series of experiments with different fertilizers on wheat, barley, and oats the best average results for 13 years have been with barnyard manure (about equal parts of horse manure and cow manure), and slightly better results have been secured from the use of fresh manure than from well-rotted manure.

The itemized cost of growing different crops at the Central farm are reported, with an estimate of the cost of digestible dry matter in each crop.

At the Ottawa Station an experiment was conducted in planting potatoes at different depths from 1 to 8 in. Level cultivation was adopted and so but little soil was thrown on the potatoes after planting. The best average yields for three years were obtained from planting 1 in. deep. As in previous years, it was found that most of the tubers were formed within 4 in. of the surface of the soil, even where the seed had been planted deeper, and where the sets were planted less than 4 in. deep nearly all the tubers were formed between that and the surface of the soil. At the farm in the Maritime Provinces barnyard manure was compared with commercial fertilizers on early potatoes, the results with the different fertilizers showing the largest yields from the plants treated with manure.

Some experiments were made at different stations to compare the growth of various grains as mixtures and as pure grains. At Ottawa the best yields of grain were obtained from a mixture of 1 bu. each of barley, oats, and peas, and a mixture composed of ½ bu. of wheat, 1 bu. of oats, ¾ bu. of peas, and ¾ bu. of barley. The yields of grain of these two mixtures grown on 2-acre plats were practically the same, but the yield of oats alone, which was the largest in the series, was about one-third greater. As in the previous year in the Maritime Provinces a seeding mixture of 2 bu. of oats, 1 bu. of barley, and ½ bu. of peas gave a higher yield of grain than oats grown alone, and sowing this mixture at the rate of 3 bu. per acre gave larger yields than smaller amounts. In British Columbia a mixture of 1 bu. each of peas, oats, and barley gave slightly better yields than a similar mixture of peas, oats, and wheat.

There was practically no difference in yield of clover from seed inoculated with Nitragin and from untreated seed at the British Columbia farm.

The highest average yields in experiments of sowing wheat, oats, and barley 1, 2, and 3 in. deep at the Manitoba Station were obtained from the medium depth of sowing. A variety test with 56 varieties of tobacco was conducted at the Central Station as to the time of ripening and productiveness. The results of only 6 varieties, all of which had fully matured September 7, are recorded in a table. No conclusions are drawn.

The results of a comparative chemical study of Red Fife, Preston, Stanley, and

Percy wheats and moisture determinations of a number of Manitoba wheats made at the station are recorded.

On account of the unfavorable season the sugar-beet analyses show unsatisfactory results.

Field crops, vegetables, and fruits, L. M. Geismar (*Michigan Sta. Bul. 186, pp. 8–17, pls. 8*).—This bulletin is the first report of the branch station in the Upper Peninsula. The work here set forth includes mainly experimental cultures made in 1900. Meteorological observations for a part of the season are reported in tables and the results of cultural and variety tests are briefly given. Tests on trial plats were made with oats, barley, spring rye, field peas, potatoes, rape, pumpkins, millet, and corn. Swedish turnips, beets, mangels, carrots, parsnips, salsify, lettuce, radishes, cabbage, onions, sugar beets, celery, and beans were tested in addition to the crops already mentioned. In most cases satisfactory and promising results were obtained, but in some instances abnormal weather conditions which prevailed interfered with the trials. The varieties of strawberries, gooseberries, currants, raspberries, blackberries, grapes, apples, pears, plums, and cherries, which made the best growth, are enumerated.

What varieties of cereals have given the best results in East Germany and what has been done to improve them? Gisevius (*Jahrb. Deut. Landw. Gesell., 15 (1900), pp. 225–246*).—In this paper the varieties of spring and winter oats, spring and winter rye, oats, barley, and potatoes which have given the best results are enumerated.

Range grass and forage plant experiments at Highmore, South Dakota, F. Lamson-Scribner (*U. S. Dept. Agr., Division of Agrostology Circ. 33, pp. 5*).—This circular is a report of progress in experiments begun in 1899 (E. S. R., 11, p. 1032). It is based upon notes made by L. W. Carter, who had immediate charge of the work, and consists of brief records by plats. The grasses which gave promise the first year and again gave good results last year were: Smooth bunch grass (*Poa lævigata*), Nevada blue grass (*P. nevadensis*), King's fescue (*Festuca kingii*), Oregon brome grass (*Bromus unioloides*). Japanese barnyard millet, common or foxtail millet, amber cane, Egyptian corn and milo maize, and Dwarf Victoria rape produced good yields.

The culture of winter barley, A. Schmid (*Deut. Landw. Presse, 28 (1901), No. 7, p. 48*).—An article on the culture of winter barley, with a discussion of its value for feeding purposes.

Seed corn and some standard varieties for Illinois, A. D. Shamel (*Illinois Sta. Bul. 63, pp. 29–56, figs. 13, map 1*).—This bulletin treats of the necessary qualities of seed corn, presents a list of the various characteristics of corn by which varieties may be systematically studied, and describes a number of varieties adapted to Illinois conditions. In the discussion of seed corn the author considers uniformity, vitality, and pedigree. The varieties described are Reid Yellow Dent, Golden Eagle, Iowa Silver Mine, Riley Favorite, White Superior, Leaming, and Boone County White. The description of each variety includes its history and a detailed enumeration of the characteristics of the ear, which are also illustrated in the figures. Abstracts from the constitution and by-laws of the Illinois Seed Corn Breeders' Association are appended.

Experiments with American varieties of corn, E. Ramm and C. Momsen (*Deut. Landw. Presse, 28 (1901), No. 10, p. 72, figs. 3*).—The results with Mitchell Extra Early, Early Giant, and Extra Early grown from American seed are reported. The Mitchell Extra Early was the only variety that ripened its grain.

Researches on the utilization of furze, A. C. Girard (*Ann. Agron., 27 (1901), No. 1, pp. 5–16*).—A discussion of the utilization of furze (*Ulex europea*) for bedding for stock and as a fertilizer and a green manure. Chemical analyses of the plant are reported.

Oats as grain and fodder, J. M. Bartlett (*Maine Sta. Bul. 70, pp. 9–24*).—This bulletin discusses the importance and value of oats as grain and fodder and reports the results of analyses of oats grown in different parts of the State. Samples collected from 11 different regions, representing nearly all the oat growing sections of the State, were analyzed and the results are given in the following table:

Composition of the grain of oats grown in different parts of Maine.

Variety.	Weight per bushel.	Water.	Ash.	Protein.	Crude fiber.	Nitrogen-free extract.	Fat.	Heat of combustion per gram.
	Pounds.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Calories.*
Variety not given	....	8.39	3.03	10.63	13.92	59.27	4.76	4.247

Parker	41½	11.69	2.91	11.56	10.62	57.29	5.93	4.294
Common Western	32½	9.09	3.91	12.57	11.71	56.08	6.64	....
Siberian	37	11.16	2.85	12.12	9.18	59.03	5.66	....
Hogan	41	9.46	2.84	11.50	11.03	60.13	5.04	4.291

The results show that there is not so great a difference in the composition of light and heavy oats as is usually supposed, and the author concludes that the food value is about the same. Previously reported analyses of oat hay cut at different stages of growth, of different parts of the oat plant, of oat and pea and oat and vetch hays, and oats and oat products, and digestion coefficients of these substances obtained in experiments with sheep are tabulated (E. S. R., 11, pp. 964, 965, and 971).

Old and new varieties of oats and the composition of the straw and the grain, A. P. Aitken (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13* (*1901*), *pp. 276–295*).—This paper discusses the strength, quality and quantity of the straw, the weight, color and quality of the grain, and the tillering power of Waverly, Tartar King, Potato, Pioneer, Abundance, Goldfinder and American Beauty oats. The advantage of changing seed is shown by tabulated results of experiments in this line. The straw and grain of the different varieties were analyzed and the results are shown in tables and discussed at some length. The report on the test of varieties upon which this article is based has been previously noted. (E. S. R., 13, p. 131.)

Variety tests with oats, H. Biedenkopf (*Sächs. Landw. Ztschr., 49* (*1901*), *No. 4, pp. 65–70*).

Ramie congress in Paris, A. Schulte (*Beihefte Tropenpflanzer, 5* (*1901*), *No. 2, pp. 53–58*).—An article discussing the ramie decorticating machines tested in connection with the congress held at the Paris Exposition of 1900.

Correlative variation in rye, C. Debruyker (*Handelingen van het derde Vlaamsch Natuur—en Geneeskundig Congress. Antwerp, 1899, pp. 76–88*).—In a previous paper the author has shown that correlation exists between the length of the culm and the head, and the upper internode and the head of the rye plant. The deviation from the average length was greater in the head than in the first internode. This paper is the second contribution on the subject, and the purpose of the experiment here described was to determine whether descendants of plants showing such correlation would also show similar correlation. In one bed (No. 3) seeds were planted from plants of which both the spikes and the upper internodes were as near the average as possible. In beds 1 and 2 the seeds were taken from plants having the shortest heads, those in No. 1 being from plants with the shortest internodes and those in No. 2 from plants with the longest internodes. In beds 4 and 5, seeds from the longest ears were sown, those in No. 4 being from plants with the shortest internodes and those in No. 5 from plants with the longest internodes. Seeds from heads midway between the shortest and the average were planted in bed No. 6, while bed No. 7 was planted with seeds from heads intermediate between the longest and the average. The seeds were planted separately and at convenient distances. The results from these plants and those from the mother plants are compared in a table. In 1897 the results showed great variations in the length of the upper internode, but in the progeny of these plants there was no great difference in the lengths of the first internodes and the heads. The characteristics, therefore, which distinguished the mother plant had entirely disappeared. This result is attributed to unusually favorable conditions of growth which overcame the influence of heredity. The correlation in the length of the upper internodes and of the heads is expressed as 1:1.5 for the experiments in 1897 and as 1:1 for the results obtained in beds 3, 4, and 5 in 1898. No general conclusions are drawn from these results, but the author states that when rye plants are grown under favorable conditions heredity has no apparent influence on the length of the first internodes, the culm, and the head, nor on the correlation between the lengths of the first internode and the head.—H. M. PIETERS.

Sorghum in 1899 and 1900, C. L. PENNY (*Delaware Sta. Rpt. 1900, pp. 77–85*).—The work of selective propagation hitherto reported (E. S. R., 11, p. 141) was continued in 1899, while in 1900 the possible increase in yield of sugar per acre was studied. This work has been previously discussed from a different standpoint (E. S. R., 13, p. 42). Tables are given presenting the results in detail and giving a summary of the crops for 1898 to 1900, inclusive. The experiments were conducted in 3 different localities of the State. The results from one locality show that cane grown in rows 40 in. apart on one plat and 34½ in. apart on another, containing about 20,500 and 62,000 stalks per acre, respectively, had practically the same percentage of sugar in the juice, while the purity of the thinly planted cane was 78.5 and of the thickly planted, 81.4. Thick planting increased the available sugar per ton of cane from 219 to 222 lbs. and almost doubled the yield of cane. The available sugar per acre was increased in this case from 2,416 to 4,866 lbs. Very rich cane exceeding 18 per cent of sugar in the juice did not give a high yield of cane per acre. An apparent falling off in the richness of the cane in the crops of recent years compared with those obtained in 1897 (E. S. R., 10, p. 345) is reported, but the author states that in the locality which produced the above-mentioned high yield of sugar the cane has never been notably richer. The conclusion is that close planting decreases the size of the stalks, but it is believed that so far in this work a limit of crowding which would result in a loss in the yield of sugar has not yet been reached.

Soy beans in Kansas in 1900, H. M. COTTRELL, D. H. OTIS, and J. G. HANEY (*Kansas Sta. Bul. 100, pp. 57–115, pls. 5, map 1*).—This bulletin reports the results of cultural tests with soy beans at the station and throughout the State. Reports were received from 292 farmers representing 75 of the 105 counties of the State, and the individual reports are here presented in condensed form and reviewed. At the station 59.5 acres of Early Yellow soy beans were grown, and 16 varieties of soy beans were tested on a 22-acre field, but owing to drought the yields were not satisfactory. Experiments made at the station during 12 years show that the Early Yellow is the best of the varieties tested for Kansas conditions. Suggestions on soil inoculation for soy beans and cultural directions are given. The majority of the farmers connected with the cooperative test considered soy beans a profitable crop.

Variety tests with sugar beets (*Bl. Zuckerrübenbau, 8 (1901), No. 3, pp. 38–40*).—A report on variety tests of sugar beets in Sicily.

The world's exhibit of leaf tobacco at the Paris Exposition of 1900, M. L. FLOYD (*U. S. Dept. Agr. Yearbook 1900, pp. 157–166, pls. 2*).—This article briefly describes by countries the leaf tobacco exhibits worthy of note at the Paris Exposition of 1900. The collective exhibit made by this Department and the exhibits of American tobaccos made by individuals are discussed, and the types of tobacco leaf in the individual exhibit to which awards were made are pointed out. A description is given of the awards and the methods of making them and the lessons taught by the tobacco exhibits from the different countries are set forth.

Report on experiments on the manuring of turnips in 1899, R. P. Wright (*West of Scotland Agr. Col. Rpt. 1899, pp. 14*).—These experiments were conducted on 13 farms in 6 counties of Scotland, for the purpose of testing the value of various fertilizers used in different combinations for growing turnips. The kinds and quantities of fertilizers applied, their cost, and the increase in yield due to their use, together with the total yields, are given in tables. The author draws no definite conclusions, but makes the following statements:

"In some seasons nitrate of soda applied wholly as a top-dressing to the turnip crop is distinctly less effective than when it is applied either wholly or partially in the drills.

"Potash forms an essential and a profitable constituent of an artificial manure for turnips, and its omission reduces both the crop and the profits."

Successful wheat growing in semiarid districts, M. A. Carleton (*U. S. Dept. Agr. Yearbook 1900, pp. 529–542, pls. 4*).—The successful culture of wheat in that region of the Great Plains lying between the 99th and 102d meridian is discussed in this article and the types of varieties of wheat best adapted for the semiarid regions are described. The author states that varieties may be selected from the red spring wheats and the macaroni wheats of Russian and Siberian origin, which on account of being more resistant to adverse conditions would produce larger average yields than the varieties now grown in the region to which he refers. The conditions under which these wheats are grown in Russia are pointed out and the methods of culture described. Cultural directions for growing wheat in the semiarid region are given and a method for maintaining and improving the quality of wheat is suggested.

A five-year rotation and subsoiling, G. Heuzé (*Jour. Agr. Prat., 1901, I, No. 6, pp. 187, 188*).—A discussion on the management of calcareous soils wet in winter and dry in summer.

Commercial plant introduction, J. G. Smith (*U. S. Dept. Agr. Yearbook 1900, pp. 131–144*).—This article discusses the work of plant introduction by the Department of Agriculture and points out the results that have accrued from successful importations. The plant introduction work as outlined by the author comprises the introduction of new crops, improved strains of crops and of new varieties for plant breeders. The plants and crops introduced during the past four years have been tested as a rule by the experiment stations and the results obtained are here briefly summarized.

Report on plant-breeding establishments, Edler (*Jahrb. Deut. Landw. Gesell., 15 (1900), pp. 403–426*).—A report on 11 private seed-growing and plant-breeding establishments in Germany.

The breeding of agricultural plants, C. Fruwirth (*Die Züchtung landwirtschaftlicher Kulturpflanzen. Berlin: Paul Parey, 1900, pp. 267*).—The book treats of breeding cereals, beets, potatoes, grasses, and other forage plants. The physiological phase of plant breeding and the methods of selection and crossing are discussed. A chapter on the management of plant breeding is also given.

HORTICULTURE.

Fruits, vegetables, flowers, and ornamental shrubs at the experimental farms in Canada, W. T. Macoun, W. S. Blair, S. A. Bedford, A. Mackay, T. A. Sharpe (*Canada Expt. Farms Rpts. 1900, pp. 97–119, 123–127, 132–143, 314–333, 368–389, 409–427, 456–475*).—Reports are here given on the fruits, vegetables, flowers, and ornamental shrubs grown at the Central Station in Ottawa, and at each of the branch stations in the Maritime Provinces, Manitoba, Northwest Territories, and British Columbia. The reports are similar in character to those for 1899 (E. S. R., 12, p. 548). The preponderance of data given relates to comparison of varieties and tests of their adaptability to the various localities in which the stations are located. The better varieties of fruits and vegetables, as shown by the station tests, are given in lists for the benefit of farmers. Cultural directions for strawberries are given in two of the papers.

At the Central Station common red and mammoth clovers, sown broadcast at the rate of 12 lbs. per acre, have made the best cover crops for orchards. On light soils, however, alfalfa, seeded at the rate of 15 lbs. per acre, has done best. Hairy vetch (*Vicia villosa*) has proved especially valuable in dry districts where it is difficult to get a catch of clover. It has not proved hardy at Ottawa.

W. T. Macoun includes in his report a descriptive list of good woody and annual climbers which may be used for decorative purposes.

In the Maritime Provinces no difference was found in the time string beans were ready for market, whether planted in hills 2 by 3 ft. apart or in rows. Further experiments in soaking sweet corn seed in warm water 12 hours before sowing showed no apparent difference in the growth of the resulting plants, whether they were soaked or not soaked, and it would appear that there is no gain whatever in soaking sweet corn for seed.

Good results are reported from the Manitoba Station with cross-bred apples. A good crop of saskatoon (*Amelanchier alnifolia*), a native fruit, was secured during the season.

Treatment of winter muskmelons, A. Griffin (*Florists' Exchange, 13 (1901), No. 14, p. 391, fig. 1*).—The seeds are sown in 3-in. flower pots, the plants repotted when the first rough leaf is partly developed, one plant in each pot, and later planted out in the benches 2 ft. apart in a compost of loam and cow manure made firm. The plants are staked and trellised and when about 5 or 6 ft. high the growing point is taken out. The main laterals, which are then thrown out, are stopped when they have made 4 or 5 leaves. Fruit should not be allowed to develop on these laterals; but should be grown on the sublaterals, which spring from the axile of the leaves of the main laterals. The fruit is not allowed to set until 4 or 5 flowers have developed on a plant. The plants should be stopped about 3 leaves above the fruit. When the plants are about 2 ft. high a "collar" of lime ½ in. thick and 2 or 3 in. from the stem is placed around the plant to prevent canker. While the fruit is ripening only enough water is given to keep the plants from wilting. The temperature of the house is maintained at about 65° F. at night and runs up to 80° in the daytime.

Melons in pots, C. Edwards (*Garden, 59 (1901), No. 1534, p. 266*).—The author grows melons in 10-in. pots rammed two-thirds full of a rather heavy loam. On this the plants are placed and soil added to just cover the ball. The pots are kept in a small greenhouse having a night temperature of 65° F. and a day temperature 10° higher. From 1 to 4 melons are grown on the trellised vines.

The "Fikongo" (Brachystelma bingeri): A new asclepiad of the French Soudan with edible tubers, A. Chevalier (*Rev. Cult. Coloniales, 8 (1901), No. 70, pp. 65–71, fig. 1*).—A botanical description is given of this plant, which is said to form an important part of the diet of the natives. The roots have the appearance of turnips and taste something like them. The histology of the plant is also given.

Testing commercial varieties of vegetables, W. W. Tracy, jr. (*U. S. Dept. Agr. Yearbook 1900, pp. 543–555*).—The author announces the inauguration by the Botanical Division of this Department of a series of thorough tests and accurate descriptions of trade varieties of vegetables grown in this country. The advantages of such tests and descriptions are pointed out, requisites of adequate testing given, and the details of methods followed by the Division in testing varieties briefly noted. Lettuce will be one of the first subjects investigated. As an example of the inaccurate naming of certain varieties of this vegetable, the case of Black Seeded Tennis Ball is stated. Of this variety 34 alleged synonyms were found in seedsmen's catalogues, then of these 34 names there were numerous alleged synonyms, then synonyms of these, until altogether 151 names were collected. Many of these alleged synonyms, however, are known to be entirely distinct varieties. It is to obtain accurate reliable information along these lines with different vegetables that this work is being undertaken.

The development of the trucking interests, F. S. Earle (*U. S. Dept. Agr. Yearbook 1900, pp. 437-452*).—A historical and geographical review of truck farming in this country, with popular accounts of transportation, marketing, packing, and grading of truck produce.

Growth of the North Carolina trucking industry (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 4, pp. 31, 32*).—Some statistics are given of the vegetables, muskmelons, dewberries, strawberries, potatoes, etc., shipped from the trucking district along the Atlantic coast of North Carolina in 1900, with comparative data for earlier years in some instances. The production of strawberries has increased from 5,254,016 qt. in 1897 to 11,044,064 qt. in 1900.

Report of the horticulturist, G. H. Powell (*Delaware Sta. Rpt. 1900, pp. 99-141, figs. 9*).—This report covers the following subjects: The sour cherries of America, pollination and thinning of pears, and a preliminary report on the pollination of apples. The nomenclature in use in cherry literature is discussed, and the probable origin of the words Amarelle, Kentish, Morello, Griotte, and Weichsel, is pointed out.

The sour cherry (*Prunus cerasus*) is arranged in 4 groups: Montmorency group, (English) Morello, Brusseler Braune, and Vladimir. Historical and descriptive notes are given on the more important varieties under each group. For commercial orchards in the East the author prefers Montmorency and Morello. Where earliness is the principal end sought, Richmond is recommended. Other varieties that seem worthy of trial are as follows: "*Montmorency group.*—June Amarelle, King, Lancaster, Sklanka, Wier No. 2; *Morello group.*—Double Natte; *Brusseler Braune group.*—Bessarabian, Brusseler Braune. For the West the Ostheim may be added to the Morello group, also Wragg, where it differs from Morello; and for Canada the Ostheim, Minnesota, and Kloskov Morello."

In the experimental work with Kieffer pears, the problems studied were the degree of fertility or sterility of the variety, the influence of several different pears used as pollenizers, and the behavior of the variety in different places. Pollen from Duchess, Bartlett, Howell, Lawrence, Garber, Le Conte, and Kieffer was used. Out of 873 crosses on Kieffer, 647 or 76.4 per cent started to grow. When Kieffer was pollenized by itself only 25 out of 596 pollenized blossoms started to grow. This is but 4.2 per cent. There was a considerable variation in the susceptibility of the Kieffer to its own pollen in different localities.

The vegetative influence of the pollen from different sources was noted. In the case of self-pollenized Kieffer blossoms the pear starts slowly into growth, very gradually assumes a dark green color, and is retarded in subsequent development. "The cross-fertilized pear, on the other hand, begins a most active development immediately, and at the end of 2 weeks is twice the size of the self-fertilized fruit."

For practical purposes, the author states that Kieffer should be considered self-sterile in Delaware. There is no entirely satisfactory variety for use as a pollenizer for Kieffer. The Garber seems to be one of the most promising. Le Conte is considered undesirable, as it is susceptible to core rot. Dwarf Bartlett, Duchess, Manning, or Howell may be used. The practical orchard deductions from the experiment are to the effect that while Kieffer may bear in solid blocks, better fruit is obtained if it is cross pollenized, and for this purpose every third row in the orchard should be planted to a variety other than Kieffer.

In the experiment in thinning Kieffer pears, the fruit was removed when the pears were about the size of a robin's egg. The trees were 8 years of age, about 20 ft. high, and loaded with fruit. The pears were thinned so that no two were closer than 6 in. It required about 20 minutes to thin each tree and the cost was about 5 cts. per tree. The number of pears per ⅝ bu. basket averaged 80 on the thinned trees, and on 6 check trees it averaged 92. On the thinned trees 83 per cent of the fruit was No. 1 grade, while on the unthinned trees but 61 per cent was of No. 1 grade. A wind storm interfered with the experiment so that no conclusions regarding the profit of thinning could be drawn.

Some observations were made on the number of blossoms that appear on pear trees and the fruits that set. One 6-year-old Kieffer tree produced 3,910 blossoms, 11 per cent of which set fruit, and 7 per cent matured fruit. The tree was overloaded. A 5-year-old Bartlett tree produced 2,151 blossoms, but 3 per cent of which matured fruit and the tree was not well filled. A 5-year-old Howell tree produced 1,258 blossoms, 5 per cent of which matured fruit.

The cross-pollinating experiments with apples were made with Stayman pollenized by itself, and by Paragon, York Imperial, and Missouri Pippin; Paragon pollenized by itself and by Stayman; York Imperial pollenized by itself and by Missouri Pippin, and Missouri Pippin pollenized by itself and by York Imperial. The results obtained show that for practical orchard purposes all these varieties may be considered self-sterile. York Imperial is weakly self-fertile. There was a complete lack of affinity between the pistils and pollen of Stayman and Paragon, no fruit developing whatever when these varieties were intercrossed.

Commercial pear culture, M. B. WAITE (*U. S. Dept. Agr. Yearbook 1900, pp. 369–396, pls. 3*).—A popular discussion of the subject, including detailed directions for locating, planting, cultivating, fertilizing, and pruning commercial pear orchards in different sections of the country; picking, packing, and marketing of fruit; and spraying the trees for protection from insects and diseases.

Some notes on pears for export, G. QUINN (*Jour. Agr. and Ind. South Australia, 4 (1901), No. 9, pp. 703–709, figs. 6*).—The author believes that pears for shipping should be carefully padded from each other by means of wood wool. Brief descriptions are given of the following pears considered of importance in the Australian shipping trade: Josephine de Malines, Winter Nelis, Glou Morceau, Vicar of Winkfield, Beurre Clairgeau, and L'Inconnue.

Native plums, E. S. GOFF (*Wisconsin Sta. Bul. 87, pp. 31, figs. 12*).—This bulletin considers the following topics: Methods of plum culture, the culinary uses of native plums, varieties, blooming period of plums, thickness of the skins, and the longevity of Americana plums. Some data are also presented on the self-fertility or sterility of native plums.

A mulch of marsh hay 6 in. deep was applied to an orchard in grass. The mulch was put on in the winter after the ground had been packed by rain. The sod was completely killed by the mulch except where there was quack grass. The benefits from the mulch were shown in a more healthy foliage and an increase in the size and quantity of the fruit produced. Some advantages claimed for this sort of mulch are that it saves the labor of cultivation; prevents the damage that cultivation causes to the trees; makes a clean cover for the ground, which is so desirable at packing time; and adds fertilizing materials to the soil as it decays. If kept 4 in. deep it prevents the growth of weeds. Its chief advantage, however, is in the superior quality and size of the fruit grown. The strongest objection to its use seems to be its tendency to induce the roots to grow almost on top of the ground, which makes them much more easily affected by cold in severe winters. The mulch also increases the danger from fire.

The author states that in order to secure the finest fruit and to prevent deterioration in the size from year to year, thinning is necessary with most of the Americana varieties. Thinning decreases the total yield. In experiments at the station, thinning to 1 in. apart decreased the yield about 35 per cent and thinning to 2 in. apart about 61 per cent. "Where the market does not discriminate in price between medium sized and large plums, thinning will not pay unless the trees decidedly overbear. In this case it will pay for the benefit of the trees." In thinning, all plums stung by the curculio should be removed. Early thinning is desirable, but late thinning is better than none. The plums should be left not nearer than $1\frac{1}{2}$ to 2 in. apart. The value in thinning Japaneses trees, the author thinks, is largely confined to the good effects on the tree itself.

Seedling trees of native plums at the station when not transplanted sometimes bear freely the third year after planting. If transplanted the third spring, they bear the following season. The plan followed by the station in testing seedlings is to thin out the trees in the nursery row to 4 ft. apart the third spring after planting, which allows of the fruiting of a part of the trees. Those thinned out are set in the orchard 5 ft. apart each way. It is claimed that the fruit borne by the seedling trees the first 2 bearing years will largely pay the cost of growing them.

Descriptions of a number of native varieties, supplementary to those previously given (E. S. R., 10, p. 45), are recorded. The varieties considered most promising for market are Aitkin, Barnsback, Bomberger, Brittlewood, De Soto, Japan Cross, Diana, Etta, Freeman, Hammer, Haag (when sprayed for rot), Hart De Soto, Nellie Blanche, North Star, Ocheeda, Piper, Poole Pride, Quaker, Silas Wilson, Springer, Surprise, and Wyant. "These varieties have been large in size, productive, and, with few exceptions, excellent in quality."

Under the caption of culinary uses for plums, directions are given for canning, drying, preserving, and otherwise putting up plums.

In order to determine whether inclosing the blossoms in paper sacks, as is done in experiments on the self-fertility or sterility of plums, has a harmful effect by shutting out light, the ends of the branches of several varieties which gave evidence of blossoming freely were inserted in large glass beakers, the mouth of the beakers being closed with 2 thicknesses of cheese cloth. The branches in the beakers blossomed normally and produced pollen in abundance, but in not a single instance did fruit set. These results are taken as confirming the conclusions of Waugh that practically all varieties of plums are sterile to their own pollen and must be cross fertilized. The weight of the anthers, dimensions of the pollen grains, and number of stamens of 21 varieties of *Prunus americana*, 3 each of *P. domestica*, *P. triflora*, and *P. hortulana*, and 1 each of *P. myrobalana* and *P. angustifolia*, are shown in tabular form. The author states that he is able to trace no relation between the productiveness of varieties and the size of their anthers and pollen grains. The blooming season of a large number of varieties is given and the author states that a comparison of the records of previous years shows that the order of blooming of different varieties is fairly constant from year to year.

To determine whether native varieties might not be propagated in the same manner as the Marianna plum by cuttings, cuttings were taken from all the main varieties and seedlings of the Americana, Chickasaw, and Hortulana species. These were placed in the propagating bed in the spring and subjected to mild bottom heat for several weeks. "With the single exception of the Marianna, all failed to root."

An objection frequently made to Americana plums is the thickness and toughness of the skins. "As a guide to breeding with the view of reducing the thickness of the skin in the Americana plums, a brief study has been made of the skin of . . . 2 varieties of the Americana species, and 1 each of the Domestica, Triflora, Hortulana, and Chickasaw species." Illustrations are given of a cross-section of the skin of the different varieties magnified about 15 times. The skin of Wildgoose (Hortulana) was found thinnest of all the varieties under observation. As this species is regarded as a hybrid between the Chickasaw and Americana species, "there is every reason to hope that other hybrids between the Chickasaw or Hortulana species and the Americana plums may produce the thinness of skin that is so much desired." Some suggestions are given for breeding the native plums, and as a guide to those interested in the subject, the following list is offered for plum breeding with the belief expressed that the different varieties mentioned possess in a high degree the qualities assigned to them: "Surprise for quality, Brittlewood for size, Freeman for color, Aitkin for earliness, and Wildgoose for thinness of skin."

Notes on the prune, principally from a Californian point of view, S. C. LAMB (*Jour. Roy. Hort. Soc.* [*London*], *23* (*1900*), *No. 3, pp. 350–376, figs. 17, map 1*).—This discusses the introduction and development of the prune industry in California, and gives methods of culture employed, including methods of grading, drying, and packing. The principal varieties of California prunes are described in considerable detail, and notes given on diseases and insect enemies of prunes, and their control.

The date palm and its culture, W. T. SWINGLE (*U. S. Dept. Agr. Yearbook 1900, pp. 453–490, pls. 9, figs. 4*).—A popular account is given of the history, importation, and culture of the date palm in this country. The date palm is shown to be adapted to only a few localities in the southwestern part of the country, which have a hot and dry climate. The Colorado Desert, it is believed, will probably prove the best date growing region in the country, if not in the world. There are also many places in Arizona and California where the culture of date palms can be undertaken with good hope of success, as well as in some few localities in New Mexico, Texas, and Nevada. In 1899–1900 420 young date palms, comprising about 27 of the best known western Sahara varieties, including the famous Deglet noor variety, were imported by this Department and are now being grown experimentally in the Salt River Valley, Arizona. About 3 dozen plants of the Rhars, considered one of the best early dates for drying, were also sent to California and are now being grown experimentally under the auspices of the University of California.

Fig drying, C. H. GORMAN (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 3, pp. 367–369, fig. 1*).—Specific directions for drying figs and packing for shipment.

Grape fruit classified, (*Rural Californian, 24* (*1901*), *No. 4, pp. 132, 133*).—The California committee on pomelo culture finds a total of 10 varieties of grape fruit grown in that State, of which Thursby, Foggs Improved Sweet, Nectar, and Seedless are highly recommended. All 10 varieties are briefly described.

Pineapple culture in southwest Florida, F. G. TISE (*Rural New Yorker, 60* (*1901*), *No. 2676, p. 338*).—The methods practiced are noted in detail.

Propagating the mango, J. B. BEACH (*Florida Agr., 28* (*1901*), *No. 18, p. 273*).—The author has had some success in budding mangoes, but inarching has resulted most satisfactorily.

Frost and fruits, A. C. FULLER (*Pacific Rural Press, 61* (*1901*), *No. 19, p. 292*).—The author presents some data to show the value of burr clover and grasses in the prune orchard as a protection against frost.

Orchard cover crops, J. CRAIG (*Proc. West. New York Hort. Soc. 1901, pp. 12–17*).—The benefits of cover crops and the plants most suited for the purpose are discussed.

Mistakes in orchard management and how they may be avoided, J. ETTLE (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1901*), *No. 3, pp. 256–285, figs. 33*).—This is a popular discussion of the practical details of orchard work and of the mistakes made in selecting varieties and seeds, planting, staking, pruning, and manuring trees. The work is considered from the standpoint of nurserymen, landlord, and tenant.

Common mistakes in fruit culture, G. BUNYARD (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1901*), *No. 3, pp. 317–322*).—Common mistakes in the setting, watering, cultivation, pruning, root pruning, fruit thinning, and purchasing trees are pointed out, with suggestions in each instance as to right methods.

Shade in coffee culture, O. F. COOK (*U. S. Dept. Agr., Division of Botany Bul. 25, pp. 79, pls. 16*).—A review of the literature on the value of shade in coffee culture, together with an extensive list of all the common names used for shade trees and crops grown with coffee in the various regions of the world. The conclusions of the author relative to the importance of shade in coffee culture are as follows:

"A canvass of the subject of shade in coffee culture shows that there is no basis in reason or in observed fact for the belief that shade is a general necessity for the coffee plant, even when grown at low elevations. On the contrary, it is extremely probable that the beneficial effects resulting from shade are quite apart from the shadow cast upon the coffee tree. The beneficial effects connected with shade arise from the protection afforded against drought, erosion, and winds. The planting of shade trees for these purposes is accordingly determined by local conditions of climate and soil, and furnishes no reason for the general planting of shade trees. In regions not affected by injurious climatic extremes the planting of shade trees is justified from the cultural standpoint only by the increased fertility imparted to the soil by means of the nitrogen-fixing root tubercles of leguminous species. This view has not been made the subject of experimental demonstration, but it seems to accord with all the facts thus far ascertained. The benefits of leguminous fertilizing are quite apart from the shading of the coffee, and under suitable cultural conditions are also to be secured from shrubs and herbs belonging to the same natural family. The relative utility and availability of the various shade trees and soiling crops is a subject of vast importance in coffee culture and in other agricultural industries of the Tropics. The combinations of such cultures as coffee and cacao with leguminous trees and plants of maximum cultural and commercial value afford many complex, scientific, and practical problems bearing upon the rise of mixed farming in the Tropics, and are thus worthy of serious experimental attention."

Strawberries, E. W. Wooster (*Trans. Maine State Pomol. Soc. 1897, pp. 88–95*).—Methods of strawberry culture in Maine are discussed and some figures given showing the cost and profits of growing an acre of berries. The total cost for preparing the ground, setting plants, harvesting, and marketing the crop was $430.50. The product was 5,000 qts. of berries which sold for 12 cts. per quart, or $600—net gain, $169.50.

Experiments on the manuring of vines in the department of Aude, M. G. Barbut (*Essais sur la fumure des vignes dans le département de l'Aude en 1899. Paris, 1900, pp. 32*).—The value of nitrate of soda as a fertilizer for vineyards was compared with sulphate of ammonia, oil cake, dried blood, barnyard manure, and a number of complete commercial fertilizers, omitting in some cases one essential element. The tests were carried out in 3 vine-growing districts and in 12 different vineyards. An analysis is given of the soil in each instance, and the variety of grapes grown noted. The results, which are given in tabular form, show the nitrate generally superior to other forms of nitrogenous fertilizers for grapes.

The vine in New South Wales (*Sci. Amer. Sup., 51 (1901), No. 1323, pp. 21212, 21213*).—Historical notes on the development of the industry, with some statistical data on its present status.

Raisin drying (*Gard. and Field, 26 (1901), No. 10, p. 185*).—Outline of the sun drying and lye processes.

Cold storage, L. C. Corbett (*West Virginia Sta. Bul. 74, pp. 51–80, figs. 3*).—Besides a discussion of the profits of cold storage, the results of some experiments with apples and chestnuts in cold storage are given, and chapters added on "Moisture in cold storage," as stated by J. E. Seibel in his Compend of mechanical refrigeration; and "Materials of construction," as stated by A. J. Wallace-Taylor in his publication on Refrigerating and ice making. The author outlines a plan for the building of a cold-storage room, giving methods of construction and materials used.

From a number of calculations which the author makes, it is deduced that cold-storage houses on the farm will pay when they have a capacity of at least a thousand barrels of fruit. The greater the capacity of the storage house the relatively cheaper the cost of construction and of storage per barrel.

Where field stone is abundant, grout walls, which are durable, effective, and cheap, can be built. Sewer pipes laid deep underground for a considerable distance may be used for reducing the temperature of the storage room.

Practical experience in West Virginia has shown that the later the Willow and Rome Beauty can be placed in cold storage without being actually frozen on the trees, the better they will keep. In comparing the loss of weight of headed and open barrels of apples in cold storage for 150 days, the loss in the headed barrel, which weighed in the beginning 139½ lbs., was 4 lbs., while the loss in the barrel weighing the same but not headed was 4½ lbs. The greatest loss in the stored fruit occurred during the first month of storage.

A record is given of experiments in keeping apples in sealed darkened jars, sealed clear glass jars, and on the open shelf in a dark chamber and in a light chamber, in cold storage. The results show an advantage in favor of storing in closed receptacles as against open crates. Of the varieties placed on open shelves, the York Imperial lost least in weight and the Baldwin most. The fruit in the light, with the exception of York Imperial, lost more in weight than fruit in darkness. From the beginning of the test, January 4, up to March 5, all the fruit kept in perfect condition. After this date Baldwins were affected by the dry rot and the York Imperials with "scald." On March 26 Greenings were also affected by "scald." In regard to this the author is of the opinion that "when the true cause for 'scald' is discovered it will be a direct result of the physiological condition of the apple when it went into storage."

The fruit was analyzed when it was put in cold storage in January, and again the latter part of April. Very little change took place. The acid content decreased slightly, and there was a slight falling off of sugar content with Ben Davis, York Imperial, and Rhode Island Greening, and a slight gain with Baldwin.

In the cold storage of chestnuts, a quantity weighing nearly 177 lbs. was spread in a rack 4 in. deep, 30 in. wide, and 6 ft. long, covered top and bottom with a wire screen. After spreading the nuts in the cage it was suspended from the ceiling of the cold chamber, and temperature maintained at 32° F. "Under these conditions the loss of weight was 11 lbs. 3 oz. The quality of the kernel was maintained in a remarkable manner, and by some the nuts in May were adjudged better than in the fall. The insects, too, were so completely benumbed, if not entirely killed, that they did no damage to the nuts after being placed in store." The opinions of a number of horticulturists and commission men on the quality of the nuts and the probable profits in storing chestnuts are quoted, and are to the effect that while the quality of the stored nuts is satisfactory, there is as yet no market for them after the regular chestnut season closes in December.

A table, quoted from Seibel, is given, showing the temperature for keeping a number of fruits and vegetables in cold storage.

The influence of refrigeration on the fruit industry, W. A. TAYLOR (*U. S. Dept. Agr. Yearbook 1900, pp. 561–580, pls. 5*).—This reviews the historical development of refrigeration and cold storage; shows the influence of refrigeration as exercised in the development of certain fruit and vegetable districts; the effects of refrigeration upon the apple trade, etc. The value of cold storage and refrigeration in transit on the development of the fruit industry is brought out especially.

Cold or cool storage of fruit, W. CRUMP, G. BUNYARD, ET AL. (*Garden, 59 (1901), No. 1534, pp. 266, 267*).—The desirability and proper mode of underground cellar storage for apples in England are pointed out.

Memorandum respecting cold storage and the utility of collecting stations (*Ontario: Govt., 1900, pp. 16*).—The value of cold storage in furthering agriculture and foreign shipments of fruit, vegetables, and other farm produce is pointed out.

Canning and pulping fruit (*Jour. Dept. Agr. West. Australia, 3 (1901), No. 3, pp. 211–214*).—Directions are given for canning apricots, peaches, plums, pears, figs, gooseberries, and tomatoes, and for putting up the same without sugar.

Nomenclature, S. A. Beach (*Proc. West. New York Hort. Soc. 1901, pp. 76–78*).—Synonyms for a number of the more important orchard and small fruits are given.

Carnations, C. H. Herbert (*Garden, 59 (1901), No. 1537, pp. 317, 318*).—The culture, fertilizing, seed sowing, and classification of carnations are popularly considered.

The tulip, J. Douglas (*Gard. Chron., 3. ser., 29 (1901), No. 748, pp. 264–266*).—Notes on the history, changes of fashion, culture, and raising of seedling tulips.

Native California bulbs, C. H. Shinn (*Land of Sunshine, 14 (1901), No. 4, pp. 276–289, figs. 10*).—The work of Carl Purdy in developing the California native bulb industry is outlined.

FORESTRY.

Forest extension in the middle West, W. L. Hall (*U. S. Dept. Agr. Yearbook 1900, pp. 145–156, pls. 4*).—The author maintains that the time has arrived for the extensive development of forest plantations throughout the middle West, and suggests plans for carrying out the work. While in the past there has been considerable tree planting, it has generally been aimlessly done, without system in planting or management, and as a result there are but few thrifty plantations. A number of successful plantations are briefly described and the purposes for which timber may be grown and the best varieties suited for different purposes are indicated. Among the species adapted to planting throughout the middle West, the author enumerates osage orange, black locust, hardy catalpa, red cedar, black walnut, bur, post, and white oaks, green and white ash, tamarack, and Russian mulberry. These trees are not all adapted to the same conditions, and the hardy catalpa is believed to offer a better prospect for successful growing than any other. The author indicates the different portions of the country to which the above species are best adapted. Brief suggestions for future plantations are given and attention called to the plan of preparing working systems in cooperation with the Bureau of Forestry of this Department.

Practical forestry in the southern Appalachians, O. W. Price (*U. S. Dept. Agr. Yearbook 1900, pp. 357–368, pls. 6*).—The general characteristics of the mountain region of western North Carolina and eastern Tennessee are described. This region is noted for the richness of its forest flora, and the distribution of species is indicated. The local systems of lumbering are described, showing that not only is there no provision made for future crop, but that the methods pursued are very wasteful. The occurrence and effect of forest fires in this region are commented upon. It appears that by far the greatest number of fires are the result of burning over the woods under the belief that better pasturage will be obtained. Suggestions are given for the proper management of this forest region, and the means for successful reproduction of the desirable species are shown.

Our forest reservations, J. W. Toumey (*Pop. Sci. Mo., 59 (1901), No. 2, pp. 115–128, figs. 13*).—The author popularly describes the forest conditions found in the National and State forest reserves, shows some of the advantages to be derived from the establishment of reserves, and points out some of the chief enemies of forestry, such as overgrazing, forest fires, etc.

Forestry in the British colonies, W. Brown (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13 (1901), pp. 236–244*).—A brief review is given of forestry as practiced in the British Colonies of Canada, Australia, and Cape of Good Hope. In the Cape of Good Hope region, South Australia, New South Wales, and Western Australia beginnings have been made which are more or less promising; while in Victoria, New Zealand, Tasmania, and Queensland but little has been done in the way of forestry management. In Canada some independent forestry has been begun, but little has been accomplished thus far.

The forest of Fontainebleau, France, E. M. Moir (*Indian Forester, 27 (1901),* *No. 4, pp. 174–181*).—A description is given of the state forests of Fontainebleau, and the principal species of trees are described. Oak with an undergrowth of beech and hornbeam occupies about 46 per cent of the forest, Scotch fir about 20 per cent, and the remainder consists of mixed forest. The author describes the different working plans under which the forest has been managed. The first were prepared in 1861, modified in 1880, and still further amended in 1892, under which plan it is now being worked. The net annual income derived from the state forest is said to be about 28 francs per hectare.

Forest trees and shrubs, S. A. BEDFORD (*Canada Expt. Farms Repts. 1900, pp. 372–376*).—Notes are given on the present condition of the forest tree and shrub plantation, hedges, and arboretum. The past season was a very unfavorable one for forest tree growth, as a long continued spring drought interfered in a marked degree with seedlings, cuttings, and newly planted trees. A list of about 90 species and varieties of trees and shrubs, which have withstood the winter at Manitoba, is given. A report is given on the present condition of the hedges which were begun in 1895, in which the adaptability of the different plants for hedge purposes is briefly described. During the season covered by the report, planting in the arboretum was continued, particular attention being paid to maple, poplar, and other rapid growing trees; and a list of the new varieties added during 1900 is given.

SEEDS—WEEDS.

The quality of clover seed offered in the French market, E. SCHRIBAUX (*Jour. Agr. Prat., 1901, I, No. 11, pp. 342, 343*).—The author calls attention to the poor quality of clover seed now in the French market. The hot summer of 1900 proved very detrimental to the proper development and ripening of seeds, and as a result seed merchants have mixed their old stocks with the new to the detriment of the quality. Of 422 samples of clover seed already examined, the author found only 58.7 per cent which gave a germination amounting to 85 per cent or more, while 15 per cent germinated less than 50 per cent of its seeds. The specimens examined showed a decided increase in the amount of cuscuta, and the author suggests that purchasers of clover seed should exercise care in seeing that the quality is the best to be obtained. Other things being equal, the author shows a decided preference for the smaller sized seeds and recommends their purchase even at an increased price. For sowing in France he recommends that clover seeds should be obtained from the northern or cooler parts of Europe. Seed coming from the south of Europe and from America is said not to be suited to French conditions.

The seed industry in Germany (*Florists' Exchange, 13 (1901), No. 6, p. 123*).—A brief sketch is given of the seed industry, together with statistics of the area devoted to many varieties and their production.

Dodder in alfalfa, J. WHITELEY (*Queensland Agr. Jour., 8 (1901), No. 5, p. 333*).—The author recommends for the destruction of dodder growing in alfalfa fields the cutting of the alfalfa in infested regions and destroying it by fire. The cut-over areas are then to be covered with a mulch of straw or dry grass, 4 to 6 in. in depth. This mulch effectually chokes the dodder but will admit the alfalfa growing through it.

A new treatment for the destruction of cuscuta, CHEFDEBIEN (*Rev. Vit., 15 (1901), No. 385, pp. 498–500*).—The author recommends for the destruction of cuscuta in meadows where irrigation is possible the thorough flooding of the fields, after cutting away the grass in the infested regions; and, a day or two after the soil is dried over the parts of the field affected by the dodder, to sow broadcast nitrate of soda at the rate of 250 to 380 kg. per hectare. The best form in which the nitrate of soda is used is a crystalline form. This fertilizer and the irrigation have the effect of stimulating the growth of the grasses and the nitrate of soda, which is present in the crystalline form, is sufficiently injurious to the dodder to destroy it. In meadows or alfalfa fields not capable of irrigation, it is recommended that the infested spots be cut, artificially watered, and then treated with the nitrate of soda in the same manner as recommended above.

The water hyacinth (*Queensland Agr. Jour., 8 (1901), No. 5, pp. 368, 369*).—Notes are given upon the rapid spread of the water hyacinth in some of the rivers of Australia.

Eradication of charlock by spraying, W. SOMERVILLE (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13 (1901), pp. 10–17*).—A popular account is given of the occurrence of charlock, the nature of injury produced by it upon various crops, and a review given of the experiments which have been conducted for its eradication by spraying with solutions of copper and iron sulphate. The results obtained are briefly summarized and suggestions given for the preparation of the herbicides, the proper time for spraying, form of spraying machines, etc.

Spraying for the destruction of mustard, J. FLETCHER (*Canada Expt. Farms Rpts. 1900, pp. 248, 249*).—Experiments were conducted under the author's direction, in which the efficiency of spraying wild mustard with solutions of copper sulphate was tested. The results were in the main satisfactory, although the experiments were carried out rather late in the season. In general, it seems that, when young, charlock may be destroyed with a 2 per cent solution of copper sulphate at the rate of 40 gal. per acre, but if the plants are in flower as much as 60 gal. of a 4 per cent solution will be required.

Investigations on the effect of various salt solutions upon weeds and cultivated plants, B. STEGLICH (*Ztschr. Pflanzenkrank., 11 (1901), No. 1, pp. 31–33*).—A report is given of a number of experiments on the effect of a 20 per cent solution of iron sulphate, 15 and 30 per cent solutions of sodium nitrate, ammonium sulphate, potassium chlorid, and magnesium chlorid, when sprayed over cultivated plants and weeds. Cereals were not permanently injured by any of the solutions, and beets were only seriously affected by the iron sulphate solution. Potatoes were either seriously injured or killed by all of them, and serious injury followed the use of the stronger solutions upon beans, peas, vetches, young clover, lupines, and flax, and slight injury was observed on old clover plants. The only weeds that were killed by all of the different solutions were wild radish and charlock. Thistles were injured by the stronger solutions. The sow thistle was seriously affected by the stronger solutions of ammonium sulphate and potassium chlorid, and the same solutions were proved injurious to some extent upon species of Rumex. Knotweed (*Polygonum persicaria*) was killed by the 30 per cent solutions of sodium nitrate and calcium chlorid, while other species of knotweeds were not affected by the chemicals.

Weed-killing compounds, F. T. SHUTT (*Canada Expt. Farms Rpts. 1900, p. 187*).—A report is given of an analysis of Harvesta, a chemical compound which is sold for the purpose of destroying weeds in gravel paths. The analysis showed the compound to consist of arsenite of soda and common salt. Formulas are given for the preparation of a number of other weed-killing compounds. As all these chemicals seriously injure soils intended for cultivation, they should be used only where culture is not contemplated.

DISEASES OF PLANTS.

Report of the mycologist, F. D. CHESTER (*Delaware Sta. Rpt. 1900, pp. 36–46, figs. 7*).—In continuation of the report of the previous year (E. S. R., 12, p. 761), the work carried on for the treatment of apple scab is reviewed and a summary given of the results obtained the fifth consecutive year. During the season covered by this report both treated and untreated trees yielded good crops. The Winesap trees showed little difference to be attributed to the spraying. In the case of the Strawberry apples the results were more evident, as the yield of first-class fruit on the sprayed trees was considerably in excess of that upon the unsprayed ones.

Notes are given on the bacterial pear blight caused by *Bacillus amylovorus*, and the organism described. A number of inoculation experiments were conducted from which it was found that only the more tender and succulent parts of trees become infested and that second-year wood is not liable to become diseased even when injured or punctured. No infection results from the mere contact of the organisms with the surface of plants, and mechanical contact of blighted with healthy portions of trees is not liable to result in infection. As a means for preventing the spread of this disease the author recommends pruning of the blighted terminal shoots, and several weeks after blooming is suggested as the best time for performing this operation, since at that time all the infection of the year is liable to show itself.

The canker in apple and pear trees, due to *Sphæropsis malorum*, is described at some length. This disease has been quite injurious in some parts of the State. It is frequently mistaken for fire blight, but can be readily distinguished by the shrinking and cracking of the bark over the infected areas. All diseased wood should be cut out and burned and the main trunk and body of the trees be protected with a wash of whale-oil soap, slaked lime, water, and wood ashes, or ordinary Bordeaux mixture with enough lime added to bring it to the consistency of whitewash.

Pear blight and pear canker, F. D. Chester (*Delaware Sta. Bul. 52, pp. 8, figs. 7*).—This is essentially a reprint from the Annual Report of the Station for 1900. (See above.)

Investigations on a parasite of flax, E. Laurent (*Bul. Agr.* [*Brussels*], *16* (*1900*), *No. 6, pp. 511–554, pl. 1*).—A report is given of a study made to ascertain the cause of a blight of flax. The author claims that it is due to the fungus *Asterocystis radicis*. This fungus plays an essential rôle in the development of the disease, although it is frequently followed by a number of other fungi. In addition to flax, it has been found that this fungus is parasitic upon the roots of a number of other plants, especially when the plants are young. Among the known host plants are mentioned spinach, radish, beets, peas, beans, alfalfa, white clover, cress, mustard, spurry, and flax. The fungus, it is found, can enter the roots only at a certain stage in their development, and the author conducted an extensive series of experiments to determine this period. In the case of flax, it is not possible to gain entrance after the thirteenth or fourteenth day from germination. It develops in the parenchyma and root hairs of the young root. It is propagated immediately by zoospores, which are very sensible to drying and to fungicides. For the preservation of the fungus, there are developed within the roots winter spores which are liberated by the decay of the roots. As a means for preventing the disease, rotation of crops is recommended, but it is stated that flax should not be grown on infested soil for at least 7 years after the fungus is known to be present in the soil.

Treatment of oats for smut, A. D. Shamel (*Illinois Sta. Bul. 64, pp. 57–72, figs. 6*).—The amount and nature of oat smut are described, and suggestions given for prevention by means of the hot water and formalin treatments. Experiments were conducted in which the seed was heated in water at temperatures of 125, 132, 137, and 140° F., and the amount of smut, yield of grain and straw determined. Similar areas were sown with seed taken from the same lot, but not given any treatment, which showed from $2\frac{1}{2}$ to 9 per cent smut in the crop, the yield of grain varying from $27\frac{1}{2}$ to 46 bu.; while in the different treatments the amount of smut varied from 0 to 5 per cent, and the grain crop from $22\frac{1}{2}$ to 50 bu. The same varieties of oats were submerged in a formalin solution, consisting of 1 pt. of formalin to 25 gal. of water. The oats were placed in sacks and immersed for 10 minutes, after which they were immediately sown. The resulting crop contained no smut, and the yield of grain was 31.2 to 69.3 bu. per acre.

Formalin as a preventive of oat smut, W. Stuart (*Indiana Sta. Bul. 87, pp.*

26).—The results of 3 years' observation on the use of formalin as a means for the prevention of oat smut are given. In the investigations considerable variation was found in the content of formalin as sold by chemical supply firms. The variation consisted not only of differences in quantity, but in the specific gravity of the solution. In the experiments the different strengths of solution were reduced so as to be comparable. Comparisons were made between hot water and formalin for the prevention of oat smut, in which the hot water proved entirely efficient, seed treated 10 minutes at 135° F. being wholly without smut, while those soaked in formalin solutions showed a few smutted plants. The efficiency of the formalin was thoroughly established, and the ease with which it may be applied renders it preferable to the hot-water treatment. The effect of sprinkling or soaking the seed was tested. The seed which was sprinkled was spread on a floor and thoroughly moistened with formalin solution. The effect of this treatment was compared with seed soaked for from ½ to 4 hours, the sprinkling method being found less efficient. The comparative value of formalin purchased in bulk and that which is put on the market in pound bottles was tested, in which no material difference was found in the two kinds of formalin used. Apparently the cheaper formalin was just as efficient as the more costly article purchased in the makers' bottles. In the course of the investigations the effect of thorough screening of seed for smut prevention was tested, in which a portion of badly smutted seed was thoroughly screened and passed through a fanning mill and then seeded, which gave a decrease of 17 per cent in the amount of smut in the crop. The influence of formalin on the yield of grain showed some remarkable results in the crop of 1899. The gains on the plats in which the seed had been soaked in formalin solutions varied from 26 to 86 per cent over the yield obtained on the check plats. The experiments were repeated in 1900, and while there was an increase noted for the treated seed, it was less than that reported for the previous year. The resistance of the smut spores to formalin and hot water was tested, with results already noted (E. S. R., 12, p. 768). It is shown that the smut spores are less resistant than grain, and that the solution continues to act upon the spores as long as the seed is wet.

The author recommends the use of a 1:60 formalin solution in which seed is soaked from 1 to 2 hours, or ½ hour soaking in a 1:45 solution. If the seed is sprinkled a 1:45 solution is recommended and the seed should be covered from 2 to 4 hours. As this strength of solution is slightly injurious to the germination of the seed, a greater amount of seed should be sown. The cost of treatment is said to be 1⅗ cts. per bushel. The practical advantage obtained from treating seed oats with formalin varies from \$1.60 to \$4.20 per acre, as shown by the author's experiments.

The prevention of oat smut, E. S. Goff (*Wisconsin Sta. Spec. Bul., Mar., 1901, pp. 4, figs. 1*).—A popular description is given of oat smut, the amount of injury caused by the fungus, and methods of prevention. The principal means suggested is the use of formaldehyde in which it is recommended that the seed be soaked or sprinkled with 1 lb. of formalin to 45 gal. of water. The cost of the treatment of the seed oats for 25 acres is placed at \$1.20, and the increased yield due to the lack of smut would give a net profit of \$11.80.

The value of formaldehyde for the prevention of potato scab and directions for its use are also mentioned.

Formalin and Massel powder as preventives of smut in oats and barley, W. Saunders (*Canada Expt. Farms Rpts. 1900, p. 12*).—Oats and barley were treated with a solution of formalin for different lengths of time, and with a fungicide known as Massel powder. In every case the amount of disease in the treated plats was less than in those plats the seed of which had not been given any treatment, but there was little preference as to the method of treatment.

Experiments to prevent smut in oats and barley, R. Robertson (*Canada Expt. Farms Rpts. 1900, pp. 283–285*).—A report is given of experiments in which formalin and Massel powder were tested for the prevention of smuts of these crops. The results obtained are decidedly in favor of the formalin treatment.

Test of smut preventives for wheat, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1900, p. 342*).—A brief report is given in which copper sulphate, formalin, and Massel powder were tested for preventing the smut on Red Fife wheat. The treatment in all cases practically prevented the occurrence of smut, while the plats in which the seed had not been treated gave more than 10 per cent smutted heads.

Test of smut preventives for oats and barley, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1900, pp. 348–350*).—Formalin and Massel powder as means for the prevention of the smut of oats and barley were tested, and in the case of the oats the report shows that the Massel powder did not possess much value as a preventive, while formalin treatments practically prevented all smut. In the experiments with barley the best results were obtained where the seed had been soaked for 5 to 15 minutes in a solution of 4½ oz. formalin to 10 gal. of water.

Test of copper sulphate as a preventive of smut in wheat, A. MACKAY (*Canada Expt. Farms Rpts. 1900, p. 394*).—A brief account is given of experiments with copper sulphate as a preventive of smut in spring wheat, in which seed soaked for 15 minutes gave a crop of wheat free from smut.

Test of formalin and Massel powder for the prevention of smut in oats and barley, A. MACKAY (*Canada Expt. Farms Rpts. 1900, pp. 397–399*).—The efficiency of both these fungicides for the prevention of smut of oats and barley is shown. The formalin treatment, in which the seed is soaked for 1 hour, gave the best results.

Formalin and Massel powder as preventives for smut, T. A. SHARPE (*Canada Expt. Farms Rpts. 1900, pp. 454, 455*).—In the experiments reported none of the treatments seemed to be efficient in preventing the occurrence of smut to any appreciable degree.

Experiments with Bordeaux mixture as a preventive of potato rot, W. S. BLAIR (*Canada Expt. Farms Rpts. 1900, pp. 334, 335*).—A brief report is given of spraying experiments with Bordeaux mixture on 9 varieties of potatoes, which were given 4 applications of the fungicide. The unsprayed plants at the end of the season were badly blighted, while the sprayed ones remained green and were practically free from rot. With a single exception, the yield from the sprayed plats of all varieties was in excess of that from the unsprayed.

Diseases of sugar cane, Z. KAMERLING and H. SURINGAR (*Gecombin. Meded. Proefstats. Oost- en West Java. Oost Java, 3. ser., 1900, No. 22; West Java, 1900, No. 50; reprinted from Arch. Java Suikerind., 1900, No. 24, pp. 28*).—The authors describe unsatisfactory growth and premature death of sugar cane as a result of the root rot, susceptibility of varieties to the disease, effect of fertilizing and culture on the root rot, and a bacterial disease of sugar cane.

The first symptom of root disease in the sugar cane is the unsatisfactory growth due to the inadequate water supply, which is interfered with by reason of the decay of the roots. New roots are formed above the diseased ones, but these in turn soon become affected until finally the root system is reduced to a dense mat in about 6 cm. of surface soil. During the first severe drought the plants wilt, and soon the dead leaves have the grayish-brown appearance characteristic of this disease. If diseased plants are removed to healthy soil the new roots formed among the decaying ones remain healthy, seeming to show that the disease is caused by unfavorable soil conditions. Inoculation experiments with juice from diseased canes failed to give results, but it was observed that canes into which distilled water had been injected made a better growth than those receiving either healthy or diseased juice.

The effects of wilting and premature death may be partly overcome by flooding the fields as soon as the presence of the disease is noticed. Cutting off the leaves to prevent evaporation is also practiced. Plants that die prematurely should be cut at once in order to save what juice there is. The juice is easily worked, but is small in quantity and of poor quality. Tables are given showing that the purity quotient as well as the percentage of available sugar is much lower in diseased than in healthy tissue.

Experiments with fertilizers generally gave negative results, though manure was of some benefit from increasing the humus in the soil. Lime also had a beneficial effect in a few cases. It was not possible to control the disease by draining the soil, although this had some influence in retarding its appearance. All experiments indicate that the root rot is due in some manner still unexplained to the physical condition of the soil.

Regarding the resistance of varieties the author found that all varieties are liable to the disease, but the kind known as Djamprohriel is the most resistant.

In 1898 a disease of sugar cane was described under the name of bacteriosis, by Raciborski. It is characterized by the decay of the tissue in the lower part of the stem, the decay being accompanied by a strong sour odor. It appears most frequently where plants suffer from too much water, the immediate cause being certain usually harmless ground bacteria, which multiply in the cells already broken down by an excess of water and an insufficient supply of air. The disease is not truly parasitic, but is due to the unfavorable conditions under which the cane grows. Infection experiments all failed except when conditions were provided similar to those under which the plants become diseased in the field, and in those cases the check plants as well as the infected ones became diseased.—H. M. PIETERS.

Finger and toe of cruciferous plants (*Jour. Bd. Agr.* [*London*], *7* (*1900*), *No. 3, pp. 350–352*).—A brief account is given of the disease generally known as club root of cruciferous plants, and the use of lime at the rate of 3 tons per acre is recommended as a preventive treatment. As the fungus causing this disease attacks a great number of plants of the mustard family, special attention should be paid to weeds, such as charlock, wild mustard, and shepherd's purse.

Notes on celery blight, C. O. TOWNSEND (*Maryland Sta. Bul. 74, pp. 167–182, figs. 9*).—A description is given of the celery blight (*Cercospora apii*) and an account of observations and experiments made in 1898, 1899, and 1900, in which the effect of shading and spraying the plants with ammoniacal copper carbonate solution and Bordeaux mixture is given. As a result of the experiments it is shown that the celery blight may be kept under control by the use of either of the fungicides. The tabular report shows the best results were obtained where the plants were sprayed once a week with Bordeaux mixture, but the author believes that ammoniacal copper carbonate would prove as satisfactory should the treatment be begun when the plants are in the seed bed and continue throughout the season until the weather becomes cool enough to prevent the development of the fungus. Shading retarded to some extent the progress of the disease, but did not prevent it completely.

Onion smut, A. D. SELBY (*Ohio Sta. Bul. 122, pp. 71–84, figs. 4*).—A brief account is given of the history of the onion smut fungus (*Urocystis cepulæ*), its distribution and manner of infection are described, and general directions given for the prevention of its spread. A preliminary account is given of experiments conducted for the prevention of this disease. Trials with sulphur and a solution of formaldehyde, and the use of phosphatic fertilizers were made in 1899 without any definite results. In 1890 field trials were made with the use of sulphur, various solutions of formaldehyde, salicylate of soda, salicylic acid, and lime. The results of these different treatments are shown in tabular form, and it appears that the germination of the seed was injured to some extent by a treatment of sulphur, salicylic acid, salicylate of soda, and lime slaked by sprinkling water upon it after application; while favorable influence on germination was exerted by the formalin and possibly by soil treatment of lime. The results obtained by the different treatments showed a decided superiority for the plats which had received formalin and lime, and based upon the preliminary experiment given the author recommends the application of formalin at the rate of

1 lb. to 35 to 50 gal. of water, to be applied with a sprinkler on the scattered seeds, after which they are promptly covered with earth; or the application of stone lime, spreading it before slaking and either covering or harrowing the ground soon after. Further experiments are to be conducted to establish the commercial value of the methods indicated.

The Fusicladiums of fruit trees, R. ADERHOLD (*Centbl. Bakt. u. Par., 2. Abt., 6 (1900), No. 18, pp. 593–595, pl. 1*).—In a previous paper[1] the author gave the results of his investigations on *Fusicladium dendriticum* and *F. pirinum*, and showed that they were associated in their perithecial form with *Venturia inæqualis* and *V. pirina*. In the present paper studies on the host plants and scientific relationships are discussed, especial attention being given to *F. cerasi*. For this species the author describes the perithecial form as *Venturia cerasi*, n. sp. Its host plants are said to be the various stone fruits in cultivation and doubtless many of the wild species of Prunus. The host plants for *F. dendriticum* are said to be *Pyrus malus* and its related species. A variety also occurs on Sorbus, and in all probability attacks various species of Cratægus. *F. pirinum* attacks species of Pyrus belonging to the group Pirophora. Infection experiments with *F. pirinum* showed the spores began germination at about 2° C., and were very active between 10 and 20° C. The entrance of the mycelium to the host plant is believed to be due to the presence of a ferment. The period of incubation was found to be from 12 to 14 days. As a means for combating these diseases, the author recommends the collection and burning of all fallen leaves, winter spraying with a strong copper sulphate solution, and 3 applications of Bordeaux mixture during the growing season.

The Fusicladiums of fruit trees, R. ADERHOLD (*Landw. Jahrb., 29 (1900), No. 4–5, pp. 541–588, pls. 4*).—The author describes at length a number of species of Fusicladium which occur on the more common fruit trees. The biology of the fungi, their scientific relationships, and numerous inoculation experiments are given, together with suggestions for the prevention of the diseases. The substance of this paper is noted above.

Monilia fructigena as a cause of diseases of fruit trees, L. MONTEMARTINI (*Riv. Patol. Veg., 8 (1900), Nos. 7–12, pp. 210–218*).—A description is given of this fungus, which causes the rot of many fruits. Its parasitism and methods of propagation are described. Various remedial measures are suggested, among them the use of sulphur on the ripening fruit, or spraying with Bordeaux mixture. A bibliography of about 50 titles relating to this subject concludes the paper.

The fungus diseases of orange trees in Brazil, F. NOACK (*Ztschr. Pflanzenkrank., 10 (1900), No. 6, pp. 321–335, pl. 1*).—The author describes a number of diseases of orange trees caused by parasitic fungi, several of the species of which have been hitherto undescribed. The fungi causing these diseases are *Mycosphærella loefgreni*, n. sp., *Septoria loefgreni*, n. sp., *Ophionectria coccicola*, *Colletotrichum glœosporioides*, *Glœosporium spegazzini*, and *Didymella citri*, n. sp. The technical characters of the new species are given, the nature of their attack upon the host, and, so far as known, suggestions given for the prevention of the disease.

Diseases of the pear, L. DE NOBELE (*Bul. Arbor. et Flor., 1900, pp. 45–48, 124–127, 138–140, 199–201, 238–240*).

A monograph of the Peronosporaceæ, A. N. BERLESE (*Riv. Patol. Veg., 9 (1900), Nos. 1–5, pp. 1–126, figs. 21*).—This contribution is in continuation of a previous paper (E. S. R., 10, p. 561), treating of the downy mildews, etc. In the present paper the genera Cystopus, Phytophthora, Basidiophora, Plasmopora, and Sclerospora are described. The morphological and biological characters of the fungi are described at some length, in addition to the usual systematic diagnosis of the species. Where the fungi are the cause of diseases of important economic crops the method of attack

[1] Landw. Jahrb., 1896, p. 875.

and means for prevention are discussed at considerable length. The number of species recognized by the author are as follows: Cystopus, 13; Phytophthora, 4; Basidiophora, 1; Plasmopora, 18; Sclerospora, 4.

Concerning a grape disease in the Caucasus region, L. Montemartini and R. Farneti (*Atti Inst. Bot. Univ. Pavia, 2. ser., 7 (1900), pp. 15; abs. in Bot. Centbl., 85 (1901), No. 12, pp. 204, 205*).—The authors have made a study of the fungus causing a disease of grapes in the Caucasus, the general appearance of which is similar to that of the black rot. It differs, however, from the black-rot fungus, *Physalospora* [*Lœstadia*] *bidwellii*, and also from that more recently described as *Guignardia reniformis*. The name given the organism causing the disease is *Physalospora woroninii*, a description of which is given.

Grape rots in Ohio, A. D. Selby (*Ohio Sta. Bul. 123, pp. 85–94, figs. 3*).—A brief account is given of the different diseases to which the grapes are subject, particular attention being paid the black rot and the white or ripe rot. The influence of soil and variety upon the amount of disease is shown, and suggestions given for the prevention of these diseases by the use of fungicides.

Experiments in the prevention of grape rot, A. D. Selby and J. F. Hicks (*Ohio Sta. Bul. 123, pp. 94–102*).—A report is given of a series of experiments conducted in an Ohio vineyard in which the vines were given 7 or 8 sprayings of Bordeaux mixture, formalin solution, salicylic acid and lime, and salicylate of soda. The applications were begun April 18 and continued at intervals of about 2 weeks until the middle of August. The black rot appeared at about the usual time and destroyed nearly all the crops in the unsprayed rows, and the rows sprayed with salicylate of soda and the salicylic acid-lime solution were severely injured. The cost of spraying with 4 applications of Bordeaux mixture, followed by 3 of ammoniacal copper carbonate solution, is given at $11.39 per acre. On the unsprayed portion there were practically no marketable crops. The most favorable results were obtained where 5 applications of Bordeaux mixture were followed by 3 of ammoniacal copper carbonate. The effect of omitting some of the applications was tested and it was found that the omission of spraying the young shoots just before blossoming showed as a result a loss of 90 per cent from black rot. Earlier or later omissions of spraying showed no decided loss. The total beneficial result on the vineyard experimented upon, which contained Concord grapes, was a saving of about 50 per cent of the marketable crop. Upon more favorable soils better results have been obtained. The standard strength of Bordeaux mixture (4 lbs. of copper sulphate, 4 lbs. of lime, and 50 gal. of water) proved equally as efficient as greater strengths, and shorter intervals than 2 weeks between sprayings are recommended after June 20.

Hexenbesen on cacao trees, J. Ritzema-Bos (*Orgaan Ver. Oudleer. Rijks. Landbouwschool, 12 (1900), No. 149, pp. 220–224, figs. 3*).—The author examined branches of cacao trees affected with a disease resembling the well-known hexenbesen of the cherry. The growths are thicker than the twigs upon which they are borne. They are upright, twisted, and bear small curled leaves, on one of which were formed spores of a species of Exoascus. The disease is attributed to a new species called provisionally *Exoascus theobromæ*. The remedy suggested is persistently cutting out the abnormal growths and burning them.—H. M. PIETERS.

The dwarf mistletoe in Michigan, C. F. Wheeler (*Michigan Sta. Bul. 186, pp. 27, 28, pls. 4*).—A brief account is given of the occurrence of the dwarf mistletoe (*Arceuthobium pusillum*). This mistletoe was observed on black spruce in tamarack swamps a short distance from the station. It was noticed in a number of other places and seems to be widely distributed in the upper peninsula, having been observed in nearly every tamarack swamp to a distance of a hundred miles. In some of the swamps nearly every tree had been killed. The parasite stimulates the branches of the tree to extra growth, forming witches' brooms of considerable size, and when a number of branches are affected the tree dies as a result of the attack. A fungus

(*Wallrothiella arceuthobii*) was found parasitic in the fruit of the mistletoe, and it is thought that the fungus will to a considerable extent check the spread of the pest.

Fungus diseases of forest trees, H. von Schrenk (*U. S. Dept. Agr. Yearbook 1900, pp. 199–210, pls. 5*).—The author describes some of the more important fungus diseases to which forest trees are subject, giving special reference to such as render the wood unfit for lumber. The general nature of wood-destroying fungi is described and the method by which trees become infected indicated. Among the more destructive fungi the author describes *Trametes pini*, *Polyporus schweinitzii*, *P. sulfureus*, *P. igniarius*, *P. nigricans*, *P. annosus*, *P. rimosus*, and *P. juniperinus*. In order to save the timber it is recommended that as soon as dead or severely attacked, diseased timber should be cut. This will prevent depreciation in the value of timber and also the scattering of the spores to other trees, thus spreading the disease.

A disease of elm trees, B. G. Aliño (*Jour. Roy. Hort. Soc. [London], 23 (1900), No. 3, pp. 343–345*).—A disease affecting elm trees near Tarancon, Spain, is described. The trees at this place are largely cultivated for timber, but have recently been troubled with a disease which while not apparent on the living trees, shows itself very plainly in the timber. The trees appear healthy and there is no external sign of deterioration, nor of any fungi or insects. They seem to be in a normal condition, the foliage being abundant and fruit fully up to the normal. They continue in this condition until full grown, when cracks appear in the trunk, generally on the surface at first but increasing in depth with the age of the tree until in old specimens the cracks pierce to the heart of the tree. It often happens that no injury is present when a tree is cut, but the wood after being worked falls to pieces. The author has made a careful study of the subject, but has been unable to determine definitely the cause of this peculiar behavior of the trees. As no parasites are present it is believed to be a disturbance of the physiological functions of the tree.

Concerning some fungi occurring on tropical culture plants, A. Zimmermann (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 3, pp. 101–106; 4, pp. 139–147, figs. 24*).—Critical notes are given and new species described of a number of fungi which have been observed on economic plants in various parts of Java. The host plants in most cases were tea, coffee, cacao, betel, and *Melia azedarach*.

Two new smuts on Eriocaulon septangulare, G. P. Clinton (*Rhodora, 3 (1901), No. 28, pp. 79–82, figs. 2*).—Descriptions are given of 2 new species of smuts, namely, *Tolyposporium eriocauli* and *Ustilago eriocauli*.

A new disease of Caragana arborescens, A. von Jaczewski (*Ztschr. Pflanzenkrank., 10 (1900), No. 6, pp. 340–343*).—A description is given of a fungus disease of Caragana, which is due to attacks of an undescribed species, to which the name *Pleospora caraganæ* is given. This was previously noted from a Russian publication (E. S. R., 12, p. 859).

Chlorosis, a physiological study, C. Chevalier (*Belg. Hort. et Agr., 12 (1900), No. 9, pp. 132, 133*).

Description of the infection house and system of experiments of the Dahlem experimental field, C. von Tubeuf (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901), No. 1, pp. 161–163, figs. 4*).

ENTOMOLOGY.

Report of the entomologist, J. Fletcher (*Canada Expt. Farms Rpts. 1900, pp. 195–248, figs. 18*).—Hessian fly was unusually destructtve during the season. In some stems of infested wheat, this insect was found associated with the wheat stem maggot. The Hessian fly was active and laid eggs considerably later in the fall than is usually the case, thus necessitating a delay in the fall wheat sowing for a week or more. The wheat stem sawfly (*Cephus pygmæus*) is reported as injurious in the Northwest Territory. For combating this insect the author recommends burning or plowing under the stubble, burning unused straw in the spring, and summer fallowing every other year. Red-backed cutworm (*Carneades ochrogaster*) was injurious to turnips and other garden plants. Grasshoppers caused considerable damage to field crops but were successfully combated by burning and plowing stubble fields and by the use of hopper-dozers and poisoned bait. The species chiefly concerned were *Melanoplus packardii*, *M. atlanis*, and *Camnula pellucida*. Brief notes are given on the occurrence and injuries of white grubs, the pea weevil, the destructive pea aphis, and pea moths (*Semasia nigricana*). In combating the last-named insect the author recommends 3 sprayings with Paris green, 1 when the blossoms begin to fall, the second a week later, and a third after another 10 days.

Descriptive and economic notes are presented on the variegated cutworm (*Peridroma saucia*), and spotted cutworm (*Noctua c-nigrum*). The author describes these species in detail and gives a summary of reports of correspondents concerning their appearance and injuries. Notes are also given on parasites and predaceous enemies of these species, and a general discussion is given of the approved remedies for fighting cutworms. The cabbage plusia is reported as having attacked chrysanthemums, smilax, and other plants, as well as cabbages. Experiments with the San José scale showed that while whale-oil soap at the strength of 2 lbs. to 1 gal. of warm water killed many of the scales, it was not as effective as the crude petroleum. The latter insecticide gave good results when used with a mechanical mixture of water, containing 30 per cent of the petroleum. This mixture caused no damage to apple trees, but should be used with care on plum and peach trees. A few San José scale escaped on every tree which was treated, and the author believes that a combination of whale-oil soap and crude petroleum may be more effective. The palmer worm caused considerable damage to apple trees on the northern shore of Lake Ontario. Greenhouse leaf tier (*Phlyctænia ferrugalis*) caused some loss by its attack upon roses, violets, and chrysanthemums. As a remedial treatment the author recommends hand picking of leaves on which caterpillars are found. *Cacœcia parallela* is reported as an enemy of rose bushes in greenhouses. It attacks the leaves and draws them together by means of silk threads. In fighting this insect the author recommends hand picking of the caterpillars and spraying or fumigation with hydrocyanic-acid gas.

Brief notes are given on a number of insects injurious to forage crops, fruits, and vegetables.

A report on apiary experiments is made by John Fixter. The natural stores of 4 colonies were extracted on September 17, and in all 8 lbs. of sugar were fed to these bees. At the beginning of the feeding the average weight of hives and colonies was 33½ lbs., and at the close 52½ lbs. Experiments were made in wintering bees and in noting the effect upon the strength of the colony of various times of moving from the winter quarters. On March 10, 18 colonies were moved, 6 being placed in a sheltered apiary, 6 in a house apiary, and 6 in an exposed apiary. The balance of the colonies were taken from their winter quarters on April 8. On April 18 an examination of the colonies showed that in every instance those that were set out first had more brood and eggs and appeared to be more active than those which were set out later. A list of plants, trees, and shrubs on which bees were seen working is given. The results of experiments with comb foundations and sections showed that the smaller the sheet of foundation which was used, the more holes or gaps there were around the comb in the sections. The author recommends, therefore, that full sheets of foundation be used.

Report of the entomologist, E. D. SANDERSON (*Delaware Sta. Rpt. 1900, pp. 142–238, figs. 19, pls. 5*).—An article on the strawberry root-louse and the destructive pea louse (pp. 143–186) has already been noted (E. S. R., 12, p. 970).

Notes are given on a number of apple insects, including *Aphis sorbi*, *A. padi*, *Steganoptycha pyricolana*, *Cacœcia rosaceana*, etc. Similar notes were published in Division of Entomology Bulletin 26 (E. S. R., 12, p. 861).

A few experiments with crude petroleum as a remedy for San José scale on pear trees indicated that a 25 per cent mechanical mixture was as effective as undiluted petroleum.

Biological and economic notes are given on *Mesograpta polita*, *Myzus porosus*, a number of insects injurious to clover, horse bots, striped cucumber beetles, bollworm, harlequin cabbage bug, and corn root-louse.

A paper on hydrocyanic-acid gas as an insecticide for low-growing plants has been previously noted (E. S. R., 12, p. 861).

The diffusion of hydrocyanic-acid vapor in an inclosed space is discussed by C. L. Penny. Preliminary experiments in taking samples of air from fumigating rooms were made by the use of 5-gallon Seltzer bottles, from which the air was exhausted and into which the gas could be admitted by a movement of the stopcock. Analysis of the air and gas mixture thus obtained indicated that immediately after the generation of the hydrocyanic-acid gas there is an excess of gas around the generator. Within 2 minutes' time this excess disappears, leaving only one-third of the normal quantity of gas near the generator, while $2\frac{1}{2}$ times the normal quantity is found at the opposite end of the fumigating box. This excess rapidly diminishes and the gas increases in density around the generator so that a tendency toward equilibrium is noted, although more than 20 minutes is required for the establishment of a perfect equilibrium. These experiments were conducted in a box with a capacity of 60 cu. ft., with dimensions 8 by 3 by $2\frac{1}{2}$ ft. Similar experiments were made in boxes of different sizes and shapes, and it is concluded that in spontaneous diffusion within a closed space the quantity of hydrocyanic-acid gas at a given point may be as low as 23 per cent of the normal quantity and as high as 27.2 per cent. Inequality does not persist for a great length of time, but is sufficient to render it certain that the amount of cyanid of potassium used per cubic foot is no guarantee of a sufficient amount of gas in all parts of the space to be fumigated, or of too little to injure the plants.

Experiments in a room 20 by 19 by 10 ft. indicated that when a generator is placed near one wall, the gas rises vertically from the generator and, following the ceiling, descends on the opposite side of the room and completes the circuit by returning along the floor. Of the total amount of hydrocyanic-acid gas, about 5 per cent remains in the generators, 7 per cent is lost by leakage or surface condensation on the walls of the room, while 88 per cent is diffused and becomes effective for insecticide purposes.

The results of these experiments were made use of in further experiments in fumigating boxes. It was found that when gas was allowed to diffuse spontaneously from 1 generator, the diffusion was very unequal for a considerable length of time, and that it was possible for an animal like the guinea pig to live at least 37 minutes in the fumigation box. It is recommended that the generator be placed below the part of the fumigating box which contains the plants and that communication be made by means of numerous slits, so as to insure the rapid and equal diffusion of the gas.

Insect attacks in 1900, R. S. MacDougall (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13 (1901), pp. 296–305, figs. 7*).—*Phyllopertha horticola* is described in detail in its various stages. The adult beetle injures forest and orchard trees by feeding upon the leaves. The eggs are deposited in the soils of gardens and grass lawns, and the grass and fruit are injured chiefly by attacks upon the roots. It is recommended that adult beetles be shaken from trees early in the morning into some catching apparatus, and that infested soil be treated with from 3 to 4 tons of gas lime per acre.

Onion fly (*Phorbia ceparum*) is reported as having caused considerable injury during the year. Brief notes are given on the life history of the species. Infested plants may be recognized by the leaves changing to a yellow color. For combating this pest the use of kainit and nitrate of soda about the roots of plants is recommended, as well as scattering sand mixed with kerosene around the base.

Carrot fly (*Psila rosæ*) is described and brief notes given on its habits. In combating this insect the author recommends spraying with kerosene emulsion immediately after sowing, again after germination, and a third time after the carrots are thinned. Infested carrots should be removed and fed or otherwise disposed of.

Notes are given on *Sirex gigas* and *S. juvencus*, which are injurious to spruce, fir, larch, and pine. Notes are given on the habits and life history of these species. The eggs are usually deposited in diseased trees or such as have been accidentally wounded. Such trees should be felled and removed from the forest.

Some insects injurious to the violet, rose, and other ornamental plants, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Bul. 27, n. ser., pp. 114, pls. 4, figs. 29*).—The observations reported in this bulletin relate chiefly to insects which attack violets, but include, also, accounts of several greenhouse insects and species which are injurious to the rose, morning glory, and other ornamental plants.

Greenhouse leaf tier (*Phlyctænia rubigalis*) (pp. 7–26) attacks various greenhouse plants, including violets, and also celery, beets, cabbage, and tobacco. It feeds upon the underside of the leaves. The species is described in all its stages and notes are given on the nomenclature, distribution, literature, and food plants of the insect. The species hibernates in the larval state, but in warm greenhouses there is no true hibernating period. Hand picking, attracting the moths to light, the use of arsenical sprays, and fumigation with tobacco and hydrocyanic-acid gas, are recommended. The chief reliance should be placed on fumigation by the latter method. Detailed directions are given for the application of this remedy.

Violet sawfly (*Emphytus canadensis*) (pp. 26–35) is described and illustrated in all its stages. The larvæ feed on the lower side of the leaf by cutting holes on the surface. Eggs are laid in the substance of the leaf. Parthenogenesis is sometimes observed in this species. The treatment which is recommended is the same as for the greenhouse leaf tier.

Two-spotted red spider (*Tetranychus bimaculatus*) (pp. 35–42) is described and notes are given on its distribution, food plants, and literature relating to the species. As a remedy for this mite it is recommended that plants be sprayed with sulphur mixed with water at the rate of 1 oz. to the gallon, or with kerosene emulsion, whale-oil soap, or similar soap solutions. With violets good results have been obtained by repeated spraying with water or with a solution of a neutral soap in water. Violets should be sprayed in this manner about 3 times a week.

Black aphis (*Rhopalosiphum violæ*) (pp. 42–47) is described and illustrated. Notes are given on the injury caused by this species and on the literature relating to this species. Fumigation with hydrocyanic-acid gas or spraying with a solution of neutral soap and water is reported as an efficient remedy against this species.

Violet gall fly (*Diplosis violicola*) (pp. 47–50) folds violet leaves in such a way as to bring the upper surfaces together, forming a so-called gall. The species is described and brief notes are given on the extent of its injuries. Fumigation with hydrocyanic-acid gas and the use of buhach is recommended.

Descriptive, biological, and economic notes are presented on a number of species of cutworms and owlet moths (pp. 50–74). The species which are considered include *Peridroma saucia*, *Noctua c-nigrum*, *Prodenia commelinæ*, *P. ornithogalli*, *P. eudiopta*, and the fall army worm. It is recommended that soil for greenhouses should not be taken from areas which have been recently covered with grass or weeds, since cutworms may be contained in such soil. Cutworms are destroyed to some extent by fumigation for other insects, but the best remedy is the use of green bait, such as clover or other plants, poisoned with Paris green, or a bait known as bran arsenic mash.

For white grubs in greenhouses (pp. 74–77) the author recommends the use of bisulphid of carbon, kerosene emulsion, and poisoned baits. The last-named method is perhaps most effective. Complaints which have been received concerning injuries in greenhouses from the larvæ of *Allorhina nitida* were so indefinite that the author attributes the injury to cutworms.

Wireworms (pp. 77, 78) may be combated by the use of strong brine or salted fertilizers in the soil, when the plants will endure these substances. The form of bait recommended for these insects consists in slices of potatoes or other vegetables poisoned with arsenic.

A number of miscellaneous insects injurious to violets are discussed (pp. 79–83) and brief notes given on the methods for combating them.

Rosebud worm (*Penthina nimbatana*) (pp. 83–87) is described and illustrated and notes are given on its injuries and distribution. This species and also rose-leaf tier (*P. cyanana*) may be combated in the same manner as recommended for the greenhouse leaf tier. Brief notes are also given on *Cacœcia rosaceana*, *C. rosana*, and other species.

Fuller's rose beetle (*Aramigus fulleri*) (pp. 88–96) is described in all its stages and notes are given on the literature, distribution, and food habits of the insect. It is recommended that the beetles be destroyed by hand picking and jarring and that the larvæ be treated by injections of carbon bisulphid into the soil, or the use of kerosene emulsion and tobacco waste about the roots of the plants.

A flower beetle (*Hoplia callipyge*) (pp. 96–98) is reported as injurious to roses in parts of California. The life history of this species is not well understood, but the author recommends a line of treatment similar to that which should be adopted against the rose chafer.

Rose curculio (*Rhynchites bicolor*) (pp. 98–100) is reported as injuring roses by boring holes in the buds. The species has become of economic importance in a number of localities. Hand picking and jarring the bushes is recommended, as well as spraying with Paris green at the rate of 1 lb. to 150 gal. of water. Brief notes are also presented on other insects injurious to the rose, including *Cladius pectinicornis*, *Trichius piger*, *Elaphidion villosum*, and *Heliothis rhexiæ*.

Morning-glory leaf cutter (*Loxostege obliteralis*) (pp. 102–108) is reported as causing considerable damage to morning glories by gnawing the leafstalks on the upper side near the leaf, so that the leaves hang down and wilt. The species also occurs on peppermint and spearmint. Notes are given on its life history and habits. Spraying with arsenicals is recommended for combating this species.

Fickle midge (*Sciara inconstans*) (pp. 108–113) is described in its different stages and notes are given from correspondents on the distribution of the species. The author recommends fumigation with hydrocyanic-acid gas for the adults and the use of tobacco, bisulphid of carbon, or kerosene emulsion, about the soil of affected plants, as treatment for the larvæ.

Insect enemies of tree and fruit, and how to control them, E. C. GREEN (*Trans. Illinois Hort. Soc., n. ser., 34 (1900), pp. 114–125*).—Brief notes on insecticide methods which are most effective in controlling scale insects, tree hoppers, borers, leaf-eating caterpillars, plum curculio, and codling moth.

Insect and animal life on the Upper Peninsula Experiment Station, R. H. PETTIT (*Michigan Sta. Bul. 186, pp. 28–42, pl. 1, figs. 6*).—Brief notes are given on a species of tree-hoppers and leaf bugs, including the holly-hock bug (*Orthotylus delicatus*), fall army worm, white-marked tussock moth, fall webworm, cabbage worms, mosquitoes, wheat-head fly, flat-headed apple-tree borer, cherry-tree leaf beetle, *Phorocera doryphoræ* and *Xylococcus betulæ*. A list is given of the moths, molluscs, spiders, and insects which were found in the Upper Peninsula.

Chronological account of the Royal Entomological Station at Florence from 1886-1897, G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 161–369*).—In this article the author has brought together notes on the insects injurious to various cultivated crops and the dates of their appearance as reported to the station for a series of years.

Insects injurious to beets (*Landtmannen, 11 (1900), No. 46, pp. 571–574.*)—An account is given of the habits and life history of *Cassida nebulosa*, which is reported as being very injurious to beets. Its natural food plants are said to be species of Chenopodium and Atriplex. Spraying with Paris green proved very effective in the destruction of the pest.

Mites injurious to field crops, A. Berlese (*Riv. Patol. Veg., 8 (1900), No. 7–12, pp. 227–297, figs. 61*).—This paper contains descriptions, biological and economic notes on a large number of genera, including Pediculoides, Bryobia, Tetranychus, Tarsonemus, etc. A bibliography is given of literature relating to the subject.

The destructive green-pea louse, F. H. Chittenden (*U. S. Dept. Agr., Division of Entomology Circ. 43, 2. ser., pp. 8, figs. 3*).—A brief description is given of the insect in its different stages, together with an account of the extent of injury to peas and other plants upon which it depredates. Mention is made of a number of natural enemies of this insect, including the lady beetles, lace-wing flies, red mites, syrphus flies, and a parasitic fungus *Empusa aphidis*. Among the artificial remedies which are recommended for controlling this insect, mention should be made of the use of kerosene-soap emulsion, the brush and cultivator method, the brush and pan method, and rotation of crops.

Experiments with lime mixtures for the eradication of scale insects, W. T. Macoun (*Canada Expt. Farms Rpts. 1900, pp. 119–123*).—Experiments in whitewashing trees to retard the swelling of buds in the spring showed that this treatment was effective in destroying the oyster-shell bark-louse. The formula used was lime 60 lbs., water 24 gal., skim milk 6 gal. This produced a thick mixture which was difficult to spray. The trees were sprayed 6 times, and since this was considered too expensive for treatment against scale insects, experiments were tried to determine how many applications were necessary for this purpose. In these experiments 2 lbs. of lime were used to the gallon of water, and the trees were sprayed on November 17, 20, 27, and December 7. The mixture did not adhere as well as when skim milk was used, and began to peel off after a period of 10 days. The results indicated, however, that 2 sprayings were quite sufficient to give satisfactory results in destroying the oyster-shell bark-louse.

Further experiments were made to determine the minimum strength of lime necessary to obtain satisfactory results. These experiments, while not leading to definite conclusions in all respects, indicated that the best time to spray for this purpose is in autumn rather than winter or spring. An apple tree was sprayed twice with a solution containing 2 lbs. of lime, 1 gal. of water, 1 quart skim milk, 5 oz. of salt. The second spraying was done when the leaf buds were opening. No injury resulted to the tree. Experiments with lime mixtures on peach trees infested with the San José scale, and on plum trees infested with the New York scale, indicated that these scales were not destroyed by this method.

Experiments in Italy in destroying the scale lice of cultivated plants, G. Del Guercio (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 417–420*).—The experiments reported in this article were carried out with the assistance of Prof. E. Baroni. These experiments showed that a single treatment with a soap emulsion of oil of tar containing 1 per cent of tar was quite efficient against young scale lice just hatched, but did not completely rid the plants of infestation. A 2 or 3 per cent solution of the same mixture was very effective and plants thus treated seemed to make a vigorous growth.

The San José scale, J. Ritzema-Bos (*Tijdschr. Plantenziekten, 6 (1900), No. 5–6, pp. 152–159*).—The author discusses the dangers from importing San José scale on nursery stock and fruit, and concludes that there is little likelihood that San José scale which are imported on fruit will escape into orchards.

San José scale, Y. Sjöstedt (*Svenska Trädgårdsfor. Tidskr., 1900, Nos. 10, pp. 153–156; 11–12, pp. 180–182, figs. 6*).—A general account of the habits, life history, and remedies for this insect.

Pure kerosene for San José scale (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 2, p. 236*).—Apple trees were painted with pure kerosene during a dormant condition. The scales were all killed by the application and the trees were not injured.

Classification of Aspidiotus, G. Leonardi (*Riv. Patol. Veg., 8* (*1900*), *No. 7–12, pp. 298–369, figs. 22*).

The scale insect and mite enemies of citrus trees, C. L. Marlatt (*U. S. Dept. Agr. Yearbook 1900, pp. 247–290, pls. 6, figs. 25*).—The author presents a general account of the life history and habits of scale insects, with especial reference to those which are injurious to citrus trees. A discussion is also given of the various methods which have been found most successful in treating these insects, including various sprays and fumigation with hydrocyanic-acid gas. Special descriptive, biological, and economic notes are given on *Mytilaspis gloveri*, *M. citricola*, *Aspidiotus ficus*, *A. aurantii*, *A. hederæ*, *Parlatoria pergandei*, *Chionaspis citri*, *Lecanium oleæ*, *L. hesperidum*, *L. hemisphæricum*, *Ceroplastes floridensis*, *C. cirripediformis*, *Icerya purchasi*, *Dactylopius citri*, *Aleyrodes citri*, *Phytoptus oleivorus*, and *Tetranychus sexmaculatus*.

Phylloxera, J. A. Ortiz (*Bol. Ofic. Agr. Ganadera, 1* (*1901*), *Mar., pp. 63–67*).—A general description of the insect and a historical account of its introduction into Argentina.

Smyrna fig culture in the United States, L. O. Howard (*U. S. Dept. Agr. Yearbook 1900, pp. 79–106, pls. 7, figs. 7*).—This article contains a historical account of the introduction of the fig insect into California, with brief notes on the possibility of fig culture in the United States. The various stages of *Blastophaga grossorum* are described and illustrated.

Insects injurious to pine trees, K. Hagström (*Landtmannen, 11* (*1900*), *No. 51, pp. 821, 822*).—The life history and injurious habits of *Hylesinus piniperda* are described in considerable detail. As a remedy against this insect it is suggested that a few pine trees be felled in January and allowed to remain upon the ground until the larvæ are ready to change into the pupal condition. The bark may then be stripped from such logs and burned along with the larvæ.

Mites injurious to animals, R. S. MacDougall (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13* (*1901*), *pp. 244–276, figs. 8*).—A general scheme of classification for mites is presented and a discussion is given of injurious ticks and approved remedies for combating the common species which are injurious to animals. Among the mites which are discussed in the report, mention may be made of *Demodex folliculorum*, *Trombidium holosericeum*, *Leptus autumnalis*, species of Sarcoptes, Psoroptes, and Symbiotes, which cause mange on domestic animals, sheep tick, dog tick, and chicken mite. A general discussion is given to the subject of dips for use in the treatment of sheep scab.

Protection of animals against the attacks of flies, G. del Guercio (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 421–424*).—The author had considerable success in driving away forest flies (*Hippobosca equina*) by the use of a solution of olive oil and kerosene. Similar experiments were tried in protecting cattle against the attacks of *Tabanus autumnalis*, *T. bovinus*, and *T. morio*. An animal treated with this solution was observed for a period of 2 hours in a locality where the Tabanidæ were numerous, and during this time only 3 skin punctures were made and those were in locations which had not been reached by the insecticide. Another animal which was left without an application of the insecticide was seriously bitten by the flies. The mixture recommended by the author contains 100 parts of olive oil and 5 parts of kerosene.

Parasites of insect pests, C. Harper (*Jour. Dept. Agr. West. Australia, 3* (*1901*), *No. 2, pp. 114–122*).—This article contains notes on a dipterous parasite of grasshoppers and observations on parasites of the fruit fly and black scale. Notes are also presented by A. Despeissis on injurious rabbits, the fertilization of the Smyrna fig, and on the codling moth and bumblebee.

Dust spray, J. J. Kiser (*Trans. Illinois Hort. Soc., n. ser., 34 (1900), pp. 218–223*).—The author discusses the effectiveness and convenience of application of insecticides and fungicides in a dry form.

Chemistry of insecticides and fungicides, F. T. Shutt (*Canada Expt. Farms Rpts. 1900, pp. 185–187*).—The author made analyses of whale-oil soap and Arborine. The efficient action of whale-oil soap is supposed to require that the soap be made of potash rather than soda, since the former mixture is soft soap and the latter hard soap. Analyses of a number of the samples were made for determining the water and potash content. As compared with what is considered the standard for such soaps, these samples were somewhat deficient in potash. As whale-oil soap is frequently considered a stimulant to the growth of trees, the author made an estimate of the amount of potash in an ordinary application of this insecticide. When 2 lbs. of soap are used per gallon and about 2 gal. of the solution sprayed upon a mature tree, it is estimated that 14 lbs. of potash are sprayed upon each acre of ground. It is not believed that the potash is absorbed through the leaves, but that after being washed off upon the ground it gains entrance to trees by root absorption.

The samples of Arborine analyzed indicated that the substance is essentially a mixture of ocher, sulphur, and asafetida. It is stated that it probably acts as a deterrent against the attacks of certain insects, but that the price asked for the compound is too great in comparison with the cost of the constituents.

Bibliography of the more improtant contributions to American economic entomology, VII, N. Banks (*U. S. Dept. Agr., Division of Enotmology, pp. 113*).—A list is given containing 1,383 titles of entomological articles which appeared during the years 1897–1899, inclusive. A considerable portion of the titles listed are newspaper articles.

FOODS—NUTRITION.

A new process of bread making, G. Lebbin (*Hyg. Rundschau, 10 (1900), No. 9, pp. 409–415*).—Experiments are reported on a process of bread making in which the grain is soaked, and on the composition of the bread, and its digestibility as determined in 2 trials.

Leguminous bread, R. Fanto (*Ztschr. Angew. Chem., 1900, pp. 979, 980; abs. in Jour. Soc. Chem. Ind., 19 (1900), No. 11, p. 1031*).—A flour suitable for bread making, according to the author, is obtained by mixing bean meal and wheat gluten. Bread made in different ways from such flour mixtures is described.

Malted bread, Goodfellow (*Sanitary Home, 3 (1901), No. 5, pp. 116–118*).—A synopsis of a lecture printed in the "Epicure."

The food value of meats, Helen T. Sheldon (*Agr. Student, 7 (1901), No. 8, pp. 154, 155*).—A brief summary.

When is meat spoiled? C. Mai (*Ztschr. Untersuch. Nahr u. Genussmtl., 4 (1901), No. 1, pp. 18–21*).—Experimental data are reported. According to the author decomposition of meat may be divided into 4 stages. The first is not characterized by the presence of chemical decomposition products, although after 3 or 4 days the ratio of ammonia to total nitrogen is increased. In the second stage amin bases of the aliphatic series, especially trymethylamin can be detected as well as amido acids. The third stage is one of marked decomposition. It is characterized by the odor, etc. In this stage, the amido acids disappear and fatty acids are observed and also, at times, indol and skatol. The amins become so abundant that they may be easily isolated. Finally ptomaines, for instance, putrescin, are observed. In the fourth stage, all these bodies slowly disappear, being replaced by simpler decomposition products, until finally only ammonia is noted. Naturally the first two stages are those which are of most interest to students of nutrition. If the ammonia content of any sample of meat or meat product exceeds the normal, such goods can not longer be recommended, and if more than a trace of trymethylamin occurs, the meat is spoiled from a chemical standpoint. In case of sausages, the skins are characterized by the early occurrence of hydrogen sulphid, indol, and skatol, as well as relatively large amounts of amins and fatty acids. Therefore especial attention should be paid to the skins of the sausage and the material immediately adjoining, as this portion shows the first indications of decay.

Contribution to the subject of the elementary composition and the heat of combustion of the muscular tissue of different animals, A. Köhler (*Ztschr. Physiol. Chem., 31 (1901), No. 5–6, pp. 479–519*).—The elementary composition of the heat of combustion of a number of kinds and cuts of meat are reported in detail and the analytical methods followed are described. The average values for several sorts of meat follow:

Average composition of a number of kinds and cuts of meat.

	Carbon.	Hydrogen.	Nitrogen.	Sulphur.	Oxygen.	Heat of combustion per gram.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Calories.*
Beef	52.54	7.14	16.67	0.52	33.12	5,677.6
Pork	52.71	7.17	16.60	.59	22.95	5,675.8
Mutton	52.53	7.19	16.61	.69	22.96	5,638.7
Rabbit	52.83	7.10	16.90	......	......	5,616.6
Chicken	52.36	6.99	16.88	.5	23.28	5,617.3
Horseflesh	52.64	7.10	15.55	.64	24.08	5,599.0

The author concludes from his observations and the work of other investigators that it is not possible to extract all the fat from animal food even if the extraction is long continued.

Contribution to the examination and judging of egg pastes, A. Beythien and E. Wrampelmeyer (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 4, pp. 145–156*).—Method and results are given of the analyses of a number of samples of egg noodles and similar goods.

The value of potatoes as food, C. F. Langworthy (*U. S. Dept. Agr. Yearbook 1900, pp. 337–348, figs. 3*).—The botanical structure, chemical composition, and nutritive value of potatoes are discussed, together with the effects of cooking, flavor, and other related topics.

Food value of the sweet potato (*Queensland Agr. Jour., 7 (1901), No. 4, p. 300*).—A brief note quoting composition.

The sweet potato, G. McCarthy (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 4, pp. 33–35*).—A descriptive article giving also methods of preparation for the table.

Rice cookbook, Mrs. S. A. Knapp (*Houston, Tex.: S. F. B. Morse, 1901, pp. 1–48, figs. 15, dgms. 2*).—The food value of rice is discussed at some length, and a large number of recipes given for cooking rice.

The dietetic value of sugar, H. W. Gardner (*Birmingham: Hall & English, 1901, pp. 15; British Med. Jour., 1901, No. 2104, pp. 1010–1013*).—A general article summarizing the modern views on the subject, read before the Shropshire and Mid-Wales Branch of the British Medical Association.

The crude fiber content of shelled cocoa, F. Filsinger (*Ztschr. Oeffentl. Chem., 6 (1900), pp. 223–227, 471; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 9, pp. 400, 401*).—Results of analytical studies are reported and discussed.

Analyses of Paraguay tea, K. Dieterich (*Ber. Pharm. Gesell., 11 (1901), p. 253; abs. in Chem. Ztg., 25 (1901), No. 48, p. 184*).—The caffein content of a sample of the crop of 1898 was 0.85 per cent. A sample of the crop of 1900 contained 1.22 per cent and a cultivated article of that year 1.28 per cent.

The composition and judging of raisin wine, A. SCHNUGAUS (*Arch. Pharm., 239 (1901), No. 2, pp. 91–95*).—A descriptive article with analyses.

The dietary on troop ships (*British Med. Jour., 1901, No. 2097, p. 598*).—A brief note on the diet on British hired troop ships.

The new workhouse dietary order (*British Med. Jour., 1901, No. 2098, pp. 679–681*).—Extracts from the tables of dietaries recently ordered by the Government for the British workhouses.

The new workhouse dietaries (*British Med. Jour., 1901, No. 2098, p. 659*).—A brief discussion.

Some of the singular foods of the Filipinos, G. D. RICE (*Sci. Amer., 84 (1901), No. 3, p. 35, fig. 1*).—Notes on the use of grasshoppers, moths, and bats as food.

Are the teachings of science regarding food economy practical? A. P. BRYANT (*Dietet. and Hyg. Gaz., 17 (1901), No. 4, pp. 198–200*).—The possibility of the practical application of scientific studies of nutrition is pointed out.

The use and abuse of food preservatives, W. D. BIGELOW (*U. S. Dept. Agr. Yearbook 1900, pp. 551–560*).—The history of food preservatives is briefly reviewed and the important characteristics of a number of the more common ones are described. The author also discussed the restrictions which should attend the use of preservatives.

Report of the State Food Commissioner of Illinois, A. H. JONES (*Illinois State Food Com. Rpt. 1899–1900, pp. 122*).—A compilation of the laws of Illinois covering the inspection and sale of food products and the first year's work of the food commissioner in carrying out the provisions of those enactments.

Report of the Dairy and Food Commissioner of the State of Michigan, 1900 (*Michigan State Dairy and Food Com. Rpt. 1900, pp. 245*).—This volume includes the usual reports of inspection of foods, dairies, cheese factories and creameries, together with results of analyses for the detection of adulterants and related topics.

Fourteenth annual report of the Ohio Dairy and Food Commissioner, 1899, J. E. BLACKBURN (*Ohio State Dairy and Food Com. Rpt. 1899, pp. 317*).—Reports are given of the analyses made under the State pure-food laws of foods, condiments, and drugs. Court decisions are also included, as well as the usual statistical matter.

ANIMAL PRODUCTION.

Fodders and feeding stuffs, F. T. SHUTT (*Canada Expt. Farms Rpts. 1900, pp. 166–177*).—The author reports the composition of rape at different stages of growth, and of a number of different varieties of Lathyrus, of vetch, mangels, carrots, turnips, sugar beets, cotton-seed meal, bran, cocoanut meal, corn meal, low-grade flour feed, and condimental stock feed. The composition of the different sorts of Lathyrus and vetch follows:

Composition of varieties of Lathyrus and vetch.

	Water.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Wild pea from North Bay (*Lathyrus maritimus*)	81.01	4.22	0.24	7.63	5.35	1.55
Grass pea (*Lathyrus sativus*)	87.06	3.03	.11	4.74	3.66	1.40
Wagner's Wood Pea (*Lathyrus sylvestris* var. *Wagneri*)	83.66	4.49	.05	5.05	5.60	1.15
Purple-tufted vetch (*Vicia cracca*)	74.91	5.49	.12	10.20	7.20	2.08

Wheat and molasses in the feeding of farm animals, L. MARTIN (*Jour. Soc. Agr. Brabant-Hainaut, 1900, pp. 699, 700*).—A discussion of the subject.

Feeding stuff inspection, C. D. Woods and J. M. Bartlett (*Maine Sta. Bul. 71, pp. 25–40*).—In accordance with the State law, the protein and fat were determined in a large number of samples (collected in December, 1900) of cotton-seed meal, gluten meal, gluten feed, oil meal, cereal food by-products, and mixed feeds.

Fattening steers of different types on clover, with and without grain, R. S. Shaw (*Montana Sta. Bul. 27, pp. 3–10*).—To learn whether local farm products can be profitably used in finishing range steers for market, to what extent it is profitable to use grain with clover in a fattening ration, and to compare the relative values of typical beef animals as meat producers with those of the dairy type, a test was made with 16 steers showing Shorthorn, Hereford, Angus, Jersey, and Holstein blood. The steers were so divided that lot 2 contained 6 animals of good beef type, showing only Shorthorn and Hereford blood; lot 3 contained 5 animals of the dairy type, showing a mixture of Jersey, Holstein, Angus, and native blood, while lot 1 contained the 5 animals remaining after the others were selected. Lot 1 was fed clover only, while lots 2 and 3 were fed clover and barley. The steers weighed not far from 1,200 lbs. each at the beginning of the test, which covered 71 days. The average daily gain in the three lots was 1.73, 2.55, and 2.1 lbs. per head respectively; the cost of food per pound of gain being 6.12, 4.84, and 5.56 cents. The steers in lot 1 consumed on an average 35.3 lbs. of clover per head per day; those in lot 2, 25.5 lbs. clover and 7.9 lbs. barley; and those in lot 3, 21.6 lbs. clover and 8.6 lbs. barley. The net profits on feeding the three lots were $20.78, $33.71, and $23.44, respectively.

The steers were provided with temporary sheds and in the author's opinion this form of shelter is satisfactory. Some of the other conclusions follow:

"In our Montana valleys, where clover or alfalfa can be grown, these crops can be profitably used in the production of beef in a finished form. And the quality of these foods is such, owing to favorable conditions for the curing and storing of the hays, that only a comparatively small amount of grain is needed along with them to secure the best results.

"Barley can be profitably used in conjunction with clover and alfalfa under our State conditions. Only small quantities of grain are necessary to give maximum results. The quantity need not exceed three-quarters of a pound of grain per day for each hundred pounds of live weight. Any excess above this amount will not give a proportionately greater gain and will materially increase the cost of production. . . .

"In selecting steers to feed it is essential that only those of the beef type be used."

Steer experiments, J. H. Grisdale (*Canada Expt. Farms Rpts. 1900, pp. 73–79*).—The gains made by 3 lots of 9 steers each were studied. Lots 1 and 2 were dehorned; lot 1 was tied and lot 2 was loose. The steers in lot 3 were not dehorned, but were tied. All the steers weighed about 960 lbs. each at the beginning of the test. They were feed roots, silage, straw, and grain. In 184 days the average daily gain per steer in the 3 lots was 1.36, 1.30, and 1.49 lbs. respectively, the cost per pound of gain being 5.9, 6.5, and 6.2 cts. respectively.

The comparative gains made by yearlings, two-year-olds, and three-year-olds were tested with 2 lots of 9 animals each. Both lots were fed roots, silage, straw, and grain, the test covering some 6 months. The yearlings averaged a daily gain of 1.11 lbs., at a cost of 5 cts. per lb. Corresponding values for the two-year-olds were 1.49 lbs. and 6.2 cts., and for the three-year-olds, 1.53 lbs. and 6.8 cts.

A limited ration and a full fattening ration were compared with 2 lots of 5 steer calves each. The limited ration consisted principally of skim milk, oats, shorts, silage, and hay; the full ration, of skim milk, oats and corn, oil meal, bran, silage, and hay. In the 28 weeks of the test the average daily gain per steer on the former ration was 1.31 lbs., at a cost of 2.35 cts. per lb., and on the latter, 1.44 lbs., at a cost of 2.32 cts. per pound.

Steer feeding—dehorning, R. Robertson, S. A. Bedford, and A. Mackay (*Canada Expt. Farms Rpts. 1900, pp. 303–308, 363–365, and 428–430*).—At the Experimental Farm for the Maritime Provinces the advantages of dehorning steers were tested with 12 steers. The steers were fed loose and tied in stalls. The principal deductions follow: "Dehorning reduced the weight of a 1,200 pound steer about 50 pounds. It required about two weeks' feeding to regain the weight lost. . . . Dehorning is of no advantage when steers are tied up in stalls, except for the comfort it gives to those caring for them. The feeding of dehorned steers in a loose box is an advantage (1) in increased gain in flesh; (2) less cost for labor in attending them; (3) manure better made, requiring about 50 per cent more straw to keep them clean, which may be an advantage or a disadvantage, according to the situation and opinion of the feeder."

The comparative merits of a medium and a heavy ration were tested with 2 lots of steers. According to the author, "there did not appear to be any gain in flesh from extra feeding," while the heavier ration was the more expensive.

The effects of dehorning cattle were tested at the Brandon Experimental Farm with 3 lots of 5 steers each. In 133 days the dehorned steers tied in stalls gained 950 lbs.; those not tied gained 964 lbs. In the same time 5 steers which had not been dehorned gained 968 lbs. "The experiment, as a test of dehorning, was a very successful one, and would lead us to the conclusion that dehorning has very little effect on the animal either one way or the other."

At the Indian Head Experimental Farm a dehorning experiment was made with 3 lots of 5 animals each, all weighing about 1,200 lbs. at the beginning of the trial. They were fed a mixed ration for 16 weeks. The average gains follow: Steers, dehorned, tied in stalls, 281 lbs.; dehorned, not tied, 235 lbs.; not dehorned, tied in stalls, 234 lbs.

Fattening lambs on clover, with and without grain, R. S. Shaw (*Montana Sta. Bul. 27, pp. 11–22*).—The value of grain supplementing clover in feeding lambs for market was studied with 60 lambs divided into 3 equal lots. After a preliminary period lot 1 was fed on clover and damaged wheat, lot 2 on clover only, and lot 3 on clover and oats. Lots 1 and 3 were also given some roots. The lambs weighed about 77 lbs. at the beginning of the test, which lasted 90 days. The average daily gain of the three lots was 0.32, 0.27, and 0.35 lb. per head, respectively, the average cost per pound of gain being 3.22, 3.54, and 4.39 cents. The lambs in lot 1 consumed 6.38 lbs. of clover and 2.8 lbs. of wheat per pound of gain; those in lot 2 consumed 11.8 lbs. of clover, while in lot 3 the amounts eaten were 6.10 lbs. clover and 2.65 lbs. oats. The net profit per head for the 3 lots was 96, 82, and 62 cents, respectively.

The results obtained in feeding 20 Shropshire lambs were compared with those obtained under similar conditions in a previous test (E. S. R., 12, p. 72) with 16 Merino grade lambs, the former being of the mutton type and the latter of the wool type. The Shropshires in 10 months gained 10.58 lbs., consuming 6.10 lbs. of clover and 2.64 lbs. of grain per pound of gain, while the Merinos in the same time gained 8.97 lbs., consuming 6.43 lbs. of clover and 2.64 lbs. of grain. The cost of food per pound of gain in the two lots was 4.39 and 4.62 cts., respectively. Some of the author's conclusions follow:

"The less expensive grains can be profitably used along with clover in mutton production. They will increase the gains and improve the quality. Grains at a high price . . . render the cost of feeding too high unless used in very small amounts."

Sheep-feeding experiments at Mains of Airleywight, A. P. Aitken (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13 (1901), pp. 176–205*).—The author reports work undertaken by W. Hutcheson to supplement previous experiments (E. S. R., 12, p. 173) regarding the comparative value of common feeding stuffs for sheep. The test was begun with 7 lots of 20 sheep each. All the lots except number 7 were fed a basal ration of turnips and hay. In addition lots 2 to 6 were given, respectively, undecorticated cotton-seed cake, undecorticated cotton-seed cake and crushed maize, crushed maize, dried distillery grains, and linseed cake. Lot 7 was fed turnips and linseed cake but no hay. In 105 days of the test the average gain in lot 1 was 22.1 lbs., in the other lots the gains ranged from 34.8 lbs. with lot 4 to 39.0 lbs. with lot 5. The general deductions were summarized as follows:

"It pays to give sheep some by-fodder along with turnips and hay, but with good feeding turnips the profit is not great.

"The giving of a by-fodder shortens the time of fattening and increases the weight of the mutton (in this instance by 5 lbs. or so), but this additional weight is probably got at the sacrifice of flavor.

"Sheep fatten sooner upon turnips and linseed-cake than they do when hay is given in addition, and it does not seem that the addition of hay is attended with profit. In this instance it caused a loss of 82 cts. per head at least.

"A mixture of undecorticated cotton-cake and maize is better than the cake alone, and it is probable that a mixture of feeding-stuffs or a change of feeding-stuff as fattening proceeds is preferable to strict adherence to any one kind of by-fodder.

"Dried distillery grains has produced the best quality of mutton, but the advantage it possesses over other kinds of by-fodder is not so apparent in this as on former occasions. This is probably due to the inferior quality of the grains used."

Sheep, J. H. Grisdale and R. Robertson (*Canada Expt. Farms Rpts. 1900, pp. 81, 82, 310*).—Statements are made concerning the flocks at the Central Experimental Farm and the Nappan Experimental Farm; and the care and management of breeding ewes is discussed.

Experiments in pork production, L. Foster and L. A. Merrill (*Utah Sta. Bul. 70, pp. 343–414, figs. 7*).—Tests covering several years are reported on summer feeding and winter feeding. In the former the value of mixed pasturage, alfalfa pasturage, and the effects of exercise were the principal questions studied. The tests on winter feeding were made with special reference to the value of roots and alfalfa hay. The comparative value of spayed vs. unspayed sows and of sows vs. barrows was studied, and on the basis of the investigations as a whole a number of general questions are discussed, including the effects of feeding balanced rations, wet, dry, and soaked grain, the comparative value of different grains, grain vs. grain and skim milk, and whole milk and grain.

Summer feeding (pp. 348–384).—The feeding experiments conducted in the summer extended from 1897 to 1899, and were made with a total of 31 lots. Some of the lots were pastured (generally on mixed grasses and clover); some were fed in pens and others in yards. The rations fed consisted of skim milk or whey, grain and alfalfa, alone or in combination. The lots fed in pens and yards had less exercise than those fed in pasture, and this point is discussed in connection with the tests. Special tests were also made of the comparative value of mixed pasturage (grasses and clover) and alfalfa pasturage, and of feeding grain after pasturage.

Winter feeding (pp. 385–408).—The winter-feeding tests began in 1894 and continued until 1899, some 34 lots being included. Some of the earlier ones were conducted by A. A. Mills. In part of the tests a number of the pigs were fed in pens; others in yards. Wet and dry rations were studied as well as the comparative value of sugar beets and alfalfa, supplemented by grain. Generally speaking, the rations consisted of skim milk, whey, and mixed grasses in different proportions, alone or with alfalfa or beets. The principal deductions drawn from the summer and winter feeding tests follow:

"In pork production economic use may be made of pasture in connection with a full-grain ration. This is shown not only by the average results of all the experiments conducted, but also by every point of comparison in each separate test. The average shows the gains of the pasture sets to be 33 per cent the higher and to have been made on 10 per cent less grain.

"The average results of four seasons' experiments show quite conclusively that mixed pasture is not beneficial to pigs having a full supply of grain and skim milk.

"The average of the 7 trials, made in both pens and yards, gives results favorable to grass feeding in connection with grain rations. The pen sets having green stuff made 33 per cent greater gains than those without, and required 40 pounds less grain for each 100 pounds of gain.

"Pasture with grain rations, averaging all the experiments, gave slightly better results than green stuff cut and fed in connection with grain in pens and yards. Where lands are cheap and labor comparatively dear, it seems advisable to follow the pasture method.

"Pigs running on pasture with partial grain rations produced gains at the least cost per hundred pounds, the quantities of food required standing in the following relation: Full grain ration 100, three-fourths 94, one-half 82, and one-fourth 66. But the total gains of those receiving full-grain rations were so much greater that even with the smaller rate of profit the total net gain per pig very much exceeded that of the partial ration.

"In the quantity of grain required for 100 lbs. of gain the sets having a one-fourth grain ration excelled in every test requiring the lowest amount and giving the highest percentage of profit.

"In rate of gain the sets receiving a full grain ration were the best in all cases, making the largest total gain and giving decidedly the highest total profit.

"Alfalfa without other food, whether pastured by pigs or cut and fed to them in pens, furnished only enough nutriment for bare maintenance. When additional food was given the rates of gain were nearly proportional to the extra quantities they received.

"Alfalfa supplies a good supplementary food in connection with bran and grain, but it is too coarse and bulky to be fed alone to the pig, whose digestive tract is especially adapted to concentrates. Alfalfa hay and sugar beets each give profitable returns in connection with a limited grain ration in winter feeding.

"In 2 out of 3 experiments better results were obtained by feeding bran and corn meal or ground wheat dry than wet. The average of the 3 tests gives a result slightly favorable to the dry food in rate of gain, but favorable to the wet in the amount of food required for 100 lbs. gain."

Miscellaneous tests (pp. 408–412).—The value of rape for fall feeding was tested with 6 pigs weighing about 50 lbs. each. They were fed in a movable pen for 49 days and given daily 1 lb. of bran and chopped wheat, 1:1, per head, in addition to the rape. The average daily gain per head was 0.204 lb.

In one of the winter feeding tests part of the animals were barrows; the remainder sows. According to the authors the comparison "does not show a marked difference in gains, no more than might easily result from the variation of the pigs selected. Representing the average daily gains of the sows by 100, the barrows stand 95. The above results show but little difference in the feeding qualities of barrows and unspayed sows."

Gains made by spayed and unspayed sows were compared with 2 lots of 3 animals each. The spayed sows weighed 142 and the unspayed 178 lbs. at the beginning of the trial, which covered 116 days. They were fed barley, bran, potatoes, milk, and whey. The average daily gain per head of the spayed sows was 0.82 lb. and of the unspayed, 0.86 lb.

"In the several tests reported the feeding qualities of unspayed sows were found to be fully equal to or slightly better than those of barrows.

"In a single test with spayed and unspayed sows, the results were slightly favorable to the open sows."

Feeding pigs on grain alone, grain and sugar beets, and grain and alfalfa, R. S. Shaw (*Montana Sta. Bul. 27, pp. 23–32*).—A test was made with 3 lots of 7 pigs each. During the first period (40 days) of the test lot 1 was given damaged wheat and oats 2:1, and during the second period (26 days) barley and oats 2:1. Lot 2 was fed smaller amounts of the same grain mixture and sugar beets in addition, while lot 3 was fed the same grain mixture with alfalfa hay. The pigs weighed on an average 112 lbs. each at the beginning of the trial. The average daily gain per head of the three lots while on the wheat ration was 1.04, 1.06, and 1.00 lbs., respectively, while on the barley ration the corresponding gain was 1.46, 1.50, and 1.49 lbs. Considering the test as a whole, the pigs in lot 1 required 5.32 lbs. of grain per pound of gain, while those in lots 2 and 3 required 4.26 and 4.86 lbs., respectively. On lot 1 there was a net profit of $1.80 per head; on lot 2, of $2.28; and on lot 3, of $1.87. Some of the author's conclusions follow:

"A straight grain ration, though it produces a rapid gain, is the most expensive method of feeding. Damaged grain can not be utilized to better advantage than when converted into pork. Grains seldom reach a market price in Montana at which they can not be marketed to equal advantage in the form of pork.

"Sugar beets are a valuable adjunct to use along with grain foods for fattening hogs. While the small percentage of [nutritive material] contained in them is of value, the beneficial effects produced on digestion and the assimilation of other foods is very marked. The figures indicate that by their use a saving of grain is effected, and the quality of the meat improved.

"Alfalfa as a food adjunct for fattening hogs is valuable. While it should not be forced into a ration, cut and mixed with meal in such large quantity as to render it bulky, small quantities can be used to good advantage in this way, or supplied whole in racks. It lessens the cost of production, aids in keeping the animals in a good thrifty condition, and improves the quality of the meat produced. We have not found its use equal to sugar beets or mangels."

Molasses and maize germ molasses; feeding experiments with pigs, M. Gerlach (*Jahresber. Landw. Vers. Stat., Jersitz.-bei-Posen, 1898–99; abs. in Centbl. Agr. Chem., 30 (1901), No. 2, p. 104*).—The pigs fed maize germ and molasses made better gains than those fed meal.

Pigs, J. H. Grisdale (*Canada Expt. Farms Rpts. 1900, pp. 79–81*).—Statements are made concerning the cost of gain by pigs pastured on clover, fed steamed clover, mangels and skim milk in addition to grain, and also by 3 lots fed grain alone. One of these was fed three times a day; another was fed with a self-feeder. The cost of a pound of gain ranged from 4.2 cts. on clover pasturage and grain to 2.24 cts. on skim milk and grain.

Swine, R. Robertson (*Canada Expt. Farms Rpts. 1900, pp. 308–310*).—In addition to statistics regarding pigs kept at the Experimental Farm for the Maritime Provinces 2 tests are briefly reported. A lot of 16 pigs was pastured on good clover for 90 days and fed shorts, corn meal, and skim milk in addition. Eight similar pigs were fed in pens the same grain ration. All the pigs were then fed corn meal and skim milk for 90 days. The pigs fed part of the time on pasture made much larger gains than those fed in pens.

Buckwheat, shorts, corn meal, and crushed oats (2:1) and pea meal and crushed oats (2:1) were compared with 4 lots of 4 pigs each, skim milk being fed in addition to the grain. The average daily gain of the 4 lots was 95.14, 94.45, 94.45, and 95.32 lbs., respectively.

Swine, S. A. Bradford and A. Mackay (*Canada Expt. Farms Rpts. 1900, pp. 366–367, 430*).—Notes on the pigs at the Brandon and Indian Head Experimental Farms.

Pumpkins, J. H. Grisdale (*Canada Expt. Farms Rpts. 1900, pp. 93, 94*).—A feeding experiment with pigs is reported. "One lot fed on raw pumpkins did fairly well, making a gain of 745 lbs. in 107 days, at a cost of $3.08 per 100 lbs. gain. They ate 2,090 lbs. pumpkins and 1,981 lbs. meal half corn, half oats, peas and barley equal parts.

"Another lot of 6 pigs, fed on cooked pumpkins, did exceedingly well, making 706 lbs. increase in 99 days, at a cost of $2.96 per 100 lbs. gain. They ate 7,500 lbs. pumpkins and 1,602 lbs. meal."

The Jerusalem artichoke (*Helianthus tuberosus*), J. H. GRISDALE (*Canada Expt. Farms Rpts. 1900, pp. 94, 95*).—Six cross-bred pigs were allowed the run of a field of artichokes 10 sq. rods in extent, from October 3 to October 24. They were fed 1½ lbs. of mixed grain per day each in addition to the artichokes, which they gathered. These were eaten greedily. The average daily gain was 1.57 lbs. at a cost of 1.8 cts. per lb.

Rape (*Brassica napus*), J. H. GRISDALE (*Canada Expt. Farms Rpts. 1900, pp. 91–93*).—A test of the value of rape for pigs is briefly reported. Six pigs pastured on a plat of 30 sq. rods of rape for 114 days and fed grain in addition made an average daily gain of 1.12 lbs. per pig. The profit per pig was $4.73.

The market classes of horses, E. DAVENPORT (*Illinois Sta. Bul. 62, pp. 18–28, fig. 1*).—Road, carriage and coach, cab, bus, and draft horses and trotters are described, and their uses pointed out. The fact is noted that aside from these standard classes, horses are required for special purposes. The discussion is summarized as follows:

"Market classes and types are fixed not by the breeds but by the uses to which horses are put. As these uses are definite, the type and the class are fixed.

"As these uses are exceedingly varied, there are often wide gaps between the market classes. A horse that drops between the classes is a cheap horse, no matter how good an animal, either because there is little use for him or because the supply is unlimited. The best horse to breed is one that most fully meets a definite, constant, and strong demand, and has therefore a high average selling price.

"The cavalry horse and the fire horse are good examples of valuable horses that the breeder can not undertake to produce because the demand is too limited. The demand for them will always be satisfied from the general supply. Phenomenally high prices are as much due to the fancy of the individual purchaser as to the character of the animal. In any event they are seldom realized and are to be sought by the dealer and not by the breeder, as they represent but one out of hundreds or even thousands—too few to breed for.

"The farmer should keep himself acquainted with standard classes in steady demand at uniformly good prices, breed these, and pay no regard to high speed, phenomenal sales, or fancy values."

Horses, J. H. GRISDALE (*Canada Expt. Farms Rpts. 1900, pp. 67–69*).—Statements are made concerning the horses at the Ottawa Experimental Farm, and the gains or losses in weight are recorded for several horses on oats and barley, corn and oats, ground and unground, and on corn alone.

Horses, A. MACKAY (*Canada Expt. Farms Rpts. 1900, p. 431*).—A note on the horses at the Indian Head Experimental Farm.

French stud farm "Le Hara du Pin" (*Orgaan Ver. Oudleer. Rijks Landbouwschool, 13 (1901), No. 154, p. 86*).—A descriptive article.

Concerning the metabolism of horses, N. ZUNTZ (*Landw. Vers. Stat., 55 (1901), No. 1–2, pp. 117–128*).—A controversial article.

Experimental contributions to the theory of heredity, J. C. EWART (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13 (1901), pp. 81–134, figs. 20*).—The author reports and discusses his investigations in crossing zebras and horses with especial reference to reversion and telegony (E. S. R., 11, p. 1077).

Poultry raising, H. C. GARDINER (*Montana Sta. Bul. 26, pp. 28, pls. 4, dgms. 2*).—The station poultry equipment is described and general statements made concerning breeds, incubation, buildings, brooders, and similar topics, while a test on the value of the flashing point of several samples of oil used for heating incubators is reported.

To compare the relative merits of a lime and salt solution and a solution of water glass for preserving eggs, some 30 doz. eggs were preserved by the 2 methods for about 6 months. According to the author, "when examined the water glass was found to be the best pickle, although the lime and salt served its purpose very well; still the whites of the eggs preserved in this mixture were much more watery than the whites of those preserved in the water glass. These were difficult to distinguish from fresh eggs since the white was quite firm and the yolk stood up upon it just as though fresh. Another advantage in the water glass is that it does not seem to affect the shell of the egg as the lime mixture does, eggs from the lime and salt mixture being much more liable to crack either in cooking or handling."

The comparative value of a rather varied ration (meat, vegetables, and grain), a meat ration (meat, meal, and grain), a vegetable ration (vegetables, meal, and grain), and a ration of grain alone, was tested with 4 lots each containing 15 hens and 1 cock. In 3 months the total number of eggs laid by the 4 lots was 431, 407, 366, and 342, respectively. The fertility of the eggs from different pens was tested with an incubator. Of the eggs laid by the 4 lots, 232, 229, 223, and 239, respectively, were fertile. Definite conclusions are not drawn, but the author believes that "the percentage of fertility and strength of germ depends to considerable extent upon the conditions and feed of breeding birds."

Analyses are reported of the eggs from the different pens, but no marked differences in composition were observed. Other deductions follow:

"Variety rations give best results in feeding for eggs. Poultry feeding is very profitable under present market conditions in Montana. Special care should be given to number of hens placed with cock in securing best results from breeding birds. Feeding breeding birds should be carefully studied, with special care not to overfeed."

Poultry experiments, J. H. Stewart and H. Atwood (*West Virginia Sta. Bul. 71, pp. 385–402, figs. 2*).—The poultry houses recently built at the station are described and several feeding tests reported. The influence of warm houses upon the production of eggs was tested with 2 lots, each containing 12 Rhode Island Red pullets and 1 cock. The lots were fed on a mixed grain ration for 150 days beginning Nov. 24, under similar conditions except that lot 1 was kept in a poultry house in which special precautions were taken to insure warmth. The total number of eggs produced per fowl in warm houses was 52.39; in cold houses, 41.36.

Meat meal was compared with ground fresh meat and bone with 2 lots each containing 17 Plymouth Rock hens and 1 cock. Lot 1 was fed the meat meal and lot 2 the green bone. In this and the other tests reported they were also fed mixed grains. At the beginning of the test all the fowls weighed on an average 4.72 lbs. each; at the close, the 2 lots averaged 5.75 and 5.91 lbs. per fowl, respectively. In 120 days of the test, the hens in the 2 lots laid on an average 38.24 and 32.60 eggs, respectively. The former weighed on an average 12.75 lbs. per hundred eggs; the latter, 11.94 lbs.

In raising broilers, the object is to force them as rapidly as possible. The comparative value for this purpose of rations with wide and narrow nutritive ratios, was tested with 2 lots of 25 chicks each, the breeds represented being White Wyandottes and White Leghorns. Lot 1 was fed the nitrogenous ration and lot 2, the carbonaceous ration, the former being made up of grain, whole and ground, with green bone, and the latter of vegetable foods only, namely, whole and ground grain, including corn, wheat, and oats. The average weight of the chicks in the 2 lots at the beginning of the test was 0.92 and 0.98 lb., respectively. The total gain in 120 days of the test was 3.08 and 1.92 lbs. per chick, the cost of a pound of gain being 6.1 and 6.2 cents, respectively. "Neither ration had the proper composition for economical gains, one being too wide and the other too narrow. The influence of the food upon the health and development of the fowls was, however, very marked. The nitrogenous chickens were vigorous and hearty at all times, while the carbonaceous ones were sickly, poorly feathered, and had very little appetite for their food. A certain amount of animal protein seems to be necessary for poultry, and perhaps the poor development of the carbonaceous lot was caused as much by this factor as by the composition of the ration. Of the two breeds, the White Leghorns seemed to be much better able to thrive on the carbonaceous ration than the White Wyandottes, for they were much better feathered, and more vigorous than the White Wyandottes in the same pen."

The importance of a liberal supply of green food for laying hens was tested with 2 lots of White Leghorns about 5 years old. Each lot contained 20 hens and 2 cocks. The test covered 12 periods of 30 days each. Both lots were fed a mixed ration, largely grain, and the poultry runs furnished some grass. In addition, an abundance of cabbage, rape, and apples was fed to the lots alternately, to do away with the effects of individual peculiarities. During the test the fowls receiving green food consumed a total of 58 lbs. each of ground bone and beef scrap; those receiving no green food, 61 lbs. per fowl. The average weight of the fowls receiving green food was 3.89 lbs.; of those receiving no green food, 3.86 lbs. The total number of eggs produced per fowl on green food was 114.52; on a ration containing no green food, 90.39 per fowl. The eggs on the former ration weighed 11.89 lbs. per hundred; on the latter, 11.88 lbs.

The influence of an unrestricted range upon the hatching of eggs was also tested. Half of the station flock of White Leghorn fowls was allowed to remain undisturbed in the house and yard to which they were accustomed. The remainder of the flock was allowed to run at large. Both lots were fed the same ration. The eggs were tested in incubators; 80.5 per cent of those from poultry having free range and 24.4 per cent from those confined were unfertile. Of the fertile eggs, 83 per cent hatched in the former and 67.5 per cent in the latter case.

Poultry experiments, J. H. Stewart and H. Atwood (*West Virginia Sta. Bul. 73, pp. 35–47*).—Three tests on the loss of eggs during incubation are reported. The authors summarize the results as follows:

"Fertile eggs, when incubated in a normal manner, decrease in weight. The eggs which hatched lost 4.17 per cent of their weight during the first 5 days of incubation. During the 7 succeeding days they lost 6.35 per cent of the weight of the eggs at the end of the fifth day, and during the next 7 days lost 6.98 per cent of their weight at the end of the twelfth day. One hundred fertile eggs of average size will lose 234.9 gm., or 8.28 oz., during the first 5 days of incubation; 341.8 gm., or 12.05 oz., during the next 7 days; and 352.8 gm., or 12.44 oz., during the next 7 days.

"The unfertile eggs lost 3.6 per cent of their original weight during the first 5 days of incubation. During the 7 succeeding days they lost 5.6 per cent of what they weighed at the end of the fifth day, and during the next 7 days lost 5.6 per cent of their weight on the twelfth day. One hundred unfertile eggs will lose 217.2 gm., or 7.66 oz., during the first 5 days; 323.3 gm., or 11.40 oz., during the next 7 days; 306.9 gm., or 10.82 oz., during the next 7 days."

Report of the poultry manager, A. G. Gilbert (*Canada Expt. Farms Rpts. 1900, pp. 251–277, pls. 2, figs. 10*).—The usual data are given regarding the poultry kept at the Ottawa Station, the growth of chickens, number of eggs laid, and similar topics. General directions are also given for the management of chickens, turkeys, ducks, and geese, and the characteristics of a number of breeds of chickens are discussed. A comparison of the number of eggs hatched by hens and in incubators led to the following conclusions:

"Early spring eggs from hens which have laid steadily all winter and have been gently stimulated to do so, are not likely to produce a satisfactory percentage of strong germs. Eggs from the same hens after they have run outside give much better results. The condition of the laying stock at the end of the winter seems to be the source of the trouble."

The relative merits of a number of methods of preserving eggs were tested, including immersion in saturated limewater, in a solution containing 2 per cent sodium silicate, in a solution containing 5 per cent gum arabic and 1 per cent formalin, in one containing 5 per cent gum arabic and 5 per cent salicylic acid, and in one containing 5 per cent dextrin and 5 per cent salicylic acid. Eggs were also dipped for a moment in sulphuric acid, then washed and stored in a large bottle; others were dipped momentarily in sulphuric acid, washed and dipped in alkaline ammonium oxalate, then stored in a large bottle. Some of the eggs stored in limewater were first rubbed with vaseline.

"These experiments corroborate many of the results obtained last year, and give further proof of the excellence of the eggs preserved in saturated limewater. We think that, on the whole, 2 per cent sodium silicate gives better results than the 10 per cent solution experimented with last year, but we are also of the opinion that limewater is superior to both as an egg preservative. Moreover, it is cheaper and pleasanter to handle."

The eggs preserved in a solution containing 1 per cent formalin developed a marked flavor on poaching; a sample of those in the solution containing 5 per cent gum arabic and 5 per cent salicylic acid, "though not unsightly, had a most nauseating odor and was quite unfit for food." The eggs preserved in dextrin solution and those dipped in sulphuric acid were all bad.

Poultry, 1899–1900, R. Robertson, S. A. Bedford, and A. Mackay (*Canada Expt. Farms Rpts. 1900, pp. 311 and 368*).—A brief report regarding the poultry kept at the Maritime Provinces, Brandon, and Indian Head Experimental Farms.

Squab raising, G. H. Pollard (*Reliable Poultry Jour., 8 (1901), No. 4, pp. 396–399, figs. 6*).—Squab raising for market is discussed with special reference to feeding and care, preparation for market, cost of raising and related topics.

DAIRY FARMING—DAIRYING.

The development of a dairy herd, A. T. Neale (*Delaware Sta. Rpt. 1900, pp. 8–13*).—Brief notes are given on the establishment of a dairy herd at the station, and an experiment in which the utilization of weevil-eaten cowpeas for calves was tested and a trial of different rations for milch cows are reported. Feeding weevil-eaten cowpeas to 12 heifers as a substitute for wheat bran at the same price per ton resulted in a saving of $7.20 per month. A table shows the daily yield of butter from each of 3 cows at intervals from March 7 to July 30, during which time 9 rations, including different kinds of pasture, were compared. The results are briefly discussed.

Dairy studies, C. L. Penny (*Delaware Sta. Rpt. 1900, pp. 93–96*).—A comparison in tabular form is made of the records of 13 cows belonging to a private herd during 2 lactation periods. The annual amount of fluctuation in yield of fat ranged from 102 to 259 per cent and averaged 137 per cent. "Thus it seems from this experience that the average annual yield of butter fat may be expected to change about three-tenths of itself from one period of lactation to the next, and any conclusion drawn from a single year's test must be received with the reservation that it will probably increase or diminish in the following year in that proportion and possibly in a greater proportion." The production of the herd averaged 7,087 lbs. of milk and 354 lbs. of butter during the first lactation period, and 6,874 lbs. of milk and 322 lbs. of butter during the second.

In discussing briefly compensation in yield the author says: "When one entire lactation period is compared with another, in the great majority of cases even partial compensation between weight of milk and percentage of fat does not exist. Whatever cause may tend to increase the average flow of milk through a lactation period, in the great majority of cases increases also the percentage of fat." Earlier work along this line was published in the report of the station for 1898 (E. S. R., 11, p. 485).

Dairy herd records, J. H. Grisdale and R. Robertson (*Canada Expt. Farms Rpts. 1900, pp. 69–71, 302, 303*).—Records for one year of 20 cows at the Central Experimental Farm and of 32 cows at the Experimental Farm for the Maritime Provinces are summarized in tabular form.

Dairy Bulletin (*Ontario Agr. Col. and Expt. Farm Bul. 114, pp. 40*).—This is made up of introductory remarks by H. H. Dean on the feeding and care of dairy cows and on the payment for milk at factories, and short popular articles as follows: Hints on the care of milk for creameries and cheese factories, by R. W. Stratton; Cheese-making, by G. H. Barr; Milk testing, by J. A. McFeeters; The alkaline solution—its preparation and use, by R. Harcourt; Separators and the separation of milk, by M. Sprague; Butter making, by J. Stonehouse; Hand cream separators, by T. A. Wiancko; and Butter making on the farm, by Laura Rose.

Jerseys: Some notes on their origin, improvement, merits, and local history, A. Gorrie (*Queensland Agr. Jour., 8 (1901), No. 5, pp. 348–351, figs. 4*).—A popular article relating more especially to the history of the Jersey cattle in Queensland, Australia.

The red Danish milch cattle, Bohsen (*Milch Ztg., 30 (1901), No. 22, pp. 338–342, figs. 7*).

Alfalfa for dairymen, G. F. Weston (*Hoard's Dairyman, 32 (1901), No. 19, pp. 410, 411*).—A popular article on the history of alfalfa, method of culture and value as a food for dairy cattle. This paper was prepared at Biltmore Farm, North Carolina, and considers especially the conditions in that section.

Alcohol in spent distillery wash used as a food for cows, G. Heinzelmann (*Ztschr. Spiritusind., 24 (1901), pp. 107, 108; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 5, p. 491*).—The author states that milk and butter from cows fed on spent wash from a distillery had an objectionable potato-like or alcoholic odor. The trouble was found to be due to the presence of from 0.2 to 2.8 per cent of alcohol left in the wash by reason of defective distillation.

Milking, J. Petersen (*Agr. Jour. Cape Good Hope, 18 (1901), No. 8, pp. 472–477*).—A prize-winning essay on How to milk, composed at the Dalum Agricultural College, Odense, Denmark. Translation by A. Muller.

Time of milking, J. H. Grisdale (*Canada Expt. Farms Rpts. 1900, pp. 71–73*).—Tabulated data are given for an experiment in which the effect of milking cows at equal and unequal intervals was studied. The test included 4 cows and covered 3 periods of 10 days each with short transition periods. During the first and third periods the cows were milked at 6 a. m. and 4.30 p. m., and during the second period at 6 a. m. and 6 p. m. The results showed that where the intervals between milkings were unequal the richer milk was produced after the shorter interval, and that where the intervals between milkings were equal there was no appreciable difference in either the quantity or the quality of the milk, morning and evening.

Progress of dairying in Kansas, D. H. Otis (*Creamery Jour., 11 (1901), No. 142, pp. 6, 7*).—A description of the growth and present status of the dairy industry in Kansas. Some statistical matter is incorporated.

Denmark's dairy progress, M. Mortensen (*Creamery Jour., 11 (1901), No. 140, pp. 20, 21, figs. 3.*)—Short biographies of T. R. Segelcke, V. Storch, and N. J. Fjord, and their great work in establishing the dairy industry of Denmark.

Solids in cow's milk. The diurnal variations in the amounts of fat and solids-not-fat, H. Ingle (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13 (1901), pp. 218–236*).—The results are presented of 700 or 800 analyses of the milk of 18 cows, extending over a period of 21 days, each cow's milk being collected and analyzed separately morning and evening. The cows were milked at their usual time, 6 a. m. and 3 p. m., showing very unequal intervals between the milkings. In some cases the amount of fat was below 2 per cent, while in others ranging above 6 per cent, one case of 7 per cent being noted. Samples from certain animals contained less than 2 or 3 per cent, and within a few days they contained 5 or 6 per cent. The milk from cows near the end of the lactation period showed the least variation from day to day, and was, as a rule, of higher quality than that from cows yielding a large amount. The difference between the morning's and evening's milk was mostly in the percentage of fat, the remainder of the solids showing little variation. A cow yielding large quantities of milk gave a product lower in solids-not-fat than those near the end of lactation. The average composition of the morning's milk was fat 3.2 per cent, solids-not-fat 9.2 per cent; evening's milk, fat 4.5 per cent, solids-not-fat, 8.9 per cent.

Variation in milk tests, F. W. BOUSKA (*Hoard's Dairyman, 32 (1901), No. 24, pp. 512, 513*).—A discussion of the causes of the changes in the milk tests with the same animal from day to day.

Variations in milk tests, T. L. HAECKER (*Hoard's Dairyman, 32 (1901), No. 22, pp. 470, 471*).—An address before the Lincoln, Nebr., convention, outlining results at the Minnesota Experiment Station.

The physical state in which fat exists in cream, H. D. and S. O. RICHMOND (*Analyst, 26 (1901), No. 302, pp. 117–123*).—It was found that there was a distinct change in the density of cream at about the melting point of fat, while no such change was observed with separated milk. This led the authors to study the question whether fat in milk was always liquid, as it was expected that owing to the different heat capacities of solid and liquid fat, there would be a change in the rate of heating at the melting point of the fat. The plan adopted in studying this question was to heat 20 cc. of cream in a tube with a stirrer bearing a thermometer reading to 0.1° C., the readings being made every 15 seconds. The estimations were made with cream that had been kept in the refrigerator 18 hours, and with cream that had been heated to 50° C. and rapidly cooled down to 15°. The results are given in tables and also platted. With well cooled cream it appears that there was a change in the specific heat capacity, and a slight though distinct absorption of heat at about 34°. With heated cream rapidly cooled, a very slight change occurred at this point. The only possible change that could produce these results is the melting of the fat. The authors conclude that in well cooled cream the fat is solid, while with rapidly cooled cream it is mostly liquid, though there is a distinct indication that it had become slightly solidified in a quarter of an hour. The melting is practically instantaneous.

Detection and estimation of preservatives in milk, M. W. BLYTH (*Analyst, 26 (1901), No. 303, pp. 148–151*).—The author proposes a method for detecting preservatives in milk which permits the examination of a large number of samples in a short time. Ten cc. of the suspected milk and of a control sample known to be free from preservatives are measured into test tubes. To each there is added a strong, slightly alkaline solution of litmus. If the tubes are not of the same color, a half normal solution of sodium hydrate is added drop by drop to the suspected sample until it is of the same color as the check. The tubes are then plugged with cotton, and both heated in the water bath for 10 min. at 80° C. They are afterwards inoculated with ½ cc. of a solution of ½ cc. of sour milk in 100 cc. of water, shaken, and kept 24 hours at a temperature between 15 and 22° C. Tubes containing preservatives will remain blue or pink, while those without will become white in the same way as the check. The length of time it takes for the blue or pink color to become white depends upon the quantity of the preservative present. Having found the samples which contain preservatives, the nature of them must be determined by the ordinary methods.

This method is also recommended for the determination of the amount of formic aldehyde in the sample. A series of samples is made up with known amounts of this preservative, and the quantity in the sample under investigation is estimated by comparison.

Pasteurization and milk preservation, with a chapter on the city milk supply, J. H. Monrad (*Winnetka, Ill.: Pub. by the author [1901], 2 ed. enl., pp. 137, figs. 124.*

Report of the committee on milk and cream regulations to the Board of Agriculture of Great Britain (*Public Health, 13 (1901), No. 8, pp. 580–587*).—The committee was appointed to inquire and report as to what regulations might be made for determining the deficiency in the normal constituents of milk and cream or the addition of extraneous matter which should be taken as an indication of adulteration. The effect of feeding, weather, period of lactation, intervals of milking, etc., are discussed. Among other considerations it is reported to be the sense of the committee that when the total milk solids are less than 12 per cent and the butter fat less than 3.25 per cent, the milk shall be deemed to be deficient and either mixed with separated milk, or water, or some portion of its normal fat removed.

The acid proof micro-organisms of dairy products, E. Schütz (*Landw. Jahrb., 30 (1901), No. 1–2, pp. 223–257, figs. 4*).—The author has made a study of tubercle and similar bacilli in milk and butter and presents a table for identifying the several species discussed. The literature of the subject is reviewed and a bibliography appended.

Milk for creameries, J. A. Ruddick (*Ontario Dept. Agr., Dairy Division Bul. 3, n. ser., 1901, pp. 7*).—Directions for the creamery owners, the butter maker and the patrons on the handling of milk for creameries.

American butter in Hawaii, J. D. Avery, jr. (*Creamery Jour., 11 (1901), No. 140, pp. 1, 2*).—A discussion of the production and trade in butter and eggs in the Territory of Hawaii.

The composition of Dutch butter, J. Clark (*Analyst, 26 (1901), No. 302, pp. 113–117*).—The author made a large number of analyses of butter from the North of the Netherlands, employing the Leffmann-Beam method. From the results, he finds the average volatile acid content to be 5.17 per cent. In 7 samples this fell below 4.5 per cent. In several of the latter cases the author was able to prove the genuineness of the butter. The low volatile acid content was not due to adulteration of the butter, but to natural causes which seemed to appear mainly from about the middle of September to the middle of November. This is said to be due to the exposure of the cattle and indifferent feeding.

Low Reichert-Meissl value of Dutch butter L. T. Reicher (*Ztschr. Angew. Chem., 14 (1901) No. 6, pp. 125–129*).—The author made extended investigations in the Amsterdam public laboratory of butter from the same cows from 1894 to 1901. The maximum and minimum results for each year are given in tables. The numbers are frequently very low, those in the autumn being invariably less than those obtained during the rest of the year.

The influence of the food and weather upon the Reichert-Meissl number of Holland butter, A. J. Swaving (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 13, pp. 577–585*).—The experiment was carried out at the Experiment Station at Goes, Netherlands, with 8 cows. The age of the animal, time of calving, food, manner of feeding, etc., were noted. The refractometer, Reichert-Meissl, Hehner, Hübl, and Crismer numbers were determined, together with the specific gravity of the butters.

It was found that late pasturing, because of the nature of the food, lowered the Reichert-Meissl number and increased the Crismer number of the butter fat. The early stabling of the cows raised the Reichert-Meissl number, while the Crismer number did not exceed the limit of 57°. The alteration in the feeding caused directly a change in the composition of the fat, resulting in the lowering of the Reichert-Meissl number and the increasing of the refractometer, the Crismer number, etc. It would appear that late pasturing causes no particular lowering of the Reichert-Meissl number provided forage crops were fed in conjunction.

Faults in creamery butter, G. L. McKay (*Creamery Jour., 11 (1901), No. 140, p. 18*).—A discussion of the use of salt and the production of the proper percentage of water.

The Cole butter-making process, F. T. Shutt (*Canada Expt. Farms Rpts. 1900, pp. 188–191*).—"This method or process consists simply of blowing air, previously warmed by water to a temperature between 70° and 80° F., through well ripened cream contained in a cylindrical glass vessel 21 in. high and 13 in. in diameter." The promoter of this method claimed that 20 to 30 per cent more butter could be obtained than by any other method. Two trials were made. In the first the loss of fat in the buttermilk was 5.07 per cent of the total fat supplied in the cream. In the second trial the Cole process was compared with the ordinary method on the same lot of cream. Twenty-seven lbs. of cream was used in each case, the yield of butter being, respectively, 8.125 and 8.656 lbs. and the loss of fat in the buttermilk, respectively, 4.61 and 0.54 per cent of the total fat supplied in the cream, showing that less butter could be obtained by the Cole process and that the loss of fat in the buttermilk was greater. The author gives data and quotes authorities to show that there is no formation of fat from albuminoids during the ripening of cream.

The payment for milk in cooperative creameries on the basis of quality, M. Henseval (*Bul. Agr.* [*Brussels*], *17 (1901), No. 3, pp. 324–332*).—A discussion of paying for milk on the basis of quality, together with the results of the comparison of different milks and mixtures of the same.

Export butter trade, G. S. Thomson (*Jour. Agr. and Ind. South Australia, 4 (1901), No. 10, pp. 801–805*).—A report of the exportation of butter from Australia to England during the past season with special reference to the grading of the product.

Butter and egg storage in Belgium (*Station, Farm, and Dairy, 4 (1901), No. 42, pp. 940, 941*).

A simple apparatus for simultaneously estimating the fat and the water in butter, H. Poda (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 11, pp. 492–496, figs. 5*).—In the described method the sample of butter is treated with concentrated sulphuric acid in a specially constructed apparatus and is heated in boiling water for some time. The tube is afterwards whirled and the amount of resulting fat and nonfat read off on a scale marked upon the cylinder.

A comparison of results shows the method to vary not more than 0.2 per cent from the usual method. The apparatus is claimed to be applicable to the work of creameries, and 6 examinations may be completed within half an hour.

Milk for cheese factories, J. A. Ruddick (*Ontario Dept. Agr., Dairy Division Bul. 2, n. ser., 1901, pp. 7*).—Directions for the factory owners, the cheese maker, and patrons on the handling of milk for cheese factories.

Cheese making, M. A. O'Callaghan (*Agr. Gaz., New South Wales, 12 (1901), No. 6, pp. 702–707*).—Methods employed in England in making Cheddar cheese, Coulommiers or soft new milk cheese, Gervais cream cheese, Cambridgeshire cream cheese, Port du Salut, and Cream cheese.

Cause and prevention of acidy cheese, J. A. Ruddick (*Amer. Cheesemaker, 16 (1901), No. 185, p. 4*).—Cheese more or less faded in color and showing a rough surface is called "acidy" or "acid cut." As a rule such cheese is made from overripe milk in which too much acid is developed before the curd has been sufficiently firmed. If the whey is all removed while the curd is still in a soft condition it is difficult to expel the surplus. The remedy for sour cheese is to get rid of the whey quickly so that the curd will be firm before the acid develops. This may be accomplished by cutting the curd finer and running off a portion of the whey as soon as the heating is finished or even before. However, the whey should not be wholly removed until the curd has acquired the desired firmness and elasticity. It should be remembered that such handling of the curd causes a considerable loss in yield. This may be avoided by having milk in a less acid condition.

Manufacture of soft cheese, E. B. von Heyne (*Hoard's Dairyman, 32 (1901), No. 18, p. 384*).—Methods employed in the manufacture of Fromage de Brie, Camembert, and Neufchatel cheese in Minnesota.

Condition of the cheese industry in New Zealand, J. A. Ruddick (*Amer. Cheesemaker, 16 (1901), No. 184, pp. 1, 2*).

Dairy products at the Paris Exposition of 1900, H. E. Alvord (*U. S. Dept. Agr. Yearbook 1900, pp. 599–624, pls. 5*).—A detailed account of the exhibits of different countries and the awards of the jury.

VETERINARY SCIENCE AND PRACTICE.

The stock-poisoning plants of Montana, preliminary report, V. K. Chesnut and E. V. Wilcox (*U. S. Dept. Agr., Division of Botany Bul. 26, pp. 150, pls. 37*).—This bulletin contains a report on an investigation of the poisonous plants of the State during 1900, together with observations previously made along the same line. The subjects considered in the report include the following: Summer and winter ranges for sheep; effect of alkali on stock; herding and other details of the management of sheep; water supply on the ranges; altitude of the ranges; climatic conditions of the season of 1900; influence of heavy rain storms, snow storms, driving and trailing sheep, hunger, state of vegetation, and stage of the growth of plants, upon the poisoning of sheep; acclimatization of stock to the range; variation and localization of the poisonous substances in plants; variations in the feeding habits of stock, with reference to poisonous plants; extent of stock poisoning; experiments on rabbits; displacing poisonous plants by forage plants; herding stock away from dangerous areas; eradication of poisonous plants by digging; popular methods of treating poisoned animals; permanganate of potash as a chemical antidote and directions for using it; method of drenching; bloat; nonpoisonous plants which are mechanically dangerous, and a special discussion of the more important poisonous plants, species of less importance, plants which are suspected of being poisonous, and doubtful plants which have been suspected. The most important poisonous plants of Montana are considered to be *Zygadenus venenosus, Delphinium glaucum, D. bicolor, Cicuta occidentalis, Aragallus spicatus, A. lagopus, A. splendens, Lupinus leucophyllus, L. sericeus,* and *L. cyaneus.* Besides these more important species, evidence is given on the poisonous nature of 12 plants of less economic importance, and brief notes are given on the economic value or harmlessness of 14 species which have been suspected by stockmen of being poisonous. Besides these species brief notes are given on 23 other plants which have been suspected of being poisonous, but concerning which evidence is not sufficient to warrant a positive declaration.

Many experiments were made in the treatment of poisoned animals and especially promising results were obtained from the use of permanganate of potash as an oxidizing agent to be administered as soon as possible after the symptoms of poisoning are manifested. From experiments with this substance on sheep and cattle it was found that the majority of animals recover from the effects of poisoning rather rapidly after administration of solutions of potassium permanganate directly into the stomach. The methods for administering the permanganate included drenching the animals and injecting through the body walls directly into the stomach. No striking advantage was noted in favor of one or the other method, but the direct injection into the stomach is perhaps to be preferred where the stockman has had some experience in administering medicines in this manner.

Experiments on sheep and cattle were supplemented by numerous experiments on rabbits during which these animals were fed on specimens of suspected plants or extracts made from these plants.

Some poisonous plants of the northern stock ranges, V. K. Chesnut (*U. S. Dept. Agr. Yearbook 1900, pp. 305–324, pls. 3, figs. 4*).—This article contains notes on some of the more important poisonous plants, with especial reference to the conditions which exist in Montana. The discussion is partly based on Bulletin 26 of the Division of Botany of this Department (see p. 283).

Tetanus treated by the antitetanus serum, DABERT (*Jour. Méd. Vét. et Zootech., 5. ser., 5 (1901), Jan., pp. 22, 23*).—Brief notes on the symptoms of disease and the successful use of antitetanus serum in one case of tetanus in the horse.

Contagious diseases of animals, H. MITCHELL (*New Jersey State Bd. Agr. Rpt. 1899–1900, pp. 119–122*).—This article contains a brief account of an outbreak of anthrax, together with a tabulated statement showing the extent of other contagious diseases.

Report of the board of agriculture as cattle commissioners, C. J. BELL (*Vermont State Bd. Agr. Rpt. 1900, pp. 117–135*).—A copy is given of the regulations of the board with regard to inspection and quarantine of cattle and other animals. Brief notes are given on tuberculin tests as carried out under the direction of the board and upon glanders in horses. The nodular disease of sheep caused by the presence of *Œsophagostoma columbianum* in the walls of the intestines, is reported as having prevailed to some extent.

Actinomycosis in animals, R. HARTL (*Berlin. Thierärztl. Wchnschr., 1901, No. 1, pp. 1–6, figs. 2*).—This article contains a detailed description of the clinical symptoms and post-mortem findings of cases of actinomycosis in horses, cats, and dogs. In horses the disease assumes a form which resembles farcy, and has been mistaken for the latter. Ulcers with a persistent discharge are formed in the skin. In one case the whole abdominal wall was changed into a hard, fibrous mass containing numerous small ulcers. The author made numerous cultures of the organism obtained from these cases, the greater proportion of such cultures being made in agar-agar and sugar bouillon. Considerable variation was noted in different forms of the micro-organisms thus obtained, and it is suggested that the relationship of the different forms of the disease may ultimately be more clearly defined than at the present.

Bovine tuberculosis in Wisconsin, H. L. RUSSELL and E. G. HASTINGS (*Wisconsin Sta. Bul. 84, pp. 16, figs. 4*).—About 1,200 animals in suspected herds and 1,000 in unsuspected herds in Wisconsin were tested with tuberculin. The percentage of reacting animals varied from 2.2 to 95 per cent in different herds. The average percentage of tuberculous animals in the State is considered rather small. A statistical account is given of the percentage of tuberculous animals in other States, and brief notes are presented on the geographical distribution of tuberculosis in Wisconsin, the spread of the disease from herd to herd, its introduction through tuberculous animals, the advisability of State quarantine, mode of dissemination within a herd, and methods of treating reacting animals and controlling the disease.

Report of tuberculosis commission (*New Jersey State Bd. Agr. Rpt. 1899–1900, pp. 111–116*).—Brief recommendations regarding sanitary measures to be adopted in preventing the spread of tuberculosis among cattle and the transmission of the disease from cattle to man.

The suppression of bovine tuberculosis, A. PETERS (*Rhode Island State Bd. Agr. Rpt. 1900, pp. 200–215*).—A discussion of the views which are held at present with regard to the infectiousness of the flesh and milk of tuberculous animals and the control of the disease by means of government regulations.

Blackleg, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 18 (1901), No. 2, pp. 67–73*).—The symptoms and post-mortem conditions of this disease are described. Brief notes are given on hygienic measures to be adopted for preventing outbreaks of the disease, and directions are given for using blackleg vaccine.

The significance of the fungiform papillæ in the diagnosis of foot-and-mouth disease, H. LEUTSCH (*Ztschr. Fleisch. u. Milchhyg., 11 (1901), No. 5, pp. 142, 143, fig. 1*).—From an anatomical study of the tongue in cases of this disease, it was found that the epithelium becomes elevated, so that the fungiform papillæ appear to be sunken in small depressions. This character is considered of diagnostic value for foot-and-mouth disease.

Study of a case of pneumonia of calf, F. D. CHESTER (*Delaware Sta. Rpt. 1900, pp. 46–52, figs. 2*).—A report is made on a case of pneumonia in a calf, with a detailed statement of post-mortem findings and cultural and pathogenic properties of the organism which was isolated from diseased tissue. This organism was found upon inoculation to be pathogenic to guinea pigs and rabbits. A guinea pig and a calf were inoculated by inhalation of a fine mist containing the organism.

Differential diagnosis of contagious pleuro-pneumonia, F. HAUPTMANN (*Berlin Thierärztl. Wchnschr., 1901, No. 5, pp. 65–67*).—The author describes from cases which occurred in his practice the detailed pathological changes which are considered to be characteristic in diagnosing this disease.

Pneumonia and inoculation against this disease, REINLÄNDER (*Ztschr. Veterinärk., 13 (1901), No. 2, pp. 53–62*).—The author describes the symptoms of this disease and the circumstances of a severe outbreak which occurred in army horses. A number of experiments were tried in protective inoculation, without very promising results. The author concludes that the inoculation method thus far employed will probably not yield favorable results until the organism of the disease has been isolated and studied.

Stoppage of the milk duct in the teat and its treatment, M. STREBEL (*Schweiz. Arch. Thierh., 43 (1901), No. 1, pp. 12–18*).—This condition may be congenital or may be due to mechanical injuries. When the duct is closed by thin membranes, it may be safely opened by the use of the probe. The author discusses the conditions which determine the most practical treatment to be adopted in different cases.

Experimental transmission of Texas fever, LIGNIÈRES (*Rec. Méd. Vét., Paris, 8. ser., 7 (1900), No. 23, pp. 118–180*).—The author conducted extensive experiments with Texas fever in Argentina. It was found impossible to inoculate experimentally the horse, ass, sheep, pig, dog, cat, rat, mouse, and domestic fowl. A number of forms of the disease were noted in cattle inoculated experimentally, and the peculiar features of clinical symptoms and pathological lesions in these forms are described in detail. In this connection the author made numerous counts of blood corpuscles and recorded the variations in number of red blood corpuscles and in the body temperature during the progress of the disease. The tick which is instrumental in transmitting Texas fever in Argentina is called *Rhipicephalus annulatus microplus*. The author describes minutely the external form and anatomy of this tick in its different stages. Experiments were made in producing Texas fever experimentally by infestation with ticks taken from diseased animals. In one case the disease was thus produced by ticks from an animal which was apparently healthy. The author discusses the various objections which have been raised against the theory concerning the agency of ticks in spreading Texas fever.

Experiments conducted for the purpose of determining whether Texas fever could be transmitted through the agency of certain flies gave negative results in all cases. The author describes the geographical distribution of the disease in Argentina, and discusses in a brief section the importance of the disease to the cattle industry. Since Texas fever is most commonly confounded with anthrax, a parallel table is given showing the characteristic symptoms of the 2 diseases. Experiments in the use of quinin in treating Texas fever showed that this substance is without true curative value for this disease.

The author reviews the literature concerning the methods of destroying the cattle ticks and methods of producing immunity in susceptible animals. A number of experiments in blood inoculation for the purpose of producing immunity gave good results. The author concludes that the disease is transmitted only by the agency of ticks, and that preventive vaccination may be successfully carried out, although little hope is to be entertained of curing actual cases by serum inoculations. A bibliography of the subject is added.

Horse sickness of South Africa, E. NOCARD (*Rec. Méd. Vét., Paris, 8. ser., 8 (1901), No 2, pp. 37–51, fig. 1*).—The author discusses the serious outbreaks of this disease among horses at the beginning of the South African war. Charts are given showing details of the clinical history of a number of cases. The organism of the disease has not been isolated, but it is believed by the author to be a protozoan parasite, which is probably transmitted by means of some insect, possibly the mosquito.

Malignant œdema in the horse, E. ZSCHOKKE (*Schweiz. Arch. Thierh., 43 (1901), No. 1, pp. 20–24*).—In one case the disease developed in consequence of stepping on a nail. The wound was treated with lysol, but 9 days afterward the disease appeared. The symptoms and the course of the disease are described in this and several other cases.

Sheep pox, E. PERRONCITO (*Gior. R. Soc. Accad. Vet. Ital., 50 (1901), No. 3, pp. 64, 65*).—Brief notes on the history and unusual severity of an outbreak of this disease during the past year. The author discusses the methods which have thus far been adopted for preventing the spread of the disease.

Dourine, J. DE DOES (*Veeartsenijk. Bladen v. Nederl.-Indië, 13 (1900), No. 2, pp. 104–164.*)—This disease prevailed to an unusual extent during the past season in Soemedang. The author discusses in detail the history of a large number of cases. The pathogenic organism was not isolated.

Hog-cholera remedy, C. L. PENNY (*Delaware Sta. Rpt. 1900, pp. 96–98*).—An analysis was made of a proprietary preparation sold as a "preventive and cure for hog cholera," and the results are compared with a formula recommended by the Bureau of Animal Industry of this Department. It is thought that the compounder meant to follow the formula of the Department and the author questions whether a remedy prepared in this way should be sold under a proprietary name.

In this connection an examination was made of 41 samples of antimony sulphid sold by retail druggists in Delaware and other States. The results showed that 33 samples were entirely free from antimony in any form.

Rabies: Its cause, frequency, and treatment, D. E. SALMON (*U. S. Dept. Agr. Yearbook 1900, pp. 211–246*).—A discussion of the cause, nature, distribution, and means of treating this disease, with historical notes on the success which has been obtained along this line in other countries.

Diseases of poultry, A. G. GILBERT (*Canada Expt. Farms Rpts. 1900, p. 259*).—In cases of outbreaks of infectious diseases the author recommends thorough disinfection of the premises. For the destruction of lice a fluid preparation containing 4 oz. of corrosive sublimate and 4 oz. of common salt was found efficient. These substances should be dissolved in from 2 to 4 qts. of water, and all parts of poultry houses should be thoroughly sprayed. This treatment may be followed by whitewashing.

Asthenia or going-light of fowls, F. D. CHESTER (*Delaware Sta. Rpt. 1900, pp. 52–60, fig. 1*).—From cases of this disease the author isolated 2 organisms, one of which was the coli bacillus and the other similar to *Bacillus vulgaris*. Detailed statements are given concerning the morphological and cultural characters of the organism, and a table is presented comparing the organism with *Bacterium astheniæ*, as described by Dawson.

When fed to young chickens in ordinary food, this organism produced a rapidly fatal disease. Asthenia occurs more frequently in young chickens than in older ones. Apparently the organism is not pathogenic for old fowls, except to a limited extent. It is considered merely a virulent form of the coli bacillus.

Entero-hepatitis or blackhead of fowls, F. D. CHESTER and A. ROBIN (*Delaware Sta. Rpt. 1900, pp. 60–66, figs. 3*).—This disease, which has been known as occurring in turkeys, is now reported as attacking chickens. A detailed report is given on the technical methods employed in preparing and studying pathological tissue. In affected livers certain bodies were seen in some of the cells, which are suspected of being young stages of the parasitic organism which causes the disease.

Notes on parasites, 55-57, C. W. STILES and A. HASSALL (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 34, pp. 4*).—The authors describe a pupa-like stage of *Ornithodoros megnini* and discuss the synonymy of *Boophilus australis* and *B. bovis*. *Strongylus contortus* and *Cysticercus tenuicollis* are reported as having been found in a specimen of mule deer which died at the National Zoological Park.

On disinfection, W. L. MACKENZIE (*Vet. Jour., 52 (1901), No. 308, pp. 100–108*).—The author discusses the practical value for disinfecting purposes of light, fresh air, sulphurus acid, corrosive sublimate, chlorid of lime, lysol, carbolic acid, and formaldehyde.

Stable disinfection, F. P. GORHAM (*Rhode Island State Bd. Agr. Rpt. 1900, pp. 315–322*).—The author gives a brief account of tuberculosis, glanders, and other diseases, with notes on disinfection of stables after outbreaks of these diseases by means of formalin, carbolic acid, carbol-sulphuric acid, creolin, and chlorid of lime.

The laws of the Grand Duchy of Hessen relating to indemnities for animals affected with anthrax, blackleg, and hog cholera, LORENZ (*Ztschr. Thiermed., 5 (1901), No. 1, pp. 12–63*).—This article contains copies of regulations relating to the subject, an elaborate discussion by the author on the sanitary measures to be adopted in outbreaks of these diseases, and on the methods of preventive inoculation which promise to yield the best results.

AGRICULTURAL ENGINEERING.

The carrying capacities of irrigation canals, S. FORTIER (*Utah Sta. Bul. 71, pp. 55, figs. 42*).—This is a report of 64 experiments made during the summer of 1897 on irrigation channels varying in size from small ditches carrying a few miner's inches to large canals carrying as high as 225 second-feet, and including nearly every form of ditch common to western America.

"The object sought was to ascertain as accurately as possible the existing conditions of ditches and canals that had been in operation for a number of years. In order to obtain the volume which flowed in any particular ditch and compare it with some well-known empirical formula, such as Kutter's or Chezy's, it was necessary to ascertain the slope of the surface of the water, the sectional area of the water, the mean velocity, and the ratio between the water area and the wetted perimeter."

Other objects which the author had in view was to ascertain the form which channels assume when acted upon by water and the atmosphere and to determine the values of the coefficient of roughness (n) under different conditions.

The discharge was measured either by a current meter or by a Cippoletti trapezoidal weir, special precautions being taken to secure the conditions necessary for accurate measurements. The current meter measurements recorded are in every case the mean of from 3 to 6 readings. The average cross sections were obtained "by platting in different colors on a large scale the three or more cross sections taken in the field. A new perimeter was then adopted which represented the average of all those platted. Its length was found by a pair of dividers and the area of the average section by a planimeter.

"The slope of a canal represented by the fall of a given portion, usually from 50 to 300 ft., divided by the distance, was determined by a new Buff and Berger 18 in. level and a leveling rod reading to thousandths of a foot.

"The method followed in determining the slope was to drive small finishing wire nails into the tops of submerged oak stakes at each end of the section to be tested. It was not always possible to have the top of the nail coincide exactly with the surface of the water, but this difference introduced no error in the results, provided the heads of both nails occupied the same relative position to the surface of the water. In the case of pulsations or slight waves caused by winds, the tops of both nails were even with the highest or lowest water surfaces."

From the data reported the author draws the following conclusions:

"(1) Sections of canals in earth, although carefully built of a trapezoidal form, with the bottom width horizontal, soon change to segments resembling those of an ellipse.

"(2) In all large or medium sized canals in earth, berms are necessary in order to prevent a portion of the excavated material from rolling into the canal.

"(3) The carrying capacity of new irrigation canals and ditches during the first season of their operation are less than in subsequent seasons, providing the same conditions are maintained.

"(4) The coefficient of friction in canals well lined with sediment in good order and long in use is less than has been usually supposed.

"(5) The frictional resistance of coarse materials, such as gravel, pebbles, or cobble rock, depends to a large extent on whether such material is well packed or loose.

"(6) That a rough channel exerts a greater influence in retarding the flow of a small ditch than the same degree of roughness exerts on the large canal or river.

"(7) In the past, canal builders have to a great extent overlooked the injurious effects of the growth of aquatic plants.

"(8) The effect of water plants in checking the flow and lessening the capacity of irrigation canals may be much greater than a rough uneven channel.

"(9) In parts of the arid West where such vegetation grows abundantly the canals should be built in such a way as to prevent its growth, or, if this is impracticable, to facilitate its removal."

"On account of the dissimilarity between the physical conditions of the channel from which the present values of (n) have been derived and the ditches and canals of irrigated America, the writer has attempted to assign values for (n) which would be more in accordance with the conditions which now exist in the Rocky Mountain States. Future experiments in which the details are more accurately conducted may, however, modify the values of (n) as here given." The proposed values for the coefficient of friction (n) for different kinds of irrigation ditches and canals are as follows:

"n=.0175 for canals in earth in excellent condition, well coated with sediment, regular in cross section and free from vegetation, loose pebbles, and cobble rock.

"n=.020 for canals in earth in good condition, lined with well-packed gravel partly covered with sediment and free from vegetation.

"n=.0225 for canals in earth in fair condition, the wetted surface being lined with sediment with an occasional patch of low-water plants, or composed of loose gravel without vegetation.

"n=.0250 for canals in earth in average condition having few sharp bends and being fairly uniform in cross section; the water slopes and bottom being lined with sediment and low water plants, or composed of loose gravel and fragments of rock less than 2 inches in diameter and free from vegetation.

"n=.0275 for canals in earth below the average in grade, alignment and cross section; having indentations on the sides, the edges in places partially filled with earth and gravel, and the lining composed of coarse gravel and cobble rock unpacked. This value would also apply to a smooth, regular surface if the channel were partially filled with aquatic plants.

"n=.0300 for canals in earth in rather bad condition having the bed partially covered with débris; or having comparatively smooth sides and bottom with bunches of grass and weeds projecting into the water and more or less aquatic plants growing in the channel.

"n=.0350 for small ditches having a small uneven bed and for canals in earth in fairly good condition but partially filled with aquatic plants.

"n=.040 for canals in earth whose channels are about half full of aquatic vegetation.

"n=.050 for canals in earth whose channels are about two-thirds full of aquatic vegetation."

Practical irrigation, C. T. Johnston and J. D. Stannard (*U. S. Dept. Agr. Yearbook 1900, pp. 491–512, figs. 9*).—This article explains methods of laying out and constructing small ditches with varying grades and cross sections, the laying out of field laterals, methods of applying water to crops, when to irrigate, and cost of building and maintaining a ditch.

A study of the practice of irrigation on the plain of Urgel, Spain, P. Philippar (*Ann. Agron., 27 (1901), No. 5, pp. 220–237, fig. 1*).—This article describes quite fully the system of water management and methods of irrigation practiced in this region, and discusses the results obtained.

The Chapman subirrigation plant (*California Cult., 16 (1901), No. 20, p. 305, fig. 1*).—A brief description.

Tenth Biennial Report of the State Engineer to the Governor of Colorado, 1899 and 1900 (*Colorado State Eng. Rpt. 1899 and 1900, pp. 396, pls. 11*).—This is an account of operations during the 2 years ended November 30, 1900, and includes a list of the irrigation officers with recommendations regarding the improvement of the irrigation system of the State; reports on the internal improvements made; an abstract of supreme court decisions relating to irrigation; reports of superintendents of irrigation and water commissioners; ditch and reservoir filings; seepage measurements and ditch ratings; and gagings of streams with comparative tables of discharge.

Agricultural machinery at the Paris Exposition of 1900, G. Coupan (*Bul. Soc. Agr. France, n. ser., 32 (1900), Dec. 15, pp. 469–479, figs. 5; 33 (1901), Jan. 1, pp. 43–49, figs. 4; Jan. 15, pp. 97–106, figs. 11; Feb. 1, pp. 165–176, figs. 5; Feb. 15, pp. 280–286, figs. 4; Mar. 1, pp. 362–370, figs. 5*).—Brief notes are given on plows, cultivators, scarifiers, pulverizers, rollers, harrows, mechanical diggers, fertilizer distributers, seed drills and planters, hoes, pumps, hydraulic rams and other water lifts, agricultural artillery, harvesting machines of all kinds, threshing machines, and presses, mills, and other machines for preparing crops for handling and use.

Results of tests of alcohol motors in Germany, E. Leplae (*Les résultats des essais de moteurs à alcool en Allemagne. Brecht: L. Braeckmans, 1901, pp. 17*).

The selection of materials for macadam roads, L. W. Page (*U. S. Dept. Agr. Yearbook 1900, pp. 349–356*).—This article discusses the importance of the physical properties of rock in road building and of a record of traffic for proposed roads and methods of measuring traffic, the adaptation of material to different kinds of traffic, and methods of determining the value of rocks for road building. Attention is called to the establishment of a road material laboratory in the Division of Chemistry of this Department and the plan and purpose of the work to be undertaken is explained.

Mountain roads, J. W. Abbott (*U. S. Dept. Agr. Yearbook 1900, pp. 183–198, pls. 3*).—The construction and maintenance of such roads are discussed in a popular manner.

Construction and care of earth roads, I. O. Baker (*Illinois Sta. Bul. 65, pp. 73–93, fig. 1*).—This bulletin is "addressed to the farmers chiefly," and deals with the subject under three main heads—construction, maintenance, and administration.

Good dirt roads for Mississippi, J. W. Fox and W. L. Hutchinson (*Mississippi Sta. Bul. 67, pp. 16, figs. 6*).—The road laws of Mississippi are briefly summarized and the system of road maintenance of the State is discussed. Methods of building and maintaining dirt roads are briefly explained.

STATISTICS—MISCELLANEOUS.

Twelfth Annual Report of Delaware Station, 1900 (*Delaware Sta. Rpt. 1900, pp. 259*).—This includes a financial statement for the fiscal year ended June 30, 1900, the organization list of the station, and reports of the heads of departments, including a number of articles abstracted elsewhere, and a reprint of Bulletin 51 of the station on pedigreed sorghum as a source of cane sugar (E. S. R., 13, p. 42).

Thirteenth Annual Report of Louisiana Stations, 1900 (*Louisiana Stas. Rpt. 1900, pp. 22*).—An account is given of the work at the Sugar Station at Audubon Park, the State Station at Baton Rouge, and the North Louisiana Station at Calhoun. The report also contains the organization lists of the stations and a financial statement for the fiscal year ended June 30, 1900.

The Upper Peninsula Experiment Station, C. D. Smith (*Michigan Sta. Bul. 186, pp. 4–8*).—This contains the act of the State legislature establishing the Upper Peninsula Experiment Station, a description of the station farm, including an analysis of the underlying rock, and a brief outline of the work already accomplished.

Bulletins of Alabama Station (*Index to Vol. VIII, Buls. 108–112, pp. 191–201*).

Finances—meteorology—index (*Maine Sta. Bul. 69, pp. 191–228+8*).—This contains a list of acknowledgments, meteorological observations noted elsewhere, a financial statement for the fiscal year ended June 30, 1900, an index to the annual reports for 1897 to 1900, the organization list of the station, and brief notes on the aim and work of the station by the director.

Experimental work in agriculture, C. Schreiber (*Rev. Gén. Agron.* [*Louvain*], *10* (*1901*) *No. 1, pp. 21–29*).—This article discusses the work of the experiment stations, the experimental fields, and the fields of demonstration as they exist in Belgium.

Yearbook of the Department of Agriculture, 1900 (*U. S. Dept. Agr. Yearbook, 1900, pp. 888, pls. 87, figs. 88*).—This includes a general report by the Secretary on the operations of the Department during the year, 30 semipopular articles on miscellaneous subjects noted elsewhere, a brief biographical sketch of William Saunders, and an appendix containing the usual summary of useful information on various subjects of interest to farmers. A new feature of the appendix is the publication of requirements for admission to the agricultural departments of the land-grant colleges, and the cost of attendance.

Crop Reporter (*U. S. Dept. Agr., Division of Statistics Crop Reporter, Vol. 3, Nos. 1–3, pp. 8 each*).—These numbers contain statistical data on the condition of crops in the different States and Territories on May 1, June 1, and July 1, 1901, and a number of articles on miscellaneous subjects, including the following: Production of oats and barley in Russia since 1883, agricultural organizations in France, the cotton crop of India, the wheat crop of India in 1901, the intercontinental wheat trade, principal grain crops of Austria in 1900, principal food crops of Bulgaria in 1898 and 1899, the corn crop of Mexico, the crop reporting service of the Division of Statistics of the Department of Agriculture, the farmers' interest in foreign crop reports, and production of maize and millet in Russia since 1883.

The cotton crop of 1899–1900, J. L. Watkins (*U. S. Dept. Agr., Division of Statistics Bul. 19, pp. 46*).—This bulletin is the customary annual report presenting statistical data on the cotton crop of the different States and Territories as shown by the movement of the crop from the plantation to points of export or consumption. In addition, statistical information is given on the growth of cotton spinning in the South, the sea island cotton crop of 1899–1900, the value of the cotton crop of 1899–1900, the cost of picking cotton, exports and imports of cotton, consumption of American cotton by foreign countries, the world's cotton spindles and their consumption, the cotton production and acreage since 1894, exports of cotton from Brazilian ports, movement of cotton from Asiatic to European Russia, the Mexican crop and world's cotton crops since 1865. The total crop for the year is estimated at 9,935,990 commercial bales, valued at $329,269,332. Of this, the sea island crop amounted to 98,338 bales, valued at $5,578,536.

Foreign imports of American tobacco (*Spec. [U. S.] Consular Rpts., 20 (1900), pt. 1, pp. 71–133*).—A series of reports on the tobacco imports of all the important countries of the world.

Influence of rye on the price of wheat, E. T. PETERS (*U. S. Dept. Agr. Yearbook 1900, pp. 167–182*).—In this article the price of wheat in its relation to the world's supply of breadstuffs, the world's wheat crop, and especially the world's rye production are discussed.

Our foreign trade in agricultural products, 1891–1900, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Bul. 23, pp. 61*).—A detailed statistical review of the foreign trade of the United States for the 10 fiscal years 1891–1900. In 1900 the value of the leading agricultural exports amounted to $844,616,530, the principal articles being breadstuffs, cotton, meat products, live animals, tobacco, oil cake and oil-cake meal, vegetable oils, fruits and nuts, dairy products, and seeds. The value of the leading agricultural imports amounted to $420,139,288, the principal articles being sugar, hides and skins, coffee, silk, vegetable fibers, wool, fruits and nuts, tobacco, tea, wines, vegetable oils, and cocoa.

Our trade with Scandinavia, 1890–1900, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Bul. 22, pp. 124*).—This is a statistical review of the trade of the United States with Denmark, Sweden, and Norway during the fiscal years 1890–1900. The exports to these three countries increased in valuation from $9,000,000 in 1890 to $29,000,000 in 1900. The imports were valued at $4,000,000 in 1890 and $5,000,000 in 1900.

Agricultural imports and exports, 1896–1900, F. H. HITCHCOCK (*U. S. Dept. Agr , Section of Foreign Markets Circ. 23, pp. 16*).—Statistical tables showing the character, quantity, and value of the agricultural imports and exports of the United States during each of the five fiscal years, 1896–1900.

Agricultural returns for Great Britain, 1900 (*London: Wyman & Sons, 1901, pp. XLIX + 259*).—This report shows the acreage and produce of crops, prices of corn, and number of live stock with agricultural statistics for the United Kingdom, British possessions and foreign countries.

The course of prices of farm implements and machinery for a series of years, G. K. HOLMES (*U. S. Dept. Agr., Division of Statistics Bul. 18, pp. 31*).—The prices of farm implements and machinery for 1860, 1880, 1890, 1895, and 1900 on about July 1 for each of these years were obtained from manufacturers and the figures are here presented in tables. The magnitude of the industry of manufacturing agricultural implements and some of the economic results of machinery produced in the cultivation and harvesting of corn and wheat and the making of hay are pointed out. The change in price of different implements and machines is briefly discussed.

Agriculture in the Twelfth Census, LEG. POWERS (*Amer. Mo. Rev. of Reviews, 23 (1901), No. 134, pp. 321–323*).—A statistical summary dealing mainly with the number of farms in the United States in 1900 and their value.

Notes on the agriculture of Réunion, F. STUHLMANN (*Beihefte Tropenpflanzer, 2 (1901), No. 1, pp. 29, figs. 3*).

Visit to Great Britain and France, W. SAUNDERS (*Canada Expt. Farms Rpts. 1900, pp. 44–66, pl. 1*).—Notes on a trip made by the author, with a paper read before the British Association on the results of experimental work in agriculture in Canada under government organization.

Free delivery of rural mails, C. H. GREATHOUSE (*U. S. Dept. Agr. Yearbook 1900, pp. 513–528, pls. 4, maps 2*).—The author reviews the growth of the rural free delivery of mails in the United States, discusses the advantages and disadvantages of the system, quotes the opinions of a number of farmers as to rural free delivery, and gives directions as to the method of procedure in starting new routes.

Agricultural education in France, C. B. Smith (*U. S. Dept. Agr. Yearbook 1900, pp. 115–130*).—A paper on this subject in which are popularly discussed the French national department of agriculture, national schools of agriculture, practical agricultural schools, farm schools, agriculture as taught in the public schools, departmental and special professors of agriculture and their functions, and agricultural experiment stations and laboratories of France.

"France has, in all, 12 institutions for teaching agriculture of the first and second degrees, 43 for teaching the third degrees, 34 for pure practice of apprenticeship, 3,362 fields of demonstration, 77 establishments for analysis and agricultural research, and 214 departmental and special professors of agriculture, who give instruction yearly to 300,000 adult farmers and conduct agricultural classes in the normal schools for men and in the rural primary schools."

NOTES.

Alabama College and Station.—E. M. Wilcox, Ph. D., formerly of the Oklahoma College and Station, has been appointed professor of biology and horticulture in the college and biologist of the station, vice F. S. Earle, who, as previously noted, has gone to the New York Botanic Gardens. G. F. Freeman has been appointed secretary of the station. H. Harold Hume and H. A. Houghton have severed their connection with the institution.

Alabama Tuskegee Station.—The station is preparing a set of nature-study leaflets, to be placed in the hands of school-teachers. These teachers will be urged to conduct a child's garden in connection with their schools, and to teach something of nature study in a practical way. Farmers' leaflets, written in plain and simple language and dealing with the various phases of farm work, are being issued. The institute keeps in touch with its constituents by means of farmers' conferences held monthly in different localities, delegates from these conferences being sent to the monthly meetings which are held at the institute.

Arizona Station.—John J. Thornber, A. M., has assumed the duties of botanist of the station, filling the vacancy caused by the resignation of David Griffiths, now of the Bureau of Plant Industry of this Department. Mr. Thornber will be chiefly occupied with the study of grazing conditions in the southwest, especially with reference to the administration and reclamation of worn-out ranges. He has been occupied for the past four years with the study of similar problems in Nebraska.

California University and Station.—A. M. dal Piaz, assistant in viticulture, has resigned, and E. H. Twight, a graduate of the Viticultural College of Montpellier, France, has been appointed in his place. A. R. Ward, D. V. M., formerly of Cornell University and Station, has been appointed veterinarian of the station. A dairy school has been established in connection with the college of agriculture. J. H. Barber, foreman of the Paso Robles Station, has been transferred to the station at Jackson, while Foreman J. W. Neal of the latter goes to the Paso Robles Station.

Colorado Station.—An insectary is being built for the entomological section of the station. The governing board has decided to reconvey to the State 160 acres of land, formerly used as a portion of the Rockyford Substation. This reduces the substation to an area of 40 acres, most of which will be leased.

Connecticut Storrs College and Station.—President G. W. Flint and four members of the college faculty have been relieved. H. W. Conn, of Wesleyan University, has been appointed lecturer on agricultural bacteriology in the college, and placed in charge of the dairy experimentation of the station. The latter will be carried on in part at Storrs and in part at the biological laboratory of Wesleyan University.

Delaware College and Station.—C. P. Close, formerly of the Utah College and Station, has been appointed horticulturist to succeed G. Harold Powell. The latter has become assistant pomologist in this Department, vice W. A. Taylor, who has been promoted to have charge of the field experiments in pomology.

Georgia Station.—S. H. Fulton, of South Haven, Mich., has accepted the appointment as biologist and horticulturist of the station, vice A. L. Quaintance. C. L. Willoughby, of the Missouri Station, has been elected dairyman of the station, vice H. J. Wing, who retires December 1, 1901.

Idaho University and Station.—Charles A. Peters, Ph. D. (Yale), has been appointed station chemist and professor of chemistry in the university, to succeed S. Avery, who resigned at the close of the academic year to return to the University of Nebraska. Charles N. Little, Ph. D. (Yale), has been appointed professor of civil engineering in the university and irrigation engineer at the station. A new piggery, to be used in experimental work, has been erected at the college farm, at a cost of $325.

Illinois College and Station.—J. H. Skinner, formerly of Purdue University, has been appointed instructor in animal husbandry in the college and assistant in animal husbandry at the station. A. V. Stubenrauch, formerly assistant at the California Station, has been appointed assistant in horticulture at the station and instructor in horticulture in the college. A. C. Beal, a graduate of the University of Illinois, has been appointed assistant in horticulture in the college. C. F. Hottes, formerly assistant in botany in the university and for the past three years a student at the University of Bonn, Germany, has been appointed assistant in botany at the station and instructor in botany in the college. Heinrich Hasselbring, formerly assistant in horticulture at the New York State Station, has been appointed assistant in vegetable pathology at the station. H. E. Ward, formerly instructor in soil physics in the university, has been made instructor in bacteriology in the college and chief assistant in soil bacteriology in the station. Wm. H. Knox, formerly of the South Dakota College and Station, has been appointed instructor in soil physics in the college and chief assistant in soil physics at the station. Coates P. Bull, a graduate of the Minnesota Agricultural College, has been appointed instructor in farm crops in the college and assistant in farm crops at the station. His special investigation work will be in plant breeding. R. S. Woodrow has been appointed field assistant in sugar-beet investigations. J. H. Pettit, formerly of Cornell University, has been appointed assistant in chemistry at the station. E. M. East, a graduate of the university, has also been appointed assistant in chemistry at the station. A. J. Glover, formerly employed by the State Dairy and Food Commission of Minnesota, has been appointed chief assistant in dairy husbandry.

Purdue University and Station.—The horticultural department of the station has been strengthened by the promotion of William Stuart, who has served for some years as assistant botanist, to the position of associate station horticulturist. Professor Troop, as horticulturist, will give his attention more particularly to the fruits proper, while Mr. Stuart will develop the gardening side of the horticultural work. A limited amount of vegetable gardening will be conducted under glass, in addition to field gardening, and the station will also promote the general gardening interests of Indiana. F. S. Johnston, assistant agriculturist in the New Hampshire College and Station, has been appointed associate professor of agriculture in the university and assistant agriculturist of the station. Herman Dorner, B. S., has been appointed assistant botanist. H. E. Van Norman, who for some years has served as farm superintendent and assistant in dairying at the university, has been promoted to the position of instructor in dairying in the university and dairyman of the station. R. C. Obrecht, B. S. Agr., a graduate of the Iowa Agricultural College, 1901, has been appointed assistant in animal industry in the university and farm superintendent of the station. A. N. Hume, a graduate of the school of agriculture of the university, 1899–1900, has been appointed half-time assistant in the agricultural department of the station. On September 1 the station adopted the scheme of placing weather signals on the rural mail delivery wagons going out from Lafayette. These signals are enlarged reproductions of the weather flags, about 20 by 13½ inches, made of tin and painted. They are affixed to each side of the wagon by means of an iron frame, accommodating two flags on each side. Five wagons carry these flags, and a set is also exposed on the front of the experiment-station building. A key to the flags has been sent each person along the several rural routes.

IOWA COLLEGE AND STATION.—E. C. Myers, B. S. Agr., has been appointed instructor in agricultural chemistry in the college, and C. E. Gray, B. S. Agr., has been appointed assistant chemist of the station. Joseph E. Guthrie succeeds Wm. T. Shaw as assistant entomologist of the station. F. W. Faurot, assistant botantist, J. C. Brown, assistant chemist, and W. D. Hunter, assistant entomologist, have severed their connection with the station. The latter has become assistant in the Division of Entomology of this Department.

KANSAS COLLEGE AND STATION.—The board of regents has divided the farm department into the agricultural department and the department of dairy husbandry. H. M. Cottrell remains in charge of the agricultural department, and D. H. Otis, who has been assistant in dairying for some years, is placed in charge of the department of dairy husbandry. He becomes at the same time professor of dairying in the college. Dr. N. S. Mayo, recently of the Storrs Agricultural College, has been elected professor of veterinary science in the college and veterinarian of the station, a position formerly held by him. F. C. Weber, B. S., a recent graduate of the Ohio State University, has been elected assistant chemist, vice R. W. Clothier, resigned. J. M. Westgate, assistant botanist, resigned his position August 1 to take a course of study.

MAINE UNIVERSITY.—A. W. Harris has resigned the presidency of the university to accept the position of director of the Jacob Tome Institute, at Port Deposit, Md.

MARYLAND COLLEGE AND STATION.—J. B. S. Norton, M. S., has been appointed botanist and pathologist in the college and station, which makes him ex-officio State pathologist. Professor Norton is a graduate of the Kansas Agricultural College and has spent several years at the Missouri Botanical Gardens. F. H. Blodgett, B. S., of Rutgers College, New Jersey, has been appointed his assistant.

MISSOURI STATION.—J. C. Whitten, horticulturist, has been granted leave of absence for 16 months to study horticultural methods in Europe. W. L. Howard, B. S., a graduate of the University of Missouri, 1901, has been appointed assistant in horticulture, to succeed N. O. Booth, who has resigned to accept the position of assistant horticulturist at the New York State Station. F. B. Mumford, professor of agriculture, has returned from a 16 months' study of live-stock husbandry in Europe and resumed his duties. Plans for the dairy building, and for a live stock judging pavilion and veterinary laboratories have been approved, and work on these buildings will be begun at once.

MISSOURI STATE FRUIT STATION.—C. B. McAfee, of Springfield, has been appointed a member of the board of trustees at the station in place of M. T. Davis, resigned. The experiment-station building, to be used for offices and laboratories, has been completed.

NEBRASKA STATION.—Henry B. Slade, A. B., has been appointed assistant station chemist in place of R. W. Thatcher, who, as previously noted, has gone to the Washington Station.

NEW HAMPSHIRE COLLEGE AND STATION.—W. D. Gibbs, professor of agronomy in the Ohio State University, has been elected professor of agriculture and director of the station, and will enter upon his new duties January 1, 1902. He succeeds C. W. Burkett, who, as noted below, has gone to North Carolina. Marion Imes, assistant in veterinary science and dairying, has resigned to accept a position in the Bureau of Animal Industry of this Department. H. P. Richardson, assistant in agriculture and farm superintendent, has resigned to accept the position of poultryman in the North Carolina Station. Temporary arrangements have been made for carrying on the work of the agricultural department, and the college year has begun with an increased number of students in the courses of agriculture, horticulture, and forestry.

New Mexico College and Station.—Pending the election of a successor to President F. W. Sanders, Francis E. Lester, registrar of the institution, is executive officer in charge of the college. The station is investigating the best methods of irrigating from wells, and is collecting data from persons who have had experience with this system. J. J. Vernon and J. D. Tinsley have made a tour of investigation in the Pecos Valley, in southeastern New Mexico, to study the stock interests and the soil and irrigation conditions in that valley, in the course of which considerable data and information of value to the station in its work were obtained. During the past summer E. O. Wooton was engaged in investigating the timber and grazing interests of southeastern New Mexico, under the direction of the Bureau of Forestry of this Department.

New York Cornell Station.—O. F. Henziker has been appointed bacteriologist of the station, vice A. R. Ward, who, as noted above, has gone to the California Station.

New York State Station.—H. J. Eustace, a graduate of Michigan Agricultural College, 1901, has been chosen student assistant in botany. Edwin B. Hart has resumed his duties as assistant chemist, after a year's leave of absence spent in study in Germany. J. Arthur LeClerc, assistant chemist, has been granted one year's leave, also for the purpose of study in Europ.an universities. Amasa D. Cook has resigned his position as assistant chemist, to complete a course of post-graduate study at Cornell University. The director's residence is rapidly approaching completion.

North Carolina College and Station.—Charles W. Burkett, formerly of the New Hampshire College and Station, has been elected professor of agriculture in the college and agriculturist of the station, vice B. Irby. Tait Butler, formerly of the Kansas College and Station, has been elected professor of animal industry in the college and veterinarian of the station. F. L. Stevens, Ph. D. (University of Chicago), has been elected botanist of the station. W. F. Massey has resigned his connection with the college and now devotes all his time to station work in horticulture. In addition to the work already in progress, an experiment in the winter growing of lettuce under glass, with a view to determining the best varieties, as well as fertilizer requirements and methods of preventing rust, has been started. An experiment has been planned with beef cattle, and a number of thoroughbred animals will be added to the station herd, with a view to improving the cattle of the section and showing what can be done with stock in connection with cotton farming. The station will erect a special barn for these animals, and will make experiments in feeding grasses and forage plants a prominent feature of the work. The State department of agriculture has conducted, under the direction of the State chemist, considerable experimental work during the past two years. This work has been confined mainly to surveying, classifying, and mapping the soils of the State, and to conducting on some of the typical soils fertilizer, variety, culture, and new-crop tests. In this connection the department has secured two farms on type areas of the coastal plain section of the State.

Oklahoma College and Station.—The vacancy caused by the resignation of E. M. Wilcox, who has gone to Alabama, has been filled by the appointment of Walter R. Shaw, Ph. D., as botanist and entomologist in the college and station. Work has commenced on the new buildings for the college and station. An addition to the library building, to contain quarters for the departments of botany and entomology and domestic economy, and an auditorium, an engineering building, and a barn comprise the chief improvements, the cost of which will be $54,000.

Oregon College and Station.—F. M. McElfresh has resigned his position as assistant in zoology and entomology, and William T. Shaw, recently of the Iowa College and Station, has been elected to fill the vacancy as biologist in the college.

Porto Rico Station.—At the recent meeting of the American Association for the Advancement of Science L. M. Underwood read a paper before the botanical section on "The location of a tropical research station in Porto Rico," in the course of which he advocated the location of the agricultural experiment station of Porto Rico where it would also be available as a station for general botanical research, and suggested the eastern half of the island, especially the region between Arecibo and Utnado, as presenting the most favorable conditions for agricultural experiments and for botanical research, combined with accessibility. His suggestion, as far as it related to the establishment of a botanical laboratory for research in connection with the proposed experiment station, was embodied in a resolution which was adopted by the section. Thus far the station has not been permanently located, as the island has been looked to to provide the necessary land, and for various reasons none of the tracts yet offered has been accepted. Some preliminary experiments have been undertaken on land which has been leased at Rio Piedras, near San Juan, and temporary stables will be erected. The experiments here will consist largely in the growing of annual crops and vegetables, together with the propagation, grafting, and assembling of nursery stock that will be needed when permanent lands can be secured. Work has already been commenced in the interior on the improvement of the coffee by selection of seed and by propagating in seed beds prepared for the purpose. As soon as the present crop is gathered an effort will be made to improve an old grove by thinning, pruning, reducing the shade, cultivation, and whatever practical methods give promise of good results. James Mackinlay, of New York, has been appointed assistant agriculturist to the station, and O. W. Barrett, of Vermont, entomologist and botanist.

Rhode Island College and Station.—B. L. Hartwell, first assistant chemist, has been granted leave of absence for the purpose of taking a course in chemistry at the University of Pennsylvania. G. F. Parmenter, assistant chemist, has resigned to accept a position as instructor in chemistry at Brown University. Martha Austin, assistant chemist, and Thos. H. Taylor, jr., poultryman, have also resigned. The work of investigation in connection with poultry has been assigned to Cooper Curtice, biologist of the station. The station is now conducting experiments for the purpose of ascertaining the best and most economical means of rearing incubator chicks. Experimental work is also in progress in connection with fowl cholera, goose cholera, and blackhead of turkeys. An old building is being remodeled to suit the requirements of the work in connection with the rearing of incubator chicks. The entire poultry plant of the station and college has been moved from land leased by the college to a location on the college farm. The agricultural instruction of the college is now in charge of F. W. Card, assisted by J. A. Tillinghast. The latter has general supervision of the college farm and continues in charge of the details in the field experiments.

South Carolina College and Station.—D. H. Henry, B. S., has been appointed assistant chemist of the station. A new incubator and brooder house is being built, and a dry house for evaporating sweet potatoes and a laboratory for teaching soil physics, in connection with the agricultural lecture room, are being equipped. The farmers of the State manifested increased interest in farmers' institutes during the past summer. The field institutes were more largely attended, and the college institute had an attendance of nearly 500 representative farmers from every part of the State. Letters requesting information have doubled in number during the past year.

Tennessee Station.—S. E. Barnes, a graduate of the Iowa Agricultural College, has been elected dairyman, vice George A. Flickinger, resigned. Provision has been made for a working farm foreman, so that John R. Fain, who is at present farm manager, may have more time to devote to experimental work, especially in the line of animal husbandry. The unprecedented flood which swept over the university farm in September practically destroyed one or two of the more important feeding experiments contemplated for the fall and winter.

UTAH STATION.—W. D. Beers, B. S., has been appointed assistant in irrigation engineering. J. A. Wright, secretary of the State board of horticulture, has been placed in charge of the horticultural work of the station, vice C. P. Close, who, as noted above, has gone to the Delaware College and Station. Mr. Wright has had charge of the Southern Utah Experiment Station at St. George. This station was established by the State legislature two years ago, and an appropriation of $6,000 made for its maintenance for the biennial term. It is under the control of the State board of horticulture. It has a tract of about 40 acres of land and a house for the foreman. The purpose is to devote it quite largely to the study of problems in fruit culture.

VERMONT STATION.—E. S. Gregg has been appointed dairyman of the station, vice G. W. Strong.

WEST VIRGINIA UNIVERSITY AND STATION.—K. C. Davis, Ph. D., a graduate of Kansas Agricultural College and Cornell University, and instructor in botany in the Minnesota State Normal School, has been elected professor of horticulture in the university and horticulturist of the station, vice L. C. Corbett, who has become horticulturist in this Department in charge of the Arlington experimental farm.

WISCONSIN UNIVERSITY AND STATION.—F. H. King, in charge of the department of agricultural physics of the university, has resigned to assume charge of the work in soil climatology in the Bureau of Soils of this Department. A. R. Whitson, for some time past assistant professor in agricultural physics, has been placed in charge of the department vacated by Professor King. E. G. Hastings, assistant bacteriologist of the station, has been granted leave of absence for a year's study in Europe, and John F. Nicholson has been appointed in his place.

MEETING OF THE AMERICAN POMOLOGICAL SOCIETY.—The thirty-seventh biennial meeting of this society was held in Buffalo September 12 and 13, 1901. There were present about 250 delegates, 174 of whom were accredited. These represented 30 States, including Ontario. The exhibits of the society were large and of high quality. Among these was an exhibit of grapes, apples, pears, peaches, and muskmelons, part of which were grown under glass and against walls by a French organization of commercial growers (Syndicat Central des Primeuristes Française). This was made in the nature of a return for the American exhibit in Paris. The fruit was eleven days in transit and much of it was spoiled, particularly the melons and the thin-skinned grapes.

The committee on awards gave out in all 16 silver and 10 bronze Wilder medals, 2 silver and 2 bronze medals being awarded the French exhibitors. The medals were not given out as awards for competitive exhibits, but rather as awards for exhibits of superior merit.

President Charles L. Watrouse, Secretary W. A. Taylor, and Treasurer L. R. Taft were retained as officers of the association.

Following the president's address, in which the progress in pomology for the past half century was reviewed, W. T. Macoun discussed the subject of orchard renovation in the fruit districts of Ontario. At Ottawa drought is not feared, and apple growers keep their orchards in sod and have good success. The experimental orchard at Ottawa is located on sandy land with a cold subsoil not well drained. Red clover is the cover crop used. It is cut from four to six times in a season, each time just before the blossoms appear, and left to lie on the ground. The crop is believed to evaporate a large amount of moisture from the soil, thus aerating it and making it drier and warmer and adding a large amount of humus to it. The oyster-shell bark louse is controlled by spraying the tree with a lime wash made in the proportion of 1 to 2 pounds of slacked lime to a gallon of water and strained.

In Michigan orchards L. R. Taft placed spraying as the first requisite of successful apple growing, manuring second, and cultivation third. Tobacco dust was recommended for the root aphis. The experience of L. C. Corbett in West Virginia was also in favor of this treatment for the root aphis.

Quality and market was the subject of a paper by Charles W. Garfield. It was pointed out that the aim of the grower should be to place on the market fruit of superior quality in the best condition. F. A. Waugh made a distinction between table quality and market quality, stating that for wholesale purposes quantities of fruit of uniform grade were demanded, while table quality was of minor importance; but for the private demand small quantities of fruit having table quality is required. Improvement in the quality of shipping apples would be had with improved methods of marketing.

L. H. Bailey contrasted the pomology of the Atlantic States with that of California. Commercialism in fruit growing increases as we recede westward from the Atlantic coast. The wholesale cultivation of a few varieties for the general market takes the place of the special varieties for special markets. The chances for success in fruit growing are as great in the East as in California. California fruit is increasing in quantity in the East but it will never compete with the special grower in the special markets of the East. Elements of success in fruit growing are (1) faith in the region where you are, (2) tillage, and (3) cooperation in large areas devoted to one particular kind of fruit.

The development and needs of the export fruit trade were discussed by L. A. Woolverton, of Ontario, G. T. Powell and Charles Foster, of New York, and H. E. Dosch, of Oregon. It was shown that strict grading and honest picking are essential, better shipping accommodations are needed, and better methods of refrigeration.

Other papers read and discussed at the meeting were as follows: Some experiments in orchard treatment, F. M. Webster; Fermentation of fruit juices by control methods, W. B. Alwood; Orchards of the Apple-Pie Ridge and river-front regions of West Virginia, L. C. Corbett; Horticultural conditions in Minnesota, S. B. Green; and University extension work in agriculture at Cornell, J. Craig.

The society decided to be represented by delegates to the New York Hybridization and Plant Breeding Conference in 1902.

The National Beekeepers Association met in joint session with the society at one of its evening sessions. Papers were read at this meeting as follows: Bees as fertilizers of flowers, J. Fletcher; Relation of bees to the orchard, M. B. Waite; Spraying fruit trees in bloom, S. A. Beach; and The pomologist and the beekeeper, H. W. Collingwood.

On the whole the meeting was generally considered one of the best ever held; the programme was crowded, and each session well attended.

Miscellaneous.—*Journal d'Agriculture Tropicale* is the title of a new monthly journal published at Paris under the editorship of J. Vilbouchevitch. The first number was issued July 31 of this year. The journal is to be devoted to the agriculture of all of the tropical countries where "the French language is employed in preference to the German, English, or Dutch languages," including the French and Portuguese colonies, Belgian Kongo, Mexico, Brazil, and other Central and South American countries, Cuba, Porto Rico, Egypt, and the island of Mauritius. The first number contains articles on sisal hemp and machines for preparing the fiber from it; the culture of peanuts; good and bad Castilloa; the dwarf mulberry of Tonkin and its value for the production of silkworms; coffee culture in the Transvaal, and bananas; and notes on new books, statistics of sisal hemp and caoutchouc, besides minor articles.

An agricultural-physiological experiment station has been established in connection with the Technical High School at Prague. The station will have a physiological, a phytopathological, and a bacteriological division, with an assistant in charge of each. Each division will be provided with a separate laboratory. Prof. Julius Stoklasa, a member of the faculty of the Technical High School, with whose agricultural investigations the readers of the Record are familiar, will be director of the new station.

A seed-control station, especially for the examination of forest seeds, has been established in connection with the Royal Prussian Forestry Academy at Eberswalde, Germany. The director of the station is Prof. Adam Schwappach.

A dairy station has been established in connection with the Agricultural Institute of Gembloux, with M. Henseval as technical director of the station.

E. Mach, director of the Institut d'Agriculture of San Michele, Tyrol, Austria, died recently at the age of 56. His manual of viticulture and œnology (*Handbuch des Weinbaues und Kellerwirthschaft*) is considered a model work on viticulture.

EXPERIMENT STATION RECORD.

Vol. XIII. No. 4.

The School of Practical Agriculture and Horticulture at Briarcliff Manor, N. Y., was regarded as something of an experiment at the time of its establishment, over a year ago, and its progress has been followed closely by persons interested in the various forms of agricultural education. As stated in its prospectus, "The school was established by the Committee for the Promotion of Agriculture of New York (now merged into the Board of Trustees) to open an independent means of livelihood for young men and women, especially of our cities; to demonstrate that higher value may be obtained from land under intelligent management, and to develop a taste for rural life."

It is situated in one of the most picturesque sections of Westchester County, within 3 miles of the Hudson River, and in immediate proximity to the Briarcliff Farms of over 6,000 acres belonging to Mr. Walter W. Law, a member of the Board of Trustees. On these farms are maintained a herd of 1,045 Jersey cattle, 487 being registered stock. The milk and butter produced are sold in New York City. There are on the farms over 1,500 pigs, 4,000 chickens, and 400 sheep. There are also extensive greenhouses, in which roses, carnations, and other flowers are produced on a large scale. The students of the school thus have exceptional opportunities for observing the operations of stock husbandry, dairying, and horticulture as conducted on a large commercial scale. The school has under its direct control a farm of 65 acres, part of which has been laid out in orchards and gardens, the remainder being devoted to farm crops. A school building and dormitory, with accommodations for about 40 instructors and students, has been erected on this farm. The other buildings are a farmhouse, greenhouse, barn, and poultry houses.

The faculty consists of a director, horticulturist, agriculturist, and instructors in nature study and cold storage.

Both men and women are admitted as students. "Applicants must have a good knowledge of English, give satisfactory references, be over 16 years of age, and in good health."

The course of study extends over two years of forty weeks each, and includes instruction in agriculture, horticulture, cold storage, and in botany, chemistry, geology, physics, agricultural zoology, entomology, meteorology, land surveying and leveling, and bookkeeping, all with special reference to agriculture and horticulture. Instruction, largely in the form of lectures, is given during the forenoon of each school day, and in the afternoon students, both men and women, engage in the operations on the farm under the supervision of their instructors. A foreman, gardener, and small force of laborers are employed, so that the farm operations go on continuously, the students doing such work as they can in the three or four hours a day that they devote to their practical exercises. The school is conducted, as its title indicates, as a practical school, and no attempt is made to furnish a general education, only such branches of science being taught as are necessary to an intelligent understanding of the practical instruction in agriculture and horticulture.

The school is maintained by tuition fees of $100 a year per pupil and a charge for board in the dormitory of $280 a year, together with funds secured by the trustees from private sources.

The present year about thirty-five students are in attendance, almost all of whom come from cities. Their ages range from 16 to 35 years, and most of them have previously had a high-school education or its equivalent, while some have enjoyed college privileges. Among them are some persons of considerable means who are studying agriculture with special reference to investments in land or the management of large estates. The school has been remarkably successful in attracting students, and has already reached the present limit of its accommodations. Plans are therefore being made for securing equipment on a larger scale. The applications for admission show that if the tuition fee and board were not so high, many more students could easily be obtained. It thus seems clear that the school is meeting a real demand for practical instruction in agriculture on an entirely different basis from that given in the agricultural colleges, and that there are a considerable number of young people in our cities who, for one reason or another, would prefer to engage in pursuits of country life, provided they had the training requisite for success in them. This school will not in any way take the place of the agricultural college or of secondary schools of agriculture maintained at public expense and intended for the instruction of boys and girls on farms. Its success is, however, one of many indications that the time is at hand for the broadening of our system of agricultural education to include secondary and special schools of agriculture and horticulture, to meet the varied needs of our youth in both city and country for training which will fit them to meet with success in practical agriculture and horticulture.

At the Briarcliff school, as elsewhere, when attempts have been made to give practical instruction in agriculture and horticulture, difficulty has been experienced in securing teachers having the requisite combination of scientific knowledge and practical skill and experience. The same difficulty presents itself when farm managers are sought among the graduates of our agricultural colleges. This presents one of the problems of higher education in agriculture as yet unsolved. Experience seems to show that the requisite practical skill and art of management required for the successful conduct of actual farm operations can not as a rule be acquired by students during the period of their life spent in school and college. They must obtain this afterwards by actual contact with the practical problems of the farm. The case is analagous to that of students in medicine or pedagogy. Just as the graduates of medical schools ought to have hospital practice before setting out as regular practitioners, and the graduates of normal schools ought to have actual school work under skilled supervision before taking charge of schools for themselves, so the graduates of agricultural colleges ought in some way to have opportunities for engaging in farm practice before they are accredited as qualified to be instructors in agriculture or farm managers. Already there is a considerable demand for well-equipped farm managers, and in the near future there are likely to be more openings for well-trained men as instructors in secondary and practical schools of agriculture. There is, therefore, encouragement for graduates of our agricultural colleges to give special attention to fitting themselves to meet such demands.

Plans are being made to hold a graduate school of agriculture at the Ohio State University in July, 1902. The first session of this school will be held under the auspices of that university, whose board of trustees has assumed financial responsibility for this new enterprise. The Association of American Agricultural Colleges and Experiment Stations at its recent session in Washington approved the proposition to hold such a school, and voted to assume responsibility for it after the first session, thus making it a cooperative enterprise for the colleges and experiment stations represented in the association.

Secretary Wilson has taken great interest in the project, and acting on his advice, the Director of this Office has consented to act as dean of the school at its first session, and other officers of the Department will be on its faculty. It is planned to hold a four weeks' session, during which advanced instruction and laboratory practice will be given in three general lines, agronomy, zootechny, and dairying. This instruction will be along both scientific and practical lines, and will be of a character to meet the requirements of advanced students. The cooperation of the leaders in agricultural education and research in this country is already assured, and there is good promise of an unusually strong faculty. A prospectus will be issued about January 15, 1902. Correspondence regarding the school should be addressed to Prof. T. F. Hunt, Columbus, Ohio.

An act for the establishment of an Insular Bureau of Agriculture was passed by the United States Philippine Commission early in October, and was made a part of the general plan of the provisional government established in the islands by the commission. The Secretary of Agriculture was invited, through the Secretary of War, to nominate a suitable person to take charge of the new bureau and its organization. Prof. F. Lamson-Scribner, for nearly eight years agrostologist of this Department, was nominated to this position, and has been formally appointed by the Philippine Commission. His title will be chief of the Insular Bureau of Agriculture, and his headquarters will be at Manila, where he will go sometime during the winter.

The present deplorable condition of agriculture in the Philippines marks the establishment of this bureau as one of the most important acts of the Philippine Commission. As stated in the annual report of the Secretary of War for the present year—

> The methods of cultivation are primitive and ineffective; the ordinary vegetables, notwithstanding the fertility of the land, are small and poor, and the stock is evidently run out and should be renewed. Many grains which are unknown to the people can undoubtedly be raised. They live chiefly on rice, and raise less than they consume.

In general, the bureau will, in the terms of the act establishing it, "seek to promote the development of the agricultural resources of the archipelago." Among other things, it will take charge of and conduct the model farms and experiment stations which were established in a number of provinces under the Spanish régime. The act provides that its organization shall be framed as nearly as may be after our National Department of Agriculture, with such variations as may be required by the differences in conditions and by the provisions of the act establishing Government laboratories for the Philippine Islands.

Professor Scribner has had wide experience in the field of agricultural botany and vegetable pathology, and is familiar with the various agricultural institutions of the country, both State and national. These qualifications will stand him in good stead in working out the lines of the new bureau, selecting its corps of workers, and effecting its organization. Considering the agricultural importance of the islands and the great opportunities for development along so many different lines, the field for research and economic work is exceedingly attractive, and the Bureau of Agriculture should in time develop into one of the strongest and most useful branches of the insular government.

THE ASH CONSTITUENTS OF PLANTS; THEIR ESTIMATION AND THEIR IMPORTANCE TO AGRICULTURAL CHEMISTRY AND AGRICULTURE.[1]

B. Tollens, Ph. D.,

Director of the Agricultural-Chemical Laboratory, University of Göttingen.

Part II.—Importance of Ash Analysis to Plant Physiology and Agricultural Chemistry.

SUMMARY OF THE VARIOUS ASH ANALYSES.

During the course of the century just closed many thousand ash analyses of various products have been made, the reports of which are widely scattered. The compilation of these by E. von Wolff in his book on ash analyses[2] was a noteworthy service and has made them easily accessible. These analyses show that as between different kinds of plants the ash content, both crude and pure ash, varies quite widely, as does also that of the same kind of plants at different stages and when grown in different localities.

The following table shows in a general way the range of ash in the dry substance of the principal categories:

Approximate range in ash content.

	Per cent.	
Cereal grains, kernels	2 – 3.5	
Cereal grains, straw	4.5– 6.5	
Grasses	3 – 9	or more.
Clovers	5 – 9	
Tree leaves	3.5–10	
Wood	0.2– 0.8	
Bark	5 – 7	
Roots and bulbs	3 – 8	or more.

In the case of some plants, as for example, *Elodea canadensis* and Equisetum, these figures are greatly exceeded.

---

[1] Continued from p. 220.

[2] Aschen-Analysen von landwirthschaftlichen Producten, Fabrik-Abfällen und wildwachsenden Pflanzen. Berlin, 1871, pt. 1; 1870–1880, pt. 2.

VARIATION OF THE FIGURES.

As illustrating the variation in the composition as well as in the total amounts of the ash, on the basis of Wolff's compilation, the following table is presented:

Variation in reported ash analyses.

	Pure ash.	In 100 parts of ash. Potassium oxid.	Calcium oxid.	Phosphoric acid.	Silica.	Chlorin.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Meadow hay	2.2–11.4	7.6–56.6	6.0–40.1	2.0–21.3	10.4–63.2	0.2–21.4
English rye grass	7.5–15.0	27.1–52.0	3.5–15.2	6.2–16.0	13.9–49.6	1.3–12.4
Red clover in bloom	4.5– 9.2	8.8–52.0	21.9–53.4	4.0–15.0	0.0–20.0	1.2–11.8
Winter wheat	1.6– 2.5	23.2–41.1	0.9– 8.2	39.2–53.7	0.0– 5.9	0.0– 3.5
Maize	1.0– 1.7	24.3–38.1	0.6– 3.8	37.6–53.7	0.0– 5.5	0.0– 4.8
Winter-wheat straw	4.5– 7.0	9.5–27.4	2.7– 8.9	2.2– 8.9	49.6–72.5	0.0– 7.4
Potato tubers	2.2– 5.8	44.0–73.6	0.4– 7.2	8.4–27.1	0.0– 8.1	0.7–12.6
Potato leaves	5.2–12.9	6.4–42.8	16.1–46.7	2.6–12.1	1.9– 9.4	2.8–10.5

Although a part of this variation may be traced to errors in the determination of the ash, the variations aside from this are unusually large, and the averages calculated from these figures can be of little value. In the case of winter-wheat straw, for example, the individual analyses run all the way from one-half the average figure to double that value, as shown by the following:

Variation in composition of ash of winter-wheat straw.

	Average.	Variation.
	Per cent.	*Per cent.*
Total ash	5.37	4.5– 7.0
In 100 parts of ash:		
Potassium oxid	13.65	9.5–27.4
Calcium oxid	5.76	2.7– 8.9
Phosphoric acid	4.81	2.2– 8.9
Silica	67.50	49.6–72.5
Chlorin	1.68	0.0– 7.4

The average is only a very general indication which can only approximate the truth when based on a very large number of determinations on samples of different origin and harvests, in which case the variations offset each other in a large measure.

CAUSES OF VARIATIONS IN THE AMOUNT AND COMPOSITION OF ASH.

Among the factors, aside from individuality, which influence the variation in composition of vegetable materials may be noted the influence of (1) the stage of growth, (2) the soil, (3) the fertilizers, (4) the available moisture, and (5) the thickness of the stand.

INFLUENCE OF THE STAGE OF GROWTH.

It is evident that the percentage of ash in the plant is not uniform during its growth, since the assimilation of the ash elements from the soil and the increase of organic matter in the plant do not always take place at the same rate. When the ash elements are taken up at a more rapid rate than that at which the organic matter is formed from the carbonic acid of the air and the nitrogenous matter of the soil, the older plants will be relatively richer in ash than where the reverse is true. When reserve matter is stored up, as when starch is stored in seed or cellulose is formed in wood, then the organic matter predominates and only a small percentage of ash is present. The same applies to the separate constituents.

Many investigations of the above points have been made, as for example, those of Arendt with oats, of Pierre with wheat, and of Zöller, Rissmüller, Dulk, Ramann, Tucker, and others with the leaves of trees.

Arendt,[1] who analyzed oats at four periods of growth, found that the content of silicic acid in the dry matter increased, up to the third period, from 17.46 to 28.62 per cent. The sulphuric acid was at its maximum in the fourth period, and the phosphoric acid in the third period, the percentage of phosphoric acid in the ash increasing from 8.93 to 11.21 in that period. The largest amounts of both potash and lime were taken up in the first period, the content of 46.94 per cent of potash and 12.24 of lime in this period decreasing in later periods to 34.48 per cent of potash and 11.59 of lime.

Pierre[2] obtained similar results with winter wheat. From May 1 to July 25, for example, the ash content of the dried plants fell from 7.98 to 3.38 per cent; the percentage of potash in the ash fell from 20.46 to 11.72, of lime from 16.28 to 11.87, and of phosphoric acid from 9.12 to 8.08, while the percentage of silicic acid in the ash rose from 32.84 to 54.26.

In beech leaves, according to Dulk,[3] the ash in the dry matter increased during the period from May 26 to November 7 from 4.68 to 6.39 per cent. The percentage of potash and phosphoric acid in the ash decreased as the season progressed, while that of lime and silicic acid increased.

In a similar way Tucker[4] obtained the following results in a study of the leaves of the plane tree:

Analyses of the ash of the leaves of the plane tree.

Date.	Pure ash.	In 100 parts of pure ash.			
		Potassium oxid.	Calcium oxid.	Phosphoric acid.	Silica.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
June 13	6.10	22.40	28.61	15.00	7.40
November 5	12.25	4.36	15.01	2.73	18.40

[1] Landw. Vers. Stat., 1 (1859), p. 65.

[2] Compt. Rend. Acad. Sci. Paris, 68 (1869), p. 1526; Jahresber. Agr. Chem., 1868–69, p. 264. See Wolff's Aschen-Analysen, pt. 2, p. 6.

[3] Landw. Vers. Stat., 18 (1875), p. 192.

[4] Jour. Landw., 48 (1900), p. 50.

In other words, with the advance of the vegetative process there was a great decrease in the potash and phosphoric acid and an increase in lime and silicic acid as well as in the total ash.

According to the researches of Grandeau and Fliche[1] 4 species of trees contained the following percentages of ash at different dates:

Ash content of young and old leaves.

Species.	Young leaves.		Old leaves.	
	Date.	Ash content.	Date.	Ash content.
		Per cent.		*Per cent.*
Black locust	May 2	6.25	Oct. 13	11.74
Birch	Apr. 30	3.84	Oct. 9	4.68
Bird cherry	Apr. 28	7.80	Oct. 2	7.24
Chestnut	May 1	4.60	Oct. 12	4.55

The wood of old trees is usually poorer in ash than that of young trees. For example, the wood of a beech tree[2] 20 years old contained 0.46 per cent of ash, that of one 40 years old, 0.45 per cent; one 50 years old, 0.36 per cent, and one 220 years old, 0.37 per cent. An oak 15 years old contained 0.53 per cent of ash, one 25 years old, 0.41 per cent; one 50 years old, 0.22 per cent, and one 345 years old, 0.22 per cent.

Bretschneider and Matzdorf found the sugar beet to contain on July 20, in an unripe state, 7.31 per cent of ash in the dry matter. With the growth of the beet and the increase of sugar the ash decreased, and by October 16 had fallen to 3.83 per cent.

The older the plant, or its parts, the greater are found to be the variations in the ash constituents, which is an indication that the storage of materials derived from the soil does not take place in the organs of plants at a uniform rate throughout the period of growth. Accordingly the percentage content of such materials as forage plants, for example, may vary considerably with the time of year. These variations may be brought about, on the one hand, by differences in the extent and activity of the roots in taking up plant nutrients, or, on the other hand, by the migration of these materials from the leaves, stems, etc., to other parts of the plant, where they are held in reserve, increasing the valuable constituents of the latter and decreasing those in the leaves, stems, etc. As pointed out by Fittbogen,[3] toward the end of the vegetative period a part of the nutritive material in the roots is conveyed to the portion of the plant above the ground.

INFLUENCE OF THE SOIL UPON THE ASH OF PLANTS.

It is evident that in soils of different composition quite different amounts of ingredients are at the disposal of plants, and it may be

[1] Ann. Chim. et Phys., 5. ser., 8 (1876), pp. 499, 500.

[2] Weber, in Wolff's Aschen-Analysen, pt. 2, p. 69; Forstl. Blätter, 1876, p. 257.

[3] Landw. Vers. Stat., 6 (1864), p. 481.

presumed that under such conditions they will take up different amounts, and accordingly will show varying percentages of these materials in their ash. Plants grown in lime soils contain more lime than those grown in sandy soils originating from sandstone. For example, Wunder[1] reports that turnips grown in a clay soil rich in lime contained 9.28 per cent of lime in the ash, while those grown in a sandy soil poor in lime contained only 5.47 per cent. Grapevine wood from a soil poor in lime and composed of gneiss, schist, and quartz contained. according to Hruschauer,[2] 32.16 per cent of lime and 34.13 per cent of potash in the ash, while that from a lime soil contained 37.16 per cent of lime and 24.93 per cent of potash in the ash.

Emmerling and Wagner[3] report that hay made from peaty meadows poor in fertilizing ingredients contained 26.30 per cent of potash, 6.50 per cent of lime, and 5.11 per cent of phosphoric acid in the ash, while hay from a good marsh soil contained 37.30 per cent of potash, 9.83 per cent of lime, and 7.28 per cent of phosphoric acid in the ash. On the other hand, the ash of the hay from the poor soil contained 41.82 per cent of silicic acid, while that from the other contained only 21.37 per cent.[4]

From an examination of oats grown on different soils Atterberg[5] found a quite variable content of potash, phosphoric acid, lime, etc., in 1,000 parts of the stalk, seed, and leaves.

INFLUENCE OF FERTILIZERS.

The composition of the ash varies especially when the soil is fertilized with varying amounts of the different ash ingredients in available form. Of the very many evidences of this, only a few cases can be cited. The ash of the sugar beet grown with different fertilizers contained, according to Hanamann,[6] the following:

Potash, lime, and phosphoric acid in ash of sugar beets.

	Potash.	Lime.	Phosphoric acid.
	Per cent.	*Per cent.*	*Per cent.*
Without fertilizers	49.22	17.81	5.78
With potash	52.97	12.31	8.41
With phosphoric acid	48.07	12.71	10.38
In other investigations:			
Without fertilizers	48.69	10.18	12.32
With potash	52.24	8.63	13.85
With phosphoric acid	49.77	8.88	16.34

[6] Landw. Jahrb., 7 (1878), p. 795; 8 (1879), p. 823; Jour. Landw., 1876, p. 41.

According to Wunder,[1] turnips grown in sand with one application of potash, and in a loam soil, contained the following percentages of potash:

Potash in turnips grown in different soils.

	Sand with potash fertilizer.			Loam soil.	
	First year.	Second year.	Third year.	First year.	Second year.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Potash in dry substance	8.15	5.92	4.73	3.95	4.90
Potash in 100 parts of ash	58.29	52.16	43.36	43.12	44.83

Hellriegel[2] found in barley plants grown in water cultures with increasing amounts of potash from 0.35 to 3.96 per cent of potash in the dry matter. E. Wolff[3] found that in oats grown in water cultures of different composition the ash contained from 18 to 54 per cent of potash, 4 to 38 per cent of lime, and 0 to 27 per cent of soda. Nessler[4] found in the ash of the grapevine the following:

Ash constituents in grapevines.

	Potash.	Lime.	Phosphoric acid.
	Per cent.	*Per cent.*	*Per cent.*
Vines not fertilized	16.76	25.66	9.02
Vines fertilized with potash	23.75	23.99	7.34

Nessler[5] states that in general the content of potash as well as of chlorin in the plant is found to be increased by the addition of these elements to the fertilizer. Pfeiffer[6] studied the effect on the chlorin content of potatoes of applying fertilizers containing no chlorids as compared with those containing chlorin, with the following results:

Chlorin in potatoes (air-dry substance).

	Per cent.
Without chlorin fertilizers:	
No potash salts	0.215
Potassium sulphate	.211
With chlorin fertilizers:	
Potassium chlorid	.279
Potassium sulphate and magnesium chlorid	.373
Kainit	.362
Rock salt	.458

Another illustration of the effect of fertilizers on the individual elements of the ash is afforded by the following analyses by Councler[7] of the ash of maple leaves (*Acer negundo*). One series was in water

[1] Land. Vers. Stat., 4 (1862), p. 266. [2] Ibid., 11 (1869), p. 136.
[3] Ibid., 11 (1869), p. 141. [4] Ibid., 16 (1873), p. 186. [5] Ibid., 40 (1892), p. 411.
[6] Ibid., 49 (1898), p. 371. [7] Ibid., 29 (1883), p. 241.

cultures and accordingly supplied with all the elements of plant growth, and the other in the soil. The following shows the composition of the crude ash:

Ash of maple leaves grown in soil and in water cultures.

	Grown in soil.	Grown in water cultures.
	Per cent.	*Per cent.*
Sand and carbon	35.98	9.15
Silica	9.94	3.24
Sulphuric acid	4.06	14.84
Phosphoric acid	1.91	8.90
Alumina	2.23	.00
Ferric oxid	.51	.74
Magnesium oxid	2.62	2.88
Calcium oxid	15.06	12.10
Sodium oxid	.37	.47
Potassium oxid	18.88	36.91
Carbon dioxid, chlorin, and loss	8.74	9.77

In an extended fertilizer experiment, organized by the late Professor Liebscher, with oats on soils from 24 estates von Seelhorst[1] obtained the following results as to the composition of the ash of the part above ground (roots not included):

Phosphoric acid and potash in oat plant (air-dry substance exclusive of roots).

	Potash.	Phosphoric acid.
	Per cent.	*Per cent.*
Not fertilized	2.122	0.588
Fertilized with potash	2.997	.597
Fertilized with phosphoric acid	2.175	.735

Atterberg[2] has made a long series of experiments. He obtained, for example, the following range of potash (in dry matter) in oats grown in sand cultures with increasing amounts of potash: In unripe harvested plants, 0.75 to 2.46 per cent; in ripe straw, 0.41 to 2.76 per cent; and in the ripe grain, 0.76 to 0.80 per cent.

He secured similar results for phosphoric acid, lime, magnesia, and nitrogen content of the plant. With increasing amounts of the respective ingredients, the yield increased and the percentage of the respective ingredients, as a rule.

In the renowned researches of Lawes and Gilbert[3] at Rothamsted the influence of the fertilizers upon the composition of the plant is shown, as in the growth of barley for 30 years with and without an application of potash. With the addition of potassium sulphate the ash of the straw contained from 27.85 to 34.43 per cent of potash, while without the potash fertilizers the straw contained only from 8.70 to 18.44 per cent of potash.

[1] Jour. Landw., 46 (1898), p. 386.

[2] Jour. Landw., 49 (1901), p. 97.

[3] See K. Bieler, Die Rothamsted Versuche. Berlin, 1896, p. 50.

Although the above examples show a marked influence of the fertilizing materials, in or applied to the soil, on the content of these materials in the ash, it should be mentioned that this effect is not always as marked and may disappear entirely or in some cases be quite the reverse of that noted. This may be due to the fact that when an element, as potash, is present in the soil or fertilizer in insufficient amount, the plants develop poorly and give only a very poor yield; while when fertilized with potash a much larger yield is obtained. When the plants grown without potash fertilizer are incinerated, an absolutely smaller amount but a relatively much larger amount of potash may be found in the ash, while the larger yield obtained with potash manuring may show an absolutely larger amount of potash without the percentage of potash being increased. It must be borne in mind that there are always several factors which influence the absolute amounts of plant food taken up by the plant, as well as the percentage composition of the ash. For example, the presence of nitrogen in the fertilizer or the soil has a great influence, since it promotes a vigorous growth, and the increased yield, consisting largely of organic matter, results in a suppression of certain ash elements of the plant (and a preponderance of others). This is shown, for example, in the above-mentioned experiments of von Seelhorst, in which the average percentages of phosphoric acid and potash in the air-dry matter of the oat plant were as follows:

Potash and phosphoric acid in oat plants differently fertilized (von Seelhorst).

Fertilizer applied.	Potash.	Phosphoric acid.
	Per cent.	*Per cent.*
Potash	2.997	0.597
Potash and nitrogen	2.292	.403
Nitrogen	1.536	.413
Without fertilizer	2.122	.588
Phosphoric acid	2.175	.735
Phosphoric acid and nitrogen	1.348	.472

INFLUENCE OF THE THICKNESS OF THE STAND.

It is well known that the growth and development of plants vary greatly with close and thin planting. It is true of plants in general that they develop better when each plant stands by itself than when they are set close together, and it is evident that this is due to the greater area of soil at the disposal of the plant, as well as the increased amount of light and air. When plants have more soil space in which to grow, they naturally have more plant food at their disposal and more moisture, and this condition must influence the amount and the composition of the plant ash. As illustrating the above points, the experiments of von Seelhorst and Panaotovic[1] with spring wheat and oats

[1] Jour. Landw., 47 (1899), p. 379.

may be noted. Pots containing equal amounts of soil, fertilizer, and moisture were planted with 1, 5, and 8 kernels, respectively, with the following results:

Yields of wheat and oats at different thicknesses.

	Number of kernels in pot.		
	1 kernel.	5 kernels.	8 kernels.
	Grams.	*Grams.*	*Grams.*
Spring wheat	43	72.6	77.2
Oats	66.4	80.8	86.6

The yield from the 1 kernel alone was relatively much greater than that from 5 or 8 kernels, and the same was true of the total ash. The percentages of total ash in the grain, and of potash, phosphoric acid, and lime in the ash were as follows:

Ash of wheat and oats grown at different thicknesses.

	Spring wheat.			Oats.		
	1 plant.	5 plants.	8 plants.	1 plant.	5 plants.	8 plants.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Total ash	2.334	2.177	2.034	3.393	3.240	3.382
In the total ash:						
Potash	34.75	29.85	44.59	17.89	12.56	21.05
Phosphoric acid	33.38	32.01	31.27	22.99	20.74	18.59
Lime	7.46	5.33	5.11	7.05	7.03	5.06

It is thus seen that there are great differences in plants grown singly as compared with 5 or 8 grown together in similar pots.

Atterberg[1] made a similar experiment with oats, and found that by thicker sowing and larger yield the percentages of potash and phosphoric acid fluctuated, while that of nitrogen was less than with thinner seeding. The nitrogen content of the straw was as follows: Thin seeding 0.94 per cent, average seeding 0.88 per cent, and thick seeding 0.68 per cent. Beseler and Maercker[2] found that increasing the thickness of the seeding had a similar influence in lessening the nitrogen content of oat grains. It is well known that the sugar content of sugar beets is much influenced by thick and thin planting, and this is also true of the ash constituents.

INFLUENCE OF AVAILABLE MOISTURE ON THE ASH.

In addition to the effect of soil, fertilizer, and thickness of seeding on the composition of the ash of plants, there are other factors at work.

[1] Jour. Landw., 49 (1901), p. 97.

[2] Centbl. Agr. Chem., 13 (1884), p. 453; Ztschr. Landw. Cent. Ver. Sachsen, 1884, Nos. 4, 5.

and among these is the presence of much or little water in the soil. The influence of water has of late been much studied, and in some cases has been found to exceed that of soil, fertilizer, and thickness of seeding.

The life-giving influence of water in the plant world is well known. The enormous irrigation enterprises in the warmer regions carry fertility everywhere, and especially where the soil is naturally rich. The work of Hellriegel[1] is of especial value in studying the importance of this factor in plant production. Fittbogen[2] has also made a careful study of this subject, and more recently A. Mayer, Pagnoul, Remy, and especially von Seelhorst[3] at Göttingen. The latter, with Tucker and Wilms,[4] has made a study of the influence of much and little water in the soil upon the taking up of fertilizing ingredients and the composition of the ash. In general it was shown that when an insufficient amount or "little water" was provided the crops of potatoes, oats, grass, and clover were diminished, and that the yield was materially increased by a medium amount or still more by "much water." In the increased crops grown with much water the percentage of ash in the dry substance was not lessened as compared with that of the crop grown with little water, but, on the contrary, was often somewhat greater, as in the case of the potato; hence it would appear that when plenty of water is present in the soil much more of the ash constituents are taken out by the plant than when there is a deficiency of water.

The percentages of potash, lime, phosphoric acid, sulphuric acid, and chlorin fluctuate with the changes in the amount of water present. This is shown in the case of potato tubers,[5] for example, as follows:

Ash of potato tubers grown with much and little water.

	Pure ash in dry substance.	In the pure ash.				
		Potash.	Lime.	Sulphuric acid.	Phosphoric acid.	Chlorin.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Unfertilized:						
Little water	3.85	59.38	1.19	10.25	15.28	10.79
Much water	4.06	56.16	3.22	9.51	15.52	13.29
Fertilized with potassium sulphate:						
Little water	3.83	61.42	1.97	8.29	14.55	10.84
Much water	4.16	60.21	3.34	8.91	13.89	11.91

There was an increase in the percentages of lime and of chlorin with the use of much water, while the potash decreased somewhat.

[1] Beiträge zu den naturwissenschaftlichen Grundlagen des Ackerbaus mit besonderen Berücksichtigung, u. s. w. Braunsceweig, 1883; Jour. Landw., 31 (1883), p. 376.

[2] Landw. Jahrb., 2 (1873), p. 353.

[3] Jour. Landw., 47 (1899), p. 369.

[4] Ibid., p. 251.

[5] Daszewski and Tollens, Jour. Landw., 48 (1900), p. 223.

Von Seelhorst[1] obtained the following percentages of phosphoric acid and potash in the dry substance of oat kernels:

Phosphoric acid and potash in oats grown with much and little water.

	Phosphoric acid.	Potash.
	Per cent.	*Per cent.*
Unfertilized:		
Little water	0.933	0.482
Much water	1.060	.616
Fertilized with potash and nitrogen:		
Little water	1.083	.462
Much water	1.151	.470

The content of potash and phosphoric acid in the grain was, therefore, considerably increased by the presence of an abundant supply of water.

Recently Langer and von Seelhorst[2] have made experiments of this kind with oats grown in sterilized sand, and Langer and Tollens have made analyses of the resulting crop, with the following results:

Fertilizing ingredients in oat roots.

Fertilizer applied.	Little water.			Much water.		
	Phosphoric acid.	Potash.	Nitrogen.	Phosphoric acid.	Potash.	Nitrogen.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Phosphoric acid	0.251	0.147	0.748	0.165	0.142	0.678
Phosphoric acid and potash			.736	.269	.247	.645
Phosphoric acid and nitrogen	.233	.116	1.138	.276	.163	.896
Phosphoric acid, potash, and nitrogen	.236	.262	1.154	.237	.189	.919

It will be seen that the results vary quite widely with the use of the different fertilizers and amounts of water.

RELATION OF THE ASH OF PLANTS TO THE FERTILIZING INGREDIENTS OF THE SOIL.

In view of the fact that the soil and the fertilizer used influence the amount and composition of the ash of plants, it would seem that an examination of the plants grown on a soil might give an indication of the plant-food constituents of the soil. This point has been studied in a comprehensive manner, first by Heinrich[3] and afterwards by Liebscher, Helmkampf, Atterberg, and others. According to some of these investigations it appears that the fertility of a soil might be measured by growing plants adapted to the particular soil and analyzing the plants, the results indicating a greater or smaller content of assimilable elements in the soil.

After Hellriegel[4] had shown that the potash content of barley straw

[1] Jour. Landw., 46 (1898), pp. 422, 423.

[2] Ibid., 49 (1901), p. 209.

[3] Grundlagen zur Beurtheilung der Ackerkrume, 1882.

[4] Landw. Vers. Stat., 11 (1869), p. 136.

might range from 0.4 to 6 per cent, according to the percentage in the soil, Heinrich used the oat plant in his experiments and analyzed the roots of the crop grown. When he found in the dry roots of oats from 0.08 to 0.1 per cent or less of potash or phosphoric acid and 0.35 or less of lime, he concluded that the soil was deficient in these materials and that the necessity of fertilizing with them was indicated.[1]

Dikow[2] confirmed Heinrich's results in general, although he employed barley and fixed the minimum for phosphoric acid in the roots at 0.13 per cent.

Atterberg[3] made a long series of investigations, among others with the oat plant. He did not analyze the roots, but the straw and the grain. In his sand cultures, in which he applied the phosphoric acid in the form of a phosphate solution containing all the way from 1 to 7 per cent of phosphoric acid, the phosphoric acid in the resulting straw rose proportionately from 0.026 to 0.792 per cent and in the grain from 0.44 to 0.95 per cent. At the same time the total yield increased, but the percentage of nitrogen in the straw diminished. He laid special stress on the determination of the ratio between the nitrogen and phosphoric acid and also the potash. He concluded that in the oat grains the ratio of nitrogen to phosphoric acid should approach as nearly as possible 100 : 55, and in the oat straw the ratio of nitrogen to potash, 100 : 100; that is, the percentage of nitrogen should equal that of potash.

Joulie[4] presented some general deductions to the effect that from plant analyses (wheat) the fertility and fertilizer needs of the soil could be determined upon; and some of Maercker's researches indicate the same conclusion.

Helmkampf[5] made a thorough study of Heinrich's method. He did not deny that the method had value, but considered spring wheat a better plant for experimental work of this kind than the oat plant. He advised, furthermore, that the part of the plant above ground, harvested during the period of bloom, be used for analysis instead of the roots. He did not give any minimum values for the individual elements, although he stated that when there was an increase in the percentage of potash, phosphoric acid, and nitrogen in the dry matter of the crop as a result of the application of these materials to the plat, the need of these materials was indicated.

In a more recent article by Atterberg[6] the minima for oats are given as follows:

---

[1] He made the same application in case of nitrogen as in the ash constituents.

[2] Jour. Landw., 39 (1891), p. 134.

[3] Landw. Jahrb., 15 (1886), p. 415; 16 (1887), p. 757; Jour. Landw., 49 (1901), p. 97.

[4] Jour. Agr. [Paris], 1889, I, No. 1058, p. 89.

[5] Jour. Landw., 40 (1892), p. 168.

[6] Ibid., 49 (1901), pp. 165, 172.

Atterberg's minima for oats.

	Ripe kernels.	Whole plant.	Half-ripe plant.
	Per cent.	*Per cent.*	*Per cent.*
Phosphoric acid	0.37	0.21	0.14
Potash	....	.37	.37
Lime	....	.08	.10
Magnesia	....	.10	.08
Nitrogen	....	.80	.68

It is seen from the above that in spite of much research and much discussion the question of judging of the soil by the results of ash analysis of the plant grown therein is not settled. It might be helpful to a further clearing up of the question to grow plants like oats or spring barley on a very poor soil and gradually increase the applications of potash, phosphoric acid, and nitrogen. With very little plant food the plants would make insufficient growth; with somewhat more the growth would be better, and gradually the amounts of fertilizers would be determined with which the plants began to make satisfactory growth. Then analysis of the resulting plants would show certain percentages of potash, phosphoric acid, and nitrogen, and thus the minimum for these elements in the plants would be found. If similar plants grown on the soil to be tested should show a content of potash, phosphoric acid, and nitrogen lower than this minimum the indication would be clear that the soil was deficient in these elements of plant food, and they should be supplied in the fertilizer.

This method of determining the fertilizing elements deficient in the soil by the analysis of the ash of the plants grown therein still requires much investigation. The percentages of potash, phosphoric acid, etc., in the plant ash, as well as the amounts in the dry matter, are, as already described, influenced not only by the plant food contained in the soil, but also by other conditions, as the water content of the soil or the amount of rainfall. Many researches are yet required to make the method practicable and reliable.

Although investigation on the subject of the ash constituents of plants has been very extensive, much still remains to be done and the subject presents an inviting field for thorough and exact research. In the present status of our knowledge such researches are much to be desired.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Analysis of fertilizers, D. Sidersky (*Analyse des engrais. Paris: Ch. Béranger, 1901, pp. 240, figs. 2*).—This book has been prepared in accordance with the action of the Second International Congress of Applied Chemistry at Paris in 1896, instructing the author to collect the various official methods of analysis of fertilizers in one publication in the French language. It contains the official methods adopted in France, Belgium, Holland, and the Grand Duchy of Luxemburg; Germany and Switzerland; Austria-Hungary; the United States, and Italy. The report of the committee appointed by the Third International Congress at Vienna in 1898 on international methods, which was adopted by the Fourth Congress at Paris in 1900, is also given, with a short account of the Kjeldahl method by Kjeldahl himself.

A contribution to the improvement of the rapid determination of water-soluble phosphoric acid in superphosphates, L. von Széll (*Landw. Vers. Stat., 55 (1901), No. 4–5, pp. 325–346; abs. in Chem. Ztg., 25 (1901), No. 52, p. 199*).—This is an account of an investigation on 7 different kinds of superphosphate of the influence on the accuracy of the determination of soluble phosphoric acid of (1) lack of uniformity in the sample, (2) different methods of extraction, (3) imperfect filtration, and (4) errors in the precipitation and subsequent operations of the determination. The results show that large errors may be introduced into the determination by lack of attention to any of the points named. As a result of his work, the author proposes the following method: Grind 20 gm. of the sample, which has been passed through a 3 mm. sieve, with water in a porcelain or glass mortar until it forms a thick broth. Gradually add more water and decant the solution into a liter shaking flask. After extracting in this way 4 or 5 times wash the insoluble residue into the flask. Fill the flask nearly to the mark and shake for ¼ to ½ hour in a shaking apparatus, complete the volume to the mark, and filter through double filter papers. If a shaking apparatus is not available allow the solution to stand 1 to 2 hours, with frequent shaking. To 50 cc. of the clear filtrate add, with vigorous stirring, just enough citrate solution (300 gm. citric acid, 1 liter of 24 per cent ammonia, and 3 liters of water) to dissolve the precipitate formed on the first addition of the citrate, then add an additional quantity of the solution equal to one-tenth the amount so used to clear up the solution. Precipitate the phosphoric acid by adding, with constant stirring, the required amount of magnesia mixture, prepared by dissolving 55 gm. of magnesium chlorid and 70 gm. of ammonium chlorid in 650 cc. of water, making the volume to 1 liter with 0.96 sp. gr. ammonia, allowing to stand 24 hours, and filtering. Twenty-five cubic centimeters of magnesia mixture is usually sufficient for the precipitation. After standing 6 to 12 hours, or after ¼ to ½ hour's mechanical stirring and 2 hours' standing, collect the precipitate on a filter, wash with 2½ per cent ammonia until free from chlorids, dry the precipitate at 100 to 120° C., char over a low flame, then ignite strongly for ½ hour, and weigh.

On the adaptability of the molybdic method to the determination of citric-acid soluble phosphoric acid in Thomas slag, O. Foerster (*Chem. Ztg., 25 (1901), No. 39, p. 421*).—To reduce the precipitation of silicic acid as much as possible the author recommends that in the precipitation with molybdic solution the beakers be allowed to stand 10 to 15 minutes in a water bath which is not higher than 80° C. at the beginning and is allowed to cool after the beakers are placed in it.

Estimation of phosphates in potable waters, A. G. WOODMAN and L. L. CAYVAN (*Jour. Amer. Chem. Soc., 23 (1901), No. 2, pp. 96–107, figs. 2*).—The ordinary colorimetric methods are criticised and the following modification is recommended: Mix 50 cc. of the sample with 3 cc. of nitric acid (sp. gr. 1.07), evaporate to dryness on a water bath, and dry the residue in a water oven for 2 hours to render silica insoluble. Dissolve in 50 cc. of water, and without filtering introduce into tube for colorimetric determination. Tubes of hard white glass 2.5 cm. in diameter and 24 cm. long to the 100 cc. mark are recommended. To the solution in these tubes add 4 cc. of ammonium molybdate solution (50 gm. per liter) and 2 cc. of nitric acid (sp. gr. 1.07), and after 3 minutes compare the color with that obtained by the use of standard solutions of sodium phosphate.

On the determination of dry matter in soil samples, H. PUCHNER (*Landw. Vers. Stat., 55 (1901), No. 4–5, pp. 309–324*).—Determinations of moisture in a large number of different kinds of soils, using various kinds of apparatus and methods, are reported. From the results obtained the conclusion is drawn that it is impossible to accurately determine moisture in soils by means of the ordinary methods of drying at 105° C. The precautions which the author suggests in order to secure accuracy are (1) cooling the dried sample only in a closed desiccator before weighing; (2) the use of a well-ventilated drying oven, so that the heated gases are rapidly removed; (3) the introduction of the sample into the drying bath only after the temperature has been raised to 105°, and (4) maintaining the temperature uniformly at 105°. The apparatus which the author considers most nearly satisfying these conditions are those of Soxhlet[1] and Ulsch.[2] It is suggested that electrical heating might be applied to this purpose with advantage.

Calcium carbonate in soils, and a new apparatus for the determination of the same by practical agriculturists, M. PASSON (*Deut. Landw. Presse, 28 (1901), No. 42, pp. 367, 368, fig. 1*).—The importance and function of active lime compounds (carbonates) in soils are discussed, and a modification of Gerlach's simplified Scheibler apparatus for the rapid determination of carbonates in soils is described. This apparatus consists of two parts, a generator and a measuring tube. The generator consists of a wide-necked glass flask, closed with a rubber stopper, through which passes the small neck of a pear-shaped flask, which reaches down into the larger flask and carries the hydrochloric acid used in driving off the carbonic acid from the soil. This smaller flask has a hole in its side through which the acid is introduced. The measuring tube is U-shaped, about 2 cm. in diameter, and 20 cm. high. The right arm is funnel-shaped at the top and has a side tube with stopcock near the bottom. The left arm carries a scale covering a volume of 4.65 cm., graduated to read to tenths of a per cent of calcium carbonate. This tube is connected with the generator by means of a rubber tube. In operation, the tube is filled with water to the zero mark of the scale. The small pear-shaped flask of the generator is filled about three-fourths full with dilute hydrochloric acid through the hole in its side. About 20 gm. of the soil to be tested is placed in the larger flask of the generator. The parts of the apparatus are then connected, and the generation of the carbon dioxid from the soil is begun by tilting the digestion flask so that the acid runs out of the hole in the side of the small flask upon the soil. The gas passes over into the measuring tube, displacing the water in the left arm and causing it to rise in the right. By means of the stopcock the level of the water is maintained at the same height in both arms of the tube. When no further gas is evolved by vigorous shaking of the generator, the

---

[1] Ztschr. Angew. Chem., 1891, p. 363.
[2] Chem. Ztg., 19 (1895), No. 51, p. 1183.

percentage of calcium carbonate is read from the scale. If 0.4 or more of calcium carbonate is thus found in the soil, application of lime is considered unnecessary.

The determination of lime in soil samples, E. HOTTER (*Ztschr. Landw. Versuchw. Oesterr., 4 (1901), No. 5, pp. 632–636; abs. in Chem. Ztg., 25 (1901), No. 58, Repert., p. 208*).—The method proposed by the author for the determination of available lime (in form of carbonate) in soils is as follows: Digest 20 gm. of the dry soil, which has been ground to pass a 15 mm. sieve, with 50 cc. of 20 per cent acetic acid for one-half hour in a boiling water bath, make the volume to 1 liter, shake thoroughly, and allow to stand for 12 hours for the solution to become clear. To 200 cc. of this solution add ammonium oxalate in excess to precipitate lime. Collect the precipitate on a filter, wash with cold water, and heat gently at first and then strongly ignite, cool, and weigh the CaO obtained. The ignited precipitate is generally colored gray or brown by manganese oxid, but the amount of this substance is usually negligible. It may be removed, however, by dissolving in dilute nitric acid, filtering, and reprecipitating the lime. Twenty comparisons of this method with the gravimetric method based upon the determination of carbon dioxid are reported. The results by the new method are as a rule higher than those given by the gravimetric method.

The complete analysis of feeding materials, C. A. BROWNE, JR., and C. P. BEISTLE (*Jour. Amer. Chem. Soc., 23 (1901), No. 4, pp. 229–236*).—A sample of distillery waste or mash analyzed by the usual method at the Pennsylvania Station showed a nitrogen-free extract content of 42.93 per cent. Of this about 25 per cent was pentosans, leaving some 15 per cent of material unaccounted for. In analyzing the latter substance by the Sherman method (E. S. R., 8, p. 951) the sum of all the ingredients in the feeding stuff was found to be 96.01, leaving a residuum of about 4 per cent. In order to determine the composition of this residuum a second series of samples was carried through as in the first case, except that the pentosans in the residues were estimated after each stage of the process. From these results it appears that several per cent of a material of a pentose nature found its way into the alcoholic or aqueous extracts, which because of its copper-reducing power would affect the sugar and dextrin determinations. As no copper-reducing bodies were removed by the alcohol, it seems that these pentoses were removed by the water. The copper-reducing power of the aqueous extract the writers believe to be due to bodies of a pentose nature, and if such be the case a serious error exists in the usual process of determining dextrin. Further tests of the results found are presented, and attention is called to the uncertainties in the analytical methods of feeding stuff analysis, as well as to the more or less arbitrary nature of the factors for calculating protein and pentosans.

The hydrochloric-acid-phloroglucin method in the determination of pentosans, E. KROBER (*Jour. Landw., 48 (1901), No. 4, pp. 357–384*).—The author made an extended study for the purpose of testing the method, and in order to determine factors for estimating furfurol and other substances from the phloroglucid obtained. He found that the results are not influenced by allowing the precipitate to stand from 14 to 20 hours. A porcelain Gooch crucible is better adapted to collecting the precipitate, and the wash water should be put through in small portions, attention being paid to the physical condition of the residue, otherwise the filtrate may show no reaction for chlorin while the residue will contain it. Should the precipitate contain chlorin, too high results will be obtained. No practical difference was found in the results when pure phloroglucin and that containing diresorcin was used. Twice as much phloroglucin as is expected of the furfurol should be used. Before adding the phloroglucin to the furfurol solution it should be dissolved in warm diluted hydrochloric acid (specific gravity 1.06). Drying the precipitate 4 hours at a temperature of from 98.5 to 100° C. is recommended. Attention is called to the fact that phloroglucid is very hydroscopic, and the author obtained better and more uniform results by cooling the Gooch crucible in a weighing bottle in the desiccator.

In studying the composition the author came to the conclusion that 1 molecule of furfurol and 1 molecule of phloroglucin unite, 2 molecules of water being eliminated. By using pure furfurol, arabinose, and xylose with the phloroglucin, factors were determined from which a table was worked out for estimating furfurol, arabinose, araban, xylose, xylan, pentose, and pentosan from the phloroglucid obtained in analysis. The table covers amounts from 0.03 and 0.3 grams; higher and lower amounts may be estimated from a formula.

The determination of pentosans, G. S. Fraps (*Amer. Chem. Jour., 25 (1901), No. 6, pp. 501–508*).—It is generally assumed that when pentosans are distilled with hydrochloric acid of 1.06 sp. gr. furfurol is the only product obtained in the distillate, precipitable by phloroglucol. The author in his work found that if the proper precautions were not taken insoluble fatty acids and an amorphous black precipitate (formed upon the distillate simply standing) were usually present, as well as a substance or substances, termed furaloid, which is precipitated by phloroglucol and destroyed, partially or wholly, by second distillation. These furaloid-yielding bodies seem to be widely distributed in nature, as all materials tested contained them in percentage varying from 6.9 to 22.6. They are hydrolized by boiling with 1.25 per cent sulphuric acid, at the same time being almost, if not entirely, destroyed. In the sample of timothy-hay excrement examined they were more highly digested than total pentosans.

As the possibility of the formation of these furaloids from true pentosans (anhydrids of pentose sugars) by distillation with hydrochloric acid was found, from results obtained on xylose, to be highly improbable, it is evident that their presence in crude furfurol affects the determination of pentoses. The author questions the expediency of determining pentosans and furaloid-yielding substances separately until more is known about pentosans.—C. B. WILLIAMS.

The nature of pentosoids and their determination, G. S. Fraps (*North Carolina Sta. Bul. 178, pp. 59–74*).—The author summarizes existing knowledge relating to pentosoids, and reports his investigation on their properties and their determination, which is described above from another source.

Determination of organic nitrogen by the methods of Kjeldahl and Will and Varrentrap, A. Van Engelen (*Rev. Internat. Falsif., 14 (1901), pp. 14–18; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 463, II, p. 343*).—The Kjeldahl method and its various modifications are briefly reviewed and experiments with pear leaves and cotton-seed meal are reported, which show that the highest percentages of nitrogen were obtained by closely following Kjeldahl's original directions, namely, digesting for 2 to 3 hours with sulphuric acid and adding potassium permanganate. For occasional determinations of nitrogen the Will and Varrentrap combustion method is considered more convenient. The author uses an iron combustion tube.

Research work in plant ash determinations conducted in connection with the Association of Official Agricultural Chemists, A. E. Shuttleworth (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 22–25*).—Two series of ash determinations comparing the official method with the author's method (E. S. R., 11, p. 304) made by C. C. Moore of the Bureau of Chemistry of this Department, G. S. Fraps of the North Carolina College of Agriculture and Mechanic Arts, and W. P. Gamble of the Ontario Agricultural College, are reported in tabular form and discussed. The author believes that volatilization and fusion in the preparation of ash are two important sources of error, and that by his method the use of calcium acetate overcomes the difficulty of fusion and the use of a closed platinum apparatus prevents volatilization.

Household tests for the detection of oleomargarine and renovated butter, G. E. Patrick (*U. S. Dept. Agr., Farmers' Bul. 131, pp. 11*).—Notes are given on renovated or process butter and on its method of manufacture, and two tests, the boiling test and the Waterhouse test, for distinguishing genuine butter from renovated butter or oleomargarine are described in a popular manner.

Volumetric estimation of boric acid, H. Lührig (*Pharm. Centralhalle, 42 (1901), pp. 50–56; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 462, II, p. 280*).—The author indorses the accuracy of Jörgensen's method, which he deems superior to Gladding's process, it being more rapid and less complicated. When testing meat for boric acid, he recommends moistening the sample with strong sodium hydroxid, evaporating to dryness with constant stirring, adding a little sodium carbonate, and then burning the dry mass to ash.

Determination of the hardness of water, M. Pleissner (*Pharm. Centralhalle, 42 (1901), pp. 145–147; abs. in Chem. Centbl., 1901, I, No. 14, p. 796*).

Determination of the addition of water to wine, A. Gautier, A. Chassevant, and M. de la Source (*Jour. Pharm. et Chim., 6. ser., 13 (1901), No. 1, pp. 14–18*).—The addition of water to wine is said to be the most common adulteration of that product and the most difficult to determine. In order to detect the addition of water, it is necessary to find the amount of alcohol, extract, tartar, and especially of the alcohol-acid. A table is presented showing the average results in the analyses of a large number of wines. Attention is called to the relation existing in pure wines between the alcohol and the acid, and the means for employing these factors in determining the purity of the wine.

BOTANY.

The effect of small quantities of toxic substances upon the higher plants, H. Coupin (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 10, pp. 645–647*).—A report is given of experiments conducted with wheat germinated in distilled water, after which it is placed in dilute solutions of a number of salts. After germination and root development had well started, the seedlings were placed in the solutions and the effect of the different solutions ascertained by the retardation of further growth. It was found that no growth took place in 15 days in solutions of the following dilution:

The toxic effect of dilute solutions on wheat seedlings.

Substance.	Strength of solution.	Substance.	Strength of solution.
Copper sulphate	1 : 700,000,000	Barium chlorid	1 : 10,000
Mercury bichlorid	1 : 30,000,000	Calcium iodid	1 : 10,000
Cadmium chlorid	1 : 10,000,000	Strontium nitrate	1 : 6,000
Silver sulphate	1 : 2,000,000	Lithium nitrate	1 : 5,000
Silver nitrate	1 : 1,000,000	Barium nitrate	1 : 4,200
Palladium chlorid	1 : 500,000	Lithium sulphate	1 : 4,000
Lead nitrate	1 : 100,000	Sodium acetate	1 : 2,000
Aluminium sulphate	1 : 50,000	Magnesium acetate	1 : 2,000
Zinc sulphate	1 : 40,000	Sodium borate	1 : 1,600
Potassium permanganate	1 : 15,000	Barium acetate	1 : 1,000
Manganese nitrate	1 : 13,000	Manganese chlorid	1 : 1,000
Lithium chlorid	1 : 12,000	Calcium bromid	1 : 400
Aluminium chlorid	1 : 10,000	Calcium chlorid	1 : 260
Magnesium iodid	1 : 10,000		

The figures given in the above table show that the effect of these toxic substances upon the higher plants is identical with that found for some of the lower fungi, and that injurious effects may be exerted by such dilute solutions as to be impossible of detection by ordinary methods.

On the absorption of metallic poisons by plants, H. Devaux (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 11, pp. 717–719*).—A report is given of experiments with salts of copper and lead upon Spirogyra and the petioles of *Aralia sieboldii* and the small roots of *Mibora verna*. The author found that all the plants were poisoned by solutions of copper and salt diluted as much as 10 million times. The metallic salt is not fixed equally in all parts of the cell. At first it is found only in the membrane, afterwards in the nucleus and nucleolus, and at length in the protoplasm. At the termination of the experiment the metals were found in all parts of the cell.

Native and introduced forage plants, J. H. Shepard, D. A. Saunders, and W. H. Knox (*South Dakota Sta. Bul. 69, pp. 54, figs. 10, pls. 3*).—This bulletin, in continuation of work previously reported (E. S. R., 6, p. 403), gives the description, geographical distribution within the State, and chemical analysis of the following grasses and forage plants: Weak spear grass (*Poa debilis*), grove meadow grass (*P. alsodes*), teff (*Eragrostis abyssinnica*), slender fescue (*Festuca octoflora*), western cord grass, slender cord grass (*Spartina gracilis*), Kalm's brome grass (*Bromus kalmii*), California brome grass (*Bromus carinatus linearis*), field brome (*Bromus arvensis*), short awned brome (*Bromus breviaristatus*), downy brome grass (*Bromus tectorum*), giant brome (*Bromus maximus*), western needle grass (*Stipa comata*), Seneca grass, holy grass (*Savastana odorata*), Minnesota muhlenbergia (*Muhlenbergia ambigua*), Montana reed grass (*Calamagrostis montanensis*), foxtail or pigeon grass (*Setaria viridis* and *S. glauca*), Japanese millet (*Panicum crus-galli gigantea*), Tambov millet (*Panicum miliaceum*), black Voronezh millet (*Panicum miliaceum*), slender wheat grass (*Agropyron tenerum*), spelt (*Triticum dicoccum*), hairy wheat (*Triticum villosum*), little barley (*Hordeum pusillum*), smooth wild rye, American rye grass (*Elymus sibericus*), bottle-brush grass (*Asperella hystrix*), sedge (*Carex lupuliformis*), early sedge (*Carex pennsylvanica*), loose flowered sedge (*Carex laxiflora*), wild buckwheat or black bindweed (*Polygonum convolvulus*), bushy knotweed (*Polygonum ramosissimum*), Australian saltbush (*Atriplex semibaccata*), mealy or gray saltbush (*Atriplex halimoides*), slender saltbush (*Atriplex leptocarpa*), wild mustard (*Brassica arvensis*), spurry or sand weed (*Spergula arvensis*), bitter vetch (*Lathyrus sativa*), serradella (*Ornithopus sativus*), yellow lupine (*Lupinus luteus*), Egyptian clover or Alexandrian clover (*Trifolium alexandrinum*), bur or spotted clover (*Medicago maculata*), beggar weed (*Desmodium tortuosum*), modiola (*Modiola decumbens*), and hairy vetch or sand vetch (*Vicia villosa*).

The autumnal translocation of material in the hop plant, C. Fruwirth and W. Zielstorff (*Landw. Vers. Stat., 55 (1901), No. 1–2, pp. 9–18*).—This is a report on a study of the hop plant to determine the translocation of matter at the end of the growing season. The plants which entered into the experiment were protected against such external influences as might have caused a loss of substance. The vines of some of the plants were removed at the time of harvesting, while those of others were left until October when the different parts were analyzed. From the results obtained the authors draw the conclusion that the diminution of nitrogen and phosphoric acid in the leaves and vines of the hop plant in the fall may be interpreted as a translocation of these substances from the leaves and vines to the remaining parts of the plants.

On the nitrogenous products of seed and seedlings of white lupines, N. J. Wassilieff (*Landw. Vers. Stat., 55 (1901), No. 1–2, pp. 45–77; Ann. Agron., 27 (1901), No. 2, pp. 81–90*).—A study was made of seeds and seedlings of the white lupine to test the hypothesis of Schulze that in the decomposition of albumen during germination there are afforded certain products, notably amido acids and hexose bases, by the decomposition of albuminoid bodies. A great portion of these products are transformed for the utilization of the plant. This transformation gives rise to asparagin and glutamin. A number of experiments were conducted in which the white lupine was used, and comparisons made with the yellow and blue lupines in which the nitrogen content of the seeds and seedlings was investigated at regular periods. The author's experiments show that the hypothesis of Schulze accords with his investigations. Asparagin is formed in the seedling to the exclusion of other products, and in the leaves asparagin is utilized for the synthetic formation of albumen.

The reserve carbohydrates of the bulb of the hyacinth, J. PARKIN (*Ann. Bot., 14 (1900), No. 53, pp. 155–157*).—Various authors have reported that the reserve carbohydrates in the bulbs of hyacinths, lilies, tulips, etc., consist of dextrin inulin, and other carbohydrates. The author has made a study of hyacinth bulbs and has found that the reserve material consists of a form of inulin. Inulin is said to include those carbohydrates which are levorotatory and which, when treated with an acid, hydrolyse to fructose. The polariscope method of distinguishing between dextrin and inulin is considered by the author the most satisfactory means of recognizing these substances. Based upon his investigations, the author states that the inulin of plants can be arranged into 3 classes, as follows:

"That found in the Compositæ and allied orders, which is precipitated in the tissues by alcohol in the form of the well-known spherocrystals, and which is practically insoluble in cold water, requiring a temperature of 50 to 55° F. for its solution.

"That characteristic of many monocotyledons, e. g. Scilla, Yucca, Phleum, and the plant now before us; it is precipitated in an amorphous form, in the tissues, as a thick lining to the inside of the cell wall and is readily soluble in cold water.

"That found in the bulb scales of species of Galanthus and Leucojum, which is precipitated in the tissues in an amorphous form, and which requires a temperature as high as 80° for its solution."

Experimental investigations on the origin of species, H. DE VRIES (*Rev. Gén. Bot., 13 (1901), No. 145, pp. 5–17, figs. 10*).—The results are given of a number of experiments made by the author, in which advantage was taken of the individual variation of plants to produce new species. The principal part of the paper is taken up with a discussion of the species of Œnothera which were produced from *Œ. lamarkiana.* The species to which names have been given are apparently quite unlike the parent plant, and in some cases possess characters of an apparently new type. Ordinarily they all reproduce themselves without any reversion to the characters of the original species. Of the 4 species which have been developed in this way, but one possesses characters which would in any way associate it with the original, and it might be regarded simply as a white variety. The new characters appeared without any attempt on the part of the investigator to control them, and possessed none of the individual characteristics of the mother plant. The changed characteristics can not be entirely attributed to individual variability.

The course of the hyphal filaments of Tilletia in the body of the wheat plant, H. L. BOLLEY (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 147, 148*).—Attention is called to an error of the author, which was published in North Dakota Station Bulletin 27 (E. S. R., 9, p. 143). In reporting the results of studying the development of the hyphæ of Tilletia he was led into the error of mistaking the dried contents of the mesophyll cells of diseased wheat straws for the knotted filaments of the fungus.

Individual prepotency in plants of the same breeding, W. W. TRACY (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 57–59*).—A brief account is given of breeding experiments in which it was desired to establish a forcing radish with a distinctly oval shaped root. The experiments were conducted for 3 years, the methods of selection being described in some detail. Wide variation in the progeny of some of the selected roots was noted and in general there was less departure from the desired type where there was a general selection of roots than where a single individual was taken as a type.

The botanic garden as an aid to agriculture, W. TRELEASE (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 103–110*).—In this article the value of botanic gardens as adjuncts to agricultural education is pointed out, and various ways in which their efficiency can be increased are described.

The value of willows in retaining the banks of streams, W. W. Rowlee (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 145, 146*).—Attention is called to the natural affinity of willows for stream banks and some of their peculiar habits of growth are described. Their shade is never intense and their root systems are deep in the soil, whereby they form dense masses at the water's edge, protecting the soil from washing, and retaining the embankments. Another advantage possessed by willows is the rapidity of their growth. Among the best species for planting are *Salix alba* and some of its varieties.

ZOOLOGY.

Notes on the food of birds, T. D. A. Cockerell (*New Mexico Sta. Bul. 37, pp. 35–52*).—The economic relation of birds to agriculture is discussed in a general way, and many special instances of the harmful or beneficial action of birds are cited. Notes are given on the feeding habits of a number of birds in New Mexico, including woodpeckers, sparrow hawk, Cooper's hawk, road runner, California cuckoo, belted kingfisher, shrike, band-tailed pigeon, poor-will, and evening grosbeak. The woodpeckers as a whole are believed to be useful and deserving of protection. The only species of woodpeckers which is considered injurious to any serious extent in New Mexico is *Sphyrapicus varius nuchalis*. All other species of woodpeckers are considered as doing far more good than harm in orchards or any other cultivated crops. An examination of the stomach contents of the sparrow hawk showed that the food of this bird was largely of an insect nature, and that the bird is, therefore, to be reckoned as beneficial. Cooper's hawk is condemned on account of its habit of feeding on small birds and poultry.

The birds of Colorado, W. W. Cooke (*Colorado Sta. Bul. 56, pp. 179–239*).—This contains corrections to Bulletins 37 and 44 of the station (E. S. R., 9, p. 209; 10, p. 521) and additional notes on the birds of Colorado.

The food of the toad, H. Garman (*Kentucky Sta. Bul. 91, pp. 60–68, fig. 1*).—A study was made of the feeding habits of toads in Kentucky, and the various insects and other food materials which were found are classified in detail. The insects found in the toad's stomach in the order of frequency of their occurrence were as follows: Ants, beetles, bugs, moths and caterpillars, crickets, flies, springtails, and thrips. Many of the most destructive insect pests were found to be eaten extensively by toads, and among such pests the following may be mentioned: Chinch bug, plant lice, leaf hoppers, Colorado potato beetle, corn-root worm, cabbage flea-beetle, strawberry-root borer, wireworm, and cricket. The toad is considered a very useful help to the farmer in the destruction of injurious insects. Brief notes are also given on the feeding habits of *Rana pipiens* and *R. clamitans*.

Zoological yearbook for 1900, P. Mayer (*Zoologischer Jahresbericht für 1900. Berlin: R. Friedländer & Son, 1901, pp. 488*).—This report contains detailed lists of biological references to the literature on all the groups of animals. A brief summary is given of the more important contributions on all subjects.

METEOROLOGY—CLIMATOLOGY.

Forests and snow, L. G. Carpenter (*Colorado Sta. Bul. 55, pp. 12, pls. 18, figs. 7*).—This bulletin attempts to bring out some of the relations of forests to water supply which have become evident in the study of one of the typical irrigation streams of Colorado, viz., the Cache la Poudre River. It contains a number of reproductions of photographs taken during June, 1899, showing the snow cover under different forest conditions at the headwaters of this stream at elevations of 9,000 ft. and over. The rainfall conditions of the State and their effect on stream flow, the effect of forest growth in conserving moisture and preventing irregular flow, and the effect of the sun and wind in melting snow are briefly explained, observations on these subjects being summarized as follows:

"(1) The mountain streams in the early irrigation season are largely supplied by melting snow.

"(2) There is a marked diurnal fluctuation, greater with high water than with low, due to the daily variations in the rate of melting.

"(3) The stream at high water may be one-half greater than at low water on the same day.

"(4) Cloudy weather in the mountains, protecting the snow from the radiation of the sun, causes the fluctuation to disappear and the flow to decrease.

"(5) This decrease is so great that the cloudiness associated with continued rain usually more than counterbalances the gain from the rain.

"(6) The loss of snow by evaporation is considerable, especially when exposed to winds.

"(7) Snow remains in the timber and in protected spots much longer than where exposed.

"(8) This is due not so much to drifting as to shelter from the radiation afforded by the forest cover.

"(9) Hence, the greater amount of forest cover the less violent the daily fluctuation, the more uniform the flow throughout the day and throughout the season, and the later the stream maintains its flow.

"(10) The loss of the forest cover means more violent fluctuation during the day, greater difficulty in regulating the headgates and keeping a uniform flow in ditches, and hence an additional difficulty in the economic distribution of water. Also the water runs off sooner, hence the stream drops earlier in the summer, and on account of the lessening of the springs, the smaller is the winter flow.

"(11) The preservation of the forest is an absolute necessity for the interest of irrigated agriculture."

Meteorological observations, J. E. Ostrander and C. L. Rice (*Massachusetts Sta. Met. Buls. 148, 149, 150, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during April, May, and June. The data are briefly discussed in general notes on the weather of each month.

Report of department of meteorology and meteorological summary, C. H. Pettee (*New Hampshire Sta. Bul. 79, pp. 33, 34, 38*).—A brief report is given of the operations of this department of the station during the year, accompanied by a monthly and an annual summary of observations on temperature, precipitation, snowfall, cloudiness, and direction of wind during the fiscal year ended June 30, 1900, with averages for each month from July 1, 1895, to June 30, 1900, inclusive. The annual summary of these observations is as follows: Temperature (degrees F.)—1899-1900, 45.5; 1895-1900, 45.7; precipitation (in.)—1899-1900, 43.59; 1895-1900, 45.5; snowfall (in.)—1899-1900, 50.5; 1895-1900, 62.1; number of days on which there was 0.01 in. precipitation—1899-1900, 77; 1895-1900, 98; prevailing direction of wind—1899-1900, northwest; clear days—1899-1900, 181. The principal meteorological characteristics of the year were lack of moisture during the growing season and an abnormally light snowfall. The precipitation was normal, but one-third of it was concentrated in 30 consecutive days, covering most of February and a part of March.

Summaries of temperature, rainfall, and sunshine, E. F. Ladd (*North Dakota Sta. Rpt. 1900, pp. 14-19*).—Tables give the maxima, minima, and mean monthly temperatures at Fargo, N. Dak., for the year 1900; a monthly record of sunshine during 1899 and 1900; total annual rainfall for the period 1892-1900; calculated and recorded daily temperatures during April-September, 1900; and mean hourly temperatures April-September, 1899.

Report of rainfall and temperatures for the year 1900 (*Ontario Agr. Col. and*

Expt. Farm Rpt. 1900, p. 7).—Tables give monthly and annual summaries of observations on temperature, rainfall, and snowfall for 1900, and maximum and minimum temperatures for 1899 and 1900.

Meteorological chart of the Great Lakes, A. J. Henry and N. B. Conger (*U. S. Dept. Agr., Weather Bureau, Meteorological Chart of the Great Lakes, 1901, No. 1, pp. 28, figs. 2, charts 4*).—This is a summary of data relating to summer storms; ice during winter of 1900 and 1901; opening of general navigation, season of 1901; fog from April 16 to May 15, 1901; wrecks and casualties from April 16 to May 31, 1901; precipitation and water levels on the Great Lakes; Weather Bureau office at Sault Ste. Marie; fog distribution on the Great Lakes.

Meteorological reports for East Africa, 1900 (*Shamba* [*Zanzibar*], *1901, No. 23, pp. 3, 4*).—Tables give (1) monthly and annual summaries of rainfall at 11 places during 1899; (2) maximum and minimum temperatures at 6 places during 1900; (3) summaries for January, February, and March, 1901, of observations at Zanzibar and Vunga on atmospheric pressure, humidity, temperature, rainfall, and wind movement; and (4) monthly and annual summaries of rainfall at Zanzibar during 19 years, 1874–1901.

Meteorological observations at Manila (*Bul. Mens. Obs. Manila, 35* (*1899*), *Apr., May, and June, pp. 57–110, charts 3*).

Climatology of the Philippine Islands (*Climatologia de Filipinas. Washington: Government Printing Office, 1900, pp. 265, pls. 64, figs. 2*).—An excerpt from a large treatise on the Philippine Archipelago published in the English and Spanish languages.

Rainfall and the temperature of the soil, A. Tolsky (*Zhur. Opuitn. Agron., 1* (*1900*), *pt. 3, pp. 266, 267*).—In a study of the relations between the amounts of rainfall and the temperatures of the soil at the Institute of Forestry at St. Petersburg in the years 1893–1897, the author found, in accordance with other observers, that the influence of rains on the distribution of heat in the soil is indirect, the precipitation increasing the humidity of the soil and thus improving its heat conductivity. Hence it frequently happens that the mean and maximum temperatures of the soil increase, especially when the latter is covered with grass.—P. FIREMAN.

The chief meteorological factors of fertility according to observations on the "Alexeevskiye" estate of P. I. Levitzki, Government Tula, A. Levitzki (*Zhur. Opuitn. Agron., 1* (*1900*), *pt. 2, pp. 147–171*).—On the basis of 14 years' observations the author finds that the size of the crops of winter rye, potatoes, and oats, depends with great certainty and regularity upon the rainfall in certain months.—P. FIREMAN.

Origin of atmospheric hydrogen, A. Gautier (*Bul. Soc. Chim. Paris, 3. ser., 25* (*1901*), *No. 5, pp. 231–235*).—Investigations are reported which lead to the conclusion that the hydrogen of the air is of volcanic origin, being produced by the action of igneous rocks on aqueous vapor.

Combustible gases of the atmosphere—atmospheric hydrogen, A. Gautier (*Ann. Chim. et Phys., 7. ser., 22* (*1901*), *Jan., pp. 5–110*).—A detailed account of the author's investigations on this subject dealing with methods used; comparative studies of the air of towns, of the country, of the sea, and of the upper atmosphere; nature of the combustible gases of the air of towns, woods, etc.; origin of these gases, especially the hydrogen (see above). The author concludes from the long series of investigations of air freed from suspended matter, here reported, that there exists normally in pure air about 20 parts of free hydrogen to 100,000 parts of air, as well as a certain amount of hydrocarbons due to exhalations from the soil, from plants, fermentations, manufactories, etc. They, however, appear to diminish as the air becomes purer. They are found in comparatively large quantities in the air of towns, to a less extent in that of the country, in very small amounts in the air of rocky plateaus and the peaks of high mountains, and are entirely absent from the pure air derived from the high regions of the atmosphere.

The character and proportions of the combustible gases found in the air are indicated by the following analysis of the air at Paris, which may be taken as representative of the air of large cities in general: One hundred liters of the air of Paris at 0° and 760 mm. pressure contain free hydrogen, 19.4 cc.; methane, 12.1 cc.; benzin ($C^6 H^6$) or similar hydrocarbons, 1.7 cc.; carbon monoxid, with traces of hydrocarbons of the Cn H2n-2 and Cn H2n groups, 0.2 cc.

Atmospheric dust observed at Tunis March 10, 1901, E. BERTAINCHAUD (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 18, pp. 1153-1155*).—The dust was essentially siliceous.

Electro-sonorous method of combating hail, G. M. SLANOÏÉWITCH (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 7, pp. 373, 374*).—The author proposes to send up in a kite or captive balloon an electric vibrator to agitate the air in the storm center and thus more effectually accomplish the result of dissipating the storm than could be done by explosives, especially if the storm center is at a considerable elevation, as is frequently the case with the more violent kinds.

The Tolmar experiments with explosives to control the weather, A. HERTZOG (*Fühling's Landw. Ztg., 50 (1901), No. 15, pp. 542-545*).—This is a brief account of attempts to dissipate storms by means of cannonading, pointing out the desirability of a more thorough investigation of the principles upon which the method rests and of its effectiveness in practice.

WATER—SOILS.

Artesian wells in North and South Dakota, W. UPHAM (*Bul. Minnesota Acad. Nat. Sci., 3 (1901), No. 3, pp. 370-379*).—Data relating to location, depth, source, and pressure of water, etc., are given for a number of wells deriving water from the Dakota sandstone, with some discussion of the character of the waters.

The geology of the artesian basin of South Dakota, D. S. McCASLIN (*Bul. Minnesota Acad. Nat. Sci., 3 (1901), No. 3, pp. 380-388*).

Drainage water and salt morasses of the Odessa sewage fields, T. SELIWANOFF (*Landw. Vers. Stat., 55 (1901), No. 6, pp. 475-478*).—A short account of observations on the soil of fields used for sewage disposal by irrigation which had become impregnated with chlorin to an injurious extent. This condition was corrected by improved drainage.

Researches on moorland waters. II, On the origin of the combined chlorin, W. ACKROYD (*Jour. Chem. Soc. [London], 79 (1901), No. 463, pp. 673, 674*).—Weekly determinations of chlorin in the water of a reservoir at Widdop in Yorkshire, November 12 to December 31, 1900, and January 7 to February 18, 1901, and in the rainfall during the same period are reported. The conclusion was reached that the combined chlorin in the reservoir water was wholly derived from the rain. For previous paper on acidity of moorland waters see E. S. R., 11, p. 312.

The systematic investigation of soils, B. W. KILGORE (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 5, pp. 38-46*).—This is the annual address of the presiding officer of the North Carolina section of American Chemical Society and gives a general discussion of this subject.

Some experiments in soil temperatures as affected by color and the moisture content of the soil, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 7, 8, pl. 1*).—An account is given of observations on 6 kinds of soil: (1) Pure black humus or vegetable matter; (2) a potting soil containing about 65 per cent of rotted sod, 20 per cent barnyard manure, and 15 per cent sand; (3) clay loam; (4) heavy clay; (5) coarse sand, and (6) fine sand, almost white. "Two sets of these samples were used, one set being kept dry and the other wet. The experiments were conducted outside, where the soils were exposed to the full influence of the sun and wind. Temperatures were observed every hour from 8 a. m. to 8 p. m." From the data obtained, curves are platted which show the rise and fall of temperature. The humus, as a rule, reached a higher temperature than any other soil, the dark potting soil standing next, followed by the open clay, heavy clay, and fine white sand. The differences in the temperature are ascribed to variations in the color, the darker samples being warmer than the lighter. It was also observed that the humus remained steadily warmer than the other soils, thus proving an exception to the rule that a soil which warms rapidly is likely to part with the heat readily.

On the relations of the soil solutions to the phosphates used as fertilizers, T. Schloesing (*Ann. Sci. Agron., 1901, I, No. 3, pp. 406–424*).—This article records observations on the solubility of tricalcium phosphate in solutions of carbon dioxid of different strengths saturated with calcium bicarbonate and free from this substance, and in water free from carbon dioxid. The methods of preparing the tricalcium phosphate and the solution of carbon dioxid and calcium bicarbonate are described, as well as those used in determining the solubility of the phosphate in the various solutions. The results reported show that the phosphate dissolved in the carbon dioxid solutions in proportion to their strength, but that it was not sensibly soluble in such solutions when saturated with calcium carbonate. The bearing of these facts on the behavior in the soil of soluble phosphates applied as fertilizers and on the formation of phosphate deposits is discussed.

Sources of the constituents of Minnesota soils, C. W. Hall (*Bul. Minnesota Acad. Nat. Sci., 3 (1901), No. 3, pp. 388–406*).—This article discusses the formation of soils and the various agents which have taken part in it, and the chemical composition of Minnesota soils and of the rocks from which they have been derived based upon analyses compiled from various sources.

"The rocks of Minnesota are classified under 5 groups: (1) Acid crystallines, (2) basic crystallines, (3) sandstones and quartzites, (4) calcareous shales, and (5) the carbonates. Among these, granitic rocks and basic eruptive, which occupy large areas beneath the drift in the northern and western portions of the State, furnish many important food elements, particularly alkalis and alkaline earths.

"The sandstones and quartzites among the most barren soil producers have mingled with other substances their beneficent uses. The calcareous and siliceous shales spring from widely divergent geologic periods and bring to the making of soils somewhat different physical and chemical factors. Their influence is wholesome and strengthening. Finally the carbonates come before the eye in this chemical review. They yield, for soil making, carbonic acid, lime, magnesia, and small quantities of other compounds. When the condition of a soil is reached, but a small percentage of these rocks is left, but this is a substantial part and enters into the constitution of the best soils of the State. They appear in full force in the southeastern corner of the State where stands a portion of that old glacial island, a tract over which the ice did not flow during the period when all the rest of the State was buried deep beneath the glacier."

Solubility of gypsum in aqueous solutions of sodium chlorid, F. K. Cameron and F. D. Gardner (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 160, 161*).—A brief note on some studies on this subject made in the Division of Soils of this Department.

Report of the Valuiki Agricultural Experiment Station (Government of Samara), 1895-96, V. S. Bogdan (*St. Petersburg: Department of Agriculture, 1900, pp. 126; abs. in Selsk. Khoz. i Lyesor., 199 (1900), Oct., pp. 235–237*).—Among the articles of interest in this report is one discussing the reclamation of alkali soils by proper management of the rainfall and the culture of plants which take up large amounts of alkali in their growth, and another on the influence of the character of the soil on the composition of the wheat grain. Experiments showed that with the increase of the salt content of alkali soils the nitrogen and ash contents of the wheat grains increased, but the absolute weight of the grain diminished. According to the author this explains the good quality of the wheat, especially with regard to high protein content, from the east and southeast of Russia, where the soils are rich in soluble salts, including nitrates.—P. FIREMAN.

Formation of sodium carbonate or black alkali by plants, F. K. CAMERON and F. D. GARDNER (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 162, 163*).—A brief note on chemical examinations of the water extract of the stems, leaves, etc., and the ash of two plants capable of withstanding relatively large amounts of alkali in the soil—creosote bush (*Covillea tridentata*), and greasewood (*Sarcobatus vermiculatus*). It was found in case of the first that while the plant contained chlorin, it was not present in the form of sodium chlorid, but probably in organic combination. The amount of sodium present was decidedly in excess of that required to neutralize the chlorin found.

[It was found that the greasewood] "contained considerable amounts of chlorids and sulphates, and that practically all of these acids were present in the plant in the form of the sodium salts as such, the plant being in this respect in marked contrast to the *Covillea tridentata* previously examined. A striking feature was the much greater percentage of ash obtained from the leaves and blossoms than from the stems, and the markedly larger percentage of alkali salts in the ash of the former. Another interesting point is that the leachings of the air-dried leaves and blossoms were shown to contain about three times as much sodium as would be necessary to balance the hydrochloric and sulphuric acids in the plant. It is, therefore, probably present very largely in organic combination and upon the decay of the plant tissues would be expected to yield large amounts of sodium carbonate."

A study of the agricultural value of the soils of Madagascar, A. MÜNTZ and E. ROUSSEAUX (*Ann. Sci. Agron., 1901, I, Nos. 1, pp. 1–98, 152–160, map 1; 2, pp. 161–253, 296–320; 3, pp. 321–398*).

The soils of the colony of the Cavaignac, Algeria, J. DUGAST (*Ann. Sci. Agron., 1901, I, No. 3, pp. 425–452, pls. 3*).—Partial mechanical and chemical analyses of 18 samples are reported. The soils are stated to be in general well supplied with nitrogen (0.063 to 0.168 per cent) and phosphoric acid (0.073 to 0.221 per cent), and to be rich in potash (0.5 to 1.228 per cent), but difficult to cultivate, being compact and impermeable. They contain a large amount of tenacious clay (32.45 to 54.77 per cent), fine calcareous sand (4.2 to 16.9 per cent) and fine siliceous sand (15.42 to 40.08 per cent), which causes them to become sticky when wet and hard when dry. The lime varies in the analyses reported from 2.826 to 13.272 per cent.

FERTILIZERS.

Influence of systems of fertilizing upon the amount and quality of the humus of the soil, W. FREAR and E. H. HESS (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 60–69*).—The importance and functions of humus in the soil are briefly discussed and an account is given of chemical examinations of soils from plats at the Pennsylvania Station which have been used since 1881 for fertilizer experiments as follows: (1) Cropping without manure, (2) manured with stable manure and lime, (3) treated with lime alone, (4) treated with crushed limestone, (5) receiving complete mineral fertilizer containing nitrate of soda, and (6) receiving complete mineral fertilizer containing sulphate of ammonia. The chemical examinations made involved determination (1) of loss on ignition, (2) organic carbon, and (3) active humus; besides hygroscopic moisture, nitrogen, and hydrogen. The results reported show that continuous cultivation on the limestone clay soils used in these experiments has not greatly diminished the amount of humus. The greatest increase in humus was found in case of the manuring with yard manure and lime, although the amount of humus was but slightly smaller in case of complete mineral fertilizer, a larger amount of nitrogen being found in the case of complete mineral fertilizer containing sulphate of ammonia than in case of that containing nitrate of soda. An examination with litmus paper showed that the limed soil was strongly alkaline, that receiving mineral fertilizer containing nitrate of soda slightly acid, and that receiving mineral fertilizer containing sulphate of ammonia strongly acid. The unmanured soil contained three-fourths of its organic matter in active form, i. e., soluble in 4 per cent ammonia water according to the Official-Grandeau method. The largest amount of active humus was found in the plat receiving mineral fertilizer containing sulphate of ammonia. The plat receiving manure and lime contained both absolutely and relatively less active humus than the unmanured plat. The supply of nitrogen was greatest in the plat receiving manure and lime. The use of lime alone apparently "rapidly diminishes humus of all kinds and results in a marked loss of nitrogen."

Experiments on the relative fertilizing value of ammonia salts, P. WAGNER (*Mitt. Deut. Landw. Gesell., 16 (1901), Nos. 10, pp. 55, 56; 11, pp. 57–60*).—Plat experiments are reported in which as a result of 36 tests with rye, oats, and barley 100 kg. of nitrate of soda produced 421 kg. of grain and 617 kg. of straw, while a corresponding amount of ammonium sulphate produced 280 kg. of grain and 402 kg. of straw. If the effect of the nitrate be taken as 100 that of the sulphate would be 67 in case of the grain and 65 in case of straw. In 9 tests with fodder beets, sugar beets, and potatoes 100 kg. of nitrate produced 34.3 of roots while the sulphate produced 16.6, the relative effect being 100:48. The difference in effect was much more marked in case of root crops than in case of grains. The yield was decidedly increased by divided applications in case of the root crops, but was not materially affected in case of the grains. The seasons of 1899 and 1900, during which the experiments were made, were not favorable to rapid nitrification and so to the quick action of ammonium sulphate. The soils used in the experiments were variable in physical character but no differences due to this fact were apparent. As regards the influence of the proportion of lime in the soil the results are inconclusive.

Investigations on the fertilizing action of the phosphoric acid of bone meal, O. KELLNER and O. BÖTTCHER (*Deut. Landw. Presse, 28 (1901), Nos. 23, pp. 194, 195, figs. 6; 24, p. 204*).—This is a continuation of experiments previously reported (E. S. R., 12, p. 323). Mustard was grown in pots containing 3.5 kg. of fine sandy loam containing in dry matter 22.4 per cent of humus and 14.3 per cent of lime. Superphosphate, Thomas slag, and steamed bone meal were used as in previous experiments, except that to one series of pots 15 gm. and to another series 30 gm. each of calcium carbonate were applied. The relative effect of the different methods of fertilizing was as follows:

Relative effect of different phosphates, with and without lime, on mustard.

	Without lime.	With 15 gm. lime.	With 30 gm. lime.
Superphosphate	100	77.7	75.5
Thomas slag	100	81.7	81.5
Bone meal	100	72.6	50.0

These figures show a decided decrease in yield when lime was applied. It is claimed that this effect of liming is not confined to the phosphoric acid of the fertilizers applied, but extends to that of the soil. These conclusions are in direct contradiction to those of Dafert and Reitmair (E. S. R., 12, p. 839), which, it is claimed, are based on unreliable data.

The most profitable amount of fertilizer to apply, M. FISCHER (*Fühling's Landw. Ztg., 50 (1901), Nos. 7, pp. 264–270; 8, pp. 295–301*).—Plat experiments with rye and oats to which different fertilizers were applied in various ways and amounts are reported. The experiments were mainly a comparison of sulphate of ammonia and nitrate of soda applied in different ways (all in one application or fractionally). In general it was found that winter grain was less benefited by the fertilizers than summer, the former producing a better crop without fertilizers than the latter. Both for winter and summer fertilizing it is best to use a combination of sulphate of ammonia and nitrate of soda. The results obtained in the use of fertilizers on one grain are not considered applicable to another.

The uses and abuses of fertilizer formulas, S. M. TRACY (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 164–168*).—The unreliability of the fertilizer formulas commonly recommended and of the need of care in preparing formulas for fertilizers for special purposes are pointed out.

The manurial value of ashes, mucks, seaweed, and bone, C. D. WOODS (*Maine Sta. Bul. 74, pp. 65–88*).—A popular discussion of the fertilizing value of these materials, accompanied by compilations of analyses of wood ashes, mucks, and seaweeds.

Seaweed as a fertilizer, F. W. MOORE (*New Hampshire Sta. Bul. 79, p. 9*).—Analyses of 1 sample each of kelp and mixed seaweed from the coast of New Hampshire are reported.

The composition of the sewage of the town of Odessa, T. SELIWANOFF, CHONIA, MOTSCHAU, and BOUDAREW (*Landw. Vers. Stat., 55 (1901), No. 6, pp. 463–474*).—The results reported show great daily, and even hourly, variation in the composition of the sewage, especially in the insoluble matter. The sewage of this town was apparently more concentrated than that of other large cities of the world.

Report on official inspection of commercial fertilizers and agricultural chemicals during the season of 1900, C. A. GOESSMANN ET AL. (*Massachusetts Sta. Rpt. 1900, pp. 55–63*).—This report includes a comparison of the quality of the fertilizers examined during 1899 and 1900; the trade values of the fertilizing ingredients in fertilizing materials during the same years, with an explanation of the use of these data in calculating the approximate value of a fertilizer; a table showing the average composition of fertilizers examined during 1900; and a list of brands of fertilizers licensed by manufacturers and dealers under the provisions of the State law during the year. Except in case of fertilizers containing only 2 essential constituents the goods examined during 1900 were decidedly superior to those inspected during the previous year.

Report on general work in the chemical laboratory, C. A. GOESSMANN (*Massachusetts Sta. Rpt. 1900, pp. 64–70*).—This includes a list of miscellaneous materials sent to the station and examined during the year; notes on wood ashes, comparing the quality of samples examined during 1899 and 1900; a brief discussion of the agricultural value of sewage sludge, with analyses of 8 samples of the material; and notes on phosphatic slag as a source of phosphoric acid for manurial purposes, accompanied by analyses of 9 samples of slag examined at the station.

Analyses of commercial fertilizers, M. B. HARDIN (*South Carolina Sta. Bul. 60, pp. 24*).—This bulletin contains the analyses of 186 samples of fertilizers collected during the season of 1900–1901, with a discussion of the composition and valuation of fertilizers and the laws and regulations governing the sale of commercial fertilizers in South Carolina.

The world's production of phosphates, MAIZIÈRES (*L'Engrais, 16 (1901), No. 28, pp. 662–664*).

FIELD CROPS.

Report of the agriculturist, W. P. BROOKS and H. M. THOMSON (*Massachusetts Sta. Rpt. 1900, pp. 91–123*).—The experiments here reported include fertilizer, soil, and variety tests with different field and garden crops, and are in continuation of work previously reported (E. S. R., 12, p. 226).

Experiments to determine the relative value of fertilizers supplying nitrogen were begun in 1890 and the crops grown, given in their order, were oats, rye, soy beans, oats, soy beans, oats, soy beans, oats, oats, clover, and potatoes. The relative efficiency of the different materials was found to be as follows: Nitrate of soda 100, barnyard manure 90, sulphate of ammonia 89, dried blood 86, and the plats without nitrogen 68. Owing to the humus and mineral substances furnished by barnyard manure in addition to nitrogen, the author considers its efficiency really higher than the availability of nitrogen alone would show. The results further showed that the efficiency of sulphate of ammonia is largely increased when the soil is well supplied with lime.

Plowing under the stubble and roots of soy beans and clover was found to be very advantageous to subsequent crops. The plats on which this test was made had received no nitrogen in the fertilizer for 16 seasons, still after this long period potatoes on clover sod gave a crop equal to 95.3 per cent of the yield on plats which had yearly been given a fair amount of fertilizer containing nitrogen. This season the nitrogen plats yielded 219.3 bu. of potatoes per acre, or an increase of 10.3 bu. as compared with the no-nitrogen plats.

Comparative tests with muriate and high-grade sulphate of potash have been in progress since 1892. Both salts were applied yearly at the rate of 400 lbs. per acre, but this season only 250 lbs. were used. Considering the results for the entire period, clover, cabbage, and soy beans generally gave the best returns on the sulphate plats, while corn, grasses, oats, barley, vetches, and sugar beets gave equally good yields on the muriate plats. The sulphate plats produced the best quality of potatoes and sugar beets. Considering all the crops except the clover, the efficiency of the muriate was 98.1 per cent of that of the sulphate, and taking into consideration only those crops which showed a preference for the sulphate, its efficiency was 88.6 per cent of that of the sulphate. The conclusion of the authors favors the use of the sulphate at present prices. The results with early and late garden crops were also in favor of the use of sulphate of potash, especially in the case of early crops.

The series of experiments with nitrate of soda, dried blood, and sulphate of ammonia in progress since 1891, showed that up to 1898 nitrate of soda was with one exception the most efficient source of nitrogen. During the period of these tests only commercial fertilizers were applied.

From 1890 to 1893 inclusive, dissolved boneblack, ground South Carolina rock, ground Florida rock, Mona guano, and phosphatic slag were compared on the basis of their money value, i. e., the cost of quantities applied being the same in all cases. The soil had been liberally supplied with nitrogen and potash since the beginning of the experiment, but no phosphate has been applied since 1893. The results for the entire period indicate that the liberal use of natural phosphates produces profitable crops and that in a long series of years their substitution, at least in part, for the higher priced dissolved phosphates may prove economical. None of these natural phosphates seemed suitable for cruciferous crops. There was practically no difference in the economic results from South Carolina rock, Mona guano, and phosphatic slag. The quantity of Florida phosphate used contained more phosphoric acid than any of the others but it becomes soluble very slowly. For ordinary farm and garden crops the use of the natural phosphates in connection with a moderate quantity of one of the dissolved phosphates is recommended. A comparison of phosphates on the basis of an equal application of phosphoric acid, in progress for three years, showed that phosphatic slag furnished phosphoric acid in a very available form, yielding about as much as dissolved boneblack; that the phosphoric acid of Florida soft phosphate was rendered available with great slowness; and that steamed bone meal appeared inferior in availability to raw bone meal.

The results for the twelfth season of a soil test with grass are reported, in which the same fertilizers or combinations were applied to the same plats continuously.

Nitrate of soda alone or in combination gave a large increase. "It is especially noteworthy that nitrate of soda alone, applied to a plat which has now received no other fertilizer for 12 years, gives a crop of hay amounting to almost $1\frac{1}{4}$ tons. This plat last year gave a crop of corn at the rate of something less than 14 bu. per acre. The plat to which nitrate of potash alone has been applied during the past 12 years gave us last year a yield of corn at the rate of nearly 50 bu. per acre. The hay crop this year is 1,140 lbs."

A soil test with onions was continued this season with the same fertilizer applications used the previous year, i. e., different combinations of nitrate of soda, dissolved boneblack, and muriate of potash at the rate of 320, 640, and 320 lbs. per acre, respectively (E. S. R., 12, p. 22). This year the limed portion of the plat, which yearly received the mixture of all three fertilizers, yielded nearly 500 bu. per acre of well-cured onions, while the unlimed portion produced only 136.9 bu. Good crops were obtained only on those plats which received annual applications of potash. The limed portion of the plats yearly manured with muriate of potash alone produced 383 bu. per acre, as compared with 311 bu. for nitrate of soda and potash, and 380 bu. for dissolved boneblack and potash. The effects of potash far exceeded those of either of the other elements. The results further show that the use of muriate of potash makes the employment of lime absolutely necessary. Applications of muriate of potash and nitrate of soda without lime proved injurious. The use of dissolved boneblack greatly promoted the perfect ripening of the crop, and corrected in a large measure the injurious effects following the use of muriate of potash. This is considered due largely to the considerable quantities of sulphate of lime or land plaster contained in all dissolved phosphates. Practical advice on fertilizers for onions based on the results obtained are given.

A special corn fertilizer was compared with an application richer in potash. The fertilizer applied furnished the same amount of plant food as an application of 1,800 lbs. per acre, containing an average of 2.37 per cent of nitrogen, 10 per cent of phosphoric acid, and 4.3 per cent of potash. The other applications contained slightly more nitrogen, much less phosphoric acid, and considerably more potash. All plats received in addition a ton of lime per acre. The yield with the special fertilizer was 77.50 bu. of shelled corn per acre and 6,270 lbs. of stover, and with the fertilizer richer in potash, 73.75 bu. of corn and 6,280 lbs. of stover. This series of experiments, carried on for 10 years, has shown that corn can be successfully grown on fertilizers alone. The average financial results of a comparison of barnyard manure alone and with potash for corn were in favor of barnyard manure and potash.

The results of experiments with soy beans and cowpeas for green manuring showed that the Medium Green soy bean produced 5,386 lbs. of dry matter and 167.3 lbs. of nitrogen per acre, the Wonderful cowpea 3,622 lbs. of dry matter and 80.4 lbs. of nitrogen, and the Black cowpea 3,389 lbs. of dry matter and 62.1 lbs. of nitrogen. The work was conducted on a medium loam soil retentive of moisture and during a season of sufficient rainfall.

The use of 150 lbs. per acre of nitrate of soda on meadows, applied July 1, after the first crop of hay had been made, gave in one case an apparent increase of 816 lbs. of rowen per acre, and in another 600 lbs. The experiment is not considered conclusive as regards the most profitable quantity of nitrate of soda to be used. A similar experiment in progress since 1893 consisted in applying 1 ton of wood ashes, 600 lbs. of ground bone and 200 lbs. of muriate of potash, and 8 tons of barnyard manure per acre in rotation on grass land. This year this system was modified by adding 64 lbs. of nitrate of soda to the application of wood ashes and 83 lbs. to the application of bone and potash. The plat fertilized with wood ashes and nitrate of soda produced the best yields, followed by the plat which had received ground bone, potash, and nitrate of soda. The average yield of hay and rowen for the 3 plats was 6,510 lbs. per acre. Since the beginning of the test the plats receiving barnyard manure have averaged 6,817 lbs. per acre, the plats receiving bone and potash 6,626 lbs., and those receiving wood ashes, 6,371 lbs.

The Woburn Pot-culture Station, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England, 3. ser., 11 (1900), pt. 4, pp. 553–604, figs. 17*).—This article deals with the inception and general arrangement of the Pot-culture Station at Woburn, and further discusses in detail the work of the station during 1898 and 1899. The experiments discussed are grouped under two heads, namely, the Hills experiments, consisting of a study of different chemical substances in their relation to plant growth when applied to the soil, and miscellaneous pot-culture experiments bearing on different agricultural questions.

The Hills experiments.—These are named for E. H. Hills, who bequeathed a considerable sum to the Royal Agricultural Society of England for the purpose of carrying out investigations on the value of "tertiary ash," under which term he included compounds of fluorin, manganese, iodin, bromin, titanium, and lithia. The first year the experiments were made with calcium fluorid, calcium oxid, manganese oxid, sodium iodid, sodium bromid, sodium chlorid, titanium oxid, ferric oxid, lithium chlorid, and calcium chlorid applied at the rate of 5 cwt. per acre. The selected crops—wheat, barley, mustard, peas, and red clover—were grown in pots. The experiments with wheat showed that sodium iodid applied at the rate of 5 cwt. per acre kills the plant. Sodium bromid seemed to do no harm at first, but later on weakened the plant and reduced the yield. It also seemed to check the growth of the roots and to cause the root stocks to send out fresh roots. Lithium chlorid also had a retarding influence in the beginning, but subsequently the plants grew and matured fairly well. The sodium chlorid pot gave practically the same results as the unmanured pot. Sodium iodid and lithium chlorid retarded germination and lowered the proportion of germinating seed.

The pots to which sodium iodid had been applied gave off a decided iodin odor, and the soil in them was rendered impervious to water. The effects on barley were much the same as on wheat. Sodium iodid, applied at the rate of 2 cwt. per acre, seemed to have no injurious effects on either wheat or barley. Sodium iodid and lithium chlorid prevented the growth of mustard, lithium chlorid being the more effectual. Sodium bromid at first showed no injurious effects on the mustard plant, but in the end affected it quite seriously. The sodium chlorid and sodium bromid injured peas eventually, although they at first seemed harmless. Sodium iodid and lithium chlorid prevented the pea seed from germinating properly, but when applied at the rate of 2 cwt. per acre, these substances effected a small improvement. The experiments with red clover were the same as with the other crops, with the exception that sodium iodid and lithium chlorid were applied at the rate of 2 cwt. per acre. Results of the experiments with clover for this and the following season were not conclusive, and the statements made regarding the outcome of the test were that lithium chlorid prevented the proper growth of the red clover, while sodium iodid and sodium bromid did not this season have the injurious effects noted with the cereal crops. The second year the plan of the experiments was somewhat changed, the investigation being limited to tests with sodium iodid and sodium bromid applied in different quantities and at different times. It is concluded from the experiments made during the 2 years that sodium iodid and sodium bromid, even at the rate of ½ cwt. per acre, are injurious to wheat, whether applied at the time of sowing or later on, and that they apparently check root development. Soaking the seed in a 1 per cent solution of either salt exercised a good influence on the wheat plant and increased the yield. The tests with barley gave much the same results, with the exception that the effect of sodium bromid was not so marked, and the results with clover were practically the same as those with barley. The results of a test with mangel-wurzels added to the experiments this year show that sodium iodid at the rate of 1 cwt. per acre, applied either at the time of sowing or as a top-dressing, was decidedly injurious and that sodium bromid used at the rate of either 1 or 2 cwt. per acre was also injurious, but when applied as a top-dressing did not injure the crop any more than the same amount of sodium chlorid applied in the same way.

Miscellaneous pot-culture experiments.—This work consisted of experiments with wheat and barley on thick and thin sowing, and the use of large and small seed, a study of hard and soft wheat, an investigation on wheat smut, and several fertilizer tests. The results of thick and thin seeding are presented in the following table:

Results of pot experiments on thick vs. thin sowing of wheat.

Number of seeds sown per pot.	Rate per acre.	Weight of grain.	Weight of straw.	Yield per plant.	
				Grain.	Straw.
	Pecks.	*Grams.*	*Grams.*	*Grams.*	*Grams.*
5	2.7	5.6	11.3	1.11	2.27
10	5.5	5.9	11.4	.59	1.14
15	8.3	4.9	10.6	.34	.73
20	12.0	4.8	11.2	.24	.57

On May 4 the average number of shoots per plant was 6.1 for the thin seeding, and 3.5 for thick seeding; and on June 6 there were 7 and 2.6 shoots per plant, respectively. With barley thick seeding did quite as well as thin seeding. The experiments with small and large seed showed practically no difference in the results, and this was the case with wheat as well as barley.

The test of hard and soft wheat indicated that soft wheat does not necessarily produce starchy grain, or hard wheat glutinous grain, and that there are other determining factors with a more powerful influence in this direction than the seed sown. The dry grain from hard wheat was found to contain 2.57 per cent of nitrogen and the grain from soft wheat 1.94 per cent.

The results further indicate that heavy soils produce a more glutinous wheat than light sandy soil. In these tests soft wheat was sown on heavy soil but the produce was entirely hard wheat.

The investigation on wheat smut consisted of a comparative test of the ordinary smut remedies. Nitrate of soda containing 2.15 per cent of potassium perchlorate, applied at the rate of 1 cwt. per acre, had no injurious effect on barley as compared with nitrate of soda free from perchlorates. The use of "Martellin," a silicate of potassium fertilizer, had no beneficial effect on red clover.

Report of the agriculturist, R. S. Shaw (*Montana Sta. Bul. 28, pp. 10–13*).—Yields of wheat, oats, and barley grown under the Campbell system and under general methods of culture are given. The author concludes that "the Campbell system will not compete with methods of irrigation, though it may hold an important place in crop producing in arid regions where water is not available." Yields of wheat, oats, barley, clover, peas, and sugar beets grown in rotation experiments are also given. Results of feeding experiments with steers, sheep, and pigs reported in Bulletin 27 of the station (E. S. R., 13, pp. 270, 271, 273) are briefly summarized.

Grain and forage crops, J. H. Shepperd and A. M. Ten Eyck (*North Dakota Sta. Rpt. 1900, pp. 59–97*).—The work here reported, covering the seasons of 1899 and 1900, is largely in continuation of experiments described in a previous bulletin (E. S. R., 11, p. 331). The results obtained are shown in tables and briefly discussed.

Wheat.—Sixty-three varieties of wheat were grown in 1899 and 51 in 1900. In 1899, 15 varieties yielded over 24 bu. per acre. The leading sorts were: Pererodka U. S. No. 2954, and Kubanka U. S. No. 2953, yielding 34.9 and 30.1 bu. per acre, respectively. Bolton Blue Stem, Experiment Station Fife, Red Fife and Glyndon (774) yielded on the average for 6 successive years, 24.2, 23.5, 22.8 and 22.8 bu. per acre, respectively. Many of the wheats tested were originated by the station or imported varieties from Russia. A few of the new varieties are described. The results for 1900 were not considered conclusive and are not reported. The average results from 23 tests with home-grown seed and with wheat originally from this station but grown at the Minnesota Station from 1 to 9 years, showed a gain of 2.44 bu. per acre in favor of the home-grown seed. Five and a half pecks of seed wheat per acre gave the best average results for 7 trials, including the last 2 seasons. The yields as compared with the rate of seeding were not very uniform.

Oats.—Twenty-five varieties of oats, of which 8 had been tested for 6 years or more, were grown during the 2 seasons. In 1899 only 3 varieties were injured by rust, namely, Black Beauty, Tobolsk, and Swedish Select. Archangel also rusted but to a less degree. In 1900, weather conditions interfered with the successful growth of the crop. Tartarian, American White Banner, Race Horse, Black Beauty, Archangel, White Russian and Lincoln produced the largest average yields for 6 years tests.

Barley.—In both seasons 25 varieties of barley were grown in the field trials. Success, Culver, French Chevalier, Minnesota No. 105, Manshury, Sisolsk, 2-rowed Manshury and Odessa, in the order mentioned, gave the largest average results for the two seasons, the yields ranging from 31 to 37½ bu. per acre. The best returns from varieties grown for 3 successive years were obtained from French Chevalier, Culver, Manshury, Odessa, Salzer Silver King, and Bernard, in the order given. The average yields varied from 34.4 to 39.4 bu. per acre. In 1900 the late-maturing varieties gave enough heavier yield to affect the average for 3 years to such an extent that they ranked highest.

Spelt.—Of 4 varieties of spelt grown in 1899 the 2 best yielding varieties, Common and Yaroslaf Spelt, were given a further trial the following year. The Common yielded 32.69 bu. per acre, while the Yaroslaf, a Russian variety, yielded 28.56 bu. per acre. In 1899 the yield had been 69.1 and 74.1 bu. per acre, respectively. A comparison of the average yield for 3 years of the best producing varieties of barley and oats, with the highest yielding spelt, shows an advantage of 45 lbs. over oats and 73 lbs. over barley in favor of the splet.

Millet.—A number of varieties of millet have been grown by the station for several years. The highest average yield of seed per acre for the 2 seasons, 43.9 bu., was produced by the German millet. When grown from North Dakota seed this millet gave 1½ tons less fodder per acre, but about a ton more grain than when grown from southern seed. The millet also produced more grain per acre than either oats or barley.

Flax.—Four varieties, Riga Fibre, Common, Russian, and Odessa were on trial in 1900. The Russian yielded the most seed, 16 bu. per acre, and the Riga Fibre produced the heaviest yield of straw, 1,683 lbs. per acre. These 2 varieties also matured earlier than the other sorts. The Riga Fibre flax produces more straw and less seed than seed flax varieties. A 3 years' trial of growing flax and wheat together is reported and the results are compared with the yields obtained when the crops were grown separately. The financial results were only very slightly in favor of the unmixed grain. Wheat grown with flax was poorer in quality than wheat grown alone, while flax grown alone was poorer in quality than when mixed with wheat. The results of other tests indicate that flax should be sown about the time the wheat is coming up instead of sowing the mixed seed. Sowing 4 pecks of wheat and 2 pecks of flax per acre gave the largest yield. Different amounts of seed were sown per acre to study the effect on the yield and quality of straw, fiber, and seed, but the results were not conclusive. Sowing from 2 to 4 pecks per acre produced the heaviest and longest straw, but more branched and less long straight straw than thicker seeding. In the dry season of 1900 from 4 to 6 pecks per acre produced more profitable yields of seed than thinner sowing.

Buckwheat.—Among 6 varieties tested, 2 introduced Russian varieties, designated as Russian No. 1 and Orenberg No. 6, gave the best results.

Potatoes.—Forty varieties were tested in 1899, and 12 of these had been grown the previous year. Sixteen of the 40 kinds grown in 1899 were planted for trial in 1900. The varieties giving the best average yields for the last 2 seasons were Early Dawn, Thoroughbred, Early Ohio, Burpee Superior, Six Weeks, Freeman, Secretary Wilson, Early Andes, and Carman No. 1. Early Ohio, Early Dawn, and Early Andes are recommended as good early potatoes. The results of experiments on the thickness of planting showed a general decrease in yield as the distance between the hills increased. The seed in this case had been cut from 2 to 3 eyes to the piece and planted about 4 in. deep. Doubling the quantity of seed per hill decreased the yield and proved detrimental to the quality of the tubers. Planting potatoes from 3 to 5 in. deep gave the largest yields but a poorer quality of tubers than deeper planting. Shallow and flat cultivation gave larger yields than deep cultivation and hilling.

Report of the experimentalist, C. A. Zavitz (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 96–125, figs. 5*).—The work here presented consists largely of variety tests, and is in continuation of experiments conducted in previous years (E. S. R., 12, p. 328). Other work of the experimental department is briefly noted. The results of 10 years' experiments show that Joanette Black oats gave the largest average yield of all varieties tested. Sixty-seven varieties were grown this season, and among them Probsteier, White Siberian, Mennonite, Daubeney, Waterloo, and New Electric, in the order given, produced the largest yields. Vanhouten, Scottish Chief, and Black Irish were the least productive varieties in the test, giving less than one-half the yield of the best yielding sorts. The grain per measured bushel of Whiteside, Early Dawson, Mortgage Lifter, White Dutch, White Superior Scotch, and Washington weighed over 40 lbs., but it was observed that varieties producing heavy grain are usually only moderate yielders, and that the grain is generally thick in the hull. The earliest varieties, Alaska, Daubeney, and Black Mesdag ripened about the 25th of July. Seed of 6 different varieties grown in Missouri, but originally from the Ontario Agricultural College, was compared with seed grown at the college, and the results of this single test showed that the Missouri seed produced the largest yields and the Ontario seed the heaviest grain.

The experiments with barley show that the 6-rowed varieties have given much better results than the 2-rowed varieties. Manshury barley has been compared with the widely cultivated Common 6-rowed barley for 12 years, and the results show an average yield of 66.8 bu. of grain and 1.9 tons of straw per acre for the Manshury and 57.9 bu. of grain and 1.6 tons of straw for the Common 6-rowed. The average weight per bushel of Common 6-rowed was 52.7 lbs., or 1.6 lbs. greater than the weight of the Manshury. Of the 19 varieties tested this season, California Brewing, Four-Rowed Canadian, and Six-Rowed Baxter Improved gave the best yields. The heaviest grain weighed 54.6 lbs. per bushel and was produced by the Oderbrucker variety. The average results for several years show that the best 2-rowed barley yielded about 14 bu. per acre less than the best 6-rowed variety. The 2-rowed varieties giving the best average yields for a period of several successive years were New Zealand, Chevalier, Gold Foil Hansford, French Chevalier, Empress, Two-Rowed Canadian, and Kinna Kulla. Of the varieties tested in 1900 Two-Rowed Canadian, Duckbill, Vermont Champion, and Jaramn Selected Beardless produced the highest yields.

Of 12 varieties of hulless barley grown this year Guy Mayle and Black Hulless were the best grain producers. Purple and Black Hulless yielded the heaviest grain, the weight per measured bushel being 64 and 62¾ lbs., respectively. Hulless barley usually weighs about 60 lbs. per bu.

Twenty-eight varieties of spring wheat were tested this season, and among them Red Fern, Bart Tremenia, Pringle Champion, and Wild Goose, in the order mentioned, gave best returns. Harrison Bearded, Bart Tremenia, Wild Goose, Konisburg, and Blue Democrat produced the heaviest grain per measured bushel. The Wild Goose is the best macaroni wheat grown in Ontario and is largely exported to Italy and France. Other varieties of this class grown at the college, namely, Medeah, Bart Tremenia, Sorentina, and Algiers have each given better results than any of the finer varieties of spring wheat. Most varieties of spring wheat gave better results than Salzer spelt. Of the 33 best varieties of winter wheat grown for 5 years, Dawson Golden Chaff, Egyptian Amber, Imperial Amber, Early Genesee Giant, and Reliable, in the order mentioned, gave the best results, the yields ranging from 50.9 to 56.7 bu. per acre. The lowest average yields for 6 years were produced by Treadwell, Turkey Red, and Velvet Chaff. All the varieties tested yielded over 40 bu. per acre. Large plump seed produced a better yield and a heavier grain than small plump, shrunken, and broken seed. The last week of August proved the better time for sowing winter wheat. The results of drilling and broadcasting the same quantity of seed were practically equal. Peas, as a green manure for winter wheat, gave better results than buckwheat, but an application of 20 tons of barnyard manure on a bare summer fallow gave better yields than either. Winter wheat after clover gave better returns than when grown after grass. The largest yields of grain and straw and the heaviest weight per measured bushel were obtained by allowing the grain to ripen fully.

The 4 varieties of spring rye under test yielded from 34.5 to 38.7 bu. per acre in the following order: Dakota Mammoth rye, Prolific spring rye, Common rye, and Colorado Giant rye. Very good results were obtained from winter rye, the two varieties grown, Mammoth and Common, yielding 71.4 and 70 bu. per acre, respectively.

The largest average yields per acre of peas grown for 6 years were obtained from White Wonder, New Zealand Field, Early Britain, Egyptian Mummy, New Zealand Brown, and Tall White Marrowfat. In 7 years' tests the Grass peas produced an average of 2.3 tons of straw and a little over 23 bu. of grain per acre. In a comparative test this season Grass peas gave a better yield than Oddfellow peas. The chick-pea (*Cicer arietinum*) has given good results at the college. The best variety of cowpeas grown was the Italian, which produced 12.3 tons per acre.

Twenty-two varieties of flint corn were tested in 1900, and of these King Philip, Angel of Midnight, Pride of Canada, Salzer South Dakota, Salzer North Dakota, Longfellow, and Genesee Valley, in the order given, produced the largest yields. Of 128 varieties of fodder corn, including dent, flint, and sweet varieties, Mammoth Cuban and Mastodon dent gave excellent satisfaction. Corn planted 2 in. deep gave the greatest total yields per acre. Planting in hills gave better results than planting in drills.

The average results of the experiments with potatoes for several years indicate that Empire State, Pearl of Savoy, American Wonder, Dempsey Seedling, and Rural New Yorker No. 2 are the best general varieties. Daisy, Rose New Invincible, Paris Rose, Irish Cups, Bovee, Six Weeks, White Elephant, and Ohio Junior yielded over 220 bu. per acre this season. Sprinkling cut seed potatoes with gypsum or land plaster increased the yield 16.4 bu. per acre. Cut potatoes planted on the same day they were cut yielded about 18 bu. more per acre than those planted 4, 5, and 6 days after cutting. The results of the distance experiments were in favor of planting 26½ in. apart, with the sets 1 ft. apart in the row. Planting 1 set in each hill gave a better yield than planting 2 or 4 sets per hill.

Hairy vetch produced an average for 4 years of 8.8 tons of green forage per acre. Alfalfa gave three cuttings and yielded 4.6 tons of hay per acre in the present year. The best mixtures of grass and clover for hay were tall oat grass and alfalfa; tall oat grass, orchard grass, mammoth red clover and alfalfa, and alfalfa and timothy. A mixture consisting of 4 lbs. of orchard grass, 4 lbs. meadow fescue, 3 lbs. tall oat grass, 2 lbs. timothy, 2 lbs. meadow foxtail, 5 lbs. alfalfa, 2 lbs. alsike clover, and 1 lb. of trefoil is recommended for permanent pastures. Among a number of grain mixtures grown for the production of grain and straw, Mansbury barley and Daubeney oats, Chevalier barley and Siberian oats, and Kinna Kulla barley and Poland White oats produced the largest yields of grain. In general, the results of experiments in sowing oats, barley, spring wheat, and peas on different dates favor the earlier sowings and tests with selected seed of these same crops show the superiority of large plump grains. Drilling oats, barley, and peas was found preferable to broadcasting.

Farm superintendence, G. E. Day (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 53–60, figs. 5*).—Brief notes are given on the different field crops grown at the college in 1900 with reference mainly to the amount of land devoted to each crop, the preparation and cultivation of the soil, the result of seeding and the yields obtained. Notes are also given on the live stock, and a financial statement of the farm department for the year is included.

Field experiments with fertilizers on corn, oats, and wheat in 1899 and 1900 (*Ohio Sta. Bul. 124, pp. 103–119*).—The general plan of these experiments and previous results have been noted (E. S. R., 12, p. 127). The changes from the general plan made in 1899 consisted in discontinuing on one plat the use of bran as a carrier of phosphoric acid, doubling the quantity of phosphoric acid and reducing the quantity of nitrogen by one-half on 4 plats and in one instance bringing tankage into comparison with other nitrogen fertilizers. The results are tabulated in detail. It is concluded from the results obtained that the relative behavior of two soils toward phosphoric acid and potash can not be determined by chemical analysis, and that the physical condition of the soil may have a greater influence on its fertility than its chemical composition. For the soils here under test phosphoric acid was found to be the most important element. Without phosphoric acid in the fertilizer application nitrogen and potash were not effective. Next to phosphoric acid, nitrogen was most needed, and it seemed most effective on the soil showing the greatest deficiency in it by chemical analysis. The results, however, indicate that where clover enters into the rotation the quantity of nitrogen which can be economically applied is far below the needs of the soil, as shown by its chemical composition. On the soil at Strongsville, which has accumulated a considerable reserve of nitrogen during a long rest in pasture, 3 per cent of nitrogen in the fertilizer application was not too much, and it is concluded that a still larger quantity might be profitably used on the badly worn soil at Wooster. Potash, although the least important of the 3 necessary elements of plant food, in these tests produced an additional increase in the yields after both nitrogen and phosphoric acid had been applied. The potash content of the 2 soils coming under this observation was practically identical, still, potash in the fertilizer application was much more effective at Wooster than at Strongsville.

Recent experiments with Alinit in the cultivation of oats and barley, A. Damseaux (*Jour. Soc. Roy. Agr. L'Est, Belg., 1900, pp. 111, 112*).

Sludge as a fertilizer for grass, A. E. Shuttleworth (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 30, 31*).—Dry sludge applied as a top-dressing at the rate of 1,000 lbs. per acre increased the yield of green timothy a little over 4 per cent. Analyses are given of sludge and barnyard manure.

A meadow for hay and pasture, G. Heuzé (*Jour. Agr. Prat., 1901, I, No. 9, p. 286*).—A note on the management of a meadow to be used as a pasture after the first cutting of hay.

Experiments with beans, A. M. Ten Eyck (*North Dakota Sta. Rpt. 1900, pp. 98–101*).—These experiments consisted of distance and variety tests. Drilling beans in rows 2 ft. apart gave the larger yield and an earlier crop than drilling in rows 3 ft. apart. In the variety test the Brown or Swedish bean stood first in yield, Dewey Navy second, and California Wonder third. The Dewey Navy is an early variety and sells well. The Great Northern and Aristook are a little earlier, but are not considered equal to the Dewey Navy on account of being dwarf and light-yielding varieties.

Experiments in corn culture, J. S. NEWMAN (*South Carolina Sta. Bul. 61, pp. 12, pls. 3*).—In this bulletin the reports of experiments on corn culture are prefaced with a brief consideration of the preparation of the soil and the cultivation of the crop. The experiments were conducted on river bottom land and embraced methods of planting and cultivation and fertilizer and variety tests. The effects of different methods of planting and cultivating were not pronounced. The best results in the distance experiments were obtained from plats on which the stalks had each from 4 to 6 sq. ft. of space. In connection with these tests it was observed that planting peas in drills between the rows of corn increased the yield, and that where the peas were sown broadcast the increase in the yield of corn was still greater. The use of commercial fertilizers did not increase the yield sufficiently to cover the cost of the application. Albemarle Prolific gave the best yield of the 7 varieties tested, but it showed the smallest percentage of shelled corn on the weight in the ear.

The culture of maize, C. GINER (*Bol. Agr. Min. é. Ind.* [*Mexico*], *10* (*1900*), *No. 2, pp. 61–93*).—An article treating in general and at some length of the culture of corn and discussing the effect of climate and cultivation on the growth, composition, and value of the plant.

Studies upon flax in 1900, H. L. BOLLEY (*North Dakota Sta. Rpt. 1900, pp. 43–45*).—A study of the uneven ripening of flax was made by sowing seed on different dates at varying depths. Seed from several supposed varieties and several different grades of one variety were used. The conclusion drawn from the results is that an equally maturing crop of flax can be grown from good uniform seed sown at a uniform depth on land of even quality. The date of sowing was not found to be an influential factor. In studying the effect of frost on young plants it was determined that plants killed back to below the 2 seed leaves will not put forth new sprouts, while plants with the seed leaves uninjured branch freely. Germination tests of flax injured by frost before it had matured showed that it had a very low germinating quality.

The removal of the hop vines immediately after the hops had been harvested (*Württemberg Wchnbl. Landw., 1901, No. 4, pp. 42, 43*).—A brief note discussing the advantages and disadvantages of this method.

Culture tests with horse beans on different soils under the same climatic conditions, J. SEISSL and E. GROSS (*Ztschr. Landw. Versuchw. Oesterr.*, *3* (*1900*), *No. 2, pp. 153–164, fig. 1*).—In these experiments the horse beans (*Vicia faba major*) were grown in pots of various kinds of soil from different sections of the country. The amount of plant food withdrawn from the different soils by the plants was calculated. Although no definite conclusions are drawn, the author calls attention to the relation existing between the yield, the assimilation of phosphoric acid by the plants, and the proportion of phosphoric acid to the sesquioxids of iron and ammonium in the soil, a factor acting on the solubility of the phosphoric acid.

Results with variety tests of lupines, EDLER (*Jahrb. Deut. Landw. Gesell.*, *15* (*1900*), *pp. 546–560*).—Cooperative tests with different species and varieties of lupines, begun in 1897, are here described and the results obtained recorded. The results show that varieties of blue lupines yielded much more seed but less straw than varieties of the yellow lupine. Only on poor, dry, sandy soils did the yellow lupines produce more seed than the blue. The yields of seed of the yellow lupine and the black lupine (*Lupinus luteus* and *L. luteus semine nigro*) were equal. The yellow lupine developed slower than the blue, requiring from 2 to 3 days more to come up, a week longer to come into bloom, and about 10 days more to ripen. The yellow lupine is much more sensitive to the lime content of the soil than the blue lupine, and its seed also has a much higher alkaloid content. The albumen content of the seeds of yellow lupines was much greater than that of blue lupines.

Soil inoculation experiments with lupines, C. SCHREIBER (*Rev. Gén. Agron. [Louvain], 9 (1900), No. 7, pp. 302–304*).—The inoculation of a field at the rate of 6,000 kg. per hectare with soil taken from land producing good lupines increased the yield of green plants, including roots, by 22,500 kg. per hectare as compared with soil not inoculated.

Autumn catch crops, P. P. DEHÉRAIN (*Bul. Soc. Nat. Agr. France, 60 (1900), No. 12, pp. 749–751*).—A discussion on the use of white lupines in this connection.

Tillage experiments with potatoes, J. L. STONE (*New York Cornell Sta. Bul. 191, pp. 167–188, fig. 1*).—This bulletin summarizes the reports from farmers who cooperated with the station in cultural experiments with potatoes in 1899 and 1900. The cultural methods recommended by the station were early or twice plowing, thorough fitting, deep planting, prolonged, frequent, level tillage, and spraying with Bordeaux mixture and Paris green. Eighty-five per cent of the reports received from the farmers who gave these methods a trial indicate profitable returns. The results of similar experiments conducted at the station from 1895 to 1899, inclusive, published in former bulletins and previously noted, are reported and briefly discussed.

The work with potatoes during the summer of 1899, H. L. BOLLEY (*North Dakota Sta. Rpt. 1900, pp. 39–43*).—From 4 varieties of potatoes—Sunlit Star, Dakota Seedling, Trumbull, and Early Ohio—the largest and best, nearly round and typical long shaped tubers were selected from the bin and planted. The results obtained confirmed the previous conclusions (E. S. R., 9, p. 942) that for form and quality of tuber the selection must be made in the field from the vine. It was found better, however, to select from the bin the shape desired than to make no selection at all. A comparison of the stem and seed ends of the tubers for seed was only slightly in favor of the seed end. Several experiments to determine the possibility of root fusion are reported, but the results in all cases were negative.

Field experiments with fertilizers on potatoes, 1894 to 1900 (*Ohio Sta. Bul. 125, pp. 121–132, dgms. 2*).—The experiments here considered have been partially reported in a former bulletin (E. S. R., 12, p. 127). They were made at the central station at Wooster and at the substations at Strongsville and Neapolis. The rotation in connection with this experiment was potatoes, wheat, and clover. Superphosphate, muriate of potash, nitrate of soda, and dried blood were applied at different rates, alone, and in different combinations. It is concluded that, after making allowance for irregularities in yields, phosphoric acid is the constituent most needed for potatoes and cereals by the soils at Wooster and Strongsville, while on the thin, sandy soil at Neapolis potash is relatively more effective than phosphoric acid. All tests showed a much greater increase from the use of the combined fertilizer than from any single constituent alone. It is considered that in a general way the results indicate that acid phosphate in moderate quantities can be profitably used in potato growing and that it is also advantageously combined with small quantities of potash and nitrogen fertilizers. In a short rotation like the one used in these experiments, and on soils which produce good crops of clover, the economy of using nitrogen fertilizers on potatoes is questioned. The results also show that it is the soil rather than the crop which determines the fertilizer required.

Report on variety tests with potatoes, F. W. RANE (*New Hampshire Sta. Bul. 79, pp. 10–15*).—The results of varieties of potatoes tested in 1900 are tabulated and each variety is briefly described.

Serradella in Campinas, G. D'UTRA (*Bol. Agr. São Paulo, 1. ser., 1900, No. 7, pp. 474–478*).—A brief description of the culture tests with serradella and a report on analyses of the plant at different periods of growth.

Experimental work with sugar beets during 1900, R. H. FORBES (*Arizona Sta. Bul. 36, pp. 187–205, maps 2*).—This bulletin is a report on cooperative culture experiments with sugar beets under the direction of the station. Each test is discussed separately and the results set forth graphically. In the Upper Gila district where this work was carried on, beet seed may be planted from about February 1 to October 15. Autumn plantings endure the winter if the beets have attained a certain size before the cold weather comes. In one instance a plat seeded September 6, on which the leaves were about 10 in. long, was not seriously injured by cold weather up to January, while a planting made September 15 on the same ground was partly destroyed by frost. On all plats the weight of the beets increased until about the first week in August. The influence of water on tonnage was shown where one-half of a plat received an extra irrigation on August 7, the average weight of the beets being increased 1.1 oz., but the quality of the beets was lowered. The average sugar content of the beets June 5 and 6, was 10.6 per cent; June 20, 11.82 per cent; July 2–6, 12.29 per cent; July 19–21, 12.27 per cent; August 3–13, 13.16 per cent, and August 27–31, 12.58 per cent. A shortage of water seemed to decrease the percentage of sugar. "These facts indicate that drought causes the beets to curtail sugar production in favor of maintenance of structural growth." Early planting is recommended to enable the beets to be comparatively mature before the hottest weather sets in. The purity of the juice was quite variable, increasing from May 23 to June 20, when the beets were growing rapidly, and decreasing after that period when the growth was lower. May 23, the average purity was 71.9, and June 20, 83.1, while the latter part of August it had fallen back to 81.25. The results obtained on a plat grown at the station showed a yield of 4,901 lbs. of total sugar per acre. These beets had been planted December 26 and attained fair size before the arrival of hot weather.

Sugar beets, W. P. Headden (*Colorado Sta. Bul. 63, pp. 31*).—This bulletin is a review of the work with sugar beets carried on at the station up to the present time and reported in the station bulletins. These bulletins have been previously noted.

Experiments with sugar beets, J. D. Towar (*Michigan Sta. Bul. 188, pp. 97–107, fig. 1*).—The experiments reported in this bulletin, including tests of various kinds of soils for sugar beets, an experiment on the time of planting beets, and distance, fertilizer, and variety tests, were conducted in 1900 on soils ranging from sand to loam. The results show that clay loam soils produce the largest tonnage and the highest percentage of sugar. The tests on muck soils indicated the possibility of a high percentage of sugar, but most pure muck soils produce beets so low in sugar content that they can not be profitably worked. This season seed planted between May 10 and 24 gave the most profitable yield, but the author considers any time between the last week in April and the last of May as suitable for planting in that latitude. Planting in rows 21 in. apart increased the yield 5 per cent as compared with planting in rows 18 or 24 in. distant. The results of experiments made to determine whether sugar beets exhaust the soil show that beets after potatoes or beans gave a better yield than beets grown after beets. Fourteen varieties were tested during the season, giving an average yield of 14.08 tons per acre with 13.63 per cent of sugar in the juice and a purity of 81.30. Austrian Special Kleinwanzlebener No. 5 produced the greatest value of crop per acre. Germination and vitality tests of the seeds of these different varieties were made and the results recorded. Austrian Special B. G. V. produced 166 sprouts from 48 seed balls, while Simon Le Grande C No. 27 grew only 126 sprouts from 72 balls, but low germination did not seem to affect the yield, for the best yielding varieties were by no means those which gave the highest percentage of germination.

Fertilizer tests with various applications were begun in 1899 and the fertilizers applied in both seasons were practically the same in quantity and quality. Stable manure applied early in the winter gave the largest yield of beets and the lowest percentage of sugar, but it proved to be the most remunerative fertilizer. When applied the day before plowing the field, the percentage of sugar in the beets was so low that the use of home-mixed fertilizers was more profitable. In no case did the use of incomplete fertilizer applications prove remunerative. Transplanting beets was found to be detrimental in every way. Meteorological conditions of the season are shown in a table.

Sugar-beet experiments for 1900, E. F. LADD (*North Dakota Sta. Rpt. 1900, pp. 20–23*).—This is a report on cooperative culture experiments with sugar beets made throughout the State. The results of analyzing the samples are given in tables. An unfavorable season prevented maturity of the beets, and the results were not satisfactory.

Sugar-beet investigations in Ohio in 1900, A. D. SELBY and J. W. AMES (*Ohio Sta. Bul. 126, pp. 133–174, figs. 8*).—This bulletin is a report on the cooperative culture tests with sugar beets throughout the State in 1900. The results of germination tests of the beet seeds used in these experiments and the meteorological data for the year and for previous seasons are reported. Seed was sent to 203 farmers in 60 different counties of the State, and of these 109 returned samples for analyses. A total of 303 samples was analyzed by the station, and the results are set forth in tables. The results for the entire State show an average of 10.9 per cent of sugar in the beets and a purity of 77.1. Dividing the State into different sections, the results for the northern section show an average of 11.3 per cent of sugar in the beets, with a purity of 77.8; for the middle section, 10.7 per cent of sugar and 77.4 purity; and for the southern section, 8.1 per cent of sugar and 67.5 purity. The bulletin further discusses the industry within the State, gives a concise description of the factory processes, and notes the advantages of certain cultural practices. The most important diseases of the sugar beet are discussed and remedial measures suggested.

Sugar-beet experiment, A. E. SHUTTLEWORTH (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 25–29*).—This article describes the experimental culture of sugar beets by farmers in 3 different localities in Ontario and reports the results obtained from these tests and reviews briefly previous experiments in this same line. In each of the 3 localities samples were taken on different dates, and it was found that there was very little increase in the size of the beets between September 25 and November 6, but the purity gradually improved. The weight of the beets in all the samples varied from 15.7 to 20.8 oz., the sugar in the juice from 13.7 to 15.3 per cent, and the purity from 81.9 to 86.8.

Sugar-beet experiments in Ontario in 1900, A. E. SHUTTLEWORTH (*Ontario Agr. Col. Bul. 113, pp. 43, figs. 9, map 1*).—This bulletin contains the report of cooperative culture tests with sugar beets conducted at 3 different centers: Aylmer, Welland, and Newmarket. The results of the analyses of different samples are recorded in tables. Directions for the cultivation of sugar beets in Ontario are given and a discussion of the cost and profit of sugar-beet culture is taken from other sources. Most of the samples analyzed showed the required sugar content for factory purposes and a correspondingly high coefficient of purity.

Nitrogenous fertilizers in the culture of sugar beets (*Sucr. Indig. et Coloniale, 57 (1901), No. 6, pp. 167–171*).—A brief account is given of experiments in the department of Aisne which showed that mixtures of nitrate of soda, sulphate of ammonia, and dried blood gave better results as regards yield and quality of beets than nitrate of soda alone.

The sugar industry in the island of Guadeloupe (*Sucr. Indig. et Coloniale., 57 (1901), No. 9, pp. 272, 273*).—A description of the sugar-cane crop and the campaign of 1900.

Brief notes on the culture of tobacco (*Tabac, 21 (1901), No. 369, pp. 2, 3*).

Notes on the culture of tobacco and its preparation, M. M. GARCIA (*Bol. Agr. Min. e. Ind. [Mexico], 10 (1900), No. 2, pp. 3–60*).—An article treating at some length the culture of tobacco in Mexico.

The drying of tobacco. I, Total weight and loss of weight, E. C. J. MOHR (*Meded. 's Lands Plantentuin, 1900, No. 41, pp. 49*).—The author studied in detail the process of drying tobacco, and determined some of the conditions that influence the quality of the dried leaf. Three stages in the drying process are distinguished: The first stage from the time the tobacco is hung until the cells of the leaf blade are dead; the second until the leaf blade is dry, covering about two days; and the third stage is characterized by the death and drying of the midrib. At its close the leaves are taken down and carried to the fermenting barn.

Before the death of the cells the passage of the cell contents is controlled by the living protoplasm, but after the death of the cell, the contents can pass freely from place to place as long as there is sufficient moisture to permit of chemical activity.

Evaporation goes on much more rapidly after the death of the cells than before, but as all the cells do not die at the same time the effect of this is not noticeable. The chemical changes which take place during the drying result in a decrease in dry matter. This is especially true during the first stage, while during the last stage there may be a slight increase of dry matter due, the author thinks, to oxidation.

The quality of the finished product depends largely upon the length of time the different stages are allowed to continue. If the drying is unduly hastened the leaf blade becomes too dry by the time the midrib is dry enough, and the danger is that the leaf will not ferment properly. As a result of this study of fresh tobacco the author finds that on properly grown plants the top leaves are heavier than the lower ones and contain a relatively larger amount of dry matter. The cells and air spaces are larger in the lower leaves, and the leaves dry more rapidly and burn better. In the upper leaves the unit of surface (1 sq. cm.) is heavier than in the lower leaves, due to the greater amount of solid matter in the cells of the upper leaves. It was also found that the green leaf was influenced by the time of day the tobacco was cut and by the weather conditions some hours or even some days before harvest. The riper the leaves were, the shorter the time needed for drying.

During harvest careful attention must be given to wet leaves, the bruising of leaves, and the sweating. Wet leaves or wet places on the leaves tend to discolor the tobacco and to make it dry unevenly. Bruising affords a point of entrance for molds.

During sweating an increase in temperature lowers the vitality of the cells, thus hastening death and the completion of the first stage in drying.

The influence of light, air, moisture, and heat are briefly discussed. In urging the necessity for ventilation the author points out that in the process of drying the air of the barn must be changed at least 500 times in order to carry off all the moisture from the leaves.—H. M. PIETERS.

Work with wheat in 1900, H. L. Bolley (*North Dakota Sta. Rpt. 1900, pp. 28–32*).—The work of wheat selection which has been in progress for several years was continued this season. Large and small grains from each of a number of selected heads were sown and the resulting plants compared. In the majority of cases, the greatest length of straw was in favor of the large seed. The total weight of straw and grain produced by 102 stools from large grains was 1,417 gm. and by the same number of stools grown from small grains, 1.328 gm. In a second test 800 of the largest, plumpest, and finest colored grains and the same number of the smallest possible grains which were plump, hard, and of similar fine quality were selected from a graded sample of Scotch Fife wheat and grown for comparison. The results showed a gain of over 10 per cent in the total weight of straw and grain in favor of the large seed. The large grains also produced heavier heads. In a third experiment, heads of wheat were harvested at different stages of maturity and cured in a dry room, the grain being left in the straw until it was sown. After a germination test, which showed perfect germination for all the samples, the seeds of the different lots were sown for comparison. The most rapid growth was made by the young plants from the most immature seed and the sprouts were longer than those from the mature grain, but these were 3 to 4 times as strong in diameter. Owing to unforeseen advantages of some of the plats, no conclusions could be drawn from the results.

Wheat studies, E. F. LADD (*North Dakota Sta. Rpt. 1900, pp. 13, 14*).—Wheats were studied to determine the percentage of nitrogen in individual heads and the heads from individual stools. It was found that individual heads ranged from 13.56 to 18.25 per cent in proteid content, and the average for the stools from 14.74 to 17.09 per cent.

Improving wheat (*Bol. Soc. Agr. Mexicana, 25 (1901), No. 11, pp. 216–218*).—A consideration of the methods of improving wheat.

Some important questions in plant breeding, W. EDLER (*Vrtljschr. Bayer. Landw. Rath., 5 (1900), No. 4, Sup., pp. 619–630*).—An article on the improvement of potatoes, beets, rye, and oats.

Silo temperatures taken by electricity, H. H. LAMSON (*New Hampshire Sta. Bul. 79, pp. 29–33, fig. 1*).—The temperature of silage was determined at different depths of the silo on a series of dates from September 9 to February 17, by means of the electrical apparatus designed by the Bureau of Soils of this Department. The method of using the apparatus is described and the different temperatures recorded by it are given in a table.

HORTICULTURE.

Vegetables in South Dakota, N. E. HANSEN and W. S. THORNBER (*South Dakota Sta. Bul. 68, pp. 105–158, pls. 12*).—Some results are given of variety and cultural tests of vegetables at the station for the 2 years 1899 and 1900. Of the different crops grown there were 49 varieties of tomatoes, 29 eggplant, 16 peppers, 10 cauliflower, 3 kohl-rabi, kale, 22 sweet corn, 47 cucumbers, 30 beets, Swiss chard, 10 okra, many summer, fall, and winter squashes and pumpkins, 62 bush beans, 28 pole beans, 11 pole and 6 dwarf Lima beans, besides several varieties each of English broad beans, artichokes, chives, dandelions, endives, garden herbs, etc. Illustrations are given of many varieties of the vegetables grown. All of the more tender plants and those requiring a long season for maturing were either started in the greenhouse or under a cold frame.

With tomatoes, plants started in a cold frame compared favorably in yield and earliness with those started in the greenhouse. When grown in a cold frame the seed were planted in bottomless tin cans or like holders, which made transplanting to the field easy. This method is practical only for small areas. Among the heaviest yielding tomatoes for the first half of August in 1899, were Earliest of All, Salzer Earliest of All, Vaughan Earliest of All, and Early Leader. For the whole season Early Leader, The Early Bird, Bright and Early, and Early Ruby were the heaviest yielders. Some experiments are under way at the station in crossing tomatoes to secure a smooth variety which will ripen its main crop in July and August. Red Cherry has been used as a mother, and crossed with Early Ruby, Bond Early Minnesota, and Ponderosa.

Of the varieties of sweet corn tested Early La Crosse, Mexican, Lackey Early, and Telephone are preferred. Of cucumbers Siberian, West India Gherkin, Jersey Extra Early Prolific, and N. K. & Co. were found especially desirable for pickling purposes, while for table use Burpee White Wonder, Green Prolific, Fordhook Improved, White Spine, and Salzer Perfection are recommended. With regard to squashes the most productive of the large fall varieties were Orange Marrow and Boston Marrow, and of the winter sorts Hubbard and Marblehead. Of the small varieties Cocoanut, Henderson Delicata, Perfect Gem, Canada Crookneck, and Der Wing were the most productive in the order mentioned.

"It is sometimes recommended to plant Lima beans with the eye down; some of Burpee's and Henderson's were tested this way, but no difference was observable from those planted in the ordinary way."

Fertilizers for garden and field vegetables, DUBBERS (*Deut. Landw. Presse, 28 (1901), No. 35, p. 305, figs. 4*).—The good results obtained in growing cabbage, celeriac, spinach, pole beans, onions, kohl-rabi, carrots, peas, etc., by combining commercial fertilizers with barnyard manure, are shown by experimental data obtained with these crops.

Seven years of experiments with bush beans, B. D. HALSTED (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 119–129*).—Cultural experiments and experiments in controlling the diseases of bush beans have been carried on since 1894, and are here summarized. Planting at depths of 1 to 1¾ in. gave the best yield. Four and one-half inches distant in the row with Golden Wax sorts has been found better than greater or less distances. The more the beans are crowded, however, the greater the amount of spot diseases. Sprinkling the plants twice daily, from August 30 to October 1, had no appreciable effect upon the foliage or pods. Irrigation nearly doubled the yield of pods but tended to increase the diseases. Mulching was found to be of value only in seasons with less than the normal rainfall. Half-shading prolonged the period of maturity of the first crop and retarded the time of blooming of the second. The pod spot and bacteriosis of beans have been controlled in a large measure by the application of Bordeaux mixture and its various modifications. Beans have yielded on the whole better on old land than on new land, though slightly more subject to diseases. Mulching beans with spotted pods tended slightly to increase the disease. More and larger tubercles have been found on plants grown on old bean lands than where grown on new lands.

The cantaloupe, H. H. GRIFFIN (*Colorado Sta. Bul. 62, pp. 3–7, 16–18, fig. 1*).—Notes are given on the methods followed in growing the Netted Gem muskmelon at Rockyford, Colo. The results of some experimental work along the line of irrigation, fertilizing, and transplanting previously reported (E. S. R., 12, p. 229) are also noted, and additional data given on the proportion of male and female flowers produced on muskmelon vines at different dates during the season.

In the culture of muskmelons in Colorado the first planting is made from May 1 to 10. The land, preferably alfalfa sod, is put into good tilth, and furrows run with a shovel plow 6 to 7 ft. apart. From 10 to 15 seed are then planted 1 in. deep in hills 5 to 6 ft. apart by the sides of the furrows. The author prefers to plant the hills first and irrigate the furrows afterwards, rather than to irrigate first, since the soil is apt to become crusted and dry if it is handled and pressed after irrigation. Cultivation should follow until the vines are 2 to 3 ft. across the hill. "Then the irrigating furrows should be run and cultivation cease, giving such hoeing as will keep down weeds."

Rockyford cantaloupes are characterized by the author as follows: "A pure Rockyford cantaloupe when ripe should have a silver colored netting which is lace-like in appearance. The skin should be green turning to a peculiar gray color when the melon is fit for shipping. The flesh should be green in color, and so sweet and luscious that it may be eaten close to the rind. The melon should have a small seed cavity and the portion of the flesh immediately surrounding it be slightly tinged with yellow. The melon should weigh about 1½ lbs. and be very solid and firm."

A few melons for shipment are picked the first week in August, but the heavy shipping does not commence until about the middle of the month. The melons are crated in 3-tier crates holding 15 perfect melons in each tier. The standard size of this crate, inside measurement, is 22 in. long, 12 in. wide, and 13 in. deep. A 2-layer crate two-thirds the size of the standard and a "pony" crate, holding 45 melons but smaller than the standard, are also in use.

Relative to the signs which indicate the time for picking the Rockyford muskmelon, the author states as follows: "When it is proper time to pick for shipment, the stem slightly parts from the melon. No stem tissue should adhere to the melon, but there should be a smooth surface where the stem was attached. The netting and skin have a peculiar grayish appearance, which is easily distinguished when one becomes accustomed to picking."

In investigating the number of flowers borne by 6 vines from June 27 until July 13, when the vines became so interlapped that the individual vines could not be distinguished, it was found that the average number of male flowers to each hill, for the whole period, was 512, and the female flowers 42. It requires about 6 weeks from the time of setting of the flowers for the fruit to ripen. Twenty ripe melons to each vine is considered a heavy yield.

Among the insect pests of the cantaloupe the flea-beetle, striped cucumber beetle, geometer or measuring worm, and the melon louse are mentioned, and appropriate remedies suggested in each instance.

Tomato report, F. W. RANE (*New Hampshire Sta. Bul. 79, pp. 16–22*).—Tabular data and descriptive notes are given on a test of 29 varieties of tomatoes. Two methods of starting tomato plants have been tested at the station. In one the plants were transplanted into small boxes, so arranged that the bottom could be easily removed and the dirt allowed to slip out, and in the other they were transplanted into 4-in. pots. The author states that the percentage of loss from transplanting was very much less when the pots were used. The pots seemed to induce early maturity and early fruitfulness. "The pot system takes more time and occupies more space, but if this year is a criterion it surely pays."

The kind of soil in which the tomatoes were planted seemed to have an effect on the amount of rot produced. Where the soil was inclined to dry out, the rot was much more prevalent, while on a loamy, moist soil there was very little rot. "Where the soil was the most clayey the rot was the worst."

The development of a tomato hybrid, W. M. MUNSON (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 41–43*).—The currant tomato was crossed on the Lorillard, using the Lorillard as pistillate parent. The first cross produced a plant almost exactly intermediate between the 2 parents. Subsequent selection resulted in enlarging the fruit and improving the quality of the same. The fruit now produced is quite uniform in size and form, a little smaller than Lorillard but superior in quality and earlier, and especially well adapted to forcing. The net weight of the product is slightly less than that of the more commonly forced varieties.

Report of the professor of horticulture, H. L. HUTT (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 61–68, figs. 4*).—This work covers briefly the results of variety tests with raspberries, blackberries, currants, gooseberries, strawberries, tomatoes, geraniums, coleuses, gladioli, and chrysanthemums. With the tomatoes it is stated that such varieties as Earliest of All, Express, Plentiful, and Atlantic Prize were practically free from rot, while some other varieties, such as Livingstone Favorite, Ignotum, Paragon, and Volunteer, lost from one-third to nearly one-half of the crop from this cause. It is thought that this loss might have been prevented had the plants been sprayed with Bordeaux mixture, but this was not done in order to ascertain the susceptibility of the different varieties to the disease. The varieties standing at the head of the list for total yield of sound ripe fruit were Earliest of All, Plentiful, Express, Atlantic Prize, and Ignotum. The first three yielded about 11 lbs. of ripe fruit per plant.

Out of 230 varieties of geraniums tested for 3 years in succession, the following have been selected as a few of the most desirable for bedding purposes: "*Scarlet*—Aceton, Director Marmy, Garden Director, General Grant, J. J. Harrison, Louis Fages, Marvel, M. A. Boleaus, Marquis de Garland, and W. A. Chalfant; *Crimson*—S. A. Nutt; *Rose*—Fanny Thorpe and La Contable; *Pink*—Eulalie, Madonna, and Mary Hill; *Salmon*—Dr. Verneull, John Good, and Mrs. E. G. Hill; *White*—Alpine Beauty, C. de Harcourt, La Favorite, and Mad. Buchner; *Silver-leaved*—Mad. Saleroi and Mrs. Parker; *Golden-leaved*—Crystal Palace Gem."

Among coleuses the following have been found most desirable: "Alhambra, Beckwith Gem, Chicago Bedder, Charming, Excelsior, Electric Light, Firecress, Firebrand, Golden Bedder, John Good, Pink Gem, Paroquet, and Rob Roy."

Among several hundred gladioli tested for 4 years the following list is given of those which can be expected to bloom from the middle of July to the end of October: "Achanti, Diamant, Deuil de Carnot, Domino Rose, Dr. Bailly, Erie, E. V. Hallock, E. Souchet, Formosa, La Parisienne, La Perle, Massena, Magenta, M. de Vilmorin, Nakomis, Nezidscott, Pacha, P. Hariot, Princeton, and Snow-white."

Of 250 varieties of chrysanthemums under test at the station for several years the following are considered good representatives of the different types and present also a wide range of colors: "*Japanese*—Autumn Glow, Georgina Pitcher, Harry Sunderbruch, Heron's Plume, Maud Dean, Mrs. W. H. Robinson, Mrs. L. Allen, O. P. Basset, Philadelphia, Pitcher and Manda, Queen, Viviand-Morel, W. H. Lincoln, and Waban; *Japanese quilled*—Good Gracious, Helen Bloodgood, Iora, Kentucky, L. B. Bird, and W. H. Rand; *Japanese hairy*—Beauty of Truro, Louis Boehmer, Leocadie Gentils, Mrs. Alpheus Hardy, and R. M. Grey; *Chinese*—Cupid, Ideality, Mrs. L. C. Maderia, Mrs. Col. Goodman, and Major Bonnaffon; *Anemone flowered*—Antonius, Condor, Descartes, Falcion, John Bunyan, Mad. Robert Owen, and Surprise; *Pompons*—Rose Travena, Golden Fleece, Black Douglas; *Single-flowered*—Eucharis and Framfield Beauty."

Report of the South Haven Substation, S. H. FULTON (*Michigan Sta. Bul. 187, pp. 49–94*).—This is the annual report on varieties of orchard and small fruits and nuts under observation at the South Haven Substation, and is similar in character to the previous reports (E. S. R., 12, p. 236). In all, the yield and characteristics of 61 varieties of raspberries, 29 blackberries, 28 currants, 20 gooseberries, 64 cherries, 113 peaches, 47 pears, 9 quinces, 47 plums, 81 grapes, 105 apples, 11 crab apples, and a number of varieties of European and Japanese chestnuts, filberts, and walnuts are tabulated, with additional notes on many of the more important or newer varieties.

Of the raspberries grown Cumberland, Eureka, and Smith Prolific are recommended for general cultivation. Conrath, Diamond, Gregg, Idaho, Kansas, and Smith Giant are also considered reliable sorts. Columbian and Shaffer were the most productive of the purple caps and are the only varieties of this class recommended for profit. Among the red varieties, Cuthbert, Loudon, and Marlboro are considered especially desirable.

Of the blackberries grown Early King was the most productive of the early varieties, Wallace of the mid-season varieties, and Fruitland of the late varieties, though the latter is not as large nor as good a berry as Ohmer, which ripened at the same time.

Chautauqua and Lancashire gave the best results among the English varieties of gooseberries grown. Downing was the most productive of the American kinds.

London Market is considered one of the most profitable market varieties of currants grown at the station. White Dutch was one of the best white varieties on trial. Champion, English, and Wales excelled among the black kinds.

Of the cherries grown Dyehouse, Montmorency, Ostheimer, Richmond, and Weir were among the most productive sour varieties. Montrueil and Magnifique gave the largest yields of the Duke varieties grown. Ida, Mary Kirtland, Napoleon, Tartarian, and Windsor excelled among the sweet varieties. A block of cherry trees left 3 years in sod did not give as good results during the season as trees under cultivation, the yield being less and the fruit smaller.

In experiments with peaches, copper sulphate (1 lb. to 20 gal. of water) applied early in the spring again proved an effectual preventive of leaf curl.

Further experiments in pruning frost-injured trees "confirm the belief that much risk is incurred in cutting the main branches of the tree back to stubs, and at the same time strengthen the opinion that a moderately severe pruning is highly beneficial. Trees given the latter treatment have grown vigorously, developing clean, new, thrifty tops, and this season were covered with healthful, dark-green foliage. For the most part they were loaded with attractive fruit of fine quality. On the other hand, trees which were pruned lightly after the usual plan of heading in and thinning out part of the new growth have grown more slowly, were marked by smaller, less thrifty foliage, bore fruit of smaller size and poorer quality, and this fall contain much more dead wood. But it must be admitted that no manner of pruning will entirely renovate a badly frozen tree. There is hardly a tree above 4 years old on the station grounds that is not rotten in trunk and main branches and is held together only by the new growth which has been made since the freeze. This being the case, the trees broke down badly in winds and under their weight of fruit this season. But trees well cut back, having made a greater development of new wood, were better able to resist influences which tended to break them down, and doubtless their lives will be considerably prolonged."

Results obtained in experiments in thinning favored more severe thinning of peaches than is commonly practiced. A distance of 10 in. between fruits seemed to be none too great in the case of the varieties experimented on. In the experiments with pears early spraying with copper sulphate (1 lb. to 15 gal. of water) proved less efficient in the prevention of scab than late spraying with Bordeaux mixture just as the fruit buds were about to open.

Grapes at the station containing vinifera blood fruited sparsely, mildewed badly, and many were inclined to be tender and weak growers. The varieties best adapted for general cultivation in the climate of the station were Winchell, Diamond, Worden, Niagara, Concord, and Delaware.

Of the foreign chestnuts grown the Paragon was by far the best variety among either the European or Japan kinds. Likewise the Japan walnut (*Juglans seiboldii*), the author states, grows rapidly, and makes a handsome tree for ornamental purposes. The nuts are borne abundantly in large clusters. The quality is good but not high. An English walnut has grown but 5 ft. in height in 11 years, and has as yet shown no signs of fruiting.

Winter irrigation of deciduous orchards, A. J. McClatchie (*Arizona Sta. Bul. 37, pp. 207–240, figs. 9*).—The greater value for orchards in southern Arizona of winter over summer irrigation has been pointed out by the station in earlier reports (E. S. R., 12, p. 1042). Some data have also been given showing the effect of winter irrigation on crop and orchard production, and on the moisture content of the soil throughout the season, to a depth of 34 ft. The work here reported includes the earlier work and some additional data. Some meteorological records are incorporated and a discussion given of the principles involved in winter and summer irrigation. In 1899–1900 irrigation of a portion of a peach and apricot orchard was begun December 16 and continued at intervals until March 5, when 3 ft. of water had been applied. No further water was given for the next 8 months, and only $2\frac{1}{2}$ in. of rainfall, divided among 5 showers, fell during this period. The orchard was plowed each way about 1 ft. deep as soon as it was dry enough in the spring and harrowed thoroughly. After each rainfall it was again harrowed to break up the crust that formed. As in the previous year the orchard thus treated showed no signs of drought and made a vigorous growth throughout the season. Both apricots and peaches matured a heavy crop of fruit of good quality. The season, especially May and June, was the hottest and driest ever known in the vicinity of the station. At the end of it the experimental orchard had a thrifty, vigorous appearance, while many other orchards in the vicinity of the station had died.

The great advantages of winter irrigation for orchards are stated by the author as follows: "During the winter the lower temperatures and the higher relative humidity cause evaporation to be much slower than during the remainder of the year. In applying water, therefore, comparatively little escapes into the atmosphere. The supply of water being greatest at that time of the year makes it possible to apply large amounts at short intervals, thus avoiding the loss that occurs if small amounts are applied at greater intervals. Then, too, the trees are dormant and the roots need little air; hence, no injury is done them by keeping the soil supermoistened, or by letting the surface bake to some extent. Consequently, cultivation after each irrigation is not necessary, much time thus being saved."

In these experiments it was found that root growth took place at depths of 10 to 16 ft. as early as February 20, when above ground there was no indication of growth whatever. Some data were also secured on the evaporation of soil moisture by weeds. A portion of the orchard which had been left uncultivated was overgrown with weeds. An examination showed that the upper 5 ft. of soil in the cultivated portion of the orchard contained about twice as much available moisture as the upper 5 ft. of the soil in which the weeds were growing.

In the irrigation experiments here reported the water content of each foot of soil from the surface down to ground water (34 ft.) was determined in different months from April to October. These data are tabulated and commented upon. The greatest amount of water was used by the trees during spring and early summer. This is the time when water for irrigation is least abundant, and "emphasizes very strongly the importance of filling the subsoil with water during the winter, when the supply is comparatively abundant." The total loss of water during the whole season was about 20 in., of which about 80 per cent was lost during the first 3 months, 16 per cent the next 3, and 4 per cent the last 3 months. The indications seem to be that deciduous orchard fruit trees in Arizona begin using water early in February.

"From this date until about the end of June the amount used evidently gradually increases, and after the latter date evidently gradually diminishes. These facts indicate plainly that much of the water should be applied as soon after the first of January as possible.

"The amount of water needed by a deciduous orchard to keep it in good condition in southern Arizona from March to November is about 21 in., which can be stored in the soil by the application of about 3 ft. during winter."

A crop of clover (*Melilotus indica*) grown in the orchard for green manuring, from December 16 to March 5, withdrew from the soil about 20 in. of water. It is calculated that in order to supply an orchard with sufficient moisture to grow a crop of green manure and to mature a fruit crop about 4 ft. of water will be required in the warm valleys of southern Arizona.

Relative to summer irrigation of orchards the author states as follows: "If about the middle of the summer water is available in abundance, it would probably be wise to give the orchard a thorough irrigation in as short a time as possible, and then follow the irrigation with a thorough plowing, as in the spring after the winter irrigation ceases. But frequent summer irrigations are decidedly not advisable under our conditions, where the soil is fairly deep and retentive of moisture."

Report on horticulture, S. M. EMERY (*Montana Sta. Bul. 28, pp. 6–10*).—Lists are given of the hardy, semihardy, and poor or useless ornamental shrubs, apples (including crabs), pears, cherries, and plums grown at the station. In a study of the relation between the maturity of the terminal buds at the beginning of winter and the hardiness of the variety, there was found to be little or no correspondence between bud maturity and the bark bursting of the stems and twigs. In a test of the Stringfellow system of root pruning, 89 trees of the Wealthy and Alexander apples were pruned back close to the tap root and the stem cut to about 12 in. These stubs were planted in clean, mellow soil with a crowbar, and irrigated twice before July 1. "At that date about 18 per cent of the trees were dead, 56 per cent were in good condition, and the rest weak. The fact that 75 per cent of the dead trees are the Alexander would indicate a marked difference in the ability of the different varieties to withstand this treatment."

Manuring of fruit trees, A. PETTS (*Jour. Hort., 53 (1901), No. 2745, pp. 388, 389*).—The best methods of using potash and liquid manures on fruit trees are noted.

Cold storage for fruit and other productions, F. R. LATCHFORD (*Ontario Fruit Growers' Assoc. Rpt. 1900, pp. 81–89*).—A popular discussion of the subject, in which the value of the Hanrahan system of cold storage is pointed out.

Storage of apples, H. H. LAMSON (*New Hampshire Sta. Bul. 79, pp. 25–29*).—The decay of the Baldwin apple was found to be due chiefly to brown rot and the common mold fungus (*Penicillium glaucum*). While these fungi are widely distributed, it is believed that apples barreled in the orchard will be less likely to be infected than if they are previously stored uncovered in dusty barns or moldy cellars. Heat and moisture are especially favorable to the growth of rot-producing fungi. Hence the value of storing apples in a dry, cool place.

In order to test the value of cold storage for apples, 12 bushel boxes of No. 1 Baldwins were put in cold storage, in Boston, where the temperature averaged about 34° F., and a check kept in the station cellar. The station cellar averaged about 40° until April, then ran up to 45° during the first half of the month and to nearly 50° during the latter half. Part of the stored fruit was wrapped with manila tissue paper in each case. One box was withdrawn from cold storage each month until June, after which date 2 were withdrawn each month until the 12 had been exhausted. The amount of sound and rotten fruit in the boxes for each of the months December 18 to August 4 is shown in tabular form. While in general there was an increase in the number of rotten apples as the season advanced, this increase was not at all uniform, and no explanation of this phenomenon is offered. In all but two instances the wrapped apples kept better than the unwrapped.

Apples in Iowa (*Rpt. Iowa Hort. Soc., 35 (1900), pp. 55–72, maps 12*).—From 150 answers to a circular letter of inquiry the secretary of the society has compiled a list of apples that may be grown with assurance all over the State of Iowa. These are Oldenburg, Yellow Transparent, Longfield, Tetofsky, Red Astrachan, Plumb Cider, Walbridge, Wealthy, Wolf River, and one crab—Whitney No. 20. Of these varieties 6 are summer apples, 3 fall apples, and only 1—the Walbridge—a long keeping winter apple. The areas where these and some other varieties thrive best are mapped out for the State.

Apple districts of West Virginia, L. C. CORBETT (*West Virginia Sta. Bul. 75, pp. 83–178, figs. 13, map 1*).—Preliminary notes are given on the apple orchards and apple crops of West Virginia and on top-grafting old trees. Following the severe freeze of March 29, 1898, an inquiry was made of special correspondents in each county of the State as to the condition of orchards, the purpose being to learn in what districts commercial fruit growing can be engaged in with a fair assurance that the crop will not be injured by any ordinary late spring frost. A map based on these replies is given which shows graphically the various localities where full and where only partial crops were reported. Another map shows graphically the areas in West Virginia reported as suited to apple culture, areas suggested as valuable for this purpose, and the areas where commercial orchards are now growing.

The relative values of 114 varieties of apples and 5 varieties of crab apples, as shown by nearly 2,000 answers to a circular letter of inquiry, for each county of the State, are brought together in a comparative table. Further separate tables are also given for each county of the State showing the varieties of table apples held in highest esteem in the county; the market varieties having the best form, color, and keeping qualities; varieties which keep in pits or cellars in fit condition for the April market; varieties which bear most regularly; varieties most exempt from or most affected by scab, etc. Under each county some notes are also appended on the adaptability of the county for fruit growing.

Apple culture and district lists of apples suitable for Ontario and Quebec, with descriptions of varieties, W. T. Macoun (*Canada Cent. Expt. Farm Bul. 37, pp. 74, figs. 12, map 1*).—A popular exposition of apple culture and orchard management in Canada, based largely on experimental work which has been carried on since 1887 at the Central Experimental Farm. The provinces of Ontario and Quebec are divided into 13 districts, according to climatic and orchard conditions, and lists given of varieties of apples best suited to each of these districts. The whole problem of apple growing in Canada is discussed, thoroughly reviewed, and descriptions given of all the varieties best suited to the different localities. A fruit map showing the approximate boundaries of the different apple districts accompanies the bulletin.

Experiments in fruit growing at the Central Experimental Farm, W. T. Macoun (*Ontario Fruit Growers' Assoc. Rpt. 1900, pp. 15–22*).—An outline of the work being done at the station, with brief notes on some of the results obtained with varieties. Fall planting has not given satisfactory results in Ottawa with apples and should not be practiced. Where trees are planted in the fall they seem to dry out and are easily injured by frost. They are also liable to be heaved. The varieties of apples best suited for growing in such districts as Ottawa are, for summer, Yellow Transparent and Duchess; for autumn, Wealthy; very early winter, McIntosh Red and Fameuse, where it can be grown with natural protection. For late winter Scott Winter, Geno, Pewaukee, and Salome are recommended. Other varieties that are perfectly hardy are Lawver, Golden Russet, and Ben Davis.

Report of the fruit experiment stations in Ontario, L. Woolverton et al. (*Ontario Fruit Expt. Stas. Rpt. 1900, pp. 79, figs. 49*).—This report is similar in character to those of previous years (E. S. R., 12, p. 1044). Additional illustrations and descriptions for the purpose of identification are given of 4 varieties of apples, 19 currants, and 1 each of peaches, blackberries, and grapes grown in Ontario. A catalogue showing the characteristics of varieties of orchard and small fruits is included for the use of planters.

Notes from the plum orchard, E. A. Popenoe and A. Dickens (*Kansas Sta. Bul. 101, pp. 117–143, pls. 26, figs. 2, charts 2*).—These are largely notes on the different varieties of European, Japanese, and native plums grown at the station, with illustrations of the more prominent varieties, nursery notes on the growth of certain varieties, and a chart showing the period of blooming and ripening of 34 varieties of plums. The experience and observations of the station warrant the recommendation of clean culture for plums and of keeping the ground shallow-cultivated or disked. Where the orchards are so located as to be exposed to winds or danger from washing they should be seeded to rye or oats, preferably oats, in August. It is claimed that the proper and persistent use of Bordeaux mixture will practically control the fungus diseases of the plum.

Figs in pots, J. Hudson (*Jour. Roy. Hort. Soc.* [*London*], *25* (*1901*), *No. 3, pp. 231–234*).—This is a popular discussion of the early and late forcing and potting of figs, specific directions being given for the care of the trees, top-dressing, watering, etc. The varieties recommended for pot culture are as follows: For early forcing, St. John or Pingo-de-Mel, followed by Brown Turkey and White Marseilles; for the main crop the last two may be grown, and also Bourjassotte, Grise, and Violette Sepor; for late forcing Negro Largo is considered one of the very best, and can be relied upon until the end of October. Following this is Nebian or Grosse Verte, which is best during September and October. The latest fig of all is D'Agen, which will last up to Christmas day. Other good varieties are White Ischia, desirable as an autumn fig, Angelique, and Black Douro.

Report on the export of tender fruits, L. Woolverton (*Ontario Fruit Growers' Assoc. Rpt. 1900, pp. 43–52*).—This is a detailed financial and critical report on the results of a number of experimental shipments of fresh fruits to England. The experience of the season indicates that with proper methods of cold storage on shipboard pears, summer apples, and even peaches may be shipped to England in perfect condition. The market for grapes will, in a large measure, need to be created, since at present there seems to be no marked demand for these fruits.

Coffee culture in Queensland, H. Newport (*Queensland Agr. Jour., 8 (1901), No. 6, pp. 437-440, pl. 1*).—This article, the ninth of a series of articles on this subject, discusses the treatment of young plants in the field.

Cacao shade (*Trinidad Bot. Dept. Bul. Misc. Inform., 1901, No. 27, pp. 330-333*).—An analysis of the flowers of the leguminous coffee shade tree known as Bois Immortel (*Erythrina umbrosa*) showed the high nitrogen content of 6 per cent, and therefore considerable manurial value. Some data are given which go to show that 250 cacao trees give a yield of about 500 lbs. of cured cacao per acre, containing 2½ per cent of nitrogen, and will therefore remove 12½ lbs. of nitrogen from the soil annually. Fifty Immortel trees, on the other hand, furnish 500 lbs. of dry flowers, which, at the low estimate of a nitrogen content of 4 per cent, return to the soil 20 lbs. of nitrogen per acre, or 7½ lbs. more than the crop of cacao removed. The flowers, however, lose their nitrogen rapidly. The analysis showed that while fresh flowers contain 6.32 per cent of nitrogen, those 2 days old contain but 5.16 per cent and those 5 days old but 4.14 per cent. The flowers bloom only in the dry season, and therefore, unless showers come opportunely to wash the nitrogen into the ground, much will be lost. The Immortel is a West India tree, reaching sometimes 60 ft. in height.

Oswego strawberries. An account of experiment with fertilizers, and records of strawberry growing, in the Oswego district, L. H. Bailey (*New York Cornell Sta. Bul. 189, pp. 119-140, figs. 4*).—Fertilizer experiments have been carried on in Oswego for a period of 3 years in cooperation with the strawberry growers, and the results obtained are here reported and commented upon. The methods of strawberry culture followed by Oswego growers are briefly outlined and a short history given of the development of the industry in Oswego, together with some statistics of shipments to the larger markets in different years.

The fertilizers used have been the sulphate and muriate of potash, dissolved rock, ashes, and nitrate of soda. These have been used singly and combined, and in smaller and larger amounts. "The fertilizers were applied to young plantations in spring after the first tillage and before the plants bloomed, a year in advance of the recorded crop. The materials were scattered alongside the row, within a few inches of the plants, and were cultivated in." The soils upon which the tests were conducted have varied from gravelly loam through meadow land to black muck.

Some contradictory data were secured on the different farms and plats, but on the whole there was considerable uniformity of results. The fertilized plats yielded on an average 5,197 qts. per acre, or about 2,000 qts. above the average. The potash and phosphatic fertilizers were much more effective than nitrogenous fertilizers, especially on lands well supplied with humus, like muck soils. The fruits grown with these fertilizers were better colored, better flavored, and firmer. The nitrogenous fertilizers, including heavy applications of barnyard manure, gave too much growth of vine, and the fruit was softer and of inferior quality. It is suggested that in these experiments the good tillage given probably supplied sufficient nitrogen in most instances.

"As to methods of planting, it may be said that the old method has been discarded—planting in rows 3 to 3½ ft. apart and the plants from 12 to 15 in. apart in rows, keeping off the runners until late in July and then allowing the runners to grow and root at will, making a matted row. In this old system many plants are almost on top of others, the roots barely in the ground, and they suffer in a season of drought. The rows are so wide that to pick fruit in the center it is almost necessary to crush fruits on the outside of the row. This system gives few large first-class fruits. The up-to-date grower starts with the assumption that the largest and highest colored fruits are found on plants along the outside of the rows, and therefore he plans to have as many outside rows as possible. This he accomplishes by having his rows closer together and much narrower. The rows are made from 30 to 36 in. apart and the plants from 18 to 24 or even 30 in. apart in the rows, much depending on the capability of the variety as a plant maker. If the plants used for a new bed are strong and start into growth vigorously the first runners are used, as it has been found that under most conditions the plants about 12 months old yield the greatest number of fine fruits. These first runners are usually 'bedded in,' i. e., planted by hand, training them along the wide way of the rows, using from 4 to 8 of the first runners and cutting off those growing later. This method of planting allows cultivation both ways until the runners start, retaining moisture and saving labor in hoeing."

The cost of growing strawberries in Oswego is estimated at $77 per acre. The bulk of the crop is shipped to New York, Boston, and Philadelphia. In 1898 about 52,263 crates were shipped and in 1900 40,284 crates. The total crop in the Oswego district in 1900 was nearly 2,000,000 qts.

Practical guide to viticulture, J. PECH (*Guide pratique du viticulteur. Montpellier: Coulet & Sons, 1901*).—This is a viticultural calendar dealing with the different kinds of work which occur each month of the year in the vineyard and cellar. It is essentially a practical manual for this work.

Grapes, C. W. MATHEWS (*Kentucky Sta. Bul. 92, pp. 71–97, figs. 7*).—Detailed popular directions for the planting, pruning, training, cultivation, and fertilizing of grapes, with notes on the insects and diseases affecting them. Eighty-seven varieties of grapes are being grown in the station vineyard. These are briefly described and their suitableness for Kentucky planting is pointed out. Of the black varieties, Moore Early, Worden, and Concord are considered best; of red varieties, Delaware, Wyoming, Brighton, and Catawba; and of white varieties, Martha and Niagara. A supplementary list of very promising recent introductions is as follows: *Black*—Aminia, Herbert, Campbell, Carman, Standard, Ozark; *Red*—Alice, Brilliant, Jefferson, Lindley, Mrs. Munson; *White*—Gold Coin, Eclipse, Geneva, Colerain, Duchess, Noah.

On the influence of early and late pruning on the productiveness of vineyards, C. MAYER (*Agr. Jour. Cape Good Hope, 18 (1901), No. 6, pp. 367, 368*).—The brief data here given show that vines pruned in the spring were somewhat more productive than when fall pruned, while the leaves were still on.

The economical manuring of vines, H. LAGATU (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), Nos. 1, pp. 10–16; 2, pp. 41–47; 3, pp. 72–78; 4, pp. 115–118; 5, pp. 134–138; 6, pp. 170–175; 7, pp. 206–212; 9, pp. 265–269; 10, pp. 298–304; 11, pp. 328–335; 13, pp. 388–395; 14, pp. 435–441; 15, pp. 472–477; 17, pp. 525–530; 18, pp. 546–550; 19, pp. 573–579*).—A comprehensive article on the nature of all the more usual fertilizers, and the manner of compounding and using them in vineyards on different soils, especially those of different lime content, and in years of different rainfall.

Grafting walnuts and hickories (*Amer. Gard., 22 (1901), No. 331, pp. 307, 308, fig. 1*).—The work of the U. S. Department of Agriculture in grafting walnuts and hickories is briefly described. The success in grafting these nuts has been greatly insured by the use of an incubator box. The scions are securely tied to the stocks with a waxed cord, and are either wrapped in bundles with moss around them or packed in layers in a box with clean sphagnum and kept at a temperature ranging from 75 to 80° F. At the end of about three weeks callusing has progressed sufficiently so that the grafts may be removed. After their removal the stocks with shortened tap roots are potted, where possible, in 6-in. pots to encourage the production of roots. When a few leaves have been formed, the potted plants are gradually hardened off and eventually put in a frame, where they pass their first year. Thus far about 75 per cent of the scions have united with the stocks.

Notes on perfumery plants and on the development of this industry in New Caledonia, E. Heckel (*Rev. Cult. Coloniales, 8 (1901), No. 76, pp. 257–265*).—The adaptability of New Caledonia to the perfumery industry is pointed out and a list given of the perfumery plants grown in New Caledonia.

Plants for perfumery and essence, J. Chapelle (*Rev. Gén. Agron. [Louvain], 10 (1901), Nos. 3, pp. 107–118; 4, pp. 163–168*).—A discussion is given of the perfumery and essence industry of Southern France. The culture of the various plants used in the industry are noted and statistics given on the importance of the industry. The regions about Nice, Grosse, and Cannes constitute the center of the industry. There is grown and treated annually about 2,500,000 kg. of orange blossoms, 3,000,000 kg. of roses, 200,000 kg. of jasmine, 150,000 kg. each of violets, acacia (*Acacia farnesiana*), and tuberoses; besides several thousand kilograms of geranium, mint, balm-mint, jonquils, mignonette, verbena, lavender, thyme, rosemary, etc.

The propagation, culture, and use of poinsettia (Euphorbia pulcherrima), N. Schneider (*Rev. Hort., 73 (1901), No. 9, pp. 221–223*).—Details are given for the outdoor and greenhouse culture of this ornamental shrub, with directions for its floral arrangement.

The groups of dahlias (*Amer. Gard., 22 (1901), No. 329, p. 270*).—Herein are considered a number of cactus varieties, decorative cactus varieties, pompon varieties, single varieties, show varieties, and fancy varieties, all briefly described as regards coloring.

Report on cactus dahlias, 1900 (*Jour. Roy. Hort. Soc. [London], 25 (1901), No. 3, pp. 390–401, fig. 1*).—An account is here given of the growth and care of 146 stocks of cactus and decorative cactus dahlias.

Lilies of Japan (*Yokohama: Yokohama Nursery Co., 1899, pp. 39, pls. 38*).—Large colored plates are given showing the flowers, stalks, and leaves of 38 Japanese lilies.

Narcissi in New Zealand, J. G. W. Ellis (*Jour. Roy. Hort. Soc. [London], 25 (1901), No. 3, pp. 337–340*).—New Zealand seems especially well adapted to the culture of Narcissi. Some notes on the methods of cultivation are given, together with lists of some of the more important varieties grown there.

Own root roses, A. Herrington (*Garden, 59 (1901), No. 1534, pp. 253, 254*).—The author has secured good results with tea roses on their own roots in New Jersey, where roses on brier roots were stunted in growth by the heat of summer and practically failed of autumnal bloom. These roses on their own roots flowered freely from June to November on a light hot soil that was paralyzing to the same roses on brier roots. A protection of oak leaves suffices for the plants in winter, and when cut back to within 2 in. of the ground each spring, they make a strong, vigorous growth and give a continuous bloom.

Violets, J. Bradley (*Florists' Exchange, 13 (1901), No. 14, pp. 388, 389*).—Cultural notes for outdoors and in frames with suggestions regarding the control of insects and diseases affecting violets.

The Aspleniums (spleenworts), C. T. Druery (*Garden, 59 (1901), No. 1537, pp. 318, 319*).—Cultural notes are given and descriptions of the maiden-hair (*Asplenium trichomanes*), black maiden-hair (*A. adinatum nigrum*), sea (*A. marinum*), and scaly (*A. ceterach*) spleenworts. The habitat of the varieties, finder and raiser of the same, etc., are also noted.

The heating and ventilating of hothouses, A. D. Mackenzie (*Jour. Roy. Hort. Soc. [London], 25 (1901), No. 3, pp. 323–327, figs. 4*).—Some of the more elementary principles in the hot-water heating of forcing houses are discussed.

Horticultural progress during the nineteenth century, J. Clayton (*Jour. Roy. Hort. Soc. [London], 25 (1901), No. 3, pp. 328–336*).—The author popularly summa rizes the century's advance in the improvement of garden vegetables, fruit, flowers, and glass houses. The increase in gardening literature and societies is also noted.

The century book of gardening; a comprehensive work for every lover of the garden, E. T. Cook (*New York: Charles Scribner's Sons, 1900, pp. XIII+610*).

SEEDS—WEEDS.

Influence of chemical solutions upon the germination of seeds, G. E. Stone and R. E. Smith (*Massachusetts Sta. Rpt. 1900, pp. 74–83*).—The authors have been studying for some time the effect of various chemical and physical agencies upon the germination of seed, the object being to determine to what degree seeds could be accelerated in their germination, and also to what extent their germinating capacity could be increased. In the present report the effect of treating seeds with solutions which are known to exist in many seeds, such as diastase, pepsin, trypsin, asparagin, and leucin, was tested. Strengths of these different ferments or enzyms, varying from 0.1 to 2 per cent, were tested upon a number of seeds. The seeds were first soaked for about 12 hours in the solutions, after which they were rinsed and placed in germinating chambers. With the seeds treated with asparagin solutions, the average increased germinations were obtained as follows: Alfalfa, 10.6 per cent; rape, 20.8 per cent; Canada field peas showed no improvement, both normal and treated seed germinating 100 per cent; buckwheat, 10.6 per cent gain; serradella, 19.8 per cent gain. In the experiments with leucin solutions the following average gains were noted: For treated buckwheat seed, 9.2 per cent; alfalfa, 7 per cent. Experiments with pepsin solutions gave 13.3 per cent increase for treated crimson clover seed, and 15.6 per cent for cucumber seed. In the experiments made with diastase solutions, black barley seed treated gave an increased germination of 7 per cent, and upland rice 11.5 per cent. In a number of the experiments the authors experienced considerable trouble from the presence of various molds. This was particularly true in experiments in which the seeds were treated with diastase solutions. The results obtained are briefly commented upon, and the conclusion reached that the study of the effects of amids and ferments and other accelerating factors upon seeds offers a promising field for further investigation.

The effect of age and length of sprouts upon the vitality of seeds, J. H. Shepperd and E. G. Schollander (*North Dakota Sta. Rpt. 1900, pp. 101–113*).—Tabulated results of these experiments here presented show that of 1-year-old wheat the vitality varied from 73 to 100 per cent, being in the majority of cases over 90 per cent. Of a sample of 2-year-old goose wheat 97 per cent germinated. Two samples of wheat taken from sheaves saved from the crop of 1895 gave 98 and 100 per cent of sprouted kernels. Of a sample of 8-year-old wheat only 3 per cent germinated. Buckwheat 7 years old showed a germination of 84 per cent. Tests were made with sprouted wheat from the crop of 1900 and in every case the sprouted seed was weakened, but the authors conclude from the results that seeding 5 per cent heavier with the wheat tested would have given a normal stand. An experiment to determine what length of sprouts wheat may have and regerminate was made with sprouted kernels of Minnesota No. 163 wheat. The grains were sprouted and allowed to grow for different lengths of time, making the first sprouts 7 days older than the last. After sprouting the kernels were taken from the germinator and thoroughly dried. The radicles and plumule were measured and the grains again placed in the germinator. The results indicate that sprouted wheat will regerminate and form healthy sprouts until the stem or plumule is $\frac{3}{4}$ in. long and that an average of 80 per cent will regerminate if the length of the stem or plumule does not exceed $\frac{1}{2}$ in. Stock and bin-burned wheat gave an average germination of 62.4 per cent, or too low for seeding purposes. Corn 6 years old which had remained upon the cob until tested required

7 days to complete its germination, when 77 per cent had sprouted. From results with oats it is concluded that old oats carried over one season in good condition are comparatively safe for seed. Eight-year-old oats taken from the sheaf at the time of testing gave a germination of 87 per cent. Other germination tests with 1-year-old barley, spelt, and flax are reported.

Studies upon weeds in 1900, H. L. Bolley (*North Dakota Sta. Rpt. 1900, pp. 48–56*).—In 1899 favorable results were reported (E. S. R., 12, p. 248) on the use of commercial copper sulphate at the rate of 1 lb. to 4 gal. of water, when sprayed upon weeds. The season when this investigation was conducted was one in which the plants were making rapid growth, and mustard, tall ragweed, and others were quickly destroyed. In 1900 an effort was made to repeat on an extensive scale the investigations of the previous year. In general the results obtained were discouraging, although it was shown that further investigation would be needed before definite statements could be made regarding the destruction of weeds by herbicides. During the dry windy weather all the plants became very resistant, and only when thoroughly wet while quite young did the treatment prove beneficial in destroying the weeds. The recommendations of the author are that if both grain and weeds are rapidly growing they can be successfully destroyed by the use of sodium arsenite or copper sulphate, the latter being most reliable. In selecting nozzles for this use, those should be employed which throw fine drops of the herbicide rather than misty sprays. The author recommends spraying just after a rain, and unless the plants are in a succulent rapidly-growing condition no treatment is advised.

Further observations are reported on the life of weed seeds in the soils of the vicinity of the station, the investigation being continued from the report of the previous year (E. S. R., 12, p. 248). The experiments on the depth of planting show that shepherd's purse does not send up plants from a depth of more than 1 in., French weed from more than 2 in.; mustard and pigeon grass send up most of their plants where the seed has been covered to a depth of 1 in., and tall ragweed did best from a depth of 2 in., although some late plants appeared when the seed was covered 4 in. deep. When covered to a depth of 4 in. all the weed seeds experimented with, except wild oats and tall ragweed, were killed.

Work is being continued on the extension of the herbarium, and a preliminary list of the seed plants of the State has been issued as Bulletin 46 (E. S. R., 13, p. 21). Observations upon the growth of red clover seed are briefly reported, from which the author believes that the presence of bumblebees or other large insects to carry the pollen is not essential, but that the plant is practically fertilized by pollen carried by the wind.

Weed notes, W. Lochhead (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 17, 18, fig. 1*).—Brief descriptions are given of a tumbleweed (*Amarantus albus*) and pigeon weed (*Lithospermum arvense*), and suggestions given for the possible eradication of these pests.

Romulea rosea, R. Helms (*Agr. Gaz. New South Wales, 12 (1901), No. 2, pp. 232–236, pl. 1*).—A description is given of this liliaceous plant, which threatens to become an exceedingly troublesome weed in New South Wales and other parts of Australia. The plant is a very aggressive one, spreading rapidly by the multiplication of its bulbs as well as the abundant development of seed. It soon forms solid masses, crowding out other species. It appears to be entirely shunned by domestic animals, whether from toughness of foliage or unpalatability is not stated. Various means of suppression are suggested, which contemplate the cutting of the plants to prevent seed formation, rooting them up and burning, or cultivation of hoed crops.

Russian thistle in Massachusetts, G. E. Stone and R. E. Smith (*Massachusetts Sta. Rpt. 1900, p. 73*).—The authors briefly report the occurrence of the Russian thistle in the State. This weed was first reported August 22, 1897, since which time the plants have shown a slight tendency to spread.

The weedy plants of Iowa, L. H. Pammel (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 173–177*).—Notes are given on the geographic distribution of a number of weeds throughout the State, and attention called to the very slow distribution of some species as compared with the rapid spread of others.

The use of chemical substances for the destruction of weeds among growing cereals, C. Dusserre (*Chron. Agr. Canton Vaud, 14 (1901), No. 9, pp. 253–256, fig. 1*).—The author comments upon the use of solutions of copper sulphate, iron sulphate, and sodium nitrate for the destruction of wild mustard, charlock, and wild radishes, and claims that experiments show that the quantity of liquid employed should be greater than that generally recommended. Where 2 to 5 per cent solutions of copper sulphate, or 10 to 20 per cent sodium nitrate, are employed, the amount of liquid, the author claims, should be from 800 to 1,000 liters per hectare, a quantity more than double that usually recommended. For the application of the herbicide the author recommends power sprayers, and one which has proved very efficient is figured and described.

A new method of cleaning roads and walks (*Gard. Chron., 3. ser., 29 (1901), No. 753, p. 358*).—A brief note is given on a machine for the destruction of weeds in drives and walks in which the direct heat of burning fuel is brought to bear on the surface of the walk, charring and killing all weeds, grasses, and fallen seeds. The machine consists mainly of an inclosed fire box for holding coke in a state of combustion and a drum containing a fan for creating a draft. The machine may be drawn about the grounds, allowing it to stand still for a few seconds. It is said to be very efficient, and to do away with the expensive work of hoeing drives, paths, etc., or the use of arsenical poisons, hot water, salt, etc.

DISEASES OF PLANTS.

Twenty years' progress in plant pathology, B. T. Galloway (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 96–102*).—While the subject of plant pathology has had its students for a century, the real development of the subject has taken place in the last 20 years. The author reviews the work of some of the pioneers on the subject, and devotes special attention to the organization and development of the study of plant pathology in this country. The progress is said to have been made in two distinct epochs; the first was concerned with the development of fungicides and means for their application for the prevention of diseases, while the second is represented by more careful research work into the life histories of the fungi and study of the normal and pathological conditions of the plants.

Flax wilt, H. L. Bolley (*North Dakota Sta. Rpt. 1900, pp. 45–48*).—A preliminary report is given of observations made upon a disease of flax, which for want of a better name the author has designated as "flax wilt." Little attention seems to have been paid to this disease in this country, although it appears to have been observed in Europe. It has been repeatedly observed that after flax has grown for a number of years upon the same land, the crop becomes very much lessened in yield. This has been attributed to impoverishment of land, but soil analyses show that this can not be the fact. The investigations of the author indicate that the disease is due to a parasitic fungus which lives in the soil and in the old decaying flax stubble. It may be transmitted to a new field by the transfer of dirt from an infected one, or by infusions made from diseased plants. Investigations made in a number of fields seem to indicate that the disease may be communicated through seed flax. The fungus appears to attack the roots of the plants most strongly at a depth of soil corresponding to the bottom of the furrow. An examination shows that the parasite fills the vessels and tissues of the roots with its filaments, cutting off the water supply and bringing about a typical wilt. A number of experiments have been inaugurated, and investigations are still in progress, the results of which are promised in a future bulletin.

Experiments on the bacterial diseases of potatoes, H. JENSEN (*Centbl. Bakt. u. Par., 2. Abt., 6 (1900), No. 20, pp. 641–648*).—Preliminary notes are given by the author upon investigations of potato diseases which have been considered as of probable bacterial origin. The first disease described is that sometimes known as brown spot. In the tubers reddish brown spots are noticed. They are of different sizes, irregularly distributed, and are bounded by cells of cork tissue. The protoplasm of the cells is massed together, and the intercellular spaces filled with a brownish substance. Thus far examinations have failed to show any connection between the spots and external conditions, and neither bacteria nor fungi have been recognized as the cause of the disease. All inoculation experiments have proved failures.

The second disease described is the bacteriosis of the potato stem. In investigating the so-called "black shank" of potato plants, the author found the diseased portions filled with various organisms, but his preliminary investigations seemed to indicate that a micrococcus was the primary cause of the trouble. Inoculation experiments showed that the disease could be readily produced and was easily transmitted. The organism was found to secrete ammonia, and through the presence of this substance it gains entrance to the host; otherwise the micrococcus appears to be a saprophyte.

Notes are given on the predisposition of potatoes to the disease, in which the varying susceptibility of different varieties is shown.

The author has investigated the statement of Wehmer (E. S. R., 10, p. 972) that bacteria are of secondary importance in the wet rot of potatoes, with the result that he differs from that author and affirms that bacteria are able to produce the disease.

Experiments with fungicides upon potatoes in 1900, C. D. WOODS (*Maine Sta. Bul. 73, pp. 49–57*).—The author reports a series of experiments to demonstrate the value of Bordeaux mixture when applied on a large scale, and also as a comparison between freshly prepared Bordeaux mixture and some of the ready-prepared fungicides on the market. The plats were given 4 sprayings with a freshly prepared Bordeaux mixture, consisting of 5 lbs. copper sulphate, 5 lbs. fresh lime, and 50 gal. of water, and comparisons made with Boxal, Adler's Bordeaux, and Blanchard's Lion brand Bordeaux mixture. In comparing the efficiency of the different mixtures, Adler's ready-made Bordeaux was found to be as efficient as that freshly prepared, while the other two kinds were slightly less so. Where small quantities of the fungicides are to be used the author believes that the ready-made or stock solutions are to be preferred to those which are made by the user.

The applications of the fungicides were made at a cost of about \$2.50 per acre for the 4 sprayings. When the potatoes were dug the crop was estimated, at the current market rate, to be worth \$106.40 per acre for the sprayed plats, as compared with \$62.60 for the unsprayed plats, giving a net return of about \$40 per acre.

How to fight potato enemies, C. D. WOODS (*Maine Sta. Bul. 73, pp. 58–64*).—The author popularly describes the principal fungus diseases and insect enemies to which the potato crop is subject, and gives suggestions for the prevention of their injuries. Formulas and directions for preparation are given for the more important fungicides and insecticides, and the different forms of apparatus recommended are described.

Experiments with potato scab, H. GARMAN (*Kentucky Sta. Bul. 91, pp. 56–59*).—The author gives a record of experiments made in the season of 1900 for the prevention of potato scab, comparisons being made between seed potatoes treated with corrosive sublimate and those soaked in various strengths of solution of formaldehyde. The seed tubers used were badly scabbed, and while the disease did not do as much harm as was expected from the condition of the seed potatoes a noticeable difference in the prevalence and extent of disease was observed in favor of the potatoes from treated seed. The lots from seed treated with formaldehyde averaged about as free from scab as those treated with corrosive sublimate.

Notes on the sugar-cane disease of the West Indies, W. T. THISELTON-DYER (*Ann. Bot., 14 (1900), No. 56, pp. 609-616*).—The author reviews the different phases of the life history of the fungus causing the more destructive cane diseases in the West Indies. Two forms are recognized as especially destructive, the rind disease and root rot. The first affects the canes, and its presence is indicated by dark red or brown marks toward the middle or base of the cane. These red splotches spread rapidly, and later black specks make their appearance on the cane between the joints, and finally the cane shrivels and dries up. The fungus bursts through the epidermis in the form of black filaments, an inch an a half or less in length. The fungus causing this disease has been given various names, *Trichosphæria sacchari* being the name adopted by the author. This fungus has been described as having several distinct phases. The root disease is characterized by the dwarfed appearance of the canes. The plant puts out fresh basal shoots, but ultimately the growth is arrested and no cane formed. If the plants be dug up the roots are nearly all dead, and those still living are marked with small red spots. Investigations are reported which show that the root disease and rind disease are really due to the same cause, and the fungus described under the name of *Colletotrichum falcatum* is really a phase of the polymorphic fungus causing the two diseases. A healthy seedling sugar cane was inoculated with spores taken from diseased roots, and at the end of 20 days developed the rind disease phase of the fungus. From this fact it is urged that great precaution should be taken to avoid planting tops which are possibly affected by the rind disease.

Concerning the mosaic disease of tobacco, IWANOSKI (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), No. 4, p. 148*).—A preliminary note is given on investigations by the author which led him to believe that the mosaic disease of tobacco is of bacterial origin. He claims to have isolated a small short bacillus which occurs in great numbers in the palisade parenchyma, which he believes is the specific cause of the disease. His complete investigations are to be published later.

Investigations on the stinking smut of wheat, H. L. BOLLEY (*North Dakota Sta. Rpt. 1900, pp. 32-38*).—In continuation of investigations previously reported (E. S. R., 12, p. 255), the author studied the influence of various factors on the stinking smut (*Tilletia fœtens*) of wheat. The question of the wintering of smut in the ground was studied by means of plats on which a large crop of smutty grain was raised in 1899. Part of the grain was removed in the usual manner, and on the other half of the plats the grain was allowed to fall to the ground without being harvested. Prior to seeding, the ground was plowed or disked and seed treated in various ways were sown. From the results of his experiments it seems apparent that little difference in the amount of smut was observed in the portions of the plats where the grain had been removed or where it had been plowed under, and there was a small amount of smut developed on all the plats. Investigations showed that there was an abundance of spores in the soil where the grain had been allowed to stand, and it was demonstrated that the smut spores retained their vitality for at least 2 years in wheat stored in the ordinary manner.

The influence of smut upon the doughing of flour and bread making was investigated, known amounts of smut being added to the flour before making the bread. The results show that flour containing smut spores did not act differently from that containing no smut. The smut spores retained their normal color, and there was no evidence of its being disseminated to the starch or bread. The only effect of smut spores in flour and bread is due to the color which they impart in mass.

The effects of soil and weather conditions were also investigated, the season being one of almost complete drought. As previously reported (E. S. R., 11, p. 361), it was again demonstrated that the greatest amount of smut was produced when the soil conditions were best for the growth of wheat from the seed. It was shown that soil which was very wet, although it did not check the development of a reasonable crop of wheat, was unfavorable to the development of smut.

The effect of different depths of seeding in dry soil was studied, the seed being sown at depths of 1, 2, 3, and 4 in. Where the seed had previously been treated with formaldehyde no smut was developed in any case. The most smut was developed where the seed was planted the deepest, an explanation of which is believed to be that the deep planting seems to secure the best conditions for the smut development as well as retarding the growth of the wheat during the period when it is susceptible to the attack of the fungus. Where the seed bed is well prepared and the grain covered to a uniform depth, not to exceed 2 in., the most desirable conditions for growth of wheat and minimum production of smut are found.

Canteloupe wilt, H. H. Griffin (*Colorado Sta. Bul. 62, pp. 7–15*).—For a number of years a blight of cantaloupes due to *Macrosporium cucumerium* has been under investigation at the station. The fungus produces small brown spots upon the leaves in the center of the hill. These spots gradually enlarge until they attain a diameter of half an inch or more, enveloping the leaf and causing its destruction. In 1899 experiments for the control of the disease were attempted in which vines were sprayed with Bordeaux mixture, and the results obtained were considered very satisfactory. The season of 1900 was dry and hot, hence unfavorable to the spread of the disease. Experiments with Bordeaux mixture were conducted in a number of places, and the results obtained were considered highly satisfactory. The average cost for spraying is stated at $4.47 per acre for 3 applications. The fungicide seemed to not only protect the vines from disease but to prolong the growing season, and as a result the cantaloupes were ripened at a considerably longer period instead of matured practically at one time.

In 1899 there appeared to be no evidence of the disease in any other locality than that of Rockyford, but in 1900 it was found in nearly all parts of the valley. The formula for Bordeaux mixture which the author recommends is 4 lbs. copper sulphate, 4 lbs. fresh lime, and 40 gals. of water. A stronger solution could be used, but good results have been obtained from that recommended.

Bacillus carotovorus, the cause of the white rot of carrots, L. R. Jones (*Centbl. Bakt. u. Par., 2. Abt., 7 (1901), Nos. 1, pp. 12–21; 2, pp. 61–68*).—The author's attention was directed to this disease of carrots in Vermont in December, 1898, when he received at the experiment station diseased specimens, together with a statement that the disease had been known for two or more years. Among the carrots harvested in 1897, at the time of harvesting, was found here and there a single diseased root. After the roots were stored in the cellar a development of the disease took place so rapidly as to destroy in the autumn and early winter almost the entire harvest. Carrots were planted in 1898 upon a field which had been fertilized with manure from animals fed with carrots, and the crop of 1898 was almost entirely destroyed by the disease. In nearly every case the disease appears as a white rot, usually attacking the crown and penetrating the root rapidly. The diseased tissue is ordinarily white, but sometimes brownish, and between the sound and diseased portions of the root a sharply drawn line intervenes. A microscopic examination failed to show the presence of any fungus, but the tissues were swarming with bacteria. Plate cultures from diseased tissue showed in a short time an abundance of the organism, which when inoculated from bouillon cultures upon carrots quickly produced the rot. The bacteria occur in the intercellular spaces and through their action dissolve the middle lamella. The destruction of this intercellular substance is very similar to that of an enzym-like cytase, but this part of the investigations has not been completed. Inoculation experiments with a great variety of plants showed the organism was capable of producing the white rot upon a number of plants in no way related to the carrot. Roots of white beets, ruta-baga, radish, parsnip, salsify, onion bulbs, young leafstalks of celery, leaves and flower stalks of hyacinth, cabbage, and green tomatoes were all more or less successfully inoculated, the characteristics of the disease being produced in a comparatively short time. In a number of instances it was found necessary to keep the inoculation material moist, as the wilting or drying of the material checked the development of the disease. The experiments in the inoculation of oranges, bananas, apples, pears, potatoes, sweet potatoes, and garden beets gave negative results; and similar results were obtained where the roots and leaves of young plants of carrot and parsnip and the stems and petioles of tomato were inoculated The methods of inoculation and the characteristics of the destruction by the organism are described. The cause of the disease is said to be a new species of bacillus, to which the name *Bacillus carotovorus* is given. In old cultures the bacillus exhibits rounded ends, but in young cultures frequently long filaments are produced. In size the individual organism varies from 1.5 to 5μ in length, and from 0.7 to 0.8μ in diameter. It stains fairly readily, and so far as known does not produce capsules. Physiological action of the organism in various culture media is described at considerable length.

As possible means for the prevention of this disease, the author recommends rotation of crops in which the soil which has become contaminated may be kept for some years in cereals, grass, potatoes, beans, or similar crops. In no case should manure from animals fed diseased carrots or should compost from garden refuse be applied to soil if the presence of the disease is suspected. When roots are to be stored they should be thoroughly dried, and as sunlight exerts a very destructive influence upon the bacteria in cultures, it is believed that spreading the roots for 2 hours in bright sunlight would destroy the organisms present in the roots. In stored roots the disease may be prevented by keeping the root cellar at a uniformly low temperature.

Cucumber diseases, H. Garman (*Kentucky Sta. Bul. 91, pp. 50–56, fig. 1*).—Descriptive notes and directions for the prevention are given in the following diseases of cucumbers, cantaloupe, and other cucurbitaceous plants: Cucumber mildew, melon and cucumber anthracnose, cucumber-leaf spot, cucumber spot, cantaloupe-leaf spot, damping off, timber rot and leaf glaze, cucumber wilt, watermelon wilt, and cucumber dodder.

Aster diseases; nematode worms; and cucumber mildew, G. E. Stone and R. E. Smith (*Massachusetts Sta. Rpt. 1900, pp. 71–73*).—The authors report extensive experiments with China asters, in which experiments were conducted with some 15,000 plants to test the effect of fertilizers, varieties, time of planting, etc., on diseases. The China aster is said to be affected by a number of serious troubles, the most prominent of which appears not to be due to any organism, but rather the result of a disturbance in the assimilative functions of the plant. The conditions which bring about this disturbance, so far as their experiments show, are not yet understood.

A peculiar disease of potted cuttings of perennial phlox was noticed during the winter which proved to be caused by a species of nematodes. This nematode, unlike the ones occurring on the roots of many plants, attacks the stem of the plant, causing an abnormal enlargement, while the leaves are stunted or in some cases reduced to mere rudiments, and the plant generally dies. The species appears to be undescribed, and this is the only reported occurrence, so far as the authors know, in the State.

During the past year the presence of the cucumber mildew (*Plasmopara cubensis*) is reported as occurring on greenhouse cucumbers in 2 distinct and remote localities. This appears to be the first time it has been observed in Massachusetts since 1889 (E. S. R., 3, p. 160).

Notes on plant diseases, W. Lochhead (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 15, 16, 18–21, figs. 3*).—A brief description is given of the celery blight (*Cercospora apii*). For its prevention the author recommends spraying the plants at intervals of 2 weeks with ammoniacal copper carbonate solution. The occurrence of asparagus rust (*Puccinia asparagi*) is noted. So far as the author's observations go, this disease was first reported in Ontario in 1899. During the season covered by the report it had spread and caused considerable injury. The different phases in the life cycle of the fungus are briefly described, and as possible methods of combating the rust the author suggests the burning of all diseased plants in the fall, besides spraying the beds with Bordeaux mixture several times after the market season is over. A brief account is given of a disease of balsam trees due to *Trimmatostroma abietina*. An account of this disease has been previously noted (E. S. R., 13, p. 63).

Spraying in bloom, S. A. BEACH and L. H. BAILEY (*New York State Sta. Bul. 196, pp. 399–460, pls. 3, figs. 6*).—The practice of spraying fruit trees in bloom, as begun a few years ago, has led to considerable controversy as to the effect of such treatment upon the yield of fruit, as well as the injury to bees. As a result of the agitation a law was passed by the legislature of the State of New York prohibiting the application of poisons to fruit trees while in blossom. The effect of such treatments upon the production of fruit has been investigated at both the New York State Station and the New York Cornell Station. During the year 1900 extensive field experiments were conducted by the Cornell Station on spraying fruit trees in bloom, which showed no decisive results. The season was one of heavy crop and little disease, and good or fair crops followed all treatments. There was no apparent injury to blossoms on trees sprayed when in full bloom.

The effect of spray mixtures on pollen and blossoms was studied by the State station both in the laboratory and in the orchard. In the laboratory, pollen grains were put into cultures which contained insecticides or fungicides, and the germination and growth compared with others placed in culture media without any fungicide or insecticide. "From these investigations it appears that if before pollination occurs the stigmatic surface of the pistil should be covered either with Bordeaux mixture alone or with arsenical poison alone, of the strength commonly used in spraying orchards, there would be no germination of any pollen which might afterwards reach the stigmatic surface, and so fertilization would be prevented and no fruit would be formed. Even the presence of lime alone, of the strength commonly used in spray mixtures, prevented the germination of pollen. Bordeaux mixture was diluted in aqueous sugar solution to 500 parts, 200 parts, 100 parts, 50 parts, 2 parts, and 1 part in 10,000 of culture media into which various kinds of pollen were introduced. Even when diluted to 50 parts in 10,000 it prevented germination to large extent, and where germination did occur the growth which followed was decidedly slow and the pollen tubes were dwarfed. When diluted to 100 parts, 200 parts, or 500 parts either no germination or practically none was found."

The effect of spray mixtures on the apple blossoms was examined, trees being sprayed in bloom and observations made at different times until the fruit had become as large as cherries. In the tests where the trees were sprayed repeatedly, so as to hit as many as possible of the new blossoms which opened from day to day, but few blossoms survived the treatment and but little fruit was set, showing that spray mixtures prevent the setting of fruit when applied to blossoms soon after they open. If the tree should have a scant amount of blossoms, serious loss might follow from such treatments. In some cases the spray mixture had a decided corrosive effect on the tissues of the stamens and pistils. In other cases pistils which showed the presence of spray mixture on the stigmatic surfaces awaited fertilization for several days, but eventually withered and died. It appeared that in these cases the spray mixture inhibited the process of fertilization. Blossoms which had been opened several days before being sprayed seemed to have reached a stage where the treatment did not check fertilization, and the fruit was set as abundantly as upon those trees which were not sprayed. The effect of spraying in bloom upon the yield was investigated with a number of varieties of apples. In the case of Hubbardston the loss per tree from spraying in bloom was 0.9 bu. of marketable fruit; with Oldenburg and Baldwin the loss was 0.4 bu.; with Tompkins King, 1½ bu.; and with Rhode Island Greening, 1¼ bu. In some cases the spraying in bloom thinned the fruit and the thinning done seemed to produce results somewhat similar to those produced when the young fruit is thinned by hand, that is, the total yield is slightly decreased, but the amount of marketable fruit is not in any way diminished. Other experiments gave contradictory results, and further tests are needed to establish a safe general conclusion on this point.

Fruit setting of sprayed blossoms, F. H. HALL, S. A. BEACH, and L. H. BAILEY (*New York State Sta. Bul. 196, popular ed., pp. 15, pl. 1, figs. 6*).—A popular summary of the above bulletin.

An experience with pear blight, D. R. PEASE (*Rural New Yorker, 60 (1901), No. 2671, pp. 245, 246*).—The author recounts his experience in attempting to combat the bacterial blight of pears and quinces. Various methods were unsuccessfully tried, but beginning with 1898 sulphur and a wash of lime and sulphur were thoroughly applied to the bark of the trees while in the dormant condition, or sprayed upon the trees when the life began to make its first appearance. The author believes that this application, made just before the blossoms appeared, prevented the appearance of blight in his pear orchard during the season of 1900. A considerable difference in susceptibility to disease was noted for different varieties of pears and quinces. Among the pears the most seriously injured were the Louise Bonne and Bartlett. Seckel was very little affected. The Orange quince trees were nearly all destroyed, while Rea was but slightly damaged.

Concerning apricot diseases, R. FARNETI (*Atti Inst. Bot. Univ. Pavia, 2. ser., 7 (1900), pp. 9; abs. in Bot. Centbl., 85 (1901), No. 12, pp. 405, 406*).—Descriptions are given of 3 new species of fungi which have been observed on the ripe or ripening fruit of the apricot. The first, to which the name *Stigmina briosiana* is given, produces small spots 1 to 2 mm. in diameter upon the fruit. The flesh of the spot dries and the fruit becomes bitter. The other fungi observed on the plant, which are concerned to some extent in causing a rot, are *Phyllosticta armenicula* and *Phoma myxæ*.

Chlorosis of fruit trees in calcareous soils, H. DAUTHENAY (*Rev. Hort., 73 (1901), No. 2, pp. 50, 51*).—The occurrence of chlorosis on fruit trees in calcareous soils is said to be quite common wherever for any reason the nutritive elements of the soil become unassimilable to the tree. The use of sulphate of iron for preventing this disease gives partial relief and, according to the author, it acts upon the lime, changing its form. This treatment alone is not sufficient, but should be supplemented by the use of proper fertilizers.

The deterioration of passion vines and fruit, W. J. ALLEN (*Agr. Gaz. New South Wales, 12 (1901), No. 2, pp. 248–250, pls. 2*).—This fruit, which is cultivated to a considerable extent in Australia, is subject to a disease which during the past season has occasioned considerable loss. The disease is characterized by a thickening and hardening of the rind, and only a small portion of the fruit develops properly, most fruits being undersized, contorted, and with little or no pulp. The disease seems to make its appearance soon after the fruit has set, and the vines appear stunted, their leaves being greatly reduced in size. Various causes are attributed as possible agents for the production of this disease, among them improper fertilizers, insufficient moisture, irrational planting, and fungus disease. Examinations of stalks and leaves of diseased plants have shown the presence of an undetermined fungus, but whether it is the primary cause of the disease or not remains to be ascertained.

Some experiments in combating grape mildew, B. CHAUZIT (*Rev. Vit., 15 (1901), No. 382, pp. 419, 420*).—During the preceding season experiments were conducted at the departmental experimental fields of Nimes for the prevention of the downy mildew of the grape. Different lots were sprayed with Bordeaux mixture of different strengths, Burgundy mixture, solutions containing cadmium, zinc, etc., as well as applications of different forms of powders. The results obtained by experiments showed that in combating this disease some form of copper, preferably the Bordeaux mixture, gave the best results.

Concerning the conidial form of the black rot fungus, G. DELACROIX (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 13, pp. 863, 864*).—A brief account is given of the conidial form of the black rot fungus which has been found in a few localities in France. This conidial form has been observed frequently in the United States, being most abundant during very rainy seasons.

ENTOMOLOGY.

Report of injurious insects and common farm pests during the year 1900, with methods of prevention and remedy, ELEANOR A. ORMEROD (*London: Simpkin, Marshall, Hamilton, Kent & Co., 1901, pp. 111, figs. 27*).—This report is the twenty-fourth of a series made by the author, and it is indicated that the publication of these reports will not be continued. *Laverna atra*, known as the pith moth (pp. 1–8), caused injuries to apple trees by tunneling into the stems just beneath the apple blossoms. The only effective preventive measure so far known consists in cutting or breaking off the infested shoots and burning them. The habits and life history of the insect are described in detail so far as known. It is not known where the eggs are deposited. Detailed notes are given on the life history and habits of 2 ash-bark beetles (*Hylesinus fraxini* and *H. crenatus*) (pp. 9–21). In combating the first species it is recommended that felled timber and dead or dying branches should be removed. The best time for doing this is in the month of June. In cases of standing ash trees which are pierced by the insects for the purpose of securing winter shelter, it is recommended that the bark be peeled off over the places where the beetles are hibernating. The second species may be treated in the same manner, with the exception that the removal of newly felled ash trunks will be of little avail, since this species infests standing trees.

Notes are given on the appearance, life history, and habits of *Bruchus rufimanus*, *B. pisorum*, *B. tristis*, *B. brachialis*, and *B. rufipes* (pp. 21–31). Descriptive notes are given for the purpose of distinguishing the different species. For treating infested seed the author recommends the usual remedies, and also the treatment of bean seed with blue vitriol. *Tylenchus devastatrix* (pp. 32–37) is reported as causing considerable injury to field beans by infesting the stems. The plants become irregularly branched and distorted. In preventing injury from these worms it is recommended that care should be exercised not to plant a susceptible crop immediately following a crop which has been badly infested. Plowing is effective if the surface be turned completely under. It is also recommended that the stubble of infested crops should be burned and that application of sulphate of potash alone or with a mixture of sulphate of ammonia be given to the soil. Experiments with gas lime showed that this was without effect in controlling the eel worm.

Hylemyia coarctata (pp. 38–43) is reported as causing considerable injury to wheat. Notes are given on the life history of the insect so far as known, and on its method of attack.

Phytoptus ribis (pp. 43–48) has continued its injurious attacks during the season. A large number of remedies have been tried, most of which are unsuccessful. The need of further experiments with hydrocyanic-acid gas is urged. It is suggested that where black currants are grown together in large areas a satisfactory way of checking the spread of the pest consists in breaking off and destroying the galls. *Pulvinaria ribesiæ* (pp. 48–52) is sometimes injurious to currants. The scale is described and notes given on its life history. In preventing the attacks of this insect, it is suggested that the currants should not be grown in an overcrowded condition. Application of soft soap and kerosene oil are reported ineffective. Economic and biological notes are given on *Plusia gamma* (pp. 53–58). The species is reported as injurious to mustard and potatoes. Arsenical poisons are recommended in destroying this insect. The pear-leaf blister mite (pp. 59–62) is described and brief notes given on its life history, habits, and means of prevention. *Diplosis pyrivora* (pp. 63–69) is spreading and becoming more injurious. In combating this species the infested pears which have fallen should be collected and destroyed. The trees may be shaken for the purpose of removing other infested fruit which does not fall. It is also recommended that cloths be spread under the trees and kept smeared with tar or other substance, which will prevent the escape of larvæ which fall or emerge from infested fruit.

Notes are given on the habits, life history, and remedies for *Scolytus pruni* (pp. 69–72), *Penthina variegana* (pp. 73–78), *Archerontia atropos* (pp. 82–84), *Lampronia rubiella* (pp. 85–88), and *Œstrus ovis* (pp. 89–94).

A planarian worm (*Bipalium kewense*) is reported as having been found in a number of greenhouses. The species is somewhat beneficial from its habit of feeding upon earthworms, and thus checking a too great prevalence of the latter in greenhouses. Short biological and economic notes are also given on *Psylla mali*, currant sawfly, *Mamestra brassicæ*, and *Retinia buoliana*.

Report on injurious insects and plant diseases in 1900, W. M. Schöyen (*Beretning om Skadeinsekter og Plantesygdomme i 1900. Christiania, 1901, pp. 34, figs. 21*).—In this report the author gives economic and biological notes on a number of injurious insects and fungus diseases affecting cereals, grasses, potatoes, cabbage, turnips, peas, beans, fruit trees, small fruits, shade trees, evergreen trees, and ornamental plants. Among the injurious insects which are discussed mention may be made of *Charæas graminis*, wireworms, cabbage-root maggot, *Silpha opaca*, destructive pea aphis, apple maggot, codling moth, *Cheimatobia brumata*, *Phyllobius argentatus*, *Hyponomeuta varabilis*, *Eriocampa adumbrata*, pear-leaf blister mite, currant sawfly, *Cossus ligniperda*, *Lasiocampa pini*, and earwigs. Notes are also given on the cereal rusts, *Glœosporium lindemuthianum*, apple scab, gooseberry rust, and *Æcidium strobilinum*.

Notes on insects, W. Lochhead (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 13–15, figs. 2*).—The buffalo carpet beetle is reported as having occurred in unusual numbers during the season. In combating this insect it is recommended that the beetles be prevented from entering houses by the use of window screens during the month of May, when the beetles are flying most actively. Infested carpets may be treated with gasoline along the borders, and the same treatment should be applied to the floors under the borders of the carpet.

The codling moth occurred in about the usual numbers. Legislation has been adopted permitting municipalities to enforce the application of bands to apple trees from the first week in June. It is urged, however, that this method is successful only when the bands are carefully examined at frequent intervals.

Many complaints are reported concerning the ravages of the Hessian fly. It is recommended that narrow strips of wheat be sown 4 or 5 weeks earlier than the main crop in order to entice the insects to lay their eggs. This wheat may then be plowed under so as to destroy the eggs.

Report of the entomologists, C. H. and H. T. Fernald (*Massachusetts Sta. Rpt. 1900, pp. 84–88*).—The San José scale is reported as having been received from 37 towns in the State, and it is believed that there are other unreported localities of infestation. Brief notes are given on periodical cicada, birch Bucculatrix, Marguerite fly, greenhouse Aleurodes, fall cankerworm, and pea louse.

Insects injurious to grain, G. d'Utra (*Bol. Agr. São Paulo, 2. ser., 1901, No. 1, pp. 1–21*).—Descriptive, economic, and biological notes on *Calandra oryzæ*, *C. granaria*, *Cathartus gemellatus*, *Tribolium ferrugineum*, *Ephestia kuehniella*, *Tinea granella*, and *Silvanus surinanensis*.

The principal insect enemies of growing wheat, C. L. Marlatt (*U. S. Dept. Agr., Farmers' Bul. 132, pp. 40, figs. 25*).—The chief insect enemies of wheat, in the order of their importance, are considered to be chinch bug, Hessian fly, wheat midge, and grain-plant louse. The wheat-straw worms, wheat-bulb worms, army worms, cutworms, and sawflies are of secondary importance, while a large variety of insects are occasionally found upon wheat. In this bulletin especial attention is devoted to the 4 insects mentioned as being of chief importance, and also to *Isosoma tritici*, *I. grande*, *Meromyza americana*, *Leucania unipuncta*, *Laphygma frugiperda*, *Cephus pygmæus*, *C. occidentalis*, and *Pachynematus extensicornis*.

The mites of sugar cane in Java, L. Zehntner (*Meded. Proefstat. Suikerriet West Java, No. 51, pp. 17, pls. 2; reprint from Arch. Java Suikerind., 1901, No. 5*).—A detailed description is given of *Tetranychus exsiccator* in all its stages, together with an account of its injuries and natural enemies. Besides several species of ladybirds which prey upon the mite, the author gives an account of *Diplosis acarivora*, which is described as a new species and as parasitic upon the mite. When the mite occurs in large numbers, it is recommended that infested plants be sprayed with petroleum emulsion.

Enemies of cucumbers and related plants, H. Garman (*Kentucky Sta. Bul. 91, pp. 3–48, figs. 14*).—Considerable work was done on the life history of the striped cucumber beetle. The beetle was found to hibernate in the adult condition, and individuals were found in the spring as early as April 12. During the latter half of July adults began to appear from the earliest eggs which were laid by the spring brood. Some of these beetles may possibly lay eggs for a second brood which matures in the fall, but it is not believed that there are over 3 or 4 broods during a season. According to the author's observations, the life history of the species occupies from 26 to 33 days. Notes are given on the food plants of the beetle. It is stated that the beetles begin to lay their eggs by the middle of June, and that the young larvæ begin to hatch about the second half of June. The average duration of larval life was found to be about 19 days. As remedial treatment for this insect the author recommends burning all leaves and rubbish, dusting plants with insect powder, spraying with Bordeaux mixture, and the use of various forms of covers. Plaster and lime were found to be ineffective. A detailed description of the species is given in all its stages, together with notes on the literature of the beetle.

Brief notes are given on the life history and habits of the spotted cucumber beetle.

The northern squash beetle (*Epilachna borealis*) is reported as causing local and periodical depredations on the cucumbers and related plants. Egg laying begins in the second half of June, and the larvæ hatch within about 10 days. For combating this species the author recommends hand picking and spraying with Paris green to which lime has been added.

As remedies for the melon aphis (*Aphis gossypii*), tobacco decoction, kerosene emulsion, fumigation with bisulphid of carbon, hydrocyanic-acid gas, and tobacco extracts are recommended. The author devised 2 forms of fumigators especially for the purpose of fumigating with tobacco extracts. One fumigator consists of a can with a tin cylinder 8 in. long and 4 in. in diameter soldered to one side. The cylinder is furnished with an opening covered with a screw cap on the upper side, into which nicotine preparations may be poured. The can is without bottom and is placed over the plant to be treated. Heat is then applied by a burner to the under side of the cylinder. The second form of fumigator consists of a wooden box, tightly calked, inverted over the plant to be treated, and a tin pail connected with the box by a tin tube 1 in. in diameter. The nicotine is placed in the pail and the heat applied to the bottom of the pail by means of a burner. Notes are given on the food plants, life history, and enemies of the melon louse.

Brief biological and economic notes are presented on *Anasa tristis*, *A. armigera*, *Leptoglossus oppositus*, *L. phyllopus*, squash borer, pickle worm, melon worm, *Cyrtoneura cæsia*, *Thrips tabaci*, and *Armadillidium vulgare*. In greenhouses attacked by the cucumber thrips the author recommends fumigation with tobacco extract and syringing plants with the same insecticide. In the field infested plants may be sprayed with tobacco extract, kerosene emulsion, or fumigated in the manner recommended for melon aphis. Experiments with Armadillidium, or greenhouse pillbug, showed that this pest possesses great resisting power to ordinary insecticides, and that tobacco decoctions and kerosene emulsions are not effective against it. In infested soil the author recommends the use of bisulphid of carbon.

Further experiments against the peach-tree borer, M. V. SLINGERLAND (*New York Cornell Sta. Bul. 192, pp. 191–196, figs. 5*).—Good results were obtained by J. M. Stedman in the use of wire-cage protectors for keeping the borer away from peach trees. As these results were different from those obtained by the author in previous experiments, the value of such protectors was again tested by further experiments. The author concludes from his experiments that the wire cage successfully used by Stedman offers "no protection against the peach-tree borer." The gas-tar treatment, which in experiments conducted by Stedman killed nearly all the trees upon which it was used, is recommended by the author as a harmless and effective remedy. Wooden wrappers, advised by Stedman and recommended for use on a large scale, are considered by the author to be no more effective than cheaper tarred paper wrappers.

San José scale investigations. I, The development of the female, V. H. LOWE and P. J. PARROTT (*New York State Sta. Bul. 193, pp. 351–368, pls. 6*).—Experiments with larvæ for the purpose of determining the duration of the period of activity were conducted in a temperature of from 70 to 76° F. None of the larvæ settled down before 12½ hours, and the average length of the period of activity was 27.7 hours. As a rule, the young larvæ remained inactive for from ½ hour to 4 hours. Observations on the rate of travel of young larvæ at a temperature of 74° F. showed that they may move 10½ ft. in a period of 6 hours. On fruit the greater number of larvæ seek the blossom end or stem end, preferring the part of the apple which is in the shade. The young remain in large numbers around the adult females. The average mortality among the larvæ of the San José scale was 39.8 per cent.

The duration of the period of growth was found to be, on an average, 49.5 days, and during this time 4 stages of growth were noted in the formation of the scale. In the first stage the body of the insect becomes covered with a secretion of white filaments, in the second stage a denser layer of waxy threads is noted among the loose threads of the first stage, while the third stage is characterized by the dull black color of the scale. The fourth stage is that of the mature insect. The first molt occurred on an average 20.7 days after birth and the second molt 29¼ days.

The effect of temperature on the development of larvæ was carefully studied by the author. At a temperature of 35° F. the larvæ settled down almost immediately and attempted to secrete scales. Some of them succeeded in this, but all the larvæ died before reaching the hibernating stage. At a temperature of 45° F. the larvæ were unable to reach the hibernating stage, but after resisting this temperature for 6 weeks continued to develop to that stage if transferred to a room with higher temperature. At a temperature of 58° F. the larvæ reached the normal hibernating stage and in one instance developed completely.

Observations were made on the means of local distribution of the San José scale, and it was found that active larvæ on leaves which were picked from the tree and allowed to be carried away by the wind were dislodged only with considerable difficulty, and it is believed that larvæ may be transported to some distance by this means. Larvæ were found clinging to grasshoppers, aphis lions, flies, and *Euphoria inda*, and may therefore be transported from tree to tree on such insects.

In studying the different stages of the San José scale the author made use of two devices for confining the scale to limited areas. Bands of cotton wool tied about small nursery trees or on the limbs of large trees at intervals of 1 to 2 in. served to confine the scales within these boundaries. Another means of accomplishing this was found in the use of metal rings, or curtain rings, set in the bark and covered with microscopic cover glasses held in place with paraffin.

San José scale investigations, II, V. H. Lowe (*New York State Sta. Bul. 194, pp. 369–384*).—The experiments reported in this bulletin were undertaken for the purpose of determining the effects of winter applications of kerosene on nursery trees and bearing trees, the percentage of oil necessary to kill scales in winter, and the effect of summer applications on healthy trees. Two series of experiments were made on nursery trees, the first lot of trees being sprayed once on November 22 and the second lot twice on November 22 and March 27. The trees were apple, pear, peach, plum, and quince, 144 in all. The peach and plum trees were found to be quite sensitive, peaches being killed with a 20 per cent mixture, and plums seriously injured with a 40 per cent mixture. Pears and apples were not injured with 1 application of the 40 per cent mixture, and the apples were not affected by 2 applications of this strength, although pears were slightly affected. Similar experiments were made on bearing trees, with the result that no injury was noted on pears, except where pure kerosene was used. Plums were not injured by 1 application of the 40 per cent mixture, but were badly affected by the pure kerosene. In experiments to determine the percentage of oil necessary to kill the San José scale it was found that the scales were not destroyed by the 20 per cent mixture of kerosene, but were killed in all cases where the 40 per cent mixture was used. In testing the effect of summer applications of kerosene, 2 grades of oil were used, 100° and 150°. The 100° oil injured the foliage of apple and pear trees in all cases, even when used in the 15 per cent mixture, when applied during May and June. The 150° oil, on the other hand, did not injure the trees except when used pure. It is concluded that kerosene may be used in winter on apple and pear trees in a 40 per cent mixture or at a sufficient strength to kill the scales without injuring the trees, but its use is impracticable on peach trees and is somewhat injurious to plums.

Brief notes are given on the method of fumigation by hydrocyanic-acid gas, and spraying with crude petroleum, and whale-oil soap.

Controlling San José scale, F. H. Hall, V. H. Lowe, and P. J. Parrott (*New York State Sta. Buls. 193 and 194, popular ed., pp. 11, pls. 2*).—This is a popular summary of Bulletins 193 and 194 of the station (see above).

Observations on Coccidæ, R. Newstead (*Ent. Mo. Mag., 2. ser., 12* (*1901*), *No. 136, pp. 81–86, figs. 5*).—The author gives descriptive and biological notes on the species of Aspidiotus, Lichtensia, Diaspis, Fiorinia, Antonina, and Dactylopius.

Classification of Parlatoria, G. Leonardi (*Riv. Patol. Veg., 8* (*1900*), *No. 7–12, pp. 203–209*).—Brief notes on the anatomy of this genus of scale insects, together with an analytical table for the determination of species.

The injurious scale insects and mealy bugs of the British Isles, R. Newstead (*Jour. Roy. Hort. Soc.* [*London*], *23* (*1900*), *No. 3, pp. 219–262, figs. 22*).—The author gives a general account of the life history, habits, and methods of combating a large number of scale insects injurious to fruit, shade trees, and other plants. A chapter is devoted to remedies and methods of prevention, in which, besides a general discussion of the subject, special recommendations are given concerning the value and methods of making kerosene emulsion, fir-tree oil, soft-soap solution, lime wash, caustic-soda wash, clay and sulphur, etc.

Woolly aphis and mistletoe, F. Peneveyre (*Chron. Agr. Canton Vaud, 14* (*1901*), *No. 5, pp. 147–150*).—The remedies which are recommended against the woolly aphis include the following formulas: Soap, 1 kg.; petroleum, 900 gm.; amyl alcohol, 500 gm.; water, 3 liters. Soap, 150 gm.; water, 1 liter; petroleum, 1,800 gm.; pure petroleum.

The damage caused by Porthesia chrysorrhœa, L. J. Lambillion (*Bul. Agr.*

[*Brussels*], *17* (*1901*), *No. 1, pp. 42–45*).—The author gives an account of the fruit trees and shade trees which are most seriously attacked by this insect, together with notes on its distribution. The damage caused by the species is said to be 10 times as great as that of the gypsy moth.

The Rutherglen bug, Nysius vinitor (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 2, p. 247*).—This insect appeared in great numbers in a cherry orchard and caused an unusual amount of damage. In combating the pest experiments were tried with a fumigating tent and hydrocyanic-acid gas. This method proved very effective and it is believed that the insects would be destroyed by using a diluted formula.

Some insects injurious to small fruits, MARY E. MURTFELDT (*Missouri State Hort. Soc. Rpt. 1900, pp. 315–324*).—Brief notes on insects which are injurious to strawberries, raspberries, and other small fruits.

Disease of the black currant caused by the gall mite, Phytoptus ribis, J. H. WILSON (*Jour. Roy. Hort. Soc.* [*London*], *23* (*1900*), *No. 3, pp. 346–349, fig. 1*).—Brief biological and descriptive notes are given on this mite. The removal and destruction of infested buds is regarded as only a temporary check and too expensive for application on a large scale. Spraying with insecticides is practically useless when the mites are protected within the bud scale. The only reliable method for extermination of the pest is found in the complete destruction of infested plants and the application of gas lime or slaked lime to the ground after the removal of the bushes.

Three unusual strawberry pests and a greenhouse pest, M. V. SLINGERLAND (*New York Cornell Sta. Bul. 190, pp. 143–164, figs. 15*).—The author's attention was called to an attack of *Cacœcia obsoletana* on strawberry fields at Westfield, N. Y. Specimens of the moth were collected and placed in breeding cages in which strawberry plants were set. The eggs were laid on the glass sides of the cages. The duration of the egg stage was found to be 10 days. The caterpillars fed chiefly on the underside of the leaves and after a few days began to roll the leaves together by means of silken threads. There are probably 3 broods of the caterpillars during the growing season, in May, July, and September. A parasite identified as *Rhysallus atriceps* was bred from a number of caterpillars. In one strawberry field an experiment was tried in spraying with Paris green at the rate of 1 lb. to 150 gal. of water, without the addition of lime. The leaves and young fruits were injured by the Paris green and only a few caterpillars were destroyed. It is recommended that where spraying is adopted, applications should be made before the blossoms open, and if another spraying is required it should be done after the fruit is picked. Arsenate of lead is recommended as more suitable than Paris green for this purpose. Mowing over the strawberry patch after the fruit is picked, and burning the leaves, is recommended as still more effective than spraying.

At Leechburg, Pa., 2 species of ground beetles (*Harpalus caliginosus* and *H. pennsylvanicus*), are reported as injuring ripe strawberries by eating the seeds and incidentally damaging the pulp to a greater or less extent. The beetles apparently attack the fruit for the purpose of getting the seeds, but when the fruit is scarce they feed upon the pulp, especially of very ripe berries. By raking off the mulch and placing a few boards between the rows, the beetles may be enticed under such protection and thus found and destroyed. They are attracted to lights and it is suggested that they may be successfully combated by means of lantern traps. The beetles may be attracted to similar traps by means of meat baits.

Biological and economic notes are given on the white fly of the strawberry belonging to the genus Aleurodes. The life cycle of these insects occupies from 4 to 5 weeks, and there are 3 or more broods during the growing season. The insects congregate mostly on the underside of the leaves, from which they suck the sap. They may be combated by a spray of kerosene emulsion, mechanical mixture of kerosene and water, or whale-oil soap, directed so as to strike the lower side of the leaves.

The greenhouse leaf tier (*Phlyctænia rubigalis*) is reported as injurious to all sorts of greenhouse plants. The caterpillars feed preferably on the underside of the leaves, eating out patches of the leaf tissues and leaving the thin skin on the upper side. The caterpillars require about 20 days in attaining their complete growth and undergo 3 molts during that time. The life cycle is passed through in from 44 to 50 days, and there may be 7 or 8 generations every year in greenhouses. This insect is easily transported on greenhouse plants in the egg state or as young caterpillars, and such plants should be examined before being set out in the greenhouse. The moths are somewhat attracted to lights, and lantern traps are recommended in combating them. Fumigation with tobacco was found ineffective. A greenhouse containing 8,000 cubic feet of space was fumigated with hydrocyanic-acid gas at the rate of 1 oz. of cyanid to each 400 ft. of space for about ½ hour. Live moths of the leaf tier kept in a wire cage were not killed by this treatment, and none of the caterpillars or pupæ was affected by it, although considerable damage was done to roses, carnations, and other plants. Further experiments with this gas indicated that the greenhouse leaf tier can not be destroyed without using the gas in a strength which is injurious to the plants. The most practical and thorough method of combating this insect is considered to be hand picking.

The phylloxera of the vine, F. T. Bioletti (*California Sta. Bul. 131, pp. 16, figs. 4*).—A brief historical review is given of the gradual distribution of phylloxera in European countries and its subsequent reimportation into California. The insect has recently appeared in several important crop-growing districts of California, which were previously regarded as exempt from its attacks. The author therefore prepared notes on the life history and habits of the phylloxera, together with a discussion of the various remedies which have been found most effective in combating the pests. Of these remedies special mention is made of carbon bisulphid, submersion, planting in sand, disinfection of cuttings, and the use of resistant vines.

Combating phylloxera in Roumania, G. N. Nicoleano (*La lutte contre le phylloxéra en Roumanie. Bucharest: Government, 1900, pp. 173, figs. 15, map 1*).—The author gives an account of the present centers of infection by this insect, experiments in treatment with bisulphid of carbon, the spread of the insect, and of the reconstruction of vineyards by the use of American vines and by other methods.

Catching the moths of Tortrix ambiguella, J. Dufour et al. (*Chron. Agr. Canton Vaud, 14 (1901), No. 8, pp. 229–237*).—This article contains an account of a method adopted for capturing moths of injurious grape caterpillars by means of a racket covered with adhesive substances. These instruments may be successfully manipulated by small children which are employed for this purpose in vineyards. The use of this method has given such promising results that it is strongly recommended.

Report on methods of combating Tortrix ambiguella in spring and summer, J. Laborde (*Bul. Min. Agr. (France), 20 (1901), No. 1, pp. 112–124*).—The author reports a large series of experiments with remedies for destroying this insect, and also *Eudemis botrana*. Remedies were tested on all stages of the insect. For destruction of the eggs, sulphuric acid, *eau de javelle*, soap and turpentine, and soap and petroleum were tested; on the larvæ, soap and nicotine, soap, nicotine and sulphate of copper, oleic acid, petroleum, bisulphid of carbon and acetic acid, and also various arsenical poisons. The conclusion is drawn from the author's experiments that attention may be most advantageously directed in the winter against the chrysalis and in the spring against the larvæ of the first generation.

Larkspur and geraniums for grasshoppers, C. Ledwidge (*Agr. Gaz. New South Wales, 12 (1901), No. 2, pp. 317, 318*).—Brief observations are given on the poisonous effects of larkspur and red geraniums on grasshoppers. It was noted that grasshoppers died very quickly after eating these plants, but it is not believed that large swarms of grasshoppers could be checked by this means.

Spray calendar (*New York Cornell Sta. Bul. 188, pp. 107–116*).—A brief discussion is given of the means for preventing attacks of fungi and insects, and suggestions are made for the protection, by spraying, of different fruits, vegetables, and ornamental plants. Formulas and directions for preparation are given for the more important fungicides and insecticides.

The general treatment of insect pests, H. Maxwell-Lefroy (*Imp. Dept. Agr. West Indies, Pamphlet No. 5, 1901, pp. 29*).—A brief discussion of injurious insects, giving general classification and an account of remedies and spraying apparatus which have been found effective. Brief notes are also given on beneficial insects, means of introduction of insect pests, and directions for collecting and forwarding specimens.

The resistance of the larval mosquito to cold, M. J. Wright (*British Med. Jour., 1901, No. 2102, Epit., pp. 882, 883*).—The observations reported in this article were made on several species of Anopheles and Culex. At a temperature sufficiently low to freeze a crust of ice on pools, the author observed mosquito larvæ in active movement in such pools. In some cases the adult mosquitoes were emerging from the nymph condition. Mosquito larvæ kept in bowls and subjected to low temperature remained alive and active until the water was frozen into a solid mass. After thawing out, some of them recovered their activity. The author believes that mosquitoes pass the winter chiefly in the larval stage.

A preliminary note on the hibernation of mosquitoes, H. E. Annett and J. E. Dutton (*British Med. Jour., 1901, No. 2104, Epit., p. 1013*).—This paper contains a discussion of the question in what stage mosquitoes pass the winter. It appears that in England species of Culex and Anopheles winter over in both the adult and the larval stages. Experiments indicate that when mosquitoes are kept in a dry cage they die within a few days, while they may be kept alive for months in a damp, cold atmosphere.

The life history of the warble flies, E. E. Austen (*Ent. Mo. Mag., 2. ser., 12 (1901), No. 136, pp. 92–95*).—This article contains a discussion of the literature on *Hypoderma bovis* and *H. lineatum*. The evidence for the supposed entrance of *H. bovis* into the mouth and subsequent penetration through the tissues to a position under the skin is considered unsatisfactory.

Report of the lecturer on apiculture, H. R. Rowson (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 136, 137*).—An experiment was conducted for the purpose of determining an economic method for using unfinished sections. Some of the supers containing unfinished sections were left on the hives, and other supers with unfinished sections were placed in front of the hives in such a way that the bees could easily remove the honey from them without danger of interference from bees belonging to other colonies. The honey from the unfinished sections outside the hives was rapidly removed and served to complete the unfinished sections within the hives. The result was satisfactory, since no robbing was observed and the sections were not stained by the bees.

It was found by experiment that protection could be afforded in the spring to colonies of bees which have been maintained in cellars during the winter by placing supers on the hives and putting the hives in chaff cushions. It was found that the heat was thus well retained in the cushion, and as a result the cluster of bees did not become contracted and the queen was able to lay eggs over a greater area of comb.

The heat of beehives and the results of varying it, Sylviac (*L'Apiculteur, n. ser., 44 (1901), No. 2, pp. 75–78*).—The author discusses this problem in a general way, and indicates the methods for determining the temperature of the inside of the hives and for determining any movements of the bees and the amount of food consumed.

The Freiburg investigations of eggs of bees, F. Dickel and A. Weismann (*Anat. Anzeiger, 19 (1901), No. 3–4, pp. 104–111*).—This discussion is controversial in nature and concerns the general problem of the influence of fertilization and heredity upon the development of the different members of bee colonies.

Notes on foul brood of bees, E. Ruffy (*Rev. Internat. Apicult., 23 (1901), No. 3, pp. 60–61*).—A brief discussion of practical methods for preventing the spread of this disease.

FOODS—NUTRITION.

The composition of jellies and jams, L. M. Tolman, L. S. Munson, and W. D. Bigelow (*Jour. Amer. Chem. Soc., 23 (1901), No. 5, pp. 347–353*).—As preliminary to the examination of a large number of commercial fruit preserves, a number of samples of fruits and of jellies and jams made from them were analyzed. The fruits examined include the apple, crab apple, pear, peach, plum, grape, orange, pineapple, huckleberry, and blackberry. Determinations were made of the solids, ash, proteids, and sugars. Total solids were determined by drying from 5 to 10 gm. in a large flat-bottomed platinum dish at 100° for from 10 to 12 hours. The solids were charred, the mass collected on a filter, exhausted with water, incinerated, and weighed. Acid was determined with decinormal potassium hydroxid, using phenolphthalein as an indicator, the results being reported in terms of sulphuric acid. Nitrogen was determined by the Gunning method. Reducing sugars were estimated by the Allihn method and cane sugar calculated by the Clerget formula, the polarization being made with a Schmidt and Haensch instrument.

The results of these examinations are tabulated. It is stated that the fruits selected, especially the apples and grapes, "were not in all cases of typical composition."

Cane sugar was found in all the fruits examined except blackberry. In the orange, peach, and pineapple it was in excess of the reducing sugar. The polarization of the Damson plum indicated an excess of dextrose over levulose. The extent of inversion in comparing jams and jellies varied with the amount of free organic acid and length of time the product was heated. There were, however, some marked exceptions to this rule. The jams and marmalades, except the crab apple products, showed a higher inversion than the corresponding jellies, because of the fact that they were heated for a longer time.

The presence of tin in canned foods, J. K. Caldwell and A. E. Parkes (*British Food Jour., 3 (1901), No. 29, pp. 146, 147*).—The authors report the presence of tin in all samples of canned fruit and vegetables which they examined. In estimating the tin, 100 gm. of the can's contents was evaporated to dryness and the residue gently charred. The residue was ground and twice extracted with warm dilute hydrochloric acid. It was then treated with sulphureted hydrogen, the tin being recovered as stannic oxid. The amount of tin in the canned vegetables—tomatoes and beans—was 0.168 grain per pound. In the fruits—pears, peaches, apricots, and pineapples—it ranged from 0.112 to 0.885 grain per pound. The length of time the articles had been canned was not known. In 2 of the samples very slight traces of lead were found.

Maple sirup from defoliated trees, F. W. Morse (*New Hampshire Sta. Bul. 79, p. 10*).—As shown by analyses, the sirup from the last run of sap from maple trees which had been stripped of their leaves the previous summer by the forest tent caterpillar did not differ materially in composition from other "last run" maple sirup. In appearance it was dark colored and clear.

Concerning the fineness of division and solution of food when chewed, J. U. Gaudenz (*Arch. Hyg., 39 (1901), No. 3, pp. 230–257, dgm. 1*).—Experiments which the author reports covered a number of common foods, including apples, bread, radishes, sandwiches, eggs, cheese, meat, macaroni, potatoes, etc. Conclusions are drawn regarding the quantity ordinarily taken at a bite and the size of particles after chewing food for a longer or shorter time. Results showing the size of the chewed particles and the amount of the different foods dissolved by the saliva are reported in detail. The author believes that a bite of normal size is sufficiently chewed in half a minute, so that there is a desire to swallow it. In general, vegetable foods were better divided by chewing than animal foods. According to these investigations, the saliva in a very short time (half a minute) dissolved the common starchy food such as macaroni and potatoes. As was to be expected, animal foods, such as egg white and meat, were not dissolved by saliva. The results are discussed at some length.

The effect of severe and prolonged muscular work on food consumption, digestion, and metabolism, W. O. Atwater and H. C. Sherman (*U. S. Dept. Agr., Office of Experiment Stations Bul. 98, pp. 1–56, fig. 1*).—A 6-day bicycle race afforded the authors an opportunity to study the food consumption by 3 of the principal contestants, as well as the digestibility of the food and the metabolism of nitrogen, the investigation being made with the view to determine the effects on these factors of severe and prolonged muscular work. The average amounts of food consumed per man per day follow:

Average daily food consumption of bicycle racers performing severe muscular work.

	Protein.	Fat.	Carbohydrates.	Fuel value.	Nutritive ratio.
	Grams.	*Grams.*	*Grams.*	*Calories.*	*1:*
Miller, during 6-day race	169	181	585	4,770	5.9
Pilkington, during 3 days of the 6-day race	211	178	509	4,610	4.3
Albert, during 6-day race	179	198	859	6,095	7.3
Albert, during preliminary period	169	153	375	3,650	4.2

The following conclusions were drawn regarding the food consumed, digestibility of the food, and the metabolism of nitrogen:

"(1) Trained athletes undergoing unusually severe exertion demand a largely increased supply of easily digested food of such kinds as 'agree' with the subject, and that the availability of such food is not greatly affected by the loss of sleep and almost continuous muscular exertion; (2) under such circumstances the metabolism of nitrogen as well as that of energy is increased, body protein being drawn upon unless the food is very abundant; and (3) trained athletes appear to be able to lose relatively large amounts of body nitrogen without any apparent ill effects.

"It is conceivable that equally severe and prolonged exertion might perhaps be undergone without increased metabolism of nitrogen, provided the supply of fuel material was very abundant. This question, however, can be settled only by experiments in which the diet is under control."

The mechanical work and efficiency of bicyclers, R. C. Carpenter (*U. S. Dept. Agr., Office of Experiment Stations Bul. 98, pp. 57–67, figs. 2*).—From the data recorded in the investigations noted above, and a number of special determinations, the author discusses the amount of work performed by 2 of the bicycle racers, its mechanical equivalent, and the apparent efficiency of the racers. As pointed out, the external resistance may be summarized under 2 general heads—that of the air and that of the bicycle.

"The total work done by Miller is computed to have been over 15,000,000 foot-pounds, or 7,500 foot-tons, on the first day, and 5,500,000 foot-pounds, or 2,750 foot-tons, on the last day of the race. . . . The average heat equivalent of the work done in the 6 days amounted to 3,102 calories. At the same time the food consumed furnished 4,957 calories, making an apparent efficiency of over 60 per cent. . . . If we assume that the equivalent exposure of the bicycle rider was 4 sq. ft., . . . the total work done each day ranged from nearly 20,000,000 to nearly 7,000,000 foot-pounds, and the corresponding heat equivalent from 6,381 to 2,256 calories, averaging 3,994 calories.

"The amount of work done by Albert was slightly less than that by Miller, ranging from 12,000,000 to 4,000,000 foot-pounds per day, with a corresponding range in heat equivalent from 3,938 to 1,334 calories. The average heat equivalent of the work done per day during the 6 days is 2,760 calories, and the average energy in the food as found by actual determination of the heat of combustion is 6,307 calories, making an apparent efficiency of nearly 45 per cent. . . .

"If the equivalent exposure of the rider is assumed as equal to 4 sq. ft., the total amount of work done each day varied from nearly 16,000,000 to a little over 5,000,000 foot-pounds, with a corresponding range in heat equivalent from 5,088 to 1,686 calories, with an average for the 6 days of 3,547 calories."

It is pointed out that in each case there is some uncertainty regarding the energy of the food consumed, since a greater or less amount of body fat was also consumed, the energy of which should be taken into account in estimating the total income. This would diminish somewhat the apparent efficiency.

"Under the conditions of the race the amount of energy exerted can be considered about the limit of human strength and endurance. This is reasonably many times greater than would be exerted by the ordinary laborer working under the routine of his usual occupation."

On the influence of food consumed upon metabolism, G. Koraen (*Skand. Arch. Physiol., 11 (1900), No. 3-4, pp. 176-197*).—The respiratory quotient and the hourly excretion of nitrogen were studied under different dietary conditions, the author being the subject. A number of his conclusions follow: When some 66 gm. of fat is consumed the total metabolism is not increased. When some 165 gm. of cane sugar is consumed it is increased somewhat, and markedly increased when 52 gm. of protein is consumed. A marked increase is also observed when a mixed diet which is rather difficult of digestion is consumed. When fasting, the hourly excretion of nitrogen is 0.414 gm.; that of carbon, 6.05 gm., with a possible error of $\pm$ 0.19 gm. These values are equivalent to 72.1 calories, with a possible error of $\pm$ 2.3 calories.

Respiration experiments with a corpulent subject when work was performed and the moisture content of the air varied, A. Broden and H. Wolpert (*Arch. Hyg., 39 (1901), No. 3, pp. 298-311*).—In these experiments the respiratory quotient was determined. The large amount of water in the respiratory products explains the great thirst experienced by corpulent persons. The experiments are discussed in considerable detail, especially with reference to the performance of work by corpulent and thin persons in the tropics.

Contribution to the subject of gastric juice and the composition of its enzyms, M. Nencki and N. Sieber (*Ztschr. Physiol. Chem., 32 (1901), No. 3-4, pp. 291-319*).—Experiments are reported and discussed.

Concerning the theory of digestion of protein, W. W. Sawjalow (*Arch. Physiol. [Pflüger], 85 (1901), No. 4-6, pp. 171-225*).—A chemical study of the digestibility of proteids with an extended discussion.

Contribution to the physiology of digestion. III, A substance increasing the flow of digestive juice, C. Radzikowski (*Arch. Physiol. [Pflüger], 84 (1901), No. 11-12, pp. 513-526*).—Studies on the effect of alcohol on peptic digestion.

Contribution to the physiology of digestion. IV, Two pepsin-forming bodies, F. R. Mark-Schnorf (*Arch. Physiol. [Pflüger], 85 (1901), No. 1-3, pp. 143-148*).—Experiments with a dog are reported which led to the conclusion that white, so-called pure dextrin neither causes a secretion of digestive juice nor formation of pepsin. Inulin and glycogen, even when chemically pure, cause the formation of pepsin without causing a secretion of digestive juice.

ANIMAL PRODUCTION.

The composition, digestibility, and feeding value of barnyard millet (Panicum crus-galli) J. B. LINDSEY (*Massachusetts Sta. Rpt. 1900, pp. 33–44*).—Proximate and ash analyses are reported of the millet plant at different stages of growth, millet seed, millet silage, millet and soy-bean silage, corn and soy-bean silage, as well as the coefficients of digestibility (obtained in experiments with sheep) of green millet, millet hay, millet and soy-bean silage, and corn and soy-bean silage. The coefficients of digestibility follow:

Coefficients of digestibility of millet, millet hay, etc.

	Dry matter.	Protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Ash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Green millet, early to late bloom	71	69	63	72	73	64
Millet hay, full bloom	56.5	47.5	48	53.5	62	43.5
Millet and soy-bean silage (2:1)	59	57	72	59	69	....
Corn and soy-bean silage (2:1)	69	65	82	75	65	....

The feeding value of millet is discussed at some length. The author's conclusions follow:

"Barnyard millet is a warm-weather plant, similar in this respect to Indian corn. As harvested in early blossom, the fodder contains less nitrogen-free extract matter, more fiber or woody matter, and rather more ash than corn fodder. The seed resembles the cereals (especially oats) in composition. It contains considerable more fiber, rather more ash, and 5 to 6 per cent less extract matter than maize.

"Barnyard millet, grown on naturally moist and fertile land, will probably yield as much dry matter per acre as corn. It has less nutritive value than the corn, the principal reason for this being that the corn can partially mature its grain and still be readily eaten by animals, while the millet must be cut when in blossom to secure it in the most desirable condition for feeding.

"It is not suitable for hay, and, while it makes a fairly satisfactory silage, it is inferior to maize as a silage crop. It furnishes a desirable green feed, especially during the month of August, and it is for this purpose that it can be most satisfactorily utilized. The millet can be used for silage in place of corn whenever it is not convenient or possible to grow the latter."

Dried distillery grains, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1900, pp. 44–50*).—Distillery grains are divided into 3 classes, those obtained in the manufacture of (1) alcohol and spirits, (2) Bourbon whisky, and (3) rye whisky. Statistics are given of the total American output of dried distillery grains and of the amount exported. The composition of a number of sorts is also given, as well as the results of digestion experiments with sheep. The average coefficients of digestibility of distillery grains of the better sort were: Dry matter, 81; protein, 74; fat, 94; and nitrogen-free extract, 32. The value of distiller's grains for milch cows is briefly spoken of.

Chemical composition and feeding value of the germ and dry residue of barley used in the manufacture of Italian beer, P. SCARAFIA (*Staz. Sper. Agr. Ital., 34 (1901), No. 4, pp. 321–337*).—Proximate and ash analyses are reported, as well as artificial digestion experiments.

Parsons Six-Dollar Feed, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1900, pp. 53, 54*).—An analysis is reported of this feeding stuff, which is said to consist principally of the hulls of different grains and other low-grade material from grain mills and elevators.

Beet pulp, A. E. SHUTTLEWORTH (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 29, 30*).—The author quotes the composition of the beet pulp and discusses its feeding value.

Composition of sunflower seeds, F. W. MORSE (*New Hampshire Sta. Bul. 79, pp. 7, 8*).—The specific gravity of sunflower seeds, relative amounts of meats and hulls, as well as the composition of both black and striped whole seeds, meats, and hulls are reported.

Composition of some poultry foods, F. W. MORSE (*New Hampshire Sta. Bul. 79, pp. 8, 9*).—Analyses of meat and bone meal, beef scraps, ground dried fish, broken crackers, middlings, and several commercial poultry feeds are reported.

The composition of purslane (Portulaca oleracea), J. B. LINDSEY (*Massachusetts Sta. Rpt. 1900, pp. 52, 53*).—The composition of purslane is reported and the uses of the plant briefly discussed.

Grape prunings as a feeding stuff for farm animals, F. GUERRIERI (*Staz. Sper. Agr. Ital., 34 (1901), No. 4, pp. 338–346*).—The author reports proximate and ash analyses of grape prunings, hay, and straw.

Breadnut (*Bul. Bot. Dept. Jamaica, n. ser., 8 (1901), No. 3, p. 42*).—It is stated that the fruit or "nut" of the breadnut (*Brosimum alicastrum*) is largely used for feeding cattle, as are also the leaves, which constitute a valuable fodder for horses and cattle. The tree also yields excellent timber.

The respiratory quotient and overfeeding of fat, M. BLEIBTREU (*Arch. Physiol. [Pflüger], 85 (1901), No. 7–8, pp. 345–400, figs. 2, pl. 1*).—With a view to obtaining data on the different sorts of animal fats, experiments were made with geese. They were overfed with ground rye mush, to which, in some cases, sugar was added. A respiration apparatus, which is described, was used to determine the respiratory quotient in connection with these investigations. The author sums up the results as follows: When full-grown lean geese are fed much more than they require of a ration rich in carbohydrates, the respiratory quotient becomes much greater than normal. The high value is caused by an increase in the amount of carbon dioxid excreted and not by a decrease in the amount of oxygen consumed. A respiratory quotient exceeding the unit value, namely, that corresponding to the combustion of body substance, shows that the transformation of carbohydrates into fat in the animal body is accompanied by a cleavage of carbon dioxid. Even when the process of digestion is most active the geese overfed with rye did not excrete any inflammable gases so far as could be determined. The milk-white color of blood serum which has often been observed in overfed geese is due to an emulsion of fat in which the drops are very minute. This condition disappears if the animal fasts for a few days, and does not occur if the animal is fed fat-free food rich in carbohydrates. It is probable, therefore, that the fat in the serum is derived from fat in the food consumed and not from newly formed body fat.

Further experiments on the resorption of artificially colored fat, E. PFLÜGER (*Arch. Physiol. [Pflüger], 85 (1901), No. 1–3, pp. 1–64*).—Additional experiments are reported and the recent work on the subject of the resorption of colored fat is critically reviewed.

Remarks on Dr. L. Holfbauer's article concerning the resorption of artificially colored fat, S. EXNER (*Arch. Physiol. [Pflüger], 84 (1901), No. 11–12, pp. 628–635, fig. 1*).—A controversial article.

The resorption of fat and soap in the large and the small intestine, H. J. HAMBURGER (*Proc. Sec. Sci. Koninkl. Akad. Wetensch. Amsterdam, 1900, II, pp. 287–298*).—Experiments with a dog are reported.

A note on the question of the digestibility of cellulose in the intestines, E. MÜLLER (*Arch. Physiol. [Pflüger], 83 (1901), No. 10–12, pp. 619–627*).—Experiments were made with the enzym of the *hepato pancreas* of a carp and also with a goat having 2 fistulas. According to the author the tests showed that with the goat sugar is not formed as an intermediate product when cellulose is rendered soluble in the intestine.

Corn vs. peas for fattening steers, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, p. 46*).—The comparative value of peas and corn as part of a ration was studied. Six steers fed corn, barley, and oats (1:1:1) for 36 days and then corn and oats (3:1) for 151 days, gained 341.5 lbs., consuming 4.73 lbs. of grain per pound of gain. Five steers fed peas, barley, and oats (1:1:1) for 36 days and then peas and oats (3:1) for 151 days, gained 348.6 lbs., consuming 4.64 lbs. of grain per pound of gain.

The meal mixture containing peas gave slightly larger gains than that containing corn; but when the relative cost per ton of corn and peas was taken into account the corn mixture gave decidedly cheaper gains. In this one test the pea mixture was not worth quite 50 cts. per ton more than the corn mixture, whereas the actual cost of the pea mixture was between $2 and $3 per ton more than the corn mixture.

Heavy, medium, and light rations for fattening steers, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 45, 46*).—Using 3 lots of 4 steers each, the comparative value of heavy, medium, and light grain rations was tested, in continuation of previous work (E. S. R., 12, p. 372), the feeding test proper covering 187 days. The average amount of grain consumed per 100 lbs. live weight by the steers receiving a heavy ration was 0.85 lb. per day; of those receiving a medium ration, 0.66 lb.; and of those receiving a light ration, 0.51 lb. The average daily gain per steer in the 3 lots was 1.80, 1.87, and 1.87 lbs., respectively, the cost of food per pound of gain being 7.67, 6.97, and 6.36 cts. From this and earlier tests a number of conclusions are drawn:

"In the average of 4 trials, a comparatively heavy meal ration gave slightly larger but more expensive gains than those obtained with lighter rations.

"In the average of 4 trials, the most economical gains were obtained by commencing with about one-third of a pound of meal per day per 100 lbs. live weight of the animals, and gradually increasing, the rate of increase being such that on the average of the whole feeding period the steers received ½ lb. of meal per day per 100 lbs. of their live weight. A finished steer is fed at a loss; therefore, in economical feeding, an effort must be made not to have the animals finished for any considerable time before they can be disposed of.

"The method of feeding recommended is suitable for somewhat long feeding periods. Shorter feeding periods would call for a more rapid increase in the meal ration."

Experiments in breeding fat lambs (*Jour. Bd. Agr. [London], 7 (1901), No. 4, pp. 482, 483*).—A test of the comparative merits of crosses of "Lleyn" ewes with Shropshire, Oxford, Suffolk, and Border Leicester rams showed that from the standpoint of early maturity of the lambs the best results were obtained with the Suffolk and Border Leicester crosses.

Digestion of oat and pea bran by sheep, A. E. SHUTTLEWORTH (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 32–34*).—Two sorts of oat dust and pea bran were analyzed and their digestibility determined with 3 sheep. The average coefficients of digestibility of the 2 materials follow:

Coefficients of digestibility of oat dust and pea bran—Experiments with sheep.

	Organic matter.	Protein.	Fat.	Nitrogen-free extract.	Crude fiber.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Oat dust; average of 6 determinations	60.86	68.15	79.01	69.51	33.48
Pea bran; average of 5 determinations	70.78	67.53	78.40	76.77	68.98

Digestion experiments with sheep, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1900, pp. 50-51*).—The digestibility of a number of feeding stuffs was tested with sheep. These include hay (largely June grasses), meadow fescue, Kentucky tall oat grass, distillery grains (5 sorts), oat feed, rye feed, Cleveland flax meal, and Parsons's Six-Dollar feed. A number of the coefficients of digestibility follow:

Digestibility of a number of feeding stuffs by sheep.

Kind of feed stuff.	Dry matter.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Hay, largely June grass in bloom (*Poa pratensis*)	59	61	47	62	57	48
Meadow fescue, full bloom (*Festuca elatior pratensis*)	61	52	54	59	67	46
Kentucky blue grass, full bloom (*Poa pratensis*)	56	57	42	53	63	42
Tall oat grass, late bloom (*Arrhenatherum elatius*)	55	51	56	58	55	41
Oat feed (large amount hulls)	34	62	92	33	27	13
Rye feed	82	80	90	88	(?)	35
Chop feed	80	67	82	84	82	....
Cleveland flax meal	87	83	76	94	(?)	21
Parsons's Six-Dollar feed	56	57	81	64	47	12

Experiments with pure-bred swine, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 47, 48, figs. 2*).—Continuing previous work (E. S. R., 12, p. 374), the relative gains made by different breeds of pigs was tested. Three animals in each lot were fed corn and 3 barley. The test covered some 4 months. The greatest gain, 0.93 lb. per pig per day, was made by the Yorkshire, and the least, 6.42 lbs., by the Tamworths. The Berkshires required the least meal per pound of gain, namely, 4.09 lbs., being followed by the other breeds in the order mentioned: Yorkshire, Duroc Jersey, Chester White, Tamworth, and Poland China, the latter requiring 4.74 lbs. The pigs were sold for export, their suitability for this purpose being judged by an expert. The Yorkshires were reported as the most suitable for the purpose.

Corn vs. barley for feeding hogs, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 48, 49*).—The comparative merits of corn and barley in the above test are discussed at some length. Each of these grains was fed with wheat middlings, at first in the proportion of 3:1, and later 1:1 and 1:3. Owing to the fact that 3 each of the Chester Whites and Tamworths were not in good condition, the results obtained with these breeds are not included. In 140 days the average daily gain by 12 pigs on corn and middlings was 0.817 lb., the meal consumed per pound of gain being 0.432 lb. The average daily gain per pig of 12 pigs fed on barley and middlings for the same period was 0.841 lb., and the meal consumed per pound of gain was 0.43 lb.

"In this experiment, therefore, the mixture of barley and middlings gave slightly better results in producing gain in weight than the mixture of corn and middlings. The difference, however, is very small, and the two foods might almost be pronounced equal in feeding value so far as this experiment goes."

Experiments with grade swine, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, p. 50*).—The comparative value of barley alone and in combination was tested with 5 lots of 5 pigs each, the special object being to determine the effect of barley upon the firmness of bacon. The test covered 120 days. On barley alone the average daily gain per pig was 0.789 lb., and the meal consumed per pound of gain, 4.58 lbs. On barley and corn (1:1), the corresponding amounts were 0.762 and 4.78 lbs.; and on barley and oats (1:1), 0.645 and 5.26 lbs. On barley and cooked mangel-wurzels (1:1) the daily gain per pig was 0.850, the meal and roots consumed per pound of gain being 3.97 and 3.61 lbs., respectively. On barley and raw mangel-wurzels the average daily gain was 0.807 and the meal and roots consumed per pound of gain 4.23 and 3.74 lbs., respectively.

"Barley alone gave larger gains than when combined with either oats or corn.

"Barley and roots gave larger gains than barley alone.

"Cooked roots gave much better results than raw roots, but it is very probable that the individuality of the animals had more to do with causing this difference than the cooking of the roots.

"In the case of cooked roots, 1 lb. of grain proved equivalent to 5.9 lbs. of roots. This is not nearly so high a value as many people place upon roots for feeding hogs; but it corresponds very closely with the results of extensive Danish experiments.

"A short experiment conducted under my direction by Mr. A. H. Crerar as a basis for his third year thesis, indicated that a pound of mixed grain is equivalent to 5.78 lbs. of raw roots. This is almost identical with the relation between cooked roots and barley stated above, and indicates that the comparison of cooked and raw roots is scarcely reliable.

"Further experiments with roots are in progress, and it is too soon to draw conclusions."

Wet vs. dry meal, G. E. Day (*Ontario Agr. and Expt. Farm Rpt. 1900, pp. 50, 51*).—A comparison was made of the relative merits of wet and dry meal as a feed for pigs with 2 lots of 4 animals each. In 7 weeks lot 1 fed wet wheat and barley meal made an average daily gain per pig of 0.957 lb. and consumed 4.89 lbs. of meal per pound of gain. On the same grains dry there was an average daily gain per pig of 1.037 lbs., the grain consumed per pound of gain being 4.52 lbs.

Influence of food upon firmness of bacon, G. E. Day (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 52, 53*).—Using the data obtained in the feeding experiments reported above, the author discusses the influence of food upon the firmness of bacon. The principal deductions follow:

"Hogs which have had plenty of exercise and a mixed diet, or that have received a reasonable allowance of dairy by-products and a mixed grain ration, until they are over 100 lbs. live weight, can be finished on corn without injury to the quality of bacon.

"Close confinement in pens from birth to time of marketing has a tendency to injure the quality of bacon, though the effect is not always well marked. The rational use of dairy by-products tends to produce bacon of excellent quality and seems to compensate largely for lack of exercise.

"Unthrifty, unfinished hogs, or those which have been kept on a mere maintenance ration to keep them from becoming too heavy while holding for a rise in prices or other reason, have a marked tendency to softness. Exclusive corn feeding during a somewhat extended period has given very unsatisfactory gains and has produced bacon of very soft, undesirable quality. The mixing of middlings with corn to the extent of two-thirds of the ration at the commencement and one-third at the close of the feeding period has not been successful in counteracting the bad effects of corn, the bacon thus produced being soft and generally undesirable. Barley, to the extent of at least half the ration, seems so have an influence in mitigating the effect of corn, but further investigation is necessary along this line. Barley, either alone or in conjunction with oats or middlings, has produced bacon of first-class quality. Peas appear to have an influence similar to barley. So far as our work has gone, roots have had no injurious effect upon the firmness of bacon, but they are being made the subject of further investigation."

Poultry experiments, W. P. Brooks and H. M. Thomson (*Massachusetts Sta. Rpt. 1900, pp. 123–129*).—With a view to testing the comparative merits of feeding a mash to poultry in the morning and in the evening, tests were made in both winter and summer with Plymouth Rocks. Two lots, each containing 20 pullets and 2 cocks, were used in each trial. In addition to the mash the fowls were fed meat scraps, and in the winter cabbage and clover also. In the winter test the fowls fed a mash in the morning laid 793 eggs in 6 months; those fed a mash in the evening laid 758 eggs.

In the summer test the fowls fed a mash in the morning laid 583 eggs in 5 months; those fed a mash in the evening, 570 eggs. The weights of the poultry at the beginning and end of the test are reported.

"It will be seen that neither in the winter nor summer experiment was there any very considerable difference in the number of eggs produced. It is, however, possibly significant, and this fact is made evident by the tables showing monthly egg yields, that during the period of shortest days the fowls receiving the evening mash laid less eggs than the others.

"The most striking result of the experiments is the great difference in the relative amounts of droppings voided during the night by the fowls under the two systems of feeding. It was noticed from the beginning, and the same remained true throughout the entire period, that the amount of droppings voided during the night by the fowls receiving the evening mash was very much greater than the amount voided by the other lot of fowls. . . .

"[This] furnishes conclusive evidence that the digestive process in the case of a soft food like a mash is very rapid. The fact that digestion among birds is relatively much more rapid than with most classes of animals has been already many times pointed out. . . .

"Our experiments indicate that the ordinary domestic fowl, as might have been supposed would be the case, is also able to digest soft foods with a degree of rapidity which seems astonishing. There has long been a general impression, and the usual practice in feeding fowls is evidence of this, that it is better to give the more solid food at night, especially during the winter, since it will 'stay by' the fowls better. Our experiments indicate that this impression is well founded and that the usual practice is correct, although they can not be considered to prove it, because, of course, it may be that a period of comparative rest for the digestive organs during the night is better than the condition of more continuous work for these organs which would follow the use of solid food at night.

"We have not obtained a sufficient difference in egg-production to be considered significant, but it is believed that the experiment, so far as it goes, indicates that it is better that the mash should be fed in the morning."

Report of the manager of the poultry department, W. R. GRAHAM (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 126–135, fig. 1*).—The rations fed and eggs produced by the station poultry during the year are discussed, as well as the proportion of eggs hatched by incubators and by hens. Brief statements are also made concerning raising broilers and ducks, and 3 feeding experiments are reported in detail.

In the first test rations consisting of ground barley, corn, oats, and buckwheat meal, alone and in combination, were compared on 8 lots of 12 chickens each, the grain in some cases being finely ground and in others coarsely ground. In 3 weeks the greatest gain, 12 lbs., was made by lot 4 on a ration of finely ground oats, corn meal, and pea meal (2 : 1 : 1), the cost of food per pound of gain being 5.15 cts. The smallest gain, 5 lbs., was made by lots 5 and 8, the rations consisting, respectively, of finely ground corn and ordinary ground oats. In these cases the cost of food per pound of gain was 8.2 and 8.3 cts., respectively.

In the second test the comparative merits of pure-bred and scrub stock were studied with 8 lots, each consisting of 6 pure-bred chickens and 6 scrubs. For 2 weeks they were fed a ration made up of barley, oats, corn, and buckwheat, alone and in combination, and coarsely and finely ground. In every case milk was fed, and in one case, lot 8, potatoes were fed in addition. For the remainder of the test they were fed, by means of a cramming machine, a ration of finely ground oats and ground buckwheat (2 : 1), mixed with twice their weight of skim milk. In each instance the greater gains were made by the pure-bred stock, the differences in their favor ranging from 5 to 8.8 lbs. Furthermore, the gain was more cheaply made by the pure-bred stock. Considering the lots as a whole, the greatest gain, 48 lbs., was made by lot 3, fed coarsely ground corn, ground buckwheat, and finely ground oats (2 : 2 : 1), and the smallest gain, 28 lbs., by lot 2, on a ration consisting of finely ground oats, coarsely ground corn meal, and ground wheat (2 : 2 : 1). As regards financial returns the gains were made most cheaply by lot 1 on a ration of ground barley, finely ground oats, and coarsely ground corn (2 : 2 : 1), the cost being 3.88 cts. per pound. Gains were made least cheaply by lot 2, the cost being 5.8 cts. per pound.

The comparative merits of cramming and natural feeding was tested with 2 lots of about 25 chickens each. Both lots were fed grain and milk. In 10 days the chickens fed from a trough consumed 40 lbs. of grain and an equal amount of milk. They gained 5 lbs., the cost of a pound of gain being 10.2 cts. In the same time the chickens fed by the cramming machine consumed 50 lbs. of grain and 100 lbs. of milk and made a total gain of 7.5 lbs., the cost per pound of gain being 9.33 cts. On an average it was found that the machine-fed chickens were each about a half pound heavier than the others and sold for about 0.75 ct. per pound more.

Egg preservation.—During the year a number of methods of preserving eggs were tested. When preserved in a solution of water glass made in the proportion of 1 part sodium silicate to 5 of water, the eggs were of fairly good flavor and all well preserved. In a solution made in the proportion of 1 part of water glass to 8 of water, the eggs kept nearly as well as in the stronger solution. This is regarded as a good preservative when it is desired to keep summer eggs for winter use. When a solution consisting of 1 part of water glass to 10 of water was used the eggs did not keep as well. A second test was made with a solution of 1 part water glass to 8 of water, "but in place of allowing the eggs to remain in the liquid, they were removed after having been in it for a week, except the last lot which was put into the solution. This lot was allowed to remain the remainder of the season.

"(*a*) The eggs, after being in the solution for a week, were removed and placed in an ordinary egg case in the cellar. They were all good when tested, but had evaporated considerably and were lacking in flavor.

"(*b*) These were the second lot of eggs to be placed in the liquid. They were handled similarly to those in *a*, and were of about equal quality.

"(*c*) These eggs were allowed to remain in the liquid. They were well preserved, all being good."

As a whole these eggs did not keep quite as well as those which remained in the 1 : 8 solution, but were superior to those kept in the weaker solution.

Eggs were also preserved in a solution of limewater and salt and in dry lime and dry salt. The first of these methods gave fairly satisfactory results; the last 2 were unsatisfactory.

Capons and caponizing, O. M. WATSON (*South Carolina Sta. Bul. 62, pp. 10, pls. 2*).—The superior market value of capons is pointed out, and the method of caponizing described. According to the author, "capons are very useful in taking care of broods of young chickens. They take them without any trouble, and care for them just as well and we think better than a hen."

DAIRY FARMING—DAIRYING.

Report of the professor of dairying, H. H. DEAN (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 37–44*).—An account is given of the different lines of investigation conducted during the year.

Milk was pasteurized at temperatures ranging from 140 to 200° F. and compared for butter-making purposes with milk heated at 90 to 100° F. before separation. Some of the results are as follows:

"The cream from the milk separated at the higher temperatures contained a higher percentage of fat, was less in bulk, churned in less time, and produced slightly more butter. . . . The creaming quality of the milk by the gravity process decreased with an increased temperature before setting. . . . The keeping quality of the butter, and also of the skim milk, was much improved by heating the whole milk to the higher temperature before separating. . . . The moisture content of the pasteurized butter was 10.77 per cent, 1 per cent less than that of butter made from unpasteurized milk."

The effect of various methods of handling butter upon the moisture content was studied, some of the results being inconclusive. Butter salted at the rate of $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, and 1 oz. of salt per pound of butter contained, respectively, 11.29, 10.47, 9.80, and 9.47 per cent of moisture, while unsalted butter contained 12.38 per cent. Butter worked with 20 revolutions of the worker contained 12.34 per cent of moisture, while that worked with 30 revolutions contained 9.43 per cent.

The overrun or excess of butter over fat in milk averaged 12.6 per cent during August with milk testing 3.4 to 3.8 per cent of fat, and 13.1 per cent during September with milk testing 3.6 to 3.9 per cent of fat.

Results of experiments in washing curd are summarized as follows: "Washing curds after milling tends to improve the flavor of cheese, especially of cheese made from curds bad in flavor. Cheese made from washed curds had a tendency to be open. There was little difference in the general quality of the cheese made from washed and unwashed curds when the milk was in good condition. Washing curds tends to reduce the yield of cheese. The average loss in our experiments was 1.12 lbs. of cured cheese per 1,000 lbs. of milk. There was not much difference in the results from washing with water at temperatures ranging from 90 to 110°. The average loss of cheese was somewhat less from washing with water at 90°, but the quality of the cheese was better with water at 110°."

Experiments in curing cheese at different temperatures gave results similar to those obtained in earlier work along this line (E. S. R., 12, p. 385). Cheese cured at 60 to 65° lost about 0.5 per cent less in weight than cheese cured at 70° and was of better quality. There was apparently no advantage in placing cheese in a warm room for one week and then removing to a cool room to finish the curing process.

Methods of caring for milk used in cheese making were investigated. Aeration was of no advantage. Where no means of cooling were employed, milk kept better over night in small than in large cans. A comparison was made of adding culture to milk at night and in the morning. When the milk was cooled to 46°, adding culture in the evening decidedly improved the quality of the cheese. Milk cooled to 48° over night and to which no culture was added produced cheese of very poor quality. Several different cultures were tested.

Rations containing, respectively, apples, apple pomace, rape, and turnip tops, with and without the addition of a material known as "Virginia cattle food" and sold for "purifying" milk, were fed to different lots of cows and butter and cheese were made from their milk. The results indicated that "the addition of 'Virginia cattle food' to the ration of rape and turnip tops improved to some extent the flavor of both cheese and butter, but in the case of apples and apple pomace no improvement was discernible."

Data are given regarding the composition of colostrum milk from 3 cows. The content of fat and total solids varied greatly. "Colostrum milk does not become normal, in many cases, so soon as is usually supposed. It is probable that instead of the eighth or ninth milking being fit for table use, in the case of some cows it is the twenty-first milking before it is normal."

Two tests were made of a substitute for cream as a food for calves. The results indicated that bran and oats fed dry were better and cheaper substitutes for cream than the one tested.

A tabulated record is given of 23 cows for the year, with a summary of the principal data. The average yield of milk was 7,179 lbs. and the average fat content 3.87 per cent.

Effect of feed on the composition of milk, butter fat, and on the consistency or body of butter, J. B. LINDSEY ET AL. (*Massachusetts Sta. Rpt. 1900, pp. 14–33*).—This is a summarized account of experiments relative to the effect of food on the quality of milk and butter, conducted at the station during a period of 6 years. The conditions of the different experiments are noted and some of the results are given in tables. Full data for the work, however, are to be published later. The effect of different quantities of protein on the composition of milk was studied in earlier work (E. S. R., 11, p. 577). The effect of fat on the composition of milk was studied in 3 experiments, 2 of which were considered as preliminary. In the third experiment, made with 10 cows and covering 16 weeks, a ration furnishing 0.5 lb. of digestible fat was compared with a ration furnishing 1.75 lbs. The effect of this ration on the composition of the butter fat and on the character of the butter was also noted. Experiments IV and V were made with 12 cows and lasted 5 weeks. Experiment VI was made with 10 cows and lasted 12 weeks. In the 3 experiments rations containing Cleveland flax meal, Chicago gluten meal, King gluten meal, and cotton-seed meal, respectively, were compared with a grain ration adopted as a standard, the effect of the different concentrated feeds on the butter fat and butter being studied. The following deductions are made from the results of the experiments:

"(1) Different amounts of protein do not seem to have any influence on the composition of the milk.

"(2) Linseed oil in flax-seed meal, when fed in considerable quantities (1.4 lbs. digestible oil daily), increased the fat percentage and decreased the nitrogenous matter of the milk. This fat increase was only temporary, the milk gradually returning (in 4 or 5 weeks) to its normal fat content. The nitrogenous matter also gradually returned to normal, but more slowly than the fat.

"(3) In general, feeds containing much oil have a tendency to slightly increase the fat content of milk when first fed. The fat percentage gradually returns to normal.

"(4) It is not practicable to feed large amounts of oil to cows, as it has a tendency to derange the digestive and milk-secreting organs.

"(5) Linseed oil effected a noticeable change in the composition of the butter fat, causing a decrease in the volatile acids and an increase in the melting point and iodin coefficient.

"(6) All oils do not produce the same effects on butter fat.

"(7) The melting point of butter fat is not always indicative of the firmness or body of butter.

"(8) An excess of linseed oil produced a soft, salvy butter, with an inferior flavor.

"(9) Linseed and corn gluten meals, with a minimum percentage of oil (3 per cent), produced a normal butter fat. The corn gluten meal produced butter with a desirable flavor and of good body.

"(10) King gluten meal (corn gluten meal with 13 per cent oil) increased the iodin coefficient of the butter fat several degrees above standard ration butter fat, and slightly depressed the melting point of the fat. This effect was probably due to the corn oil. The same meal produced butter of a very desirable flavor and body. [The author notes, however, that the body of the butter might have been considered by some as lacking in firmness.]

"(11) Cotton-seed meal produced butter fat quite similar in composition to that produced by the standard ration. The butter produced by this meal was rather crumbly when hard, and slightly salvy to the taste."

The college herd, C. W. BURKETT (*New Hampshire Sta. Bul. 79, pp. 23, 24*).—A tabulated summary of the herd record from November 1, 1899, to October 31, 1900. "The herd has been equivalent to 349 milch cows and 64 dry cows for one month, and has produced 171,883 lbs. of milk and 10,219 lbs. of butter. There has been an average of 29 cows in milk for each month, producing an average of 495 lbs. of milk and 28.6 lbs. of butter per cow, or an average yearly yield of 5,940 lbs. of milk and 343.2 lbs. of butter."

The milk supply of Copenhagen, F. C. HARRISON (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 74-77, fig. 1*).—An account is given of the operations of the company supplying milk to Copenhagen. The filtering apparatus in use is illustrated.

A biological study of pasteurized and unpasteurized milk, E. W. HAMMOND (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 77-81*).—Results of a study of the bacterial content of unpasteurized milk and milk pasteurized at different temperatures are summarized in tables. Different species of germs were isolated and inoculated into sterile milk and into guinea pigs or rabbits, the results of the inoculation being noted in each case. The author's conclusions are as follows:

"When the milk was run through the pasteurizing machine at low temperature, the effectiveness of germ destruction varied greatly. When the temperature was raised to 160° F., the effect was excellent. The number of germs was reduced, and those of a disease-producing variety were all killed. . . . Previous tests prove that continuous pasteurization has been made at too low temperatures to insure the getting rid of the germs which cause bad effects. Heating milk to a temperature of 160° F. insures the death of *Bacillus tuberculosis* in 15 minutes, reduces the number of other bacteria, and does not give a permanent cooked taste."

A study of the causes of the variation in the composition of butter, J. J. L. VAN RYN (*Landw. Vers. Stat., 55 (1901), No. 4-5, pp. 347-378*).—Owing to the controversy over the purity of certain Netherland butters during the past year, the author sought to determine those factors influencing the variations in their composition. In a long series of trials the breed, age, and time of calving of the cows were noted, and the soil, food, and method of feeding. Tables of analysis are shown, giving the refraction, specific gravity, volatile, soluble, and insoluble fatty acids and saponification and iodin numbers.

As the variations in the butter are more pronounced in the autumn the analyses were made during the last 4 months of the year. The greatest variation occurred in the volatile fatty acids; the numbers averaged by months as follows: September, 24.8; October, 23.7; November, 25.2; and December, 26.6.

Out of 428 samples, 2.3 per cent of the volatile-acid figures ranged between 17 and 21, and 6.5 per cent between 21 and 21.9.

The iodin number did not vary with the volatile fatty acid number, and there appeared to be no constant relation between the two numbers. With an increase in the volatile-acid number there was a fall in the refractometer figure.

The influence of the various factors noted upon the composition of the butter is discussed, the work of other authorities is quoted, and the influence of stall feeding is especially pointed out. In conclusion, the author states that the composition of the butter is determined by outside influences, and that care should be exercised in pronouncing a given sample adulterated.

The manipulation of sour and thickened whole milk and the partial removal of the milk foam, HAMILTON (*Molk. Ztg., 15 (1901), No. 21, pp. 361, 362, fig. 1*).—The author describes a method for neutralizing sour coagulated milk, thereby permitting the manufacture of a good article of butter. The solution for this purpose is made up of slaked lime and soda, full directions being given for its preparation. About 11 per cent of soda is added to water and enough of the lime so that a clear solution may be obtained. The amount of the solution used depends upon the acidity of the milk and the alkalinity of the soda solution. To facilitate the operation where the milk is much thickened, it is forced through a strainer and sweet milk is added. The method of adding the solution to the milk is figured and described. The milk is thoroughly stirred during the addition, litmus paper being used as an indicator.

The addition of this solution to milk that is to be sold as such is not advised, it being clearly an adulteration. With butter it is different, as the soda solution and the acid form salts that are easily eliminated from the product in butter making, passing into the buttermilk and leaving no undesirable taste in the butter. Furthermore, they do not form products any more harmful than the ordinary salt employed. In neutralizing such milk certain undesirable flavors are eliminated. Neutralized milk may be pasteurized, thereby destroying many bacteria that have an undesirable influence, and the cream inoculated with pure cultures. The neutralized milk is easily and thoroughly creamed after heating to 45° C. When the milk contains free acid, much foam is formed in separating. This is obviated by the neutralizing. The curds from neutralized milk may be made into cheese and ripened in the ordinary manner.

Influence of the addition of boric acid, borax, and sodium sulphite upon the coagulation of milk, L. Lange (*Arch. Hyg., 40 (1901), No. 2, pp. 181–186*).—The author made a study of the spontaneous coagulation and the coagulation by rennet of milk to which had been added boric acid, borax, and sodium sulphite. The varying amounts of the preservatives were added to 10 cc. of the milk and the coagulation carried out in sterilized tubes at room temperature.

The addition of boric acid to the milk gave the following results with spontaneous coagulation:

	Days.
Control coagulated in	2½
With ⅛ per cent boric acid in	3
With ¼ per cent boric acid in	4
With ½ per cent boric acid in	5½
With 1 per cent boric acid in	7
With 2 per cent boric acid	Did not coagulate.
With 4 per cent boric acid	Did not coagulate.

The time required for coagulating the milk after the addition of 0.1 cc. of a 1 per cent rennet solution is shown in the following table. The first column shows the result soon after the addition of the boric acid, and the second column 2 days later.

Coagulaion of preserved milk by rennet.

Strength of preservative.	Fresh milk.	Milk preserved two days.
	Seconds.	*Seconds.*
No preservative	165	80
⅛ per cent boric acid	125	345
¼ per cent boric acid	100	255
½ per cent boric acid	70	240
1 per cent boric acid	45	150
2 per cent boric acid	30	125
4 per cent boric acid	(a)	....

a Did not coagulate.

It will be observed that in spontaneous coagulation the process was hindered, and with above 2 per cent of boric acid no coagulation took place. With the rennet extract the time of coagulation was shortened by the use of up to 2 per cent, while with 4 per cent, as with spontaneous coagulation, no action of the rennet was possible. It would appear that the boric acid in small amounts had a deterrent effect upon the bacteria concerned in the natural coagulation of milk, while up to 2 per cent it had no unfavorable effect upon the unorganized ferment of the rennet.

With borax the results were not so striking. There was with the increased addition of this substance a slight retardation of the rennet coagulation.

The addition of from ⅛ to 1 per cent of sodium sulphite exercised no essential influence upon the coagulation of rennet; nor was the natural coagulation apparently affected by it.

The action of certain proteolytic enzyms in the ripening of cheese, O. Jensen (*Ann. Agr. Suisse, 2 (1901), No. 3, pp. 95–100*).—In the continuation of his work on the ripening of cheese (E. S. R., 12, p. 682) the author made a study of the influence of the enzyms galactase, pepsin, and trypsin in Emmenthaler cheese. Ten liters of milk was used in the manufacture of each cheese, and with the samples indicated it was heated to 90° C. and rapidly cooled to 35° C.

The cheeses were examined after 4 months, the results being reported in tables showing the soluble nitrogen, the nitrogen of decomposition of albuminoid bodies in percentages of total nitrogen, the acidity, milk sugar, taste, and the result of a bacteriological examination.

In the experiment with galactase 200 cc. of the enzym obtained by the method of Babcock and Russell was added to the milk for each cheese, together with the rennet and a small amount of calcium chlorid. The results are shown in the following table:

Influence of galactase in ripening cheese.

	In total nitrogen.		Acidity.	Bacteriological examination.
	Soluble nitrogen.	Nitrogen of decomposition.		
	Per cent.	*Per cent.*		
A. Control made from heated milk with artificial rennet.	4.95	0.83	0.3	Only *Bacillus mesentericus*, 200,000 per gm.
B. Made from heated milk with artificial rennet and galactase.	7.25	1.48	1.3	*Bact. lact. acidi*, *B.* ∝, and some colonies of *B. mesentericus*.
C. Control made from milk not heated and with natural rennet.	17.52	3.59	1.2	*Bact. lact. acidi* and *B.* ∝.
D. Made from heated milk with natural rennet and the addition of galactase.	4.07	2.44	1.3	Do.

A second series of experiments was carried out with pepsin, using 25 gm. of a commercial preparation per 100 liters of milk. The examination of the cheeses was made after 4 months, as in the previous case. The results are shown in the following table:

Influence of pepsin in ripening cheese.

	In total nitrogen.		Acidity.	Bacteriological examination.
	Soluble nitrogen.	Nitrogen of decomposition.		
	Per cent.	*Per cent.*		
E. Control made from heated milk and natural rennet.	13.18	3.55	1.2	*Bact. lact. acidi.*
F. Made from heated milk with natural rennet and the addition of pepsin.	12.71	1.93	0.8	Do.
G. Control made from heated milk with artificial rennet and the addition of lactic ferments.	4.96	2.40	1.5	*Bact. lact. acidi* and *B.* ∝.
H. Made from heated milk with artificial rennet and the addition of lactic ferments and of pepsin.	8.57	1.56	1.2	Do.

A later series of experiments was carried out using 25 gm. of a commercial preparation of trypsin per 100 liters of milk. The action upon cheese made from milk not heated was very pronounced. The results are shown in the following table:

Influence of trypsin in ripening cheese.

	In total nitrogen.		Acidity.	Bacteriological examination.
	Soluble nitrogen.	Nitrogen of decomposition.		
	Per cent.	*Per cent.*		
Control	18.62	8.60	1.3	*Bact. lact. acidi*, *B.* ∝, and *B.* ε.
With the addition of trypsin	44.69	13.94	1.8	Do.

In another experiment in which 1 gm. of trypsin was used in 100 liters of milk the cheese made did not exhibit any difference from the control. It appears that so small an amount of trypsin in the cheese is without influence in the ripening, while 25 gm. per 100 liters, as in the previous experiment, is too much, causing a bitter taste.

It was found that with cheese heated only slightly the addition of pepsin hastened the ripening, as pointed out by Babcock and Russell. The following table shows the results after 4 months with skim-milk cheese heated to only 38° C.:

Influence of pepsin in ripening cheese.

	In total nitrogen.	
	Soluble nitrogen.	Nitrogen of decomposition.
	Per cent.	*Per cent.*
Control	37.29	2.41
With the addition of pepsin	48.57	2.85

A number of speculations are made, but the results are not of sufficient number or uniformity to draw definite conclusions. The most marked indication is that of the much more intense action of trypsin over that of galactase and pepsin.

Assistance offered to cheese factories and creameries in Ontario, F. C. Harrison (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 70–72*).—Brief notes are given on a number of troubles in cheese factories and creameries due to bacterial infection, and assistance in investigating any such troubles in the Province is offered by the bacteriological department.

VETERINARY SCIENCE AND PRACTICE.

The lymph after intravenous injection of tetanus toxin and tetanus antitoxin, F. Ransom (*Ztschr. Physiol. Chem., 29 (1900), No. 4–5, pp. 349–372*).—The chief object of the author's investigation was to determine the agency of lymph in distributing tetanus toxin and tetanus antitoxin throughout the organism. As experimental animals dogs were chosen, since the thoracic duct could be readily exposed in these animals and the lymph allowed to flow out into receptacles through a canula. Before being operated upon the dogs were treated with morphin and anæsthetized. They were kept in this condition during the experimental period. The lymph was received in glass vessels from the thoracic duct, and the length of time after inoculation was noted. The blood which was studied was taken from the femoral artery. For determining the strength of toxin and antitoxin as found in the lymph or blood, inoculation tests were made with mice. The results of the author's experiments may be summarized as follows: After the tetanus toxin is injected into the blood circulation, a considerable portion of it rapidly passes into the lymph. If the blood and lymph systems are left intact, the toxin is found equally distributed in the blood and lymph 26 hours after injection. If the thoracic duct is opened shortly before the intravenous injection, the toxin content of the blood remains considerably greater than that of the lymph for 6 hours after injection. After injection of tetanus antitoxin (horse serum) into the blood, this substance rapidly finds its way into the lymph. If the thoracic duct is opened, the blood contains more antitoxin than the lymph for a period of at least 6 hours. If the thoracic duct is intact, the antitoxin does not become equally distributed in the blood and lymph after a period of 68 hours, the blood containing during this time considerably more antitoxin than the lymph. No noteworthy changes take place in the toxin or antitoxin while remaining in the blood or in the lymph. The tetanus toxin in the blood circulation behaves like normal inorganic constituents of the blood in so far as it rapidly diffuses itself throughout the organism. The tetanus antitoxin, on the other hand, behaves more nearly like the proteid materials of the blood.

Demonstration of the tetanus bacillus in decomposing bodies of animals killed by tetanus inoculation, W. Rohardt (*Hyg. Rundschau, 10 (1900), No. 8, pp. 376–381*).—The author inoculated guinea pigs and mice with soil containing tetanus spores. After the death of the experimental animals the bodies were placed in dry glass vessels and maintained at a temperature of 5° C. The results of microscopic investigation of these bodies at varying periods after death are stated in a tabular form. In a majority of cases tetanus bacilli were demonstrable either at the point of inoculation or in other tissues of the body. The pin-shaped bacilli were found for a period of 5 weeks after the death of the animals.

Annual report of the Board of Cattle Commissioners, A. Peters, L. F. Herrick, and C. A. Dennen (*Massachusetts State Bd. Cattle Com. Rpt. 1900, pp. 90*).—The chief source of expense was found in the payment of indemnities for tuberculous cattle. The management of the disease by the cattle commissioners falls under the heads of quarantine regulations and testing the entire herd at the request of the owners. A detailed discussion is given of obstacles met with in enforcing the regulations concerning the tuberculin test in interstate cattle traffic. It is stated that numerous specific cases of dishonesty in this matter were determined, and that such behavior on the part of cattle dealers and veterinarians renders the proper enforcement of quarantine laws very difficult. Tables are given showing the results of tuberculin tests on various herds. The statistics of the inspection of cattle and horses are also given.

In 3 cases of glanders guinea pigs which were inoculated with the nasal discharge developed glanders, although no lesions could be found upon post-mortem examination of the horses. It appears, therefore, that the nasal discharge may be virulent before internal lesions are developed.

During 1900 a disease resembling blackleg caused the death of a number of young cattle in different parts of Worcester County. Descriptive notes are given of post-mortem findings of a number of cases and upon cultures of material obtained from the organs of diseased animals. No cases of Texas fever were noted during the year. A few outbreaks of rabies were reported, and 11 outbreaks of hog cholera.

Bovine tuberculosis, H. H. Lamson (*New Hampshire Sta. Bul. 78, pp. 162–178, fig. 1*).—Brief popular notes are presented on the cause, methods, and sources of infection, methods of transmission, diagnosis, and pathological lesions of this disease. When the tuberculin test was applied to the college herd, numbering 55, 8 of the cattle, or 14½ per cent, reacted. Four months later 2 new cases were detected by the same means, and after another 9 months 1 other case was found. All the animals which reacted were found at the autopsy to have well-developed tubercular lesions. Tables are given showing the results of the tuberculin tests in detail.

Several experiments were conducted for the purpose of testing the milk of tuberculous cows by inoculation into guinea pigs. The guinea pigs upon which these experiments were conducted failed in every case to develop tuberculosis. Calves which were fed for 3 months with the milk of tuberculous cows showed no evidence of the disease and did not respond to tuberculin. Microscopic examinations of numerous samples of milk from condemned cows did not disclose the presence of the tubercle bacillus.

The dissemination of tubercle bacilli of cows in coughing a possible source of contagion, M. P. Ravenel (*Jour. Comp. Med. and Vet. Arch., 22 (1901), No. 1, pp. 15–18*).—For the purpose of determining the extent to which tubercle bacilli are present in the sputum of tuberculous cattle, the author constructed a nosebag, near the bottom of which was placed a shelf of soft pine wood, which was sterilized by steam each time before using. This nosebag was then adjusted to the head of tuberculous cattle. By means of this procedure the tubercle bacilli were found to be present in the bronchial secretions of every cow upon which experiments were made. It became apparent during these experiments that cows in coughing atomized their sputum and projected it into the air in small particles, which may float for a considerable period of time. The danger of human infection by means of this atomized sputum is practically confined to such persons as are in constant contact with the animals.

Guinea pigs which were inoculated with material collected from nosebags subsequently developed generalized tuberculosis in 50 per cent of the cases. Guinea pigs which were directly exposed to the breath of tuberculous cows did not become infected.

The repression of tuberculosis of cattle by sanitation, L. Pearson (*Pennsylvania Dept. Agr. Bul. 74, pp. 23*).—Experiments were conducted for the purpose of determining the effect of good and bad stable conditions on the spread and development of tuberculosis. For the experiment 2 herds of 6 cows each were selected. There were 4 healthy and 2 tuberculous cows in each herd. One stable contained 8,970 cubic feet of space and was furnished with smooth walls and fixings which could be kept scrupulously clean. The other stable contained about 3,000 cubic feet of space and dust was allowed to collect in various places in the stable during the experiment. The smaller stable was not carefully cleaned and the cows in this stable were not separated by partitions between their heads. In both stables the animals were arranged so that each healthy cow stood next to a tuberculous animal. The fodder of the 2 lots of cattle was the same during the experiment, and the cows were confined all the time except for a short period once a week, when they were led out to be weighed. The larger stable was kept as clean as possible during the entire experiment. The stalls were cleaned 3 times per day and the partitions and mangers washed with a disinfectant once a day. The floors, walls, ceilings, windows, manger, etc., were scrubbed with water and soap once a week. A bucket was reserved for the use of each cow during the entire experiment.

All of the tuberculous animals gained somewhat in weight during the first part of the experiment. This was probably due to their being dried off as soon as possible and being better fed. In order that the exposure of the healthy cows in the large, light, and well-ventilated stable and in the smaller, dark, and poorly ventilated stable might be the same, the tuberculous cows were transferred from one stable to the other every 10 days. The curious fact was developed from these experiments that the cows in the dark stable gained more in weight during the experiment than those in the light stable.

On the eighty-second day after the beginning of the experiment one of the healthy cows in the light stable and two of the healthy cows in the dark stable reacted to tuberculin. A second test, made 15 months after the beginning of the experiment, showed that 2 of the originally healthy cows in the light stable and all of the originally healthy cows in the dark stable were tuberculous. In the dark stable, which was not furnished with partitions between the heads of the cattle, the tubercle bacilli may easily have been transmitted from tuberculous to healthy cows by contact. Such means of transmission was impossible, however, in the light stable, and it is assumed that infection took place in this stable in the 2 cows which finally became tuberculous by inhaling tubercle bacilli which had been expelled into the air by the coughing of the tuberculous cows.

Treatment of tuberculosis by means of strychnin, V. Galtier (*Jour. Méd. Vét. et Zootech., 5. ser., 5 (1901), Jan., pp. 1–8*).—The author conducted experiments for the treatment of tuberculosis by means of Fowler's solution of arsenic and solutions of strychnin. The experiments were made upon goats, asses, pigs, calves, and rabbits. The experimental animals were infected by feeding with tuberculous material or by intravenous injections. The check animals were infected in the same manner. The results of these experiments may be summarized as follows: The treatment of tuberculosis by the simultaneous use of Fowler's solution and a solution of strychnin indicated some action of these substances in checking the progress of the disease. The experimental animals remained in a better condition of health than the check animals and it was determined that the progress of the disease was much hindered, and that the lesions showed a tendency to disappear. The same treatment adopted for the purpose of prevention increased the resisting power of animals to the disease, prevented the generalization of infection, and brought about a cicatrization or extinction of already-existing lesions. During these experiments it was found that a solution of strychnin given in suitable doses in the food or water, or in subcutaneous injections, had no injurious effects upon the experimental animals. The ass and pig showed an especial resisting power to relatively large doses of strychnin. The guinea pig was much more resistant than rabbits. It is concluded that strychnin in suitable doses may be advantageously administered either alone or associated with arsenic in the treatment of tuberculosis.

Government regulations to be adopted for the eradication of tuberculosis in domestic animals, KÜHNAU (*Berlin. Thierärztl. Wchnschr., 1901, No. 7, pp. 113–120*).—For the government regulation of this disease the author recommends periodical milk inspection, compulsory reporting of tuberculosis of the udder, and destruction and indemnity for such cows, pasteurization of dairy products, control of the manufacture and distribution of tuberculin, and prevention of importation of tuberculous cattle and untreated milk.

The struggle against bovine tuberculosis, B. BANG (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 81–95*).—A translation by F. C. Harrison of certain portions of Professor Bang's writings on tuberculosis.

A new method of tubercle-toxin treatment, G. LANDMANN (*Hyg. Rundschau, 10 (1900), No. 8, pp. 361–376*).—The author experimented with a compound which he calls tuberkulol. The method of preparation is as follows: Bouillon cultures of tubercle bacilli which have been brought to a high degree of virulence by repeated passages through animals, are filtered, and then the fat is extracted and the bacilli are pulverized. They are then extracted by the fractional method in physiological salt solution, beginning with a temperature of 40° C. and ending with a temperature of 100°.

Numerous experiments were made with this substance on animals and on tuber culous human patients. From these experiments the author concludes that tube kulol is much more active than any similar product produced, and that healthy animals can be immunized by injections of this substance, so that they are protected against subsequent infection from tuberculosis. Satisfactory results were also obtained from hypodermic injections of tuberkulol in tuberculous human patients.

Culture of tubercle bacillus, C. FRAENKEL (*Hyg. Rundschau, 10 (1900), No. 13, pp. 617–630*).—The author records the results of experiments in making cultures of the tubercle bacillus upon a great variety of different media of different reaction, concentration, and chemical composition.

Pathogenesis and therapy of milk fever, C. HEMPRICH (*Berlin. Thierärztl. Wchnschr., 1901, No. 6, pp. 90, 91*).—According to the author, milk fever is caused by a process of autointoxication, which is due to the production of "milk radicals." These milk radicals appear in abundance at the beginning of the process of milk secretion and antagonize the action of the liver. It is not determined whether the milk radicals are derived from the sugar, fat, or casein of the milk. In the treatment of milk fever, the object should be to check the milk secretion until the liver can metamorphose the abundant milk radicals. The author used a modification of the Schmidt treatment, as follows: 0.2 parts pure iodin, 10 parts potassic iodid, and 2,000 parts water.

Lysol in milk fever, F. C. Mason (*Veterinarian, 74 (1901), No. 878, pp. 78, 79*).—The author tested lysol in the treatment of 3 cases of milk fever, with results which indicate that this substance is as effective as chinosol and rather more so than potassium iodid. The udder was cleaned externally, milked out as dry as possible, and then received an injection of a half pint of ½ per cent solution of lysol in each quarter. Treacle was given at the same time as a drench, in doses of 2 lbs. The drench and injection were repeated if necessary, and the cows were not given anything to eat until they manifested a desire for feed.

Preventive inoculation against foot-and-mouth disease, with especial reference to the practical use of preventive serum in hogs and sheep, Loeffler and Uhlenhuth (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 1, pp. 19–25*).—The authors claim that a protective serum has been obtained which produces complete immunity in hogs and sheep. The serum was found to have similar action in cattle. In one case, where the disease broke out in a herd of 416 sheep, 28 sheep which appeared to be healthy were inoculated 2 days after the appearance of the disease in the herd. Of these sheep 7 were attacked by the disease within 2 days after inoculation, and the author believes that they were already infected before receiving the serum. The other 21 remained healthy, although all the animals which were not inoculated became infected. Similar results were obtained in other outbreaks of the disease in both sheep and hogs. During the author's experiments it became apparent that the organism of foot-and-mouth disease was so small that it readily passed through filters which were fine enough to stop ordinary bacteria. It is necessary to bear this fact in mind in order to obtain a safe and reliable protective serum.

The control of swine plague by inoculation with Höchst serum, Gaertner (*Berlin. Thierärztl. Wchnschr., 1901, No. 10, pp. 165–169*).—The author made experiments with serum manufactured in Höchst in 3 outbreaks of swine plague. Detailed notes are given on post-mortem findings on a number of animals which died of the disease, and it is stated that the differential diagnosis between this and hog cholera was comparatively easy in these outbreaks. During experiments, inoculations with the serum were made in a large number of animals of different ages, and in many cases a cure was effected in animals which seemed to be in the last stages of the disease. The results were not strictly uniform, but the author believes that the disease can be cured in a large proportion of cases by the use of this serum. It is recommended that pigs be inoculated at a young age, in order to prevent the development of the disease among them.

The bacteriology of hog cholera, G. McCarthy (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 2, pp. 23, 24*).—Brief statistical notes on the prevalence of the disease, and a statement of the effectiveness of serum treatment.

Serotherapy and serovaccination in hog cholera, Coremans (*Ann. Méd. Vét., 50 (1901), No. 1, pp. 14–22*).—A general discussion of the problem connected with the treatment of hog cholera. The author made experiments on the preventive and curative properties of serum. The duration of immunity was about 5 months after the first vaccination, and 1 year after the second.

Hog-cholera serum from cows, T. Kitt (*Monatsh. Prakt. Thierh., 12 (1901), No. 5, pp. 193–199, fig. 1*).—Repeated inoculations of virulent cultures in large doses finally produced fatal endocarditis in the cow and hog-cholera bacilli were found in large numbers in the cardiac lesions. After the cow had received 380 cc. of pure cultures, the serum showed a slight retarding effect on the progress of hog-cholera infection in mice. Later a strong serum was obtained fully as effective as that prepared from the horse.

Bacterium coli as the cause of an infectious disease of horses in west Prussia, Piorkowski and Jess (*Berlin. Thierärztl. Wchnschr., 1901, No. 4, pp. 45–

48).—Several serious outbreaks of this disease occurred and were investigated by the authors. The first symptoms were fever, followed by colicky attacks. Some of the horses died within 2 hours. A post-mortem examination disclosed perforating ulcers of the intestines and inflammation of the cœcum. One attack of the disease did not confer immunity to further attacks. The period of incubation was apparently from 8 to 14 days. From affected organs of horses the authors isolated *B. coli* in great quantities and found that it possessed an especially high virulence. An attempt to inoculate a horse by means of feeding this culture was without results. Intravenous injection, however, of the organism caused the death of the experimental animal. In case of further outbreaks of this disease the authors recommend an immediate and complete change of diet.

On the question whether bacteria can penetrate through the wall of the healthy alimentary tract, A. Schott (*Centbl. Bakt. u. Par., 1. Abt., 29* (*1900*), *Nos. 6, pp. 239–255; 7, pp. 291–297*).—This article contains an extended discussion of the literature of the subject in connection with a bibliography. The evidence thus far brought together does not support the belief that pathogenic or nonpathogenic bacteria can penetrate through the wall of the normal intestines.

AGRICULTURAL ENGINEERING.

A text-book of the physics of agriculture, F. H. King (*Madison, Wis.: Author, 1901, 2. ed., pp. XVI+604, figs. 276*).—In this book, as Professor King states, "the aim has been to present to the student who expects to be a farmer some of the fundamental principles he must understand to become successful." The author states that it is his purpose to present these principles from the physical rather than the chemical or biological standpoint, and from that of the general student and farmer rather than from that of more technical scientific agriculture. Nevertheless the book will be found to be a notable contribution to the literature of scientific agriculture in a field which has not heretofore received the attention its importance demands. The introduction deals briefly with certain general physical principles, laws, and factors, a knowledge of which is necessary to an understanding of their subsequent practical application. Other chapters deal with the nature, origin, and waste of soils; chemical and mineral nature of soils; soluble salts in soils; physical nature of soils; soil moisture; physics of plant breathing and root action; movements of soil moisture; conservation of soil moisture; relation of air to soils; soil temperature; objects, methods, and implements of tillage (especially the plow); ground water, farm wells, and drainage; principles of rural architecture, including strength of materials (posts, barn frames, etc.), warmth, light, and ventilation, principles of construction, construction of silos; farm mechanics, including principles of draft, construction and maintenance of country roads, farm motors (animal power, steam and gasoline engines, and windmills); farm machinery (general principles, belting, farm pumps, hydraulic rams); principles of weather-forecasting, including discussions of the atmosphere and its movements, and weather changes.

Cold-storage experiments, J. B. Reynolds (*Ontario Agr. Col. and Expt. Farm Rpt. 1900, pp. 3–7, figs. 3*).—Observations are reported on the amount of ice consumed by absorption through the walls of a refrigerator constructed on the plan recommended by the Dominion government. The refrigerator used had a door at the top opening into an ice-box and another in front opening into the cooling chamber. Three galvanized-iron tubes extended from the ice-box to a trough at the bottom of the cooling chamber. These served to carry off the water from the ice-box and were filled with a mixture of ice and salt in place of the ice in the box when it was desired to reduce the temperature of the refrigerator to a lower degree than could be obtained with the ice alone. A record was kept of the temperature inside and outside of the refrigerator during 20 days. From these data the factor for radiation was calculated to be 4.25, "that is, 4.25 units of heat were absorbed through 1 sq. ft. of wall, floor, or ceiling in 24 hours for each degree of difference in temperature between the outside and inside air." Observations were also made with what is termed the Hanrahan system, the essential feature of which is that the ice house is in connection with the refrigerator, so that there is a complete circuit of air. "The air of the refrigerator, having been warmed by the products stored therein, ascends a flue between the two parts of the building and at the top of the flue passes over into the ice house, where it is cooled and gradually falls to the floor. The ice rests on large slats at the floor and the air is drawn below the ice between these slats toward the refrigerator, and thus the circuit is completed." Observations during 22 days on a cold-storage system of this character, the ice house being $12 \times 12 \times 20$ and the refrigerator $12 \times 10 \times 7$, showed that the average temperature outside of the refrigerator was 68.5°; inside, 43.3°; of the dead-air space, 56.4°. It is thus clear that in order that this system may be effective and economical of ice, it is essential that the insulation should be as perfect as possible.

The quantity of water used in irrigation and the seepage loss from canals, S. Fortier (*Montana Sta. Bul. 29, pp. 44, pls. 10*).—This is an account of investigations made during 1900 in cooperation with this Office under supervision of Elwood Mead, expert in charge of irrigation investigations. Records are given of observations on the amount of water actually used in different cases in the Gallatin and Bitter Root valleys and in Yellowstone County, and on the duty of water in Middle Creek Canal. A study of the losses due to seepage and evaporation on 5 canals and their relation to the duty of water is also reported. "In addition to these investigations it was thought desirable to institute a second series of experiments for the purpose of determining the proper amount of water to apply to growing crops and the proper time to irrigate. It is intended that this series will extend through a period of at least 5 years, during which time the staple crops of Montana can be experimented on with the object of finding out how much water is necessary to produce the most valuable yields and the right time to apply it." The results with oats in 1900 are reported, but on account of the unusually dry season no conclusions are drawn.

A loss from evaporation and seepage of as much as 34.7 per cent of the total supply of water in a canal is reported and the conditions affecting seepage are discussed.

STATISTICS—MISCELLANEOUS.

Sixteenth Annual Report of Maine Station, 1900 (*Maine Sta. Rpt. 1900, pp. 228*).—This is made up of reprints of Bulletins 59–69 of the station on the following subjects: Feeding-stuff inspection (E. S. R., 12, p. 377), fertilizer inspection (E. S. R., 12, p. 324), notes on insects and plants (E. S. R., 12, pp. 312, 367), the Maine Experiment Station (E. S. R., 12, p. 599), feeding-stuff inspection (E. S. R., 12, p. 587), poultry experiments in 1899 (E. S. R., 12, pp. 585, 586), coffee substitutes (E. S. R., 12, p. 586), nut oils (E. S. R., 12, p. 516), testing grass seed (E. S. R., 12, p. 565), potato pomace (E. S. R., 12, p. 587), fertilizer inspection (E. S. R., 12, p. 737), digestion experiments with sheep (E. S. R., 12, p. 873), experiments with insecticides upon potatoes (E. S. R., 12, p. 863), and finances—meteorology—index (E. S. R., 13, p. 290).

Thirteenth Annual Report of Massachusetts Station, 1900 (*Massachusetts Sta. Rpt. 1900, pp. 132*).—This contains a brief summary of station work during the year, including a list of the officers of the station and a list of station publications now available for distribution; a financial statement for the fiscal year ended June 30, 1900; and reports of the chemists, botanists, entomologists, meteorologist, and agriculturist, outlining the work in their respective departments and giving accounts of investigations noted elsewhere.

Seventh Annual Report of Montana Station, 1900 (*Montana Sta. Bul. 28, pp. 24*).—Reports of the director and heads of departments review at some length the different lines of station work during the year. The organization list of the station, a financial statement for the fiscal year ended June 30, 1900, a list of exchanges, and a subject list of station bulletins are included. The reports of the horticulturist and agriculturist are noted elsewhere.

Twelfth Annual Report of New Hampshire Station, 1900 (*New Hampshire Sta. Bul. 79, pp. 38*).—This includes a financial statement for the fiscal year ended June 30, 1900, reports of the vice-director and heads of departments, parts of which are noted elsewhere, for the year ended October 31, 1900, and a list of station publications available for distribution.

Director's report for 1900, W. H. Jordan (*New York State Sta. Bul. 195, pp. 383–398*).—The different lines of station work, with the results obtained, are reviewed at some length. Notes are also given on the station staff, institute and inspection work, cooperative experiments, etc. A list of bulletins published in 1900 is appended.

Eleventh Annual Report of North Dakota Station, 1900 (*North Dakota Sta. Rpt. 1900, pp. 119*).—A brief report on station work by the director, departmental reports, parts of which are abstracted elsewhere, and a financial statement for the fiscal year ended June 30, 1900. Included in the report of the chemist and not noted elsewhere in this issue are analyses of 3 samples of commercial fertilizers, 14 samples of clays and cements, and 2 samples of lime rock.

Statistics of the land-grant colleges and agricultural experiment stations in the United States for the year ended June 30, 1900 (*U. S. Dept. Agr., Office of Experiment Stations Bul. 97, pp. 37*).—A summary of this has already appeared (E. S. R., 13, p. 101).

Proceedings of the fourteenth annual convention of the Association of American Agricultural Colleges and Experiment Stations, A. C. True, W. H. Beal, and H. H. Goodell (*U. S. Dept. Agr., Office of Experiment Stations Bul. 99, pp. 192, pls. 3*).—This is a detailed account of the proceedings of the New Haven convention (E. S. R., 12, p. 404).

Proceedings of the twenty-first annual meeting of the Society for the Promotion of Agricultural Science (*Proc. Soc. Prom. Agr. Sci., 1900, pp. 183*).—Articles published in the proceedings and not noted elsewhere in this issue are as follows: Syllabus for a short course on grasses and other forage plants, by W. J. Beal; University extension methods for the promotion of agricultural knowledge, by I. P. Roberts; Egyptian agricultural institutions, by D. G. Fairchild; Sub-Arctic agriculture, by C. C. Georgeson; The application of agricultural chemistry to the farm, by J. B. Weems; How to teach agricultural chemistry to best combine the science of chemistry with the application of it to the affairs of farm life, by E. B. Voorhees; The course in cryptogamic botany, by L. H. Pammel. The information contained in the following articles has been noted from other sources: The work of the society in agricultural education, by W. J. Beal (E. S. R., 12, p. 599); The chemical functions of certain soil bacteria, by F. D. Chester (E. S. R., 12, p. 729); Meteorological influences on the development of the Hessian fly, by F. M. Webster (E. S. R., 11, p. 476); Some new facts regarding the destructive green pea louse, by W. G. Johnson (E. S. R., 12, p. 861); Effects of artificial foundations on the building of honey comb, by C. P. Gillette (E. S. R., 12, p. 658); and Influence of wheat farming on soil fertility, by H. Snyder (E. S. R., 9, p. 641).

Fifth report of committee on methods of teaching agriculture (*U. S. Dept. Agr., Office of Experiment Stations Circ. 45, pp. 8*).—This report was submitted by the committee at the New Haven convention of the Association of American Agricultural Colleges and Experiment Stations, 1900. The report contains syllabi of courses in agrotechny, rural engineering, and rural economics.

NOTES.

Alaska Stations.—Isaac Jones, who has had charge of the station at Rampart for the past year, has resigned. On his way out from the interior Mr. Jones went over the trail from Eagle to Valdez with a view to obtaining definite information concerning the agricultural prospects in the Upper Tanana and Copper River valleys. The trip from Eagle to Valdez occupied 18 days. He reports that the outlook is very promising, that there are large tracts of agricultural land in that region, that grass is abundant in many places, and that the limited attempts thus far made by prospectors at gardening and grain growing have been very successful. It is hoped that funds may be provided to establish a station somewhere in that region. During the past season a comfortable two-story log house has been completed at Kenai, which will serve as office and dwelling for the superintendent in charge at that place. Two acres of land have been cleared there, in addition to that previously cleared. The work there has been mostly with grain crops, grown on a larger scale than at the other places where tested. At Sitka a four-room cottage and a good-sized barn have been completed. Small plats of grain and a great variety of vegetables, grown with a number of different fertilizers on new and old land, have constituted the principal experimental work. The past season has been unusually dry, both at Sitka and Kenai, so much so as to interfere somewhat with the experiments. It has, however, been favorable to hay making, which this year has presented no difficulties.

C. C. Georgeson, the special agent in charge of the Alaska stations, has returned to Washington, D. C., for the winter.

Florida College and Station.—Work on the new science hall, which was provided for by the last legislature, is progressing rapidly. The building is Spanish in design. It consists of a main building, three stories in height, and two wings at the rear, two stories in height, with a loggia on the first and second floors on the court side. It is expected to cost between $45,000 and $50,000.

Purdue University.—The university has received a donation of $60,000 from Mrs. Eliza Fowler, of Lafayette, Ind., for the erection and equipment of an assembly hall.

Iowa College and Station.—The contract has been let for a new laboratory building for the department of horticulture. The building will be 35 by 50 feet, two stories in height, and built of pressed brick, and will contain a large laboratory room accommodating 30 students, in which practice will be given in grafting, budding, making cuttings, potting plants, and all the practical indoor work of the horticulturist. It will also contain a large fruit room, to be used for instruction purposes, connected with two refrigerators, one for experimental work in cold storage and the other for preserving fresh fruits for study and comparison of varieties. On the second floor a photographic room, dark room, and museum are provided. In the basement are storage rooms for bulbs, grafts, and nursery stock. It is expected that the building will be one of the most complete of its kind in the country. The estimated cost is $6,000, exclusive of heating and plumbing.

Kansas College.—Possession of the Fort Hays Reservation, which was transferred by act of Congress to the State of Kansas for the use of the State Agricultural College and State Normal School, has been delayed by a controversy between the State and settlers on the reservation; but a recent decision of the courts was in favor of the State. The reservation embraces about 7,000 acres of fine prairie land lying directly south of Hays City. The plan of the agricultural college is to convert its share of the land into a model experiment farm of several thousand acres to be used for the purpose of testing drought-resisting crops, such as alfalfa, Kafir corn, soy beans, the various grasses, etc., and the comparison of methods of tillage and treatment. An appropriation of $3,000 a year for this work was made by the last State legislature. In connection with its short courses this winter, the college will offer a course in practical poultry management, to be given in February.

Nebraska University and Station.—A. T. Wiancko, B. S. A., a graduate of the Ontario Agricultural College, and recently experimentalist with the Standard Cattle Company, Ames, Nebr., has been appointed instructor in agriculture in the university and assistant agriculturist of the station.

New Mexico College and Station.—Luther Foster, recently agriculturist of the Wyoming College and Station, has been elected president of the New Mexico College and director of the station. He will enter upon his new duties at once.

North Carolina College.—Watauga Hall, occupied partly as a dormitory, and as dining room and kitchen for the whole college, was destroyed by fire the night of November 29 in the midst of a furious wind. The loss is estimated at about $10,000; the insurance is $600. About 50 students occupying the building lost all of their effects, several of them barely escaping with their lives. Temporary kitchen and dining room arrangements were quickly provided, and college exercises were but slightly interrupted. Plans for rebuilding on a better and larger scale are being considered.

Texas College and Station.—President L. L. Foster, of the Agricultural and Mechanical College of Texas, died at his home at Bryan, December 2, 1901. The board of directors met November 6 at Fort Worth for the purpose of locating the new State experiment station provided for by the recent legislature, for which $10,000 was appropriated. Over 100 delegates were present at the meeting, representing 20 different localities. After a full hearing had been given to all the localities concerned, the board decided that the station should be located in either Smith or Henderson County (east Texas). A special committee was appointed, consisting of 3 members, to decide upon the exact location.

Utah College and Station.—The new cattle and sheep barns are about completed. A soil physics laboratory and an agricultural museum have been started, and a number of improvements and additions to equipment in the dairy department have been made.

A New Experiment Station.—The Epitomist Experiment Station, maintained by the publication known as *The Agricultural Epitomist*, has been established at Spencer, Ind. Operations will be begun on a systematic basis in 1902. The farm of 590 acres includes a variety of land, furnishing an opportunity for experimenting in drainage and irrigation. An orchard and vineyard have been planted and some work commenced in growing corn and potatoes. The station has a poultry department consisting of an incubator cellar, brooder house, poultry houses and yard, and about 800 birds, including different varieties of chickens, Pekin ducks, and Toulouse geese. It also has a few Angora goats, flocks of Shropshire and of Highland blackface sheep, about 20 steers, and 3 litters of pigs. While it is to be presumed that the farm will be operated more or less on a commercial basis, the effort of those having it in charge will be "to help advance and improve agriculture in all its branches."

Personal Mention.—The presentation of a medal to M. Berthelot, the eminent chemist, in the large amphitheater of the Sorbonne, in commemoration of his services to science, occurred November 24. Berthelot's activity during more than half a century has covered nearly every branch of chemistry, and has included a number of important contributions to agriculture. His latest publication, Les carbures d'hydrogène, is a work in three large volumes, comprising an account of his labors on these compounds during the last half century. Some of the other important lines of Berthelot's work have been his researches on the synthesis of natural fats, his discovery of polyhedric alcohols, his investigations on explosives, on the fixation of nitrogen by plants, and in the domain of thermochemistry. The calorimeter bomb, which is coming into considerable use in the study of the fuel value or heats of combustion of foods and feeding stuffs, is a product of his labors in the latter direction.

Dr. Charles P. Strong, assistant surgeon in the Army, has been appointed director of the Government biological laboratory recently established in Manila. His work will be mainly along lines relating to animal pathology.

Prof. A. E. Shuttleworth, formerly chemist of the Ontario Agricultural College and Experimental Farm at Guelph, Canada, has resigned from that institution to accept the position of superintendent and chemist for a Sugar Beet Company, in Ontario, Canada. His assistant, R. Harcourt, has been appointed to fill the vacancy.

Clarence T. Johnston, assistant in irrigation investigations in this Department, will spend the winter in Egypt studying irrigation works and practice in that country. Mr. Johnston will go directly to Cairo, where he will meet the English irrigation officers and make plans for his tour, possibly joining one of the field parties. He will go up the Nile about 500 miles above Cairo, and will inspect the canal systems, levees, dams, etc., including the famous Assuan Dam across the Nile, which is approaching completion. Special attention will be given to pumping machinery, tools used in irrigation work, the maintenance of canals and levees, and similar engineering features. Mr. Johnston will arrive about the time that the Corvee or forced labor enters upon its work of repairing the canals and putting the levees in shape for the season. He will return, probably, some time in February via northern Italy, southern France, and Spain, taking in the irrigated sections of those countries.

Regierungsrath Freiherr Dr. von Tubeuf has been appointed director of the biological section of the royal board of health at Berlin, in place of Dr. B. Frank, deceased.

Prof. Dr. W. Palladin, formerly of the University of Warsaw, has become extraordinary professor of vegetable anatomy and physiology at the University of St. Petersburg.

Dr. E. Eidam, director of the Agricultural-Botanical Experiment and Seed Control Station at Breslau, has retired and has been succeeded by Dr. W. Remer as director, with J. Schleussner as assistant.

B. Minari, agricultural chemist of the soil survey of the Imperial Department of Agriculture and Commerce at Tokyo, Japan, has recently visited this country and gone over the soil work which is being carried on by this Department and a number of the experiment stations. Mr. Minari states that the soil survey of Japan, which was started several years ago, is being actively prosecuted and will eventually cover the whole country.

Miscellaneous.—An office of agricultural information (*office de renseignements agricoles*) has recently been established under the ministry of agriculture of France. It takes the place of the former bureau of agricultural statistics and food products. The object of the office is to collect statistical information in regard to agriculture and agricultural products in France and foreign countries, the market conditions, general agricultural conditions, imports, public sales, agricultural labor, and similar lines; to make practical studies on such subjects as the methods of packing and preserving, transportation, etc., of agricultural products; the conditions of buying and selling, business customs, etc., in France and foreign countries; to prepare monographs on agricultural topics; to collect technical and commercial information of interest to professors of agriculture; and to publish in abstract and otherwise the results of scientific investigations in agriculture in France and foreign countries, and the proceedings of agricultural societies, agricultural syndicates, and similar bodies. The force of the new office has been organized and the work planned, and methods of gathering and publishing data are outlined in a circular addressed to the prefects of departments and to the special and departmental professors of agriculture in France.

The new library and class-room buildings of the Ontario Agricultural College, the gift of W. E. H. Massey, are approaching completion. Mr. Massey has done much to stimulate interest in agricultural investigation, and especially on the animal husbandry side, having given liberal prizes for judging contests at the college in the past. It is with regret that we note his death at this time, on the eve of the completion of the building which his liberality made possible.

A new magazine, entitled *Country Life in America*, has recently appeared, under the editorship of Prof. L. H. Bailey. The purpose of this publication is to represent the present growing interest in country life, from both the ideal and practical standpoints. It will pay especial attention to horticultural matters, but items of current interest and progress along agricultural lines will be noted.

According to a note in *Science* the first number of a journal devoted to biological chemistry, entitled *Beiträge zur chemischen Physiologie und Pathologie: Zeitschrift für die gesammte Biochemie*, and edited by Dr. Franz Hofmeister, professor of physiological chemistry at Strasburg, has recently appeared.

EXPERIMENT STATION RECORD.

Vol. XIII. No. 5.

Less than a year and a half ago the death was noted of Sir John Bennett Lawes, of Rothamsted fame. We are now called upon to record the death of his lifelong coadjutor and friend, Sir Joseph Henry Gilbert, which occurred December 23, 1901. Thus these two men, so closely associated in their scientific work in life, were not widely separated in death. Their remarkable scientific partnership, extending over more than fifty-five years, has hardly a parallel, and their harmonious labors at Rothamsted in the cause of agricultural science have made a profound and lasting impress on the agriculture of the world. The beginning of their labors well-nigh marks the beginning of the experiment station as an institution devoted to investigation in agricultural science, and within their active lives the science of agricultural chemistry has developed and the experiment station has come to be regarded in all civilized countries as a practically indispensable institution.

Joseph Henry Gilbert was born at Hull in 1817, and was therefore in his eighty-fifth year at the time of his death. After attending the University of Glasgow and University College, London, where he devoted special attention to chemistry, he spent some time in Liebig's laboratory at Giessen, where he obtained his doctorate. Upon returning to England, two or three years were spent in teaching and in studying the chemistry of calico printing, dyeing, etc. Dr. Gilbert became associated with John B. Lawes at Rothamsted in 1843, at first superintending the laboratory investigations and later entering more generally into the field and feeding experiments and other investigations. He continued to occupy the position of director of the Rothamsted laboratory to the time of the death of Sir John Lawes, whom he succeeded as director of the Rothamsted Station.

While the opportunity for conducting the Rothamsted investigations was due to the munificence of Sir John Lawes, a large measure of credit for their scientific character and exactness is due to Dr. Gilbert, who gave to them his undivided attention through a long, active life. Indeed, Sir John, in his generosity of spirit, seemed always anxious that full credit should be given his colleague, and often paid tribute to his scientific insight and systematic methods. His high scientific attainments were recognized by many learned societies in his election to honorary membership and to high office. He was appointed Sibthorpian professor of rural economy in the University of Oxford in 1884, and reappointed for a second period of three years in 1887. He was the recipient of many and varied honors, alone and in conjunction with Sir John, and shared in the honor of the jubilee celebration at Rothamsted in 1893, being elevated to knighthood in that year.

Sir Henry Gilbert visited this country on three occasions. In 1882 and 1884 he traveled extensively in the United States and Canada to study the conditions of agriculture; and his last visit, in 1893, will be remembered with much pleasure by all who met him. The series of lectures delivered by him on that occasion, under the provisions of the Lawes Agricultural Trust, was a most interesting and valuable summary of the agricultural investigations at Rothamsted in certain lines during a period of fifty years. Upon the preparation of these lectures and their subsequent publication as a bulletin of this Office, Sir Henry bestowed a great amount of time and pains, and it was evident that he regarded them as possibly the final summing up of his and Sir John's lifelong labors in some of their most important lines.

Of late, although in quite feeble health, Sir Henry took a deep interest in the lectures of Dr. Bernard Dyer, delivered in this country in 1900, and in the final preparation of these for the press. Indeed, Dr. Dyer, in his introduction to these lectures, states that "a very large share of the credit should go to Sir Henry Gilbert, who has spent infinite pains in aiding and advising me in this work." His natural interest in having the results of the soil work at Rothamsted brought together and adequately presented was quickened by the desire to carry out the oft-expressed wish of Sir John Lawes that this might be done. It is gratifying to know that the proof sheets of these lectures reached him over a month before his death, and were a source of satisfaction to him.

The services of these lifelong collaborators at Rothamsted can hardly be separated or individualized. The qualifications of the one strengthened and supplemented those of the other. The application of the results of their combined labors and the influence of Rothamsted on agricultural investigation in general are world-wide. In the history of agricultural science, as in the current literature, each will be best known by the association of his name with that of the other, and for a long time to come the work of "Lawes and Gilbert" will constitute a basis for practice as well as a starting point for further investigation.

The system of agricultural education in England which is carried on under the county councils has never been clearly understood in this country. This is due to the fact that so little has been published which explains the work as a whole, and to the diverse character of the arrangements made in the different counties. It is perhaps incorrect to speak of the undertaking as a system, since there appears to be an entire lack of system, considering the country as a whole, and no advisory or supervisory relations exist between the county councils and the Boards of Agriculture or Education or other central agency. The funds with which the work is carried on are derived under a local taxation act of 1890 and are for technical education, which in most counties is construed to include agriculture. The county councils, in whose hands the administration of the funds is placed, are to a large extent the executive officers of the counties. Each county has been left to work out its own plan for technical instruction under this act. As the matter was largely an experiment, there was quite naturally a variety of opinion as to the best means of carrying out the purpose of the act, especially in providing instruction in agriculture. This accounts for the variety of arrangements which have been made in different counties, the grade of instruction provided, and its efficiency.

A review of this educational work carried on by the county councils is presented in the Annual Report of the Board of Agriculture on The Distribution of Grants for Agricultural Education and Research, 1900–1901. This summary is based upon the reports of the committees on technical education in the various counties of England and Wales, and shows the provisions which have been made for elementary and higher instruction in agriculture. It will be of considerable interest to those who are following the various forms of agricultural education in other countries, and will prove helpful in giving a clearer idea of the aims and methods of this rather unique system.

It is shown that the amount of money available for technical education in England and Wales under the act of 1890, excluding that which went to urban and metropolitan authorities, was about £500,000, and of this sum it is estimated that approximately £77,000 was used for agricultural instruction. While the proportion devoted to agriculture is not large, it represents in the aggregate nearly $375,000, which is a relatively large sum considering either the area covered (one-fourth larger than New York State) or the rural population.

The facilities provided by different county councils vary greatly in extent and character, but in general it may be said that they include instruction of the various grades, from the college course to the agricultural or farm school, and the most elementary courses of lectures or demonstrations, furnished by migratory schools or lecturers; together with the maintenance of demonstration plats to illustrate the culture or handling of various crops. The facilities for higher agricultural education are furnished by a number of universities and agricultural schools or institutes, which receive grants from the various counties and in return provide a certain number of scholarships for students from those counties. The University College of Wales, at Aberystwyth, for example, receives grants from six different counties. The Midland Dairy Institute is a center for a number of counties, and the Southeastern Agricultural College at Wye is supported jointly by the counties of Surrey and Kent.

In a number of counties agricultural or farm schools have been fitted up especially for this instruction, and in this undertaking adjoining counties have sometimes united. These secondary schools are of different grades, some of them covering the whole range of agriculture, others being devoted to dairying, while still others are farm schools, giving much attention to instruction in the practical operations of farming. Five or six counties have provided dairy schools, and at least four have local county farm schools of different descriptions.

The itinerant or migratory schools are a prominent feature of the elementary work in most of the counties. In conducting these each county has selected a certain number of centers, sometimes only two or three, sometimes as many as thirty or more, where the courses are given. These cover a variety of subjects, and evidently differ considerably in character. They usually comprise from five to ten exercises, but in some cases twenty or more. In most of the counties they include a traveling dairy school, and courses of lectures in agriculture and horticulture. Courses in poultry, bee keeping, farriery, cider making, and veterinary science are also common. These lectures often take the form of practical demonstrations, as in the case of dairying, pruning, and farriery. It is mentioned, for instance, that in Somersetshire the farriery van visited fifteen centers, remaining for periods of from two weeks to two months, and giving instruction to seventy-six pupils in all. A further extension of this instruction in "manual processes" includes plowing, sheep shearing, hedging, thatching, and even basket making, in some counties taking the form of competitions.

The forms of this popular instruction adopted in different counties present almost an endless variety. For example, an excursion to Holland was organized by the technical education committee for Essex farmers, for the purpose of studying agricultural education and the organization and practice of the agricultural industry in that country. In the County of Kent boys' gardens are maintained at twenty centers, the small plats being cultivated by boys admitted as pupils, under the supervision of a local instructor appointed by the committee, and prizes awarded by the county superintendent to the most meritorious. Similar prizes for gardens are awarded at other places. A county council garden is maintained on the Isle of Wight, where agricultural instruction is given daily. In Derbyshire "champion" and "ordinary" garden certificates are awarded on the basis of practical work.

The agricultural experiments carried on under the county councils are of a simple character, and for the most part are made for purposes of demonstration. Where this is the case a considerable number of centers are selected, sometimes as many as 30 or 40 in the county. In other instances grants are made to agricultural colleges or schools for the purpose of conducting more technical experiments

The data given as to the attendance indicate that the migratory schools and practical demonstrations have attracted a considerable number of pupils, and that the scholarships provided in the agricultural schools and college courses have been quite largely taken, particularly those in the secondary schools.

To the funds used for agricultural education by the county councils should be added the grants for agricultural education distributed by the Board of Agriculture. These amounted in England and Wales in 1899–1900 to £7,850, and the beneficiaries included ten institutions of the college or institute grade providing the higher forms of agricultural instruction. These were for the most part institutions which are being utilized by the county councils for the advanced courses. During the year there were upwards of seven hundred students receiving instruction at these agricultural colleges and dairy institutes. Of this number one-half were taking regular courses in general agriculture or special branches, while the remainder were attending the shorter courses, usually in dairying or poultry keeping.

After reviewing the various agencies for agricultural instruction in England, Major Craigie, the author of the report, concludes that although there may be some question as to the symmetry and uniformity of these varied facilities provided by central and local effort, the provision made for agricultural instruction is relatively as extensive as in other countries, considering the proportion of the population directly engaged in agriculture. The most material advance to be hoped for, he believes, is "that greater use may be made of the various existing types of educational facilities by the classes for whose immediate instruction they have been provided."

It will be a matter of surprise to many to know that over $400,000 of public money is expended annually for agricultural instruction in England and Wales. It may, perhaps, be questioned whether the plan of management by the county councils, which are bodies of men with a multitude of other duties of varied character similar to those of the county commissioners or supervisors in some of our States, has resulted in building up as strong institutions of various grades and as symmetrical a system of instruction as would be possible under a central agency. Under the circumstances it was probably the part of wisdom to give prominence to the elementary side of the instruction at the outset.

CONVENTION OF ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS, 1901.

D. W. May,

Office of Experiment Stations.

The eighteenth annual convention of the Association of Official Agricultural Chemists met in the lecture hall of the Columbian University, Washington, D. C., November 14, 15, and 16, 1901. The meetings were presided over by the president, L. L. Van Slyke.

In his address the president reviewed the causes which led to the creation of the association and the lines along which it has advanced. The expansion of the work has been very large, not only in amount but in character. Personal initiative has been the prime factor in advancement. From the consideration of methods of analysis the work has grown more into lines of original investigation. Something must be done tôward identifying the individual compounds, he declared, before effective methods can be provided for their estimation. He believed that the association should encourage research in all lines, with the study of methods as a secondary consideration. He called attention to the need of a much broader preparation for work by agricultural chemists. An analyst, simply, is not fitted for research work. We are being drawn more into the untried fields of life chemistry, and must take up the solution of questions that partake more of the character of advanced science. The time of the association, he believed, should be taken up more with the discussion of lines of investigation and less with methods of analysis. The special investigations of different stations should be subjects for consideration before the association. More concise reports by the referees on methods of analysis were considered advisable, and he counseled care in selecting referees for this work. Reference was made to the death of Dr. John A. Myers, a former president of the association, and the suggestion made that an evening session be held to consider his life work and to adopt suitable resolutions.

In accordance with this suggestion the association met at the Cosmos Club the evening of the first day, and adopted resolutions in recognition of Dr. Myers's services and the esteem in which he was held in the Association.

FERTILIZERS.

Nitrogen.—In the absence of the referee, W. R. Perkins, the report was read by E. B. Ferris. The work during the past year was a continuation of trials of the neutral permanganate (Street) and alkaline permanganate (Jones) methods for determining available organic nitrogen. In submitting the results obtained and the comments of the different analysts, the referee suggested that the time of digesting, in determining total nitrogen, receive the attention of the association, as samples with a high nitrogen content do not give uniform results after digesting three hours. While the results by the neutral permanganate method did not agree perfectly, the method was regarded as of value in distinguishing between the different grades of nitrogenous material as determined by vegetative tests. The referee submitted several minor modifications, and recommended that the method with these modifications be adopted provisionally, and that the alkaline permanganate method be further tested. These recommendations were adopted by the association.

Potash.—In the absence of the referee, C. L. Hare, the report was read by B. B. Ross. The accuracy of the Lindo-Gladding method in case of mixtures of acid phosphate and potash salts was investigated, and also the use of ammonium chlorid as a possible aid in securing complete solution of the potash, and a method devised by the referee, employing milk of lime for precipitating potash from neutral solution. A mixture of potassium chlorid and acid phosphate in the proportion of 5 to 95, the theoretical amount of potash present being 3.35 per cent, gave the following average results: Lindo-Gladding method, 3.12 per cent; the Lindo-Gladding method with ammonium chlorid, 3.19 per cent, and the milk of lime method, 3.15 per cent. While the addition of ammonium chlorid gave higher results, these do not warrant the conclusion that this addition is an advantage. The large amount of ammonia salts left after expelling the sulphuric acid may cause loss from sputtering. Special attention was called to the results obtained by the milk of lime method, the details of manipulation of which were given, and the results in comparison with the Lindo-Gladding method with a large number of fertilizers containing organic materials were shown. From the results of his investigations the referee suggested that the cause of the low results obtained by the official method be further investigated, and that the milk of lime method be submitted for trial during the coming year. These suggestions were adopted.

Phosphoric acid.—In the absence of the referee, H. K. Miller, the report was read by E. G. Runyan. The work on phosphoric acid consisted in testing the determination of total phosphoric acid by the official gravimetric method in comparison with the volumetric, and the determination of iron and alumina by the acetate and the molybdate methods. From the results of the past two years and the referee's experience with the modification of the volumetric method as proposed by Runyan, he considered it not only rapid but capable of giving highly satisfactory results. But few results were reported on iron and alumina, and those obtained were quite variable. With basic slag they were not at all concordant, the manganese present interfering with the determination. With ground phosphate and a mixture containing iron and alumina the acetate method as modified by Carpenter gave quite satisfactory results, but as the data on iron and alumina were meager, no conclusions were drawn or recommendations made. The desirability of the association taking some action on a method appplicable to Thomas slag was urged. The referee considered some form of the citric-acid method advisable, and the Wagner method as worthy of the most favorable consideration. The use of the term "available phosphoric acid" was deemed unwise. As phosphoric acid is in different combinations in many materials, it was not thought probable that a single method would apply in all cases.

H. A. Huston discussed the determination of iron and alumina. He stated that results by present methods are worse than those obtained ten years ago. He suggested taking up the study of new methods, believing that the correct estimation of these elements is possible, but that it is necessary for the association to proceed along new lines.

No recommendations were adopted, but from the discussion it seemed to be the sense of the association that the referee take up the study of methods for basic slag. Digestion with citric acid was considered a proper basis upon which to proceed.

SOILS.

The report on soils by the referee, M. E. Jaffa, was read by the secretary. The work of the past year related largely to methods of determining available plant food, the citric-acid method and that of fifth-normal hydrochloric acid for available potash and phosphoric acid being studied. The results for potash were too meager to allow of a definite recommendation. The tentative conclusion was reached that any soil showing 0.02 per cent of K_2O by either of the above methods is not in pressing need of potash fertilizers. More work along this line is urgently desired, and attention was called to the fact that the citric-acid method should not be discarded without further investigation. Similarly, no definite conclusions were reached with phosphoric acid. The work along the line of humus and humus nitrogen was for the purpose of determining the relation, if any, which exists between the nitrogen extracted by ammonia and that contained in the NaOH and KOH leachings. The comparison of humus nitrogen extracted by NH_3 and NaOH solutions was not very satisfactory. There was an agreement between some of the results for the nitrogen by NaOH, but those by the NH_3 solution were not concordant. The amounts of nitrogen dissolved by KOH and NaOH were identical, but in the case of 3 samples in which the percentage of humus was high the amounts of nitrogen dissolved by KOH and NaOH were comparatively low. The referee recommended more extended investigation along this line by a committee, with the referee on soils as chairman.

The Rothamsted method of sampling soils was described, and several objections pointed out. The method is deemed less applicable to the larger part of the arable lands of California than the use of a post-hole auger, as adopted by Hilgard. The latter method requires less work and less time for taking the sample, the exact point of change from surface to subsoil can be ascertained, and much less bulk has to be handled. In view of the necessity of a rational system of sampling soils, and of a method for determining the available plant food, the referee suggested that a committee be appointed for the consideration of these subjects.

W. A. Withers presented a paper on the rate of nitrification of various nitrogenous materials. W. Frear requested the consideration of the subject of determining the proportion of soluble humus in alkali soils, and made a statement of some of the results obtained at the Pennsylvania Station.

F. K. Cameron brought to the attention of the association a paper by A. Seidell on the Chemical examination of alkali soils, published as a bulletin of the Division of Soils (see p. 428). He moved that the article as printed, or modified as might be deemed necessary, be referred to the committee on recommendations, with the view that it be accepted as the official method for the chemical examination of alkali soils.

C. G. Hopkins stated that in the work on soils in Illinois there has been trouble in the separation of alkalis. After precipitating the barium hydroxid and the calcium and barium by means of ammonium carbonate, the final filtrate was found to be by no means free from barium. To overcome this error the official method was modified by precipitating the last traces of barium with ammonium sulphate. A sufficient quantity of this latter is added so that in the ignition of the residue the alkalis are converted to sulphate and rendered less liable to volatilization.

The association adopted provisionally the method followed at the Illinois Station for soil sampling, and authorized the appointment of a committee to study methods of soil sampling. The determination of potash in soils was referred to the referee for the ensuing year, and also methods for determining soluble constituents in alkali soils. It was recommended that the referee take up the subject of the mechanical analysis of soils and report at the next meeting, and also consider the determination of available plant food in soils.

ASH.

The report on ash was read by the referee, G. S. Fraps. The work during the past year was continued on lines previously followed, viz, the methods of preparing the ash. The point to which special attention was given was whether sulphur or potash is driven off when the substance is incinerated with calcium acetate in an open dish. Two methods were tested for determining sulphur, one using calcium acetate and the other being a modified nitric-acid method. From results submitted the conclusion was reached that the calcium acetate method does not give correct values for sulphur, although the results agree to a certain extent, the loss being due to the escape of organic sulphur compounds rather than to the volatilization of sulphates. The nitric-acid method, with certain modifications proposed by the referee, gave fairly satisfactory results. With potash the conclusion was reached that the calcium acetate method does not give correct results when an open dish is used, and probably not in a closed dish. The following recommendations were made: (1) That the title of this section be changed from "Methods for the analysis of ashes" to "Methods for the determination of inorganic plant constituents;" (2) that the modified nitric-acid method for determining sulphur in plants be adopted as a provisional one; (3) that the determination of chlorin be omitted until a method can be devised which will give more accurate results; and (4) that the determination of potash by ignition of the substances with sulphuric acid, as in the determination of potash in fertilizers, be adopted as an alternate method. These recommendations were adopted, and the referee was instructed to consider further the acetate method for the determination of sulphur in plants.

FOODS AND FEEDING STUFFS.

The report on foods and feeding stuffs was read by the referee, W. H. Krug. But little work was done along this line during the year. The results reported relate to the determination of moisture, starch, pentosan, and galactan. The recommendations of the referee dealt mainly with minor changes, leading to more exact methods. It was recommended that the method used for drying sugars be adopted as optional for the drying of feeding stuffs. With the phloroglucin method it was recommended that instead of using 3 gm. of material a quantity of the material be chosen so that the weight of the phloroglucin obtained shall not exceed 0.3 gm. A number of other minor modifications of this method were suggested.

A paper on the determination of pentosan-free crude fiber was presented by G. S. Fraps. The result of a test of König's method, with modifications, for determining pentosan-free crude fiber was reported. The method is found to be much shorter than the official one, the substance being digested, filtered, and washed in 3 hours. It has the following advantages: It yields a fiber practically free from pentosans, the manipulations are less complicated, and the time is shortened. It requires further study, however, in its application to cotton-seed meal. The author suggested that it be further studied by the referee.

The use of air in moisture determination, except in substances containing drying oils, was referred by the association to the referee for further study. In the diastase method for starch, 20 cc. was adopted instead of 40 cc. in digesting with malt extract. In neutralizing, sodium hydrate in a cooled solution was adopted in lieu of sodium carbonate while hot. Instead of being digested over night with malt extract, 2 or 3 hours was adopted. The recommendation for the phloroglucin method was adopted, and several other minor modifications were made. It was recommended that the referee take up the study of the König method for the determination of crude fiber.

LIQUOR AND FOOD ADULTERATION.

The report on liquor and food adulteration was submitted by the referee, W. D. Bigelow. At the last meeting of the association this subject was divided under 15 heads, with an associate referee for each subject. Thirteen reports were combined in a report which had been submitted to 106 chemists. With some minor changes, it was suggested that these reports be printed as a separate bulletin and the methods suggested be made provisional for the present. This recommendation was adopted by the association, and the title of this subject was changed to referee on food adulteration.

W. B. Alwood made a report to the association on the work carried out at the Virginia Station on the fermentation of cider. In promoting this line of work he suggested cooperation between the horticulturist and the chemist. The study relates mainly to the micro-organisms and their action. The principal object to be kept in view in this investigation is the determination of methods for controlling the fermentations in order to obtain definite and uniform products.

DAIRY PRODUCTS.

The report on dairy products was made by the referee, J. A. Le Clerc. The work during the past year has been along two lines: (1) Determination of albumin in milk, and (2) detection of renovated butter. The methods of determining the casein in milk are now very satisfactory, but the determination of albumin by different chemists has not given concordant results. In previous work along this line various substances were used for precipitating the albumin. This year the albumin was obtained solely by means of heat, it being believed that there is no distinctly albumin precipitant. The results of the various analysts are reported, and attention called to the importance of the association making a more systematic study of the nitrogen compounds in milk. No definite conclusions were drawn, but it was recommended that the work on the determination of albumin in milk be continued.

In the detection of renovated butter six methods were followed. It was the intention when the reports were all in to send out other samples, using only those methods which gave the best results. From the work as far as reported it has been found possible to determine whether the sample is or is not genuine butter. If it is not genuine butter, the ordinary chemical methods for the examination of the fat will show whether the sample is oleomargarine or renovated butter. No recommendations were made, and it was suggested that the work along this line be continued during the coming year.

G. E. Patrick read a paper on the determination of oleomargarine and renovated butter, embodying the results obtained in the Department chemical laboratory.

SUGAR.

The report on sugar was made by the referee, E. E. Ewell. He considered it more important to devise new methods for sugars than to test and try to eliminate the deficiencies of old ones. He stated that there were several important lines of work which ought to be taken up, and called attention to the great need of an official method for sugar beets. No recommendations were made except in reference to the division of the work. These were that (1) there be a referee for optical methods, (2) a referee for the determination of reducing sugars, and (3) a referee for the study of the analytical methods of the sugar industry. These recommendations were adopted.

TANNIN.

The report on tannin was read by the referee, W. K. Alsop. Four samples of tanning materials were sent out for testing by the official method and by the chromed hide powder method. A summary of the results of the cooperative work was given, and also the opinion of the various analysts. The referee concludes from these that (1) the results obtained by the use of wet chromed hide powder are more accurate than those with unchromed hide, (2) more concordant results can also be obtained in the use of the weaker solutions, (3) the method of drying has not much influence on the tannin result when the determinations are made in the same manner, and (4) the determination of soluble solids is a weak point and some method should be adopted which chemists will follow. The greatest objection to the method of using wet chromed hide was stated to have been the length of time required, which is 3 days; but by a series of experiments the referee found that there was no necessity for chroming hide longer than 1 day. He urged, therefore, that the chroming of hide powder 24 hours with 3 gm. of chrome alum per 100 gm. of hide powder be made the official method, and also advocated a provisional method for dry chromed hide, to be carefully experimented with during the coming year. In making up the solution of tanning materials it was recommended that an amount be taken sufficient to furnish 0.35–0.45 gm. of tannin per 100 cc. instead of 0.8 gm. of solids, as at present. In evaporations 50 cc. was considered too small, and 100 cc. was therefore advocated for obtaining all residues. A number of modifications were recommended in the official method.

A report of the meeting of the International Association of Leather Trades Chemists, which met at Liege, Belgium, on August 28, was made by W. H. Krug. The changes in the methods used by that Association were (1) the adoption of Freiberg hide powder, the maximum cellulose content to be 20 per cent and the manufacturer to mark each delivery with the percentage it contains; (2) the adoption of the Official Agricultural Chemists' method for used tanyard liquors. The chromed hide powder method was not very favorably considered by the International Association. In conclusion the speaker read a letter from H. R. Proctor on the correction for the absorption of the filter paper in the determination of the soluble solids, and suggested that it be made the subject of an investigation by the referee for the ensuing year.

Minor changes were made in the wording of the methods to cover the recommendations of the referee. The wet chromed hide powder method was adopted in lieu of the one now followed, and the dry chromed hide powder method was adopted as an optional one. The determination of the acidity of tan liquors was recommended for study during the ensuing year.

INSECTICIDES AND FUNGICIDES.

The report on the majority of these materials was made by the referee, L. A. Voorhees. The past year was the first year in which any analytical work of a cooperative nature has been undertaken on these materials. The results obtained by 22 analysts were reported in detail. As they were somewhat meager, the referee did not make any specific recommendations, but called the attention of the association to the following considerations: (1) That the detection and determination of formaldehyde does not properly belong to the referee on agricultural insecticides and fungicides; (2) that the content of cyanogen in cyanid of potash is of interest, but for fumigating the determination of impurities and the character of gases which they supply will be of more value; (3) that the purity of lyes for the home making of insecticide soap is of importance, but as to the soaps themselves there is much in their analysis that is of no importance to the entomologist. It was suggested that much of the matter of minor importance in the work of the referee as reported be eliminated in order to lighten the labor of his successor. With this modification it was recommended that the methods reported be continued.

The report on arsenical insecticides was made by the associate referee, J. K. Haywood. The work of determining arsenic in Paris green was reviewed, and reasons given for choosing the methods tested. These were the sodium acetate method, as the best at the present status of the analysis of Paris green for finding the arsenic content, and the water-extraction method for showing to some extent the stability of Paris green, as giving an idea of its action in orchard practice. But few results were reported. The associate recommended that the above methods be adopted provisionally, and further tested during the coming year.

L. L. Van Slyke stated that in analyzing Paris green it should be borne in mind that arsenic in soluble form is injurious to foliage, when present beyond certain amounts. The method adopted should apply to the question of determining the danger from the application of arsenic to foliage. In the speaker's laboratory a 10 per cent mixture in water is made of the Paris green, and if, after 24 hours, the amount of arsenic in solution is insufficient to damage foliage, the product is considered all right. J. K. Haywood stated that the soluble arsenic present does not go into solution under 24 hours. The result more closely approximating its action in practice is its stability as determined by its contact with water.

The sodium-acetate method for the determination of the arsenic content of Paris green, and the water-extraction method for showing the stability of Paris green, were adopted as provisional methods, and the association directed further investigation along these lines. No formal recommendations were made in regard to cyanid and formalin, but the referee was instructed to test the cyanid process for estimating the latter.

MISCELLANEOUS.

The report of the abstract committee was made by E. W. Allen. The work during the past year was outlined, which consisted of the publication of abstracts of methods of analysis, prepared by the members of the committee, in this journal. As this abstracting can be followed up by the force in the Office of Experiment Stations, the work was turned over to that Office and the committee discharged.

In view of the fact that the object of the committee on volumetric standards had been accomplished in the establishment of the Bureau of Standards, that committee was discharged. The report of the committee on food standards, defining the meaning of terms, was made by W. Frear.

The report on fertilizer legislation was presented by H. W. Wiley, and attention was called to the need of a national law covering this industry.

The constitution was amended so as to place the appointment of the referees and associates at each annual meeting in the hands of the executive committee instead of the president. The clause relating to membership was changed to read: "All persons eligible to membership shall become members *ex officio*," etc. Section 7 was amended so as to apply to all analysis in official inspection.

A resolution was adopted providing for three committees on recommendations instead of one. These were (1) to receive recommendations on the subjects of phosphoric acid, potash, nitrogen in fertilizers, soils, ash, and insecticides; (2) on dairy products, foods and feeding stuffs, sugar, and tannin; and (3) on food adulteration.

No new method or modification of an existing method is to be submitted by a referee for general test by the association until it has been tested by him with favorable results.

A resolution was adopted welcoming the action of the State dairy and food commissioners in appointing a committee to present its views upon food standards to the association.

The executive committee was asked to consider the subject of the division of the work on nitrogen.

The president elect was authorized to appoint the new committee on recommendations of referees for the succeeding year during the sittings of the convention, and a recommendation was adopted looking to an earlier report upon the recommendations of the referees.

OFFICERS OF THE ASSOCIATION.

The following were elected as officers for the coming year: President, H. J. Wheeler, Kingston, R. I.; vice-president, R. J. Davidson, Blacksburg, Va.; secretary, H. W. Wiley, Washington, D. C.; additional members of executive committee, C. G. Hopkins, Urbana, Ill., and F. D. Fuller, Geneva, N. Y.

The referees and associate referees selected for the year have not yet been announced by the executive committee.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Proceedings of the fifteenth convention of the Association of Agricultural Experiment Stations in the German Empire (*Landw. Vers. Stat., 56 (1901), No. 1, pp. 1–79*).—The fifteenth annual meeting of this Association was held in Bonn, September 14 and 15, 1900, Prof. F. Nobbe presiding.

Among the subjects considered in relation to fertilizers were the determination of phosphoric acid in Thomas slag, the perchlorates in saltpeter, the potash content of potash salts, and the purity of magnesium pyrophosphate obtained in the analysis of slag. The subject of food analysis was confined mainly to the examination of molasses feeds, attention being given more especially to the determination of fat, molasses, and water content. In seed testing there were considered methods of testing and effect of mechanical injury upon the germinating quality. Among the general subjects discussed were the changes in atomic weights, and the condition and needs of the agricultural experiment stations.

The methods of analysis of Thomas slag were considered at some length, especially the limits of variability allowable in the citrate-soluble method. The latitude adopted for citrate-soluble phosphoric acid in Thomas slag was 0.5 per cent.

A report was submitted upon the purity of magnesium pyrophosphate obtained from phosphatic slag by the direct and by the molybdate methods. A table showing comparative results of the 2 methods was given. It was found that by the molybdate method too high results were obtained when the yellow precipitate was allowed to stand a certain time before filtering. This period in which the error occurred fell between 1 and 5 hours. It was recommended that the Wagner method be further studied, as to the influence of the time elapsing between the removal of the molybdate precipitate from the water bath and its filtration; also, the influence on the result of adding a greater or less excess of magnesia.

The methods of analyzing molasses feeds were discussed at some length. Neubauer's methods of determining molasses in such feeding stuffs was adopted provisionally.

The subject of the composition of sugar-beet molasses was presented by Kellner. This considered the sugar and the nitrogen content of the usual refinery molasses with and without the presence of cane sugar, and the residual molasses from the strontium process. The results of the various analysts were given. The nitrogen content of the dry matter of ordinary molasses averaged 2.16 per cent; of the residual molasses from the strontium process 0.69 per cent.

Schulze discussed the water content of molasses feeds and recommended it as a subject for further study.

A report on molasses feeds was made by Emmerling, and the nitrogen content, fat, dry matter, sugar, molasses, and water content discussed. The quality and the composition of the various feeds appearing from time to time and their microscopic examination was later considered.

No changes of any importance were made in the methods of seed testing.

Some consideration was given to an improved method of potash determination, a paper on the subject being submitted by Schulze. The Neubauer method (E. S. R., 12, p. 714) was assigned for further testing.

The question of international atomic weights was discussed by Fresenius.

The subject of the condition and needs of the agricultural experiment stations was treated by König. Among the questions submitted for the consideration of the association were the overburdening of the stations by control work, so as to seriously hamper their experimental studies; the deficiency and the training of able assistants; the desirability of closer cooperation with the Association of German Scientists and Physicians; the improvement of the reports of the stations, and certain deficiencies in experimental work and in the applications of the results.

Proceedings of the committee on foods and feeding, of the Association of Agricultural Experiment Stations in the German Empire (*Landw. Ver. Stat.*, *56* (*1901*), *No. 1*, *pp. 81–94*).—This committee, composed of Messrs. Emmerling, Kellner, Loges, Schulze, and Weigmann, met in Berlin, February 11, 1901. The subjects considered were the preparation of food samples for analysis, the drawing of samples, the microscopic examination of rape cake, molasses feeds, the addition of phosphoric or sulphuric anhydrid in nitrogen determination, the tax on ether used by the stations, and the microscopic examination of foods.

The passing of all food materials for analysis through a millimeter sieve was made obligatory. A few minor changes were made in methods of drawing samples. With molasses feeds there were discussed the water content, the relative value of the proteid and non-proteid nitrogen, and the quantitative estimation of total and of invert sugar. A paper on the optical and gravimetric estimation of sugar in molasses feeds was presented by Schulze. The report on the addition of phosphoric or sulphuric anhydrid in nitrogen estimations was made by Kellner. Upon motion of the referee the method was referred to the committee for further study in comparison with the Gunning method.

A rapid method of determining carbonic acid in air, J. Haldane (*Jour. Hyg.* [*Cambridge*], *1* (*1901*), *No. 1*, *pp. 109–114*, *fig. 1*).—This method involves the use of a specially constructed apparatus, which is figured and described. A sample of the air is drawn into a gas burette, driven backward and forward through a potash solution, and again measured after the absorption of the carbonic acid. The difference between the 2 readings gives directly the number of volumes of carbonic acid per 10,000 in the sample of air. Trials show that the method is reliable to about 0.5 volume per 10,000, a degree of accuracy sufficient for most practical purposes.

The advantages of the method are that the apparatus can be easily carried about, an accurate result can be obtained in about 5 minutes, and no calculations are involved.

On the determination of humus in cultivated soils, K. Bieler and K. Asō (*Bul. Col. Agr. Imp. Univ. Tokyo*, *4* (*1901*), *No. 4*, *pp. 237–240*).—This article reports comparative tests of the accuracy of the determination of humus by means of (1) elementary analysis, (2) Knop's method, (3) Snyder's extraction method (E. S. R., 5, p. 932; 6, p. 691), and (4) Aschman and Faber's volumetric method (E. S. R., 11, p. 110). The results obtained indicate that the figures given by elementary analysis are too high. The amount of humus yielded by the extraction method was only 71 per cent of that indicated by elementary analysis. The percentages of humus found in the air-dry soil by the different methods were as follows: Elementary analysis 13.84 per cent, Knop's method 8.85 per cent, extraction method 9.79 per cent, volumetric method 6.95 per cent. The methods are to be further tested on different kinds of soils.

The determination of phosphoric acid in soils as ammonium phosphomolybdate by means of the centrifuge, E. Gully (*Chem. Ztg., 25 (1901), No. 39, pp. 419–421; abs. in Chem. Centbl. 1901, I, No. 25, p. 1342*).—This article reports tests by A. Baumann of the applicability of the Götz method described by Wedding[1] to the determination of phosphoric acid in soils. The essential features of the method are the precipitation of the phosphoric acid as ammonium phosphomolybdate in a graduated centrifuge cylinder; the separation of the precipitate by 4 minutes centrifugating at the rate of 1,100 to 1,200 revolutions per minute; and the reading of the volume occupied by the precipitate and calculating the results. A satisfactory agreement of the results by this method and by the gravimetric method in case of 63 samples of soil is reported.

A claim of priority regarding the determination of phosphates in potable waters, C. Lepierre (*Bul. Soc. Chem. Paris, 3. ser., 25 (1901), No. 16–17, p. 800*).—The author states that the method recently described by Woodman and Cayvan (E. S. R., 13, p. 319) is exactly the same as that described by him in a communication to the second International Congress of Applied Chemistry in 1896 (E. S. R., 10, p. 16).

Determination of calcium and magnesium in natural waters, L. W. Winkler (*Ztschr. Analyt. Chem., 40 (1901), pp. 82–92; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 463, II, p. 347*).

The determination of ammonia, nitric, and nitrous acids in natural waters, L. W. Winkler (*Chem. Ztg., 25 (1901), No. 55, pp. 586, 587*).—The methods used by the author are given in detail, being a revision of methods previously described.[2]

Determination of dissolved oxygen in waters in presence of nitrites and of organic matter, S. Rideal and C. G. Stewart (*Analyst, 26 (1901), No. 303, pp. 141–148; abs. in Chem. Centbl. 1901, II, No. 3, p. 232*).—A series of tests are reported which, in the authors' opinion, show that by their modified Winkler process—oxidizing with permanganate in acid solution, out of contact with air, in ordinary stoppered bottles of known capacity, adding soda and potassium iodid solution and determining the liberated iodin with thiosulphate and starch—it is possible to ascertain with accuracy the amount of free oxygen rapidly in highly colored and polluted field waters.

An improved method for the rapid estimation of sugar in beets, R. S. Hiltner and R. W. Thatcher (*Nebraska Sta. Rpt. 1900, pp. 49–69*).—Attention is called to the need in plant breeding, and also in factory operations, of a rapid method for estimating the sugar in beets. Present methods give satisfactory results, but are liable to certain errors which increase with more rapid manipulation. The authors propose a modified method which they have found to give very accurate results. The factors used are those required by the Schmidt and Haensch polariscope, although other instruments may be used by changing the factors accordingly.

While all beets do not contain the same percentage of water, it does not vary within very wide limits. In a long series of determinations made at the Nebraska Station during several years, the water content in nearly all cases varied between 80 and 84.5 per cent. From these results the authors state that it is possible to assume an average factor which would not vary from the true amount of water above 2 per cent, except in very rare cases. This maximum of error will not change the dilution of the sugar solution enough to create any appreciable difference in the polariscope reading. The method of determining the water content of the beets is given, and from an average assumed factor the authors construct a table showing, at a glance, the desired volume of water to be added in analysis. In carrying out this method

[1] Stahl und Eisen, 7 (1887), p. 118.

[2] Chem. Ztg., 23 (1899), p. 454.

the cold aqueous diffusion is employed. The sample is reduced to very fine pulp, placed in a tared capsule, weighed, and the amount of water as ascertained from the table is added. As the solution must be clarified as well as made up to a definite volume, there is previously added to the water 3 per cent of a solution of lead subacetate of 54.3° Brix, or specific gravity, 1.257. If acetic acid is used it may also be added to the water. The capsule containing the pulp properly diluted is covered with a disk of wood or glass inclosed in a sheet of rubber to make it fit closely, and vigorously shaken. The mixture is then poured on a dry filter and the operation carried out as usual.

This method was employed with 60 samples. The water factor assumed in preparing the table was 82 per cent. Only 5 samples showed a variation from results obtained by the hot aqueous diffusion above what might be expected in the analyses of duplicate samples by the same method. These 5 samples, which were too low by 0.2 per cent or more, were all of very low grade beets, in which there was an unusual amount of water.

For rapid work an automatic self-registering balance should be used. The capsules should be of the same weight, aluminum being a very desirable metal to be employed in their construction. The burette should be constructed so that it will fill automatically.

As the indirect method of analysis is now generally used in factories this proposed method was tried in that way, using the factor 85 for making the calculation. As compared with two other methods the proposed method was found to be applicable in indirect analysis. The advantages of the proposed method are that no specially constructed apparatus is necessary and it is susceptible of great speed of manipulation.

An improved method for the rapid estimation of sugar in beets, R. S. Hiltner and R. W. Thatcher (*Jour. Amer. Chem. Soc., 23* (*1901*), *No. 5, pp. 299–318*).—This is noted above from another source.

Determination of purity of beet juice by Krause's method, F. Ehrlich (*Ztschr. Ver. Deut. Zuckerind., 1901, pp. 3–16; abs. in Jour. Soc. Chem. Ind., 20* (*1901*), *No. 3, p. 268*).—The author made a number of experiments to determine the influence of various factors, as temperature, time of digestion, fineness of pulp, etc., on the purity of beet juice, as given by Krause's method. It was found that the temperature of digestion has an important influence on the quotient of purity. With increase of temperature, the density of the juice obtained increases, the polarization remains constant, while the quotient of purity diminishes. The fineness of the pulp has no effect on the result. As the time of digestion of the pulp increases, the amount of dry substance increases, the quotient consequently diminishing. The quotients obtained by Krause's method are in general 5 to 7 units lower than those of the old method. Some modification of Krause's method to facilitate working and obviate the de-aeration is desirable.

Methods of analysis, Graftiau (*Bul. Agr.* [*Brussels*], *17* (*1901*), *No. 2, pp. 178–182*).—In comparisons of the Kjeldahl and Gunning methods it was found that digestion was complete by the former 30 minutes after the disappearance of the reddish coloration; by the latter the total time required for digestion was reduced to 35 minutes. From a test of various forms of distilling apparatus it is concluded that such apparatus should be provided with a rectifier, a straight tube of sufficient size and length being very satisfactory for this purpose. Soda was found to be easily carried over in distilling, sulphuric acid less so, and phosphoric acid least of all.

The estimation of glycogen in flesh, G. Breustedt (*Arch. Pharm., 237* (*1899*), *p. 637; abs. in Ztschr. Analyt. Chem., 40* (*1901*), *No. 3, pp. 175–177*).

The composition of the ether extract from a number of fodders, N. Tulaikov (*Izv. Moskow Selsk. Khoz. Inst.* [*Ann. Inst. Agron. Moscow*], *6* (*1900*), *No. 4, pp. 429–439*).—This article is a contribution to the study of the ether extract of clover, alfalfa, rye straw, and oat straw. The analytical results are shown in the following table:

Fat from a number of feeding stuffs.

Feeding stuff.	Melting point.	Iodine number.	Neutral fats.	Free fatty acids.	Nonsaponifiable portion— Soluble in ether.	Insoluble in ether.	Total.	Nitrogen.	Pentosans.	Ash.	Lecithin.
			Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Clover	65°–66°	47.07	25.66	29.71	35.21	3.61	38.82	0.78	0.50	0.55	......
Alfalfa	63°	71.50	1.36	34.09	27.18	26.67	53.85	.75	.04	1.31	......
Rye straw	......	......	19.33	23.49	21.09	11.28	32.37	.37	......	.60	......
Oat straw	63°	......	2.33	9.76	28.57	43.80	72.37	.00	......	.76	6.86

In the author's opinion it is obvious that the crude fat of fodders consisted of a mixture of different compounds in which neutral fat is not the principal constituent, being exceeded by free fatty acids, including considerable quantities of the unsaturated acids. The quantitative analyses of the nonsaponifiable matter showed it to be a complicated mixture containing many other bodies belonging to the terpenes and phytostearine.—P. FIREMAN.

Outline of work on foods and feeding stuffs for 1901, W. H. KRUG (*U. S. Dept. Agr., Division of Chemistry Circ. 7, pp. 3*).—This gives the amended methods adopted at the seventeenth annual convention of the Association of Official Agricultural Chemists (E. S. R., 12, p. 507). Outlined directions are given for the determination of moisture, starch, pentosan, and galactan.

The analysis of potable water, milk, foods, and other materials, H. LAJOUX ET AL. (*L'eau potable, le lait de femme et le lait de vache, matières alimentaires et médicamenteuses. Reims: F. Michaud, 1900, pp. 172, figs. 6*).

Succinct directions for the analysis of wines, beer, cider, and vinegar, P. GOUPIL (*Tableaux synoptiques pour l'analyse des vins, de la bière, du cidre et du vinaigre. Paris: J. B. Baillière & Sons, 1900, pp. 80, figs. 10*).—Treats of the reagents, apparatus, and methods employed in determining the constituents, adulterations, and diseases of the liquors named.

The detection of arsenic in beers, brewing materials, and food, W. THOMPSON and J. P. SHENTON (*Jour. Soc. Chem. Ind., 20 (1901), No. 3, pp. 204–208*).

The pentosan content of various fruits and vegetables, C. WITTMANN (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 3, pp. 131–139*).—Tables of analyses are presented, giving the percentage of pentosans in a large number of seeds, fruits, vegetables, and beer extract.

The distinction of true extract of vanilla from liquid preparations of vanillin, W. H. HESS (*Michigan State Dairy and Food Com. Rpt. 1900, pp. 195, 196*).—While synthetic vanillin is identical with that extracted from the vanilla bean, there are other characteristics of the latter, including delicacy of aroma, which it is impossible to produce artificially. The author states that among the constituents of the vanilla bean the resin, ranging from 4 to 11 per cent, serves as a valuable means of distinguishing the artificial from the natural product. In order to obtain all the extractive matter from the bean an alkaline carbonate is sometimes added to the alcohol, thereby producing an inferior natural product deficient in flavor. A simple method is given for determining the use of alkali in extraction and also for the separation and determination of the resin.

Coumarin and vanillin; their separation, estimation, and identification in commercial flavoring extracts, W. H. HESS and A. B. PRESCOTT (*Michigan State Dairy and Food Com. Rpt. 1900, pp. 197–199*).—Tonka beans, by reason of the possession of the odoriferous principle coumarin, are often used to adulterate vanilla extract.

The determination of coumarin in the presence of vanillin has, therefore, become a problem for the analytical chemist.

A method of separation and identification is submitted by the authors. This method depends upon the aldehyde and phenol character of vanillin. The alcohol is evaporated from the extract to be examined, normal lead acetate added, and the precipitate extracted with ether. The ether solution is treated with dilute ammonia when the vanillin is extracted, leaving the coumarin. Detailed directions are then given for their identification.

Contribution to the analysis of tanning materials, J. Paessler (*Bul. Assoc. Belge Chim., 15 (1901), No. 3, pp. 115–122*).

Determination of tanning matter in tanning materials, T. Koerner (*Leather Manufacturer, 11 (1900), pp. 241–248; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 3, pp. 286, 287*).—Methods of analysis as presented and discussed in a paper read by O. Carr before the meeting of the Association of Official Agricultural Chemists, held at Washington, D. C., November, 1900.

Notes on the absorptive influence of the materials used in the determination of total soluble matter in tanning extracts, A. B. Searle (*Leather Trades Rev., 34, pp. 82–116; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 3, pp. 264, 265*).—Tests of various filter papers.

Selected methods of chemical analysis, A. Classen (*Ausgewählte Methoden der analytischen Chemie. Brunswick: Friedrich Vieweg & Son, 1901, vol. 1, pp. XX+940, figs. 78*).—Qualitative and quantitative analytical methods of determining common and rare elements and the alkalis.

The influence of agricultural chemistry on soil culture, E. Haselhoff (*Der Einfluss der Agrikulturchemie auf die Bodenkultur, 1900, pp. 10*).—A historical review.

On the velocity of chemical reactions, W. Duane (*Amer. Jour. Sci., 4. ser., 11 (1901), No. 65, pp. 349–356*).

Inorganic ferments; the preparation of colloidal metals by the electrical method and the investigation of their catalytic properties, G. Bredig (*Anorganische Fermente. Darstellung kolloidaler Metalle auf elektrischem Wege und Untersuchung ihrer katalytischen Eigenschaften. Leipsic: Engelmann, 1901, pp. 99*).

A simple method for obtaining a saturated aqueous solution of sulphuretted hydrogen, or a constant supply of the gas, F. M. Perkin (*Jour. Soc. Chem. Ind., 20 (1901), No. 5, p. 438, fig. 1*).

An automatic filtering apparatus, J. Winklhöfer (*Chem. Ztg., 25 (1901), No. 59, p. 628, fig. 1*).

Microchemical technique, T. H. Behrens (*Mikrochemische Technik. Hamburg: Leopold Voss, 1900, pp VIII+68*).

BOTANY.

Manual of the flora of the Northern States and Canada, N. L. Britton (*New York: Henry Holt & Co., 1901, pp. X+1080*).—This manual gives descriptions of the ferns, fern allies, and seed-bearing plants which are known to occur within the area extending from Newfoundland to Manitoba, and southward to the southern boundaries of Virginia, Tennessee, and Kansas. Considerably more than 4,000 species are enumerated, many of which are described for the first time. In conformity with many recent scientific publications, the metric system of measurements has been adopted throughout.

This work is based upon the text of Britton & Brown's Illustrated Flora (E. S. R., 8, p. 291), the illustrations of which have been omitted and the descriptions abridged so as to bring the subject-matter within the compass of a single volume. The systems of arrangement and nomenclature of the previous publication have been retained. References are given to the figures in the Illustrated Flora, and the only synonymy quoted is that made necessary by changes resulting from further studies of the nomenclature of many species. By the use of thin paper, narrow margins, and small clear type, the publishers have produced a compact volume that will be preferred by many to the 3 bulky volumes of the original publication.

American grasses, II, F. Lamson-Scribner (*U. S. Dept. Agr., Division of Agrostology Bul. 17, rev. ed., pp. 349, figs. 325*).—This is a revised edition of a bulletin previously mentioned (E. S. R., 11, p. 219). In the present publication the synonymy has been revised and extended, and many of the descriptions have been entirely rewritten and considerably extended so as to include brief economic notes which were omitted from the previous edition.

Plant life of Alabama, C. Mohr (*U. S. Dept. Agr., Division of Botany, Contributions from the U. S. National Herbarium, vol. 6, pp. 921, pls. 13*).—This publication gives a description of the plant life of Alabama as observed by the author during a 40-year residence in the State. A short sketch is given of the physiographical features of the State and on the general aspect of the flora of Alabama, its relation to that of adjoining States, and to the continental and extra-continental floras. A general discussion is given of the geographical distribution of plants, the floral divisions of the State introduced by the author being considered as only tentative. The general and secondary factors influencing plant distribution are mentioned and various plant formations and associations are described. Following this is given a complete enumeration of the plants, nearly 4,500 species and varieties being given. The distribution of the species in the State is indicated, and descriptive and economic notes given of many.

The genus Salix in Iowa, C. R. Ball (*Contrib. Dept. Bot. Iowa State Col. Agr. and Mech. Arts, 1900, No. 18, pp. 141–154, pls. 3*).—An enumeration is given of the willows known to occur in Iowa and the distribution of the different species throughout the State is indicated.

A monograph of the genus Melilotus, O. E. Schulz (*Bot. Jahrb. [Engler], 29 (1901), No. 5, pp. 660–735, pls. 3*).—A historical sketch is given of the genus and statements made concerning the economic value of some of the species. The morphology of the different parts of the plant is described and the geographic distribution of the species indicated. In all, 23 species are recognized.

A contribution to the knowledge of the Chytridiaceæ, R. Lüdi (*Inaug. Diss., Bern, 1900, pp. 44–62, figs. 5*).—The first part of this dissertation is given up to a description of *Synchytrium drabæ*, n. sp., in which its morphology and affinities are discussed. In the second part the biological relationship of a number of species of Synchytrium is discussed, particular attention being given to *S. taraxaci.* The results of many inoculation experiments with this fungus are reported and discussed, from which the author has decided that *S. taraxaci* is not only morphologically distinct, but also biologically. In this group the species seem to be more sharply differentiated and specialized as to host plants than is usually the case with related fungi. The results of studies on the resting spores and other means of propagation are given in conclusion, the principal studies being made with *Cladochytrium menyanthis.*

Anatomical characteristics of agarics, J. Godfrin (*Bul. Soc. Sci. Nancy, 3. ser., 1 (1900), No. 6, pp. 188–211, figs. 17*).—Describes the anatomical structure of a number of species of Panæolus.

Inventory of foreign seeds and plants, J. G. Smith (*U. S. Dept. Agr., Section of Seed and Plant Introduction, Inventory No. 8, pp. 106*).—This inventory includes the seeds and plants imported for distribution in cooperation with the various experiment stations in the country, describing numbers 3401 to 4350, inclusive. Most of these seeds and plants were collected by the special explorers of the Section, principally by D. G. Fairchild and W. T. Swingle.

Plant physiology, W. F. GANONG (*New York: Henry Holt & Co., 1901, pp. VI + 147, figs. 35*).—This book is designed principally for practical use, and with few exceptions all the experiments and recommendations described have been repeatedly tested by the author and his students. Detailed directions are given for the construction of a greenhouse and physiological laboratory, both of which are essential to the prosecution of a course of study such as is outlined. The apparatus, appliances, and plants for study are described and the more common methods of manipulation are clearly stated. The outline of a course in experimental plant physiology is given which includes a study of the structure and properties of protoplasm, the nutrition of plants, growth, reproduction, irritability, locomotion, and protection. In connection with the different chapters, bibliographies are given of important works which should be consulted by the student in the prosecution of the course.

Influence of various organic substances on the respiration of plants, W. PALLADIN (*Rev. Gén. Bot., 13 (1901), Nos. 145, pp. 18–32; 146, pp. 93–96; 147, pp. 127–136*).—In a previous publication (E. S. R., 6, p. 194) the author has shown that etiolated leaves of beans, which are rich in proteids, respire very feebly while those lacking such material, if grown in a saccharose solution, have their respiration considerably increased. In the present paper the author gives an account of experiments in which a number of different carbohydrates have been tested to ascertain their influence upon the respiration of plants. Experiments were made by cutting off the growing tips of etiolated plants and dividing them into 2 lots. One lot was placed in shallow vessels containing a solution of saccharose, and the quantity of carbon dioxid given off by this plant in a certain time was taken as the unit of comparison. The other lot of leaves was placed under identical conditions, except that a different carbohydrate was used, and the quantity of carbon dioxid liberated by this second plant was compared with that of the first. The carbon dioxid was determined by the use of Pettenkofer tubes, and in a similar manner the nondigestible proteids were determined by the Stützer method, and the total nitrogen by the Kjeldahl method. As a result of the experiments the author found that the energy of respiration depends upon the substances given the plants. Of those investigated the greatest amount of carbon dioxid per 100 gms. of fresh plant substance was secured with fructose, followed by glucose, saccharose, maltose, raffinose, glycerin, and mannite. The proportion of carbon dioxid liberated per 100 gms. of fresh weight of the plants, during 1 hour, is shown in tabular form. The author also determined that in the absence of carbohydrates the nondigestible proteids not only were not diminished during the growing of the plants, but were increased to an appreciable degree. However, the increase was much greater when solutions containing some form of sugar were at the disposal of the plant. In one case where the etiolated bean plants were placed in water culture, the nondigestible proteids in 4 days increased 13 per cent, while in the second culture containing saccharose, in the same time, the quantity of proteids was increased 39.5 per cent.

Studies concerning variegation, H. TIMPE (*Inaug. Diss., Göttingen, 1900, pp. 124; abs. in Bot. Centbl., 85 (1901), No. 3, pp. 75–77*).—A report is given of some of the phenomena attending variegation as ascertained in the study of a large number of plants. As a rule, the variegated portions of leaves are thinner than the green parts, the palisade parenchyma and intercellular spaces being considerably reduced. The quantity of tannin in leaves is usually greater in the inner tissues of the variegated areas than in the green parts, although tannin is sometimes entirely wanting in the variegated portion of the leaf. Starch is normally deposited only in the green parts of leaves, while reducing sugars are most abundant in the colorless portions. From the sugar solutions in the variegated portions of the leaves a considerable quantity of starch is formed, which is colored a reddish violet with iodin. Variegated monocotyledonous plants do not transform the sugar in their cells into starch.

Chlorophyll assimilation through cork, Mathilde Goldflus (*Rev. Gén. Bot.*, *13* (*1901*), *No. 146*, *pp. 49–92*, *pls. 2*, *figs. 2*).—A detailed report is made upon experiments in which the author sought to ascertain the effect of a cork layer on the photosynthesis of plants. The stems of a large number of plants were examined, in which there was a well-developed layer of chlorophyll parenchyma underlying the bark. Sections of these were placed in a special apparatus, the amount of carbonic acid in the atmosphere determined before respiration began, and again at periods of 12 hours. About 20 species of woody plants were examined. Chlorophyll is distributed more or less through the branches of most trees and frequently occurs in their trunks, but is there limited to the region where the cork layer is more or less ruptured and furrowed. The author found that there was considerable assimilation in the sections of stems examined, and as the chlorophyll does not disappear from these regions during the winter its functions are probably continuous throughout the year, as there seems to be nothing to indicate a winter resting stage.

Are the lower chlorophyll-bearing algæ able to assimilate atmospheric nitrogen? W. Krüger and W. Schneidewind (*Landw. Jahrb.*, *29* (*1900*), *No. 4–5*, *pp. 771–804*, *pls. 3*).—The authors report extensive experiments with several species of Stichococcus, Chlorella, and Chlorothecium, in which their ability to assimilate atmospheric nitrogen, when grown in pure cultures and sterilized media, was tested. As a result of the experiments, the authors claim that without the presence of combined nitrogen, either in organic or inorganic form, there was but slight development of the different species of algæ; while if the substratum, upon which they were grown, contained combined nitrogen they made abundant growth. There appears to be nothing to indicate that these algæ are able to fix the atmospheric nitrogen. Green algæ, according to their investigations, are unable to assimilate the free nitrogen, and when experiments are conducted that appear to show an increase in the nitrogen content, it is explained by the fact that the algæ offer conditions very favorable for the development of soil and other bacteria which are able to assimilate atmospheric nitrogen.

Concerning the modifications of structure produced in vegetable cells by freezing, plasmolysis, and wilting, L. Matruchot and M. Molliard (*Compt. Rend. Acad. Sci. Paris*, *132* (*1901*), *No. 8*, *pp. 495–498*).—A study of the effect of freezing, plasmolysis, and wilting upon the leaves of Narcissus and some other plants shows that the conditions produced by each of these phenomena are identical.

The effect of temperature and oxydizing enzyms on the formation of transitory starch, J. Grüss (*Wchnschr. Brau.*, *1899*, *No. 40; abs. in Bot. Centbl.*, *85* (*1901*), *No. 1*, *pp. 8–11; also in Jour. Roy. Micros. Soc.* [*London*], *1901*, *No. 2*, *p. 181*).—In experiments with germinating barley, the author found that the formation of transitory starch began at a temperature of 0° C. and increased in the rapidity of formation until the optimum was reached at about 30° C. At 40° C. it was checked, and ceased altogether at 50°. Intimately associated with the formation of transitory starch was found an enzym to which the name spermase is given. Sucrose is said to be the first carbohydrate used during the germination of barley, and starch is not utilized until the embryo attains a stage in its development when it is able to furnish the enzyms necessary to render the starch available. The rootlets of the young plant are said to be inclosed for a time in a kind of gum which is believed to be some form of galactan, and it contains a liquefying enzym.

Concerning the occurrence of cane sugar in plants, J. Anderssen (*Ztschr. Physiol. Chem.*, *29* (*1900*), *No. 4–5*, *pp. 423–428*).—The author identified cane sugar in the rhizome of *Aspidium felix mas* and *A. spinulosum*, and other ferns.

The effect of germination on the pentosans in seeds, A. Schöne and B. Tollens (*Jour. Landw.*, *48* (*1901*), *No. 4*, *pp. 349–354*).—An account is given of experiments with barley, wheat, and peas, in which the effect of germination upon the pentosans in the seed was investigated. Instead of being a loss in pentosans, there was found in every case a slight increase when the germination was carried to about the degree used in malting grains.

Canadian experiments with Nitragin for promoting the growth of legumes, F. T. SHUTT and A. T. CHARRON (*Trans. Roy. Soc. Canada, 2. ser., 6 (1900–1901), Sec. III, pp. 55–69, pls. 2*).—A report is given of a series of experiments with Nitragin, the results of which have already been noted (E. S. R., 10, p. 845; and 11, p. 816).

Root tubercles of alfalfa, N. PASSERINI (*Bul. Soc. Bot. Ital., 1900, pp. 16, 17; abs. in Jour. Roy. Micros. Soc. [London], 1901, No. 3, p. 297*).—According to the author the roots of alfalfa are abundantly provided with root tubercles during the first year of cultivation. Very few occur during the second year, and none at all on plants 3 or more years old. It is inferred that the plant makes use of atmospheric nitrogen only during its first year's growth, or until the roots have attained sufficient length to obtain the necessary nitrogenous food materials from the deeper soil.

Methods of plant histology, C. J. CHAMBERLAIN (*Chicago: Univ. of Chicago Press, 1901, pp. VIII + 159, figs. 74*).—This book is the outgrowth of a course of instruction in histological technology given by the author at the University of Chicago. The methods described were originally published in the *Journal of Applied Microscopy* (E. S. R., 11, p. 29), and have since been revised and enlarged. The technique is well covered, special attention being given the paraffin method, which the author believes is best adapted to the study of plant histology. In the first part of the work the principles of fixing, staining, etc., are described in sufficient detail to enable any worker to adopt the author's suggestions. In the second part the principles are applied to special subjects, the arrangement and choice of material being such as to furnish preparations for a thorough study of plant structures from Algæ to Spermatophytes. Special formulas for the different reagents and a list of class preparations are given in separate chapters.

METEOROLOGY.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 29 (1901), Nos. 4, pp. 145–199, figs. 3, charts 9; 5, pp. 201–241, pls. 4, charts 9; 6, pp. 243–289, pls. 4, fig. 1, charts 9*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts (for the months of April, May, and June, 1901), recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 4, special contributions on The theory of the formation of precipitation on mountain slopes (illus.), by F. Pockels; On the ionisation of atmospheric air, by C. T. R. Wilson; The climatology of Antigua, W. I., by W. H. Alexander; and The seasonable variations in the climate of Antigua, W. I., by H. H. Kimball; together with notes by the editor on Mr. Alexander Ashley, Mr. Charles Davis, Lorin Blodget, Hawaiian weather for February, 1901, Weather Bureau officials as instructors, earthquakes in Montana, dust storms in Burma and elsewhere, the permanence of climate, fog in New York Harbor, sleet, rainfall and grazing, the first number of the Monthly Weather Review, bombardment of hailstorms, sand dunes and the wind, the glacier as an index of climate, an old record at Pensacola, Fla., the kite work of the German Antarctic expedition, and average temperature of upper strata.

No. 5, special contributions on Some causes of the variability of earthshine, by H. H. Kimball; and Twenty years' study of snow crystals, by W. A. Bentley; and notes by the editor on the effect of the moon on vegetation, publications of the United States Weather Bureau, wind and temperature, reduction to standard gravity at Mexican stations, snowfall and its equivalent in water, hail insurance, Weather Bureau men as instructors, annual meeting of the German association of investigators and physicians, and Mr. Gustavus A. Hyde.

No. 6, special contributions on Sun spots and the weather, by H. H. Kimball; An instance of ball lightning at sea, by R. Seyboth; The climate of Harpoot, Turkey in Asia, by E. Huntington; Reforestation and rainfall in the Leeward Islands (illus.), by W. H. Alexander; Climatology of St. Kitts—comparison of barometers, by W. H. Alexander; and Weather Bureau exhibit at the Pan-American Exposition, Buffalo, N. Y., by D. T. Maring; and notes by the editor on hail and thunderstorms in Oregon, meteorology in French Indo-China, a rain of small fish, sun spots and meteorology, meteorology in the universities, the International Meteorological Congress, Paris, September 10–16, 1900, and Knut Angstrom on atmospheric absorption.

Department of meteorology, J. E. BONEBRIGHT (*Idaho Sta. Bul. 29, pp. 21–33*).—A tabular record is given of daily observations at Moscow, Idaho, on temperature, pressure, precipitation, and cloudiness during each month of 1900.

Weather and crop records for 1898, 1899, and 1900, J. H. SHEPPERD and A. M. TEN EYCK (*North Dakota Sta. Bul. 48, pp. 777–779*).—Tables are given which show the average soil and air temperatures, temperatures of mean dewpoint, relative humidity, average and total evaporation, and total rainfall for the crop-growing periods (May to August); also the monthly weather and crop records for the periods from April to September, inclusive, of each year.

Meteorological (*Rpt. Dept. Agr. Northwest Territories, 1900, pp. 5–15*).—The data reported include mean temperature and precipitation during April-September, 1900, at 12 different places in the Territories; annual precipitation at 8 places during 1886–1900, inclusive; and annual and monthly summaries of observations on precipitation and maximum, minimum, and mean temperature during 1900 at about 30 different places. The general meteorological features of the year (1900) are discussed.

General summary of meteorological observations made in different parts of Mexico during 1900 (*Bol. Mens. Obs. Met. Cent. Mexico, 1900, No. 4, pp. 46–48*).—Tabular monthly summaries of observations on atmospheric pressure, temperature, humidity, precipitation, per cent and direction of clouds, velocity and direction of the wind, and evaporation are given.

Meteorological summary, 1900, H. DUFOUR and D. VALET (*Chron. Agr. Canton Vaud, 14 (1901), No. 17, pp. 421–424*).—Monthly and annual summaries are given of observations in different parts of the Canton of Vaud, Switzerland, on temperature and rainfall during 1900 and 25 years (1874–1898); and on hours of sunshine during 1900 and 10 years (1886–1895), and intensity of sunshine during 1890 and 25 years (1876–1900). The results of semiweekly measurements of soil temperatures at 3 depths are also reported.

Report of the imperial station of meteorology and terrestrial magnetism at Vienna (*Jahrb. K. K. Central-Anst. Met. u. Erdmagnet., Vienna, n. ser., 35 (1898), pp. XXI + 145; 36 (1899), pt. 1, pp. 192*).—The detailed official report of observations in Austria during the years 1898 and 1899.

Magnetical, meteorological, and seismological observations made at the government observatory, Bombay, 1898 and 1899 (*Bombay: Government Central Press, 1901, pp. 196, charts 11*).—This report contains an account of the organization and operations of this institution during the years named, and tabular records of continuous observations with automatic instruments during 1898 and 1899; observations at 5 different hours daily during 1898 and 1899; five-day means 1898 and 1899; principal disturbances recorded by Milne's seismograph from September, 1898, to December, 1899; absolute magnetic observations, 1898 and 1899, with hourly means of declination, horizontal and vertical force, for 1894 to 1899; mean hourly values of temperature and pressure, 1876–1895, with harmonic analyses of the temperature and pressure at Colaba; and temperature, pressure, and rainfall normals, 1873–1896.

The distribution of rainfall over the land, A. J. HERBERTSON (*London: John Murray, 1901; rev. in Nature, 64 (1901), No. 1661, p. 423*).

The moon and wet days, A. B. MACDOWALL (*Nature, 64 (1901), No. 1661, p.*

424, fig. 1).—A chart is given which shows the rainfall for each lunar phase during the whole year and the summer months, April–September, compiled from observations during 24 years at Greenwich. The curves "agree in presenting a minimum between the full moon and the last quarter (the third, second, or first day before last quarter)." The maximum fluctuated between new moon and first quarter.

Investigations relating to "weather shooting," J. M. PERNTER and W. TRABERT (*Meteor. Ztschr.* [*Vienna*], *17* (*1900*), *No. 9, pp. 385–414*).—This article describes the construction and gives results of tests of various forms of apparatus used for dissipating hail storms by means of vortex rings. Numerous measurements of the velocity and force of the vortex rings produced by both vertical and horizontal firing are reported and their nature and action are discussed. In the more successful cases of horizontal firing the rings reached a distance of only about 200 meters, in vertical firing 300 meters, although sometimes going in the latter case as high as 400 meters under exceptionally favorable circumstances. In order that the system may be completely effective the cannon should be so placed as to agitate the air to a height of 800 meters, as hail clouds are sometimes that high, though never higher according to Stiger, Roberto, and others.

WATER—SOILS.

On the value of evaporometric indications to agricultural practice, N. MALUSHITSKI (*Izv. Moscow Selsk. Khoz. Inst.* [*Ann. Inst. Agron. Moscow*], *6* (*1900*), *No. 3, pp. 325–403*).—The object of the investigation here reported was to find if possible the relation between the evaporation from a free water surface (as indicated by an evaporometer) and that from bare and cultivated (covered) soils. For this purpose the author carried out several lines of experiments, viz: Observations on rainfall and on evaporation from a free water surface, and from soil in large zinc lysimeters, and in small glass lysimeters.

The evaporation from the free water surface was studied with the aid of Michelson's and of Wild's evaporometers. Wild's apparatus was found more reliable and was used in comparing the evaporation from a free water surface and from the soil.

In the experiments with the large zinc lysimeters 5 instruments were used. They were filled with soil and subsoil. The author studied with them the evaporation by oats during the whole of its period of vegetation, by rye in the fall period, from black fallow, and from sod (chiefly *Aira cæspitosa*, *Veronica latifolia*, and *Taraxacum officinale*). Since these lysimeters were heavy (weighing 131–139 kg.) and did not admit of accurate weighing, the author also experimented with 12 small glass lysimeters in which a layer of soil 10–15 cm. thick (corresponding to the medium depth of plowing in case of cereal crops) was placed. On some of the lysimeters rye was grown while the others were left without a crop.

On the basis of his own experiments and a survey of the whole literature on the subject, the author arrives at the following conclusions:

(1) The establishment of a correlation between the indications of a water evaporometer and the evaporation from a cultivated soil under natural conditions is impossible, since the structure of the soil and the state of its surface, which are in most cases beyond our control, exert an immense and varied influence on the stored up humidity as well as on its evaporation from the soil, an influence which does not affect the evaporometer.

(2) Exceptions may perhaps be admitted in the case of soils (a) saturated with moisture and (b) possessing a more or less constant amount of moisture with a constant structure and unchanging surface.

(3) The correlation in question can still less be established in case of soil covered with cultivated plants on account of the added disturbing factor of the varying evap-

oration by the plants as influenced by light, period of vegetation, humidity of the soil and air, etc.

(4) In order to measure the accumulation, evaporation, and percolation of water in the soil it is necessary to have recourse to lysimeters. If it is desirable, in addition, to trace the movement of the water under the influence of capillary forces, difference of temperature, etc., from the higher to the lower layers, and *vice versa*, there remains one of two ways open, either to construct a segmented lysimeter, consisting of a series of cylinders (each capable of being weighed separately) filled with the given soil and subsoil, or to determine the moisture by taking samples of the whole depth of the layer under investigation.

(5) The determination of the moisture of the arable soil layer at various stages of culture is possible only by taking samples for the estimation of moisture, or, perhaps, by measuring the electric conductivity of the soil as described in some recent investigations, for the determination of the moisture of the cultivated soil layer can not be made with any degree of accuracy either by means of the evaporometer or by the aid of a weighed lysimeter.—P. FIREMAN.

New evaporometer for the study of the evaporation from grass, and observations with it in the Constantine observatory in 1896, M. RIKACHEV (*Abs. in Zhur. Opuitn. Agron., 1 (1900), No. 1, pp. 115–117*).—The apparatus is claimed to be better adapted than others which have been proposed for the study of evaporation from various cultivated plants and soils under the influence of different meteorological, soil, and culture conditions. The evaporometer consists of three rectangular zinc boxes, of which the outer one is placed in the ground, while the other two, one above the other, are fitted tightly into the first one. The lower box of the last two has an entire bottom and shoulders projecting inward, while the upper one has a bottom with perforations 1 cm. in diameter, separated by distances of 1.5 cm. The upper box rests on the shoulders of the lower one. The upper box is 40 cm. long, 25 cm. wide, and 15 cm. deep. The length and width of the lower one are the same, but the depth is only 10 cm. The area of the inclosed space is about 1,000 sq. cm. In order to make observations with the apparatus, water is poured into the lower box until it forms a layer 5 cm. deep, and a thermometer is placed in the apparatus on supports provided for it. The upper box receives on its perforated bottom first a layer of coal 1 cm. thick and then a piece of sod cut to closely fit the box. Experiment showed that a piece of sod retained its fresh appearance during 3 months without the application of water. Into the sod a thermometer is introduced so that its bulb is buried to a depth of 10 cm. The whole apparatus, together with the sod and water, weighs about 24 kg. When it rains the excess of water percolates into the lower box. The presence of water here must, according to the author, maintain a constant degree of humidity in the lower layer of the upper vessel. Observations were made 3 times every day, for which purpose both inner boxes were taken out and weighed together, the temperature of the sod taken, the upper box removed, and the temperature of the water taken. The decrease of weight between two observations was taken as a measure of the evaporation from the sod during that time. When the midday observation was made the lower vessel was also weighed separately, and if an increase of water caused by a rain was noticed, the excess was poured off, leaving a layer of water weighing 4,410 gm. (5 cm. deep).

The evaporation from sod as measured by this apparatus exceeds that found by Wild's evaporometer 2 to 3 times.—P. FIREMAN.

Solution studies of salts occurring in alkali soils, F. K. CAMERON, L. J. BRIGGS, and A. SEIDELL (*U. S. Dept. Agr., Division of Soils Bul. 18, pp. 89, figs. 10*).—This is a series of technical papers giving preliminary accounts of studies made during the past year. Investigations are reported on the equilibrium between carbonates and bicarbonates in aqueous solutions, in which it is shown that when in equilibrium with the air aqueous solutions of sodium or potassium normal carbonate necessarily contain some bicarbonate, and, conversely, solutions of bicarbonate necessarily contain some normal carbonate. At equilibrium, which depends upon the concentration of the solution, the temperature, and the partial pressure of the carbon dioxid in the surrounding atmosphere, there is a definite distribution of the base between the two acids. At any given concentration the proportion of normal carbonate increases with rise of temperature. Conversely, at any given temperature the proportion of normal carbonate increases with the total concentration, provided the latter is not very great. In presence of normal or excessive amounts of carbon dioxid calcium is found almost entirely in form of bicarbonate. Magnesium, however, under the same conditions, is largely (over 50 per cent) in form of normal carbonate. "It seems probable, therefore, that the presence of much magnesium carbonate, as compared with calcium carbonate, in the soil would have a much more marked effect in producing soluble normal carbonates or the dreaded 'black alkali.'"

Studies on the solubility of gypsum in aqueous solutions of sodium chlorid (alone or in the presence of solid calcium carbonate) and of certain other electrolytes—magnesium chlorid, calcium chlorid, sodium sulphate—are reported, which developed certain facts of value in explaining the solution and transportation of gypsum in the soil, its precipitation from the soil solution in the presence of large quantities of other soluble salts, and the formation of gypsum layers at different depths in the soil as observed in many localities of the arid region. The light which these studies throw on the formation of alkali and alkali crusts has been utilized in a comprehensive classification of alkali lands on a chemical basis (E. S. R., 13, p. 232).

"It seems probable, from the results of this investigation, that wherever gypsum occurs in the soil there will be a considerable amount of calcium in the soil solution. This is now known to be a matter of great importance from a physiological point of view, enabling the plants to withstand much larger quantities of the more soluble salts than would otherwise be possible. . . .

"Calcium sulphate is much more soluble than calcium carbonate, even when there is a considerable amount of carbon dioxid present, and the solubility of the latter salt is thus increased through the formation of the more soluble hydrogen carbonate. It has therefore seemed probable that it would be better in many cases to use the sulphate for liming soils, because in this way more calcium is brought into the ground solution and its ratio to the other bases dissolved is much increased, and because its active mass in the solution is greater and its effect upon other soil components is correspondingly increased. On the other hand, it can not have the effect that either the carbonate or hydrate of lime has in counteracting an excess of carbonic or other organic acids in sour soils or in making them slightly alkaline—a condition which appears to be desirable for certain crops. Furthermore the carbonate and hydrate have certain well-marked effects on the texture of soils, which are sometimes of as much or more importance than the purely chemical results; consequently it seems desirable that the comparative value of these lime salts, or mixtures of them, on soils of various character should receive more attention than has hitherto been given, both in the laboratory and in actual field practice.

"The application of soluble mineral fertilizers to the soils of humid areas unquestionably affects the solubility of mineral components of the soils. Such cases are analogous to the gypsum solution, in that a slightly soluble substance is brought into contact with solutions of much more soluble substances. The idea suggests itself that, as with gypsum, possibly the mineral components of the soil may have maximum solubilities, in solutions of the more soluble salts of definite concentrations, far below the limit of solubility with respect to the readily soluble salts."

Investigations of the same kind on the solubility of calcium carbonate in aqueous solutions of certain electrolytes in equilibrium with atmospheric air showed "that sodium chlorid in solution has an important rôle in causing the solution, transportation through the soil, and reprecipitation of calcium carbonate, and that this rôle is modified, but does not disappear, when calcium sulphate is present. The rationale of the application of gypsum or land plaster to soils containing 'black alkali,' or sodium carbonate, resulting from the action of sodium chlorid upon calcium carbonate, is made apparent.

"Sodium sulphate has been shown to have an astonishingly great effect on the solubility of calcium carbonate, the resulting solutions containing not only hydrogen carbonate, but normal carbonate as well. Further, there is no necessary precipitation of the lime carbonate with increasing concentration with respect to sodium sulphate; but the solubility of the lime carbonate steadily increases with increasing amounts of sodium sulphate in the solution, up to the saturation point of this latter salt."

A detailed description is given of the method of chemical examination of alkali soils worked out in the laboratory of the Division along the lines indicated by the results of the investigations above noted. The salient features of this method are—

"(1) The aqueous solution of the soil alkali is made under similar conditions in all cases.

"(2) The electrical resistance of the soil solution is used in facilitating the analytical processes.

"(3) A direct determination of the total solids in the soil solution is not made.

"(4) A unique, satisfactory, and accurate volumetric method is used for the determination of carbonates and bicarbonates (E. S. R., 12, p. 819).

"(5) All the constituents, including sodium, are determined directly, and no results are obtained by difference.

"(6) The possible necessity for duplicate determinations is made evident by the calculation of the results obtained.

"(7) Finally, the report of the analysis includes the percentage of alkali present in the soil and the relative percentage composition of this alkali; it is stated in terms of the possible ions present in the solution as well as their combinations as electrolytes."

Comparative tests are reported which indicate that Congo red may in some cases be substituted with advantage for methyl orange as an indicator in the method of determining carbonates and bicarbonates referred to above.

"For some eyes and under certain conditions Congo red is to be preferred to methyl orange; for those who can use it, however, methyl orange seems to be the more delicate indicator.

"It is essential to the satisfactory use of the method that during the titration the solution should not be in contact with carbonates, bicarbonates, or metallic hydroxids in the solid phase."

Soil and soil moisture investigations, J. D. TINSLEY and J. J. VERNON (*New Mexico Sta. Bul. 38, pp. 55–95, pls. 12*). This bulletin reports the results of a study of the physical character and of the fluctuations of moisture during the season of 1900 in 12 plats of soil planted to corn. The methods and apparatus employed are described and the results of determinations of moisture on the different plats at depths of from 3 in. to 10 ft. are tabulated. A form of auger for taking soil samples and a shaker for use in mechanical analysis are described. With these exceptions the methods and apparatus were essentially those of the Division of Soils of this Department. The soils of the experimental plats were found to be very uneven in texture. This is stated to be due to the fact that 4 different factors have entered into their formation, (1) river deposit, (2) wash from the foothills, (3) sediment from irrigating water, and (4) drift of soil by the winds. In studying the porosity of the soils comparative tests were made of 4 methods, namely, Beeson's (E. S. R., 9, p. 429), Whitney's, A. Mayer's, and Wolff-Wahnschaffe's. The Wolff-Wahnschaffe method was found to give the most concordant results and was used in the examinations reported. The studies on soil moisture were conducted on the same plan as in previous years (E. S. R., 12, p. 425). Moisture determinations were made by drying and by the electrical method devised by the Division of Soils of this Department at depths of 3 to 6 and 15 to 18 in. The samples were taken the first of each month and the readings of the soil hygrometer were taken every 2 days. In 1899 sweet potatoes, winter wheat, and corn were grown on the plats on which the determinations were made. In 1900 the plats as already stated were planted to corn. The method of cultivation and irrigation of the plats is described in detail and the results of the moisture determinations are tabulated. The results are summarized as follows:

"(1) The moisture content of irrigated land is apt to vary within wide limits.

"(2) The results of this season's work indicate that when the moisture in this soil falls below a fairly definite limit the corn begins to cure. This limit lies near 20 per cent, calculated on dry weight of soil, or about 50 per cent of the water capacity of the soil, at 3 to 6 in.

"(3) The crop showed very unequal growth within short distances, the reasons for which we are not yet able to explain.

"(4) The results indicate that under the climatic conditions which prevailed during last season at least 3 irrigations are necessary to produce a crop of corn, and that the late irrigation showed more marked effect than the early irrigations.

"(5) The cultivation (as practiced this season) does not seem to have had the desired effect in conserving moisture in this soil.

"(6) Good germination is readily produced by irrigating to produce germination after planting, even when the water is quite muddy.

"(7) Subsoiling had apparently no effect either on moisture content or yield."

Soil moisture studies, J. H. SHEPPERD and A. M. TEN EYCK (*North Dakota Sta. Bul. 48, pp. 735–776, figs. 3*).—As in previous years (E. S. R., 11, p. 325), studies on soil moisture were continued during 1900 in connection with comparative tests of methods of culture of wheat (see p. 442), the same plats being used and the same methods followed as in the earlier experiments. The summarized results of 3 years' work along this line are reported in this bulletin. The growing season of 1900 was somewhat abnormal, being very dry in the earlier part and very wet in the later months. It thus gave opportunity for study of the moisture conditions of the soil under extreme conditions. The results reported show that—

"Corn land went into the winter season, November 15, 1900, with 2 in. more water in the soil than wheat or flax land, and 1 in. more than potato and millet ground, despite the heavy summer and autumn rains.

"Bare, cultivated land contained the largest amount of moisture and timothy ground the least at the close of the season.

"Little change occurred in the moisture content of the soil during the winter of 1900–1901.

"On July 24, 1900 (before the rain fell), corn ground contained 5.7 in. more water than wheat ground.

"Barren summer fallow (plowed once) with no cultivation is little better than continuous wheat growing for conserving soil moisture.

"The manured ground produced 9 per cent greater crops, but contained 5 per cent less moisture in the soil at harvest time, than did the unmanured ground.

"In the spring of 1901 the manured land contained more moisture in the surface soil than the unmanured land.

"The water table falls during the winter season, but there is little or no loss of soil moisture, and there is an actual gain of moisture in the surface soil, which is not due to rain or snow.

"The Campbell method has yielded small crops of wheat and has given no appreciable saving of soil moisture.

"Poorer yields were obtained upon shallow than upon deep plowing.

"Disk plowed land has not yielded so well as shallow plowed.

"Subsoiling has increased the yield, but required a little more water to produce the crop.

"Subsurface packing and harrowing after plowing have given a slight increase in yield, and have conserved the soil moisture.

"Rolling and harrowing have given increased yields in wheat, especially upon spring plowing, but the soil has been left drier than the ordinary plowing at harvest time.

"Harrowing wheat conserved the soil moisture and proved beneficial.

"As an average for all trials for 2 years, it required about 1 in. of water to produce 2 bu. of wheat.

"Moisture stored in the soil seems to do the crop more good than that which falls as rain during the average season."

A soil survey in Salt Lake Valley, Utah, F. D. GARDNER and J. STEWART (*Utah Sta. Bul. 72, pp. 77–114, pls. 11, figs. 5, maps 4*).—This is an account of a survey made by the station in cooperation with the Division of Soils of this Department, reprinted from Report No. 64 of the Department (E. S. R., 12, p. 522).

Some Idaho soils, H. T. BEANS (*Idaho Sta. Bul. 28, pp. 31*).—Mechanical and chemical analyses of 20 samples of soil are reported, and the results are discussed with reference to classification and distribution in the State. (See also E. S. R., 7, p. 486.) The soils of the State are tentatively grouped as follows: (1) Coarse sandy soils of the foothills and timber lands; (2) fine sandy silt soils; (3) river sand soils; (4) sandy soils of the arid regions, and (5) alkali soils.

"The first class comprises those soils formed mainly from the talus of the foothills. They are characterized, physically, by their light brown color, very coarse sandy or gravelly texture, and abundant quantities of feldspar fragments and mica. The principal chemical characteristics seem to be a low lime and nitrogen content with high percentages of phosphoric acid and potash and especially of magnesia.

"The second class includes the fine-grained soils of basaltic origin, such as are found in the Palouse and Potlatch regions. These soils are characterized by their dark color and fine texture. Mechanical analysis shows them to contain practically no coarse material, about 41 per cent of fine sand, 47 per cent of silt, and usually not over 2 per cent of clay. The distinguishing chemical features of these soils are high percentages of all the mineral plant foods except lime and unusually large amounts of organic matter and humus. Many of our best wheat soils belong in this class.

"The third class, found mostly along the larger rivers, comprises those soils formed almost entirely from river sand and 'wash.' They contain about 90 per cent moderately fine sand (mostly quartz and mica), the silt and clay having been for the most part washed out. Like most sandy soils, this type is highly insoluble in acids, contains very little organic matter, humus, and nitrogen, and has very limited capacity for retaining moisture.

"These soils are somewhat analogous physically to the early truck soils of the East, but unlike them chemically in that our river sand seems to contain large amounts of potash and phosphoric acid.

"The fourth group consists of those sandy soils of the irrigated region that do not contain an excess of soluble salts. These soils are usually of a light brown color and are made up of about 60 per cent sand and 20 per cent silt, with some gravel and clay. They are of volcanic origin and are usually rich in the mineral plant foods, but contain small percentages of nitrogen, and some are rather deficient in lime.

"The fifth group comprises the soils of the arid region that contain an excess of salts soluble in water. The term 'alkali soil' is no longer used in a derogatory sense, but means simply a soil in which there is an excessive accumulation of these salts. This excess of alkali salts may or may not be large enough to be harmful to vegetation. In any case, the alkali soils are almost without exception exceedingly rich in mineral plant food, and when the alkali condition is corrected, often form our most productive soils.

"In general, it may be said of our Idaho soils, that they are unusually rich in all the mineral plant foods except lime. The volcanic origin of the greater part of our soils makes them especially rich in potash and phosphoric acid. Some of the soils of the humid regions contain unusually high percentages of humus and nitrogen.

"The extent of 'alkali' in the State has not yet been investigated, but thus far in our soil work no soils analyzed have contained harmful amounts of either white or black alkali. The soils received from Cassia County contain both kinds of alkali, but not as yet in sufficient quantity to be dangerous to crops."

Soil analyses, F. T. Shutt (*Rpt. Dept. Agr. Northwest Territories, 1900, pp. 29–31*).—Analyses, including determinations of available potash, phosphoric acid, and lime, of 4 samples of surface soil from the Calgary Experimental Station, Northwest Territories, are reported. Two of the samples were of the same soil, irrigated and unirrigated, which were examined with a view to ascertaining the effect of irrigation on the plant food present. The results were not conclusive.

The soils of the northern marshes of the Vendee, their composition and exhaustion under culture without fertilizer, M. Artus (*Ann. Sci. Agron., 1901, I, No. 2, pp. 288–295*).—The soils of these sea marshes which have been reclaimed by natural or artificial means are very clayey and difficult to cultivate. The area included in the study here reported was about 50,000 hectares. Chemical analyses of 8 samples of the soil of the region are reported. These show that as a rule the soils are abundantly supplied with nitrogen, potash, and phosphoric acid. The latter, however, was found to be but slightly soluble in water by the Schloesing method, and the productiveness appeared to vary with the proportion of soluble phosphoric acid present. The effect of continuous culture without manure shows itself especially in the reduction of the amount of soluble phosphoric acid.

Soils, Graftiau (*Bul. Agr.* [*Brussels*], *17* (*1901*), *No. 2, pp. 170–172*).—Analyses of 9 samples of soil and subsoil of the Campine and of 1 sample of chernozem from Bulgaria are reported.

Condition of the aluminum in cultivated soils, T. Schloesing (*Compt. Rend. Acad. Sci. Paris, 132* (*1901*), *No. 20, pp. 1203–1212; abs. in Jour. Chem. Soc.* [*London*], *90* (*1901*), *No. 465, II, p. 471, and Chem. Centbl., 1901, II, No. 3, p. 222*).—The author found in examination of a number of Madagascar soils that most of them contained either free alumina or aluminum silicates readily attacked by a dilute solution of sodium hydroxid. The alumina and the silica, however, were chiefly in a sandy condition and did not increase the tenacity of the soils.

Soil temperature at Hawkesbury Agricultural College, Richmond, New South Wales, C. T. Musson (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 6, pp. 669–680, pls. 2*).—Observations extending over a period of one year, May, 1898, to April, 1899, are reported. The observations were made at depths of $\frac{1}{2}$ in., 6 in., 1 ft., and 2 ft., in a light-colored sandy loam. The daily temperature variations are charted and discussed with reference to the effect of rainfall and other conditions.

Humus and soil nitrogen, E. F. Ladd (*North Dakota Sta. Bul. 47, pp. 685–704*).—In continuation of previous investigations (E. S. R., 11, p. 224) studies were made on nitrifying organisms and the nitrates and nitrites in different soils; the percentage of nitrogen in the first and second 6 in. of the same soil at different dates; the percentage of organic matter and humus in the first and second 6 in. of plats subjected to different systems of cropping and culture; and on the changes which take place in manure heaps.

The number of colonies of ordinary bacteria in the first 3 in. of soil was found to range from 10,000 to 52,000, and of anaërobic bacteria from 400 to 8,000. Nitrifying bacteria were not found in bare summer fallow below 2 ft. Probably they do not occur normally below 18 in. In the first 6 in. of the soil there was found 415 lbs. of nitrates per foot-acre (an acre of soil to a depth of 1 ft., or 3,142,800 lbs. of soil); in the second 6 in., 234 lbs.; at a depth of 3 ft., 675 lbs.; at 7 ft., 294 lbs. Since 85 per cent of nitrifying organisms were found in the first 6 in. of soil and none were found below 2 ft. it is evident that the nitrates found at a greater depth had leached down from near the surface. The largest amount of nitrates was found in a plat on which wheat had followed peas, but "on July 14 the field on which corn had been grown the preceding year contained 39 per cent more nitrates than for the continuous wheat field. On July 30 the difference was even more marked, being 61 per cent more of nitrates." Large amounts were also found in bare fallow, but small amounts under prairie sod.

"The continuous growing of wheat, or other grains, or cultivated crop, rapidly depletes the organic matter from the second 6 in. of soil. The growing of clover and peas in a crop rotation causes a marked increase in the organic matter and humus in the soil in both the first and second 6 in. . . . Plowing under a green crop does not produce as beneficial results as come from plowing grass lands. Plowing under a green crop leaves the organic matter in a mass and not uniformly distributed throughout the soil. After grass in a crop rotation the soil shows a large increase in amount of organic matter, but less than two-thirds as much as is found in adjoining fields of native prairie soil. . . .

"Soils on which wheat has been grown continuously since 1883 were found to be in bad condition, chemically and physically. They do not retain water well in the cultivated portion, and failed to mature a crop of wheat in the dry season of 1900. The available plant food and the principal feeding ground of the wheat roots seems to be in the first 8 in. of soil. . . .

"Newly broken soils do not blow. . . . The great mass of fine roots intertwined about the particles of soil in the virgin prairie prevented the soil from blowing." The same result may be attained by adopting a system of rotation which includes grass.

"The system of agriculture most nearly ideal for maintaining soil fertility would be one with 2 years in grass followed by cultivated crop, then 2 years in grain crops, making a 5 years' rotation."

The decomposition and transformation of nitrogen compounds in soils by lower organisms, and their influence on the growth of plants, W. Krüger and W. Schneidewind (*Landw. Jahrb., 30 (1901), No. 4, pp. 633–648, pl. 1; abs. in Deut. Landw. Presse, 28 (1901), No. 73, p. 619*).—On the basis of the results of plat and vegetation experiments during 1900 the authors conclude that the effect of coarse manures in interfering with the assimilation of nitrogen of the soil by plants is due not only to denitrification but also largely to the transformation of assimilable nitrogen (including that of ammonium sulphate) into insoluble and unassimilable nitrogen compounds (albuminoid substances). For previous investigations of the authors on this subject see E. S. R., 12, p. 728.

On the action of organisms in soils and manure, L. Hiltner (*Deut. Landw. Presse, 28 (1901), Nos. 24, pp. 203, 204; 25, pp. 212, 213; 27, pp. 231, 232*).—A general discussion of this subject.

On nitrification and denitrification, A. Beddies (*Chem. Ztg., 25 (1901), No. 49, pp. 523, 524; abs. in Chem. Centbl., 1901, II, No. 3, p. 222*.

Treatise on the origin and formation of soils, L. Milch (*Die Grundlagen der Bodenkunde. Leipsic: Franz Deuticke, 1901, pp. 162; abs. in Geol. Centbl., 1 (1901), No. 19, p. 581*).—This book discusses the more important mineralogical and geological facts relating to soil formation.

The vertical movement of the surface soil, H. Darwin (*Rev. Sci., 4. ser., 16 (1901), No. 6, pp. 183, 184*).—This is a note on a communication to the Royal Society of London on observations, in continuation of those of the elder Darwin, on the rate at which stones and other objects left on the surface sink into the soil.

What is a steppe? G. I. Tanfilyev (*Abs. in Zhur. Opuitn. Agron., 1 (1900), No. 3, pp. 278, 279*).—The author gives the following definition: "A steppe is a more or less plain tract, treeless in its natural state, not subject to inundations, covered with more or less continuous sod and with a more or less dark soil layer on a subsoil rich in carbonates and other soluble salts." From deserts which are connected with it by a series of transitions, the steppe differs by containing carbonates as a predominating constituent of its soluble salts while they are also rich in soluble chlorids and sulphates.—P. FIREMAN.

Some apparatus for soil investigation, T. L. LYON and Y. NIKAIDO (*Nebraska Sta. Rpt. 1900, pp. 20–28, figs. 3*).—Apparatus for determining soil moisture and soil temperatures are described. The first consists of a sampling tube, 200 gm. soil cans of aluminum with wooden case, and double-walled constant-level oven of sheet copper containing a mixture of 3 parts of glycerin with 1 of water for drying the soil in the cans at 100° C.

The apparatus for determining soil temperatures consists of a thermometer inclosed in a hollow steel tube, which may be driven into the soil to the desired depth. "The thermometer proper consists of a thin glass bulb 3 in. long and ½ in. in diameter joined to a capillary stem 30 in. in length. The bulb and the stem are filled with mercury to such a point that the zero point of the thermometer is 15 in. above the bulb. The stem is inclosed in a glass case ½ in. in diameter at the lower or ungraduated portion, and 1 in. in diameter at the upper portion which carries the scale. This leaves a dead-air space surrounding the stem of the thermometer, which tends to prevent changes of temperature in it during the measurement of the soil temperature. The total length of the ungraduated portion of the stem is 18 in. This permits the determination of the temperature of the soil at any desired depth down to that limit." For inserting the thermometer into the soil a solid steel rod closely fitting the hollow steel tube, referred to above, is placed in the latter, the lower end, which is of the same diameter as the bulb of the thermometer, projecting a few inches below the end of the tube, and the whole is driven into the soil to the desired depth. The rod is then withdrawn and the thermometer is lowered into its place. "The bulb of the thermometer will then come in contact on all sides with the soil at the depth indicated on the tube. The mercury of the thermometer will reach a constant level, so that a reading can be taken in 10 or 15 minutes."

The electric method of Whitney and Means for the determination of the salt content of soils, K. GEDROIZ (*Zhur. Opuitn. Agron., 1 (1900), No. 1, pp. 21–48*).—This is a critical discussion of the electric method proposed by Whitney and Means for the determination of the salt content of soils.—P. FIREMAN.

FERTILIZERS.

Losses in farm manures and the value of nitrogen of such manures, E. B. VOORHEES (*New Jersey Stas. Bul. 150, pp. 27*).—This bulletin discusses, from the practical standpoint of increase in crop, the losses which occur in farm manures; the relative usefulness of the nitrogen of fresh and leached manures; and the comparative value of nitrogen in commercial forms and in natural manures. The plan of experiment has been described and the results partially reported in a previous publication (E. S. R., 12, pp. 321, 322).

"Solid manure exposed for an average of 109 days lost 37.6 lbs. of nitrogen from every 100 lbs. contained in it, 51.9 of phosphoric acid from every 100, and 47.1 of potash from every 100.

"Solid and liquid manure combined, exposed for an average of 109 days, lost 51 lbs. of nitrogen from every 100 lbs. contained in it, 51.1 of phosphoric acid from every 100, and 61.1 lbs. of potash from every 100. . . .

"On the average for 3 crops, 1 of corn and 2 of oats, the increased yield from the application of fresh solid and liquid manure combined was 3.38 times as great as from the application of the solid manure alone, though the same amount of nitrogen was applied in each case.

"The nitrogen in the leached solid manure was on the whole more effective than in the fresh, while in the leached solid and liquid combined, it was much less effective than in the fresh. The loss of the liquid portion very materially reduced the effectiveness of the manure.

"The residual effect of the nitrogen in yard manure was very considerable, and was greatest in the solid, fresh.

"Nitrogen in the commercial products, nitrate of soda, sulphate of ammonia, and dried blood, was more effective than in the natural manure products. Of these 3 forms, the nitrate was the most effective.

"In these experiments for every 100 of gain derived from nitrate of soda, there was a gain of 73.3 for sulphate of ammonia, and 65.3 for dried blood.

"There was no increase in crops obtained from the residues of the nitrate, the ammonia, and the dried blood, though in the case of the ammonia and blood a very considerable portion of the amount applied was not recovered in the first crop.

"The percentage increased yields obtained in the crop immediately following the application of the different products showed that if nitrogen in the form of nitrate, which was used as the standard, cost 15 cts. per pound, the nitrogen in the manures would be worth relative to it, as follows: Nitrogen in solid manure, fresh, 2.07 cts. per pound; nitrogen in solid and liquid manure, fresh, 6.99 cts. per pound; nitrogen in solid manure, leached, 2.41 cts. per pound; and nitrogen in solid and liquid manure, leached, 4.54 cts. per pound.

"When the residual effect of nitrogen of the manures is taken into account and no further applications of nitrate are made, the values of the nitrogen in the manures relative to the nitrate are: In solid manure, fresh, 6.22 cts. per pound; in solid and liquid manure, fresh, 11.69 cts. per pound; in solid manure, leached, 7.04 cts. per pound; and in solid and liquid manure, leached, 6.73 cts. per pound."

Experiments on the application of manure, L. MALPEAUX and E. DOREZ (*Ann. Agron., 27 (1901), No. 8, pp. 353-356*).—This is an account of experiments with fodder beets followed by wheat grown on plats on which manure was (1) plowed under as soon as applied, and (2) spread and allowed to lie on the surface about 2 months during winter before being plowed under. The results were decidedly in favor of plowing in immediately after application.

Green manuring, A. L. YAKOVLYEV (*Izv. Moscow Selsk. Khoz. Inst. [Ann. Inst. Agron. Moscow], 6 (1900), pt. 4, pp. 503-583*).—In order to compare the availability to higher plants of the nitrogen of green manure with that of nitrate of soda, various kinds of animal manures, and other nitrogenous fertilizers, the author raised crops of oats in pots using as sources of nitrogen (1) nitrate of soda, (2) liquid manure, (3) fresh horse feces, (4) fermented horse manure, (5) fresh cow manure (6) blood meal, and (7) green manure. The experiments were made on sandy soil containing 0.076 per cent of nitrogen. Each pot contained 6 kg. of soil. All the mineral nutrients were present in quantities sufficient for a maximum yield, while nitrogen was deficient. Nitrate of soda was added in amounts furnishing 0.5 gm. of nitrogen, while the other fertilizers were used in quantities containing 1 gm. of nitrogen. The largest crop was secured from the pot on which green manure was used. The order of effectiveness of the other fertilizers was—nitrate of soda, blood meal, and liquid manure. The animal manure either did not increase the yield (as was the case with the fermented horse manure) or diminished it (as was the case with the cow manure, and especially with the fresh horse feces).

Another series of experiments led the author to the conclusion that fresh green manure and dry green manure are equally effective as nitrogen fertilizers.

Other conclusions based partly upon a survey of the literature of the subject and partly on the experiments of the author, are as follows: (1) When leguminous plants are plowed under no loss of nitrogen in the gaseous state occurs owing to the absence of denitrifying bacteria, differing in this respect from the conditions noted when straw is plowed under; (2) enriching the soil in humus by green manures exerts a beneficial effect on the physical properties of light soils, increasing their capacity for moisture and improving the structure in a larger measure than barn manure, since the root residues on rotting are better adapted to that purpose, and (3) a disadvantage of green manuring is its drying effect on the soil.—P. FIREMAN.

Contribution to the knowledge of green manuring on heavy soils, F. HANASCH (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 7, pp. 772–778*).—Experiments with mustard, horse beans, vetches, and several kinds of peas and clovers are reported. The best results were obtained with white mustard followed by vetches, the poorest with field peas.

Clover and phosphorites, P. BUDRINE (*Abs. in Zhur. Opuitn. Agron., 1 (1900), No. 3, pp. 293–295*).—The author reports the results of experiments with phosphatic and other fertilizers carried out on the experiment fields of the Novo-Alexandria Agricultural Institute. The results show among other things that the crops of clover may be considerably increased by the aid of phosphorites.—P. FIREMAN.

Experiments on the relative value of nitrate of soda and sulphate of ammonia, P. WAGNER (*Mitt. Deut. Landw. Gesell., 16 (1901), Nos. 10, pp. 55, 56; 11, pp. 57–60*).—The results of these experiments show no difference in effectiveness of the fertilizers, whether the entire quantity was applied February 25, or only half the quantity applied that date and the rest on April 27. Seventy-three per cent of the nitrogen applied in nitrate of soda and 67 per cent of the sulphate of ammonia was regained in the grain and straw of barley. The total yield obtained with sulphate of ammonia was about 90 per cent of the total yield with nitrate of soda. The report discusses at some length, the relation of the kind of crop, the time of applying fertilizers, weather conditions, physical condition of the soil, and the presence of calcium carbonate in the soil to the efficiency of these fertilizers.

Fertilizer experiments with sulphate of ammonia and nitrate of soda, BONSMANN (*Deut. Landw. Presse, 18 (1901), No. 52, pp. 463, 464*).—A critical discussion of the methods which have been used by various investigators in determining the relative value of these fertilizing materials.

Experiments with chemical fertilizers on garden soils, E. FRANCAIS (*Bul. Agr. [Brussels], 17 (1901), No. 2, pp. 222–234*).—Comparative plat tests of chemical fertilizers and barnyard manure during 3 years on a variety of plants are reported. The results were to a large extent inconclusive, due probably to the originally fertile character of the soil experimented with. However, it seemed that manure was much more effective on legumes than on other common crops. This is attributed to the combined chemical, physical, and biological properties which the manure possesses in greater degree than chemical fertilizers.

The use of commercial fertilizers in winter, GERLACH (*Deut. Landw. Presse, 28 (1901), No. 61, pp. 530, 531*).

On the fertilizing value of flue ashes, J. KÖNIG (*Deut. Landw. Presse, 28 (1901), No. 69, p. 592*).—Analyses are reported which show that such ashes contain from 8.65 to 10.33 per cent of potash, 6.1 to 7.8 per cent of lime, and small amounts of phosphoric acid. The lime and potash are partly in the form of sulphate and partly silicate. The composition of this product is very variable and depends upon a number of conditions, but mainly upon the composition of the coal used in the furnaces.

The fertilizing value of stable manure when tobacco waste has been used for bedding, N. PASSERINI (*Atti. R. Accad. Econ. Agr. Georg. Firenze, 4. ser., 23 (1900), pp. 327–330*).—The tobacco waste referred to consisted mainly of midribs of the leaves.

The utilization of residues from wine making and of spoiled wine as fertilizers, F. GARRIGOU (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 4, pp. 252–254;*

abs. in Chem. Centbl., 1901, II, No. 12, p. 735).—Figures are given which show the total amount of these materials annually wasted in France, as well as the amounts of fertilizing constituents which they contain, and suggestions regarding the saving and utilization of the various by-products of the wine industry (including the ashes of the prunings and leaves) for fertilizing purposes are made.

Production of soluble potash salts from potassium feldspar (orthoclase), J. G. A. Rhodin (*Jour. Soc. Chem. Ind., 20 (1901), No. 5, pp. 439, 440*).—The author claims that by heating 100 parts of finely powdered feldspar with 53 parts of slaked lime and 40 parts of common salt to a temperature of 900° C. for an hour from 80 to 90 per cent of the potassium of the feldspar is converted into potassium chlorid.

Formation of oceanic salt deposits, particularly of the Stassfurt beds. XXII. Gypsum and anhydrite. II. The soluble anhydrite ($CaSO_4$), J. H. van't Hoff, W. Hinrichsen, and F. Weigert (*Sitzber. Kgl. Preuss. Akad. Wiss. Berlin, 1901, pp. 570–578; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 466, II, p. 506*).—Investigations are reported which indicate that gypsum is transformed into anhydrite at 98° C.

Commercial fertilizers, H. A. Huston and W. J. Jones (*Purdue Univ. Spec. Bul., July, 1901, pp. 30*).—"This bulletin contains the new fertilizer law of Indiana, the detailed report and summary of inspections made in 1900 under the old law, the analysis of manufacturers' samples made between July, 1900, and March, 1901, under the old law, and the manufacturers' guarantees made since March, 1901, under the new law."

Analysis of commercial fertilizers sold in Maryland, H. B. McDonnell et al. (*Maryland Agr. Col. Quart., 1901, No. 13, pp. 1–60*).—A report of the results of inspection of fertilizers March to June, 1901.

Complete fertilizer analyses, spring season, 1901, B. W. Kilgore et al. (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 5, pp. 3–36*).—This includes explanations of terms and of the valuation of fertilizers, freight rates, a discussion of the composition of fertilizers for special crops, recent changes in the State fertilizer law, and tabulated analyses and valuations of 581 samples of fertilizers.

Analysis of commercial fertilizers (*South Carolina Sta. Bul. 64, pp. 10*).—This bulletin is supplementary to Bulletin 60 of the station (E. S. R., 13, p. 332) and reports the results of analyses and valuations of 149 samples of fertilizing materials examined during the season of 1900–1901.

Report of chemist, M. B. Hardin (*South Carolina Sta. Rpt. 1900, pp. 9–15*).—A brief account of the work of the year in the chemical department of the station, including summaries of the general analytical work and of the results of fertilizer inspection, the latter of which have been reported in detail in previous bulletins (E. S. R., 12, p. 626). During the year ended June 30, 1900, 330 samples of fertilizers were analyzed. Of these 6 were deficient under the State law, their commercial value, based upon analysis, falling 3 per cent or more below the commercial value based upon guarantee. "Besides these there were 56 samples which fell below guarantee in one or more constituents, but whose money value was made up of an excess of other constituents." The average composition of the fertilizers examined is given.

Commercial fertilizers, 1901, J. H. Stewart and B. H. Hite (*West Virginia Sta. Bul. 76, pp. 181–195*).—This bulletin summarizes the provisions of the amended fertilizer law of West Virginia which took effect May 2, 1901, and reports analyses and valuations of 144 samples of fertilizers examined during 1900. Under the amended law manufacturers are not required to furnish certified samples of their fertilizers to the inspector, but to submit an affidavit stating not only the amount or percentage of nitrogen, potash, phosphoric acid, etc., but also the materials from which these constituents are derived and the form in which they exist in the fertilizers. The analysis fee required by the old law is replaced by a nominal registration fee of $1 per brand, the necessary revenue for carrying the new law into effect being derived from the sale of tags. It is claimed that this change to a tonnage tax will be of decided advantage to purchasers of commercial fertilizers by promoting competition and increasing the number of brands of fertilizers introduced into the State.

Laws relating to inspection, analysis, manufacture, and sale of fertilizers, cotton-seed meal, etc., in Florida (*Mo. Bul. Florida Dept. Agr., 11 (1901), No. 66, pp. 13–18*).—Gives text of the law approved May 22, 1901.

Report of the committee charged with the study of the revision of legislation relating to the adulteration of fertilizers and foods (*Bul. Agr. [Brussels], 17 (1901), No. 2, pp. 235–290*).—The provisions of the laws in force in England, Denmark, Spain, France, Hungary, Norway, Portugal, Sweden, and Switzerland are briefly given.

FIELD CROPS.

Report on the experimental work at the agricultural college at Tetschen-Liebwerd, E. GROSS (*Ztschr. Landw. Versuchsw. Oesterr., 3 (1900), No. 3, pp. 374–488, figs. 2*).—This report contains brief descriptions of tests with 8 varieties of winter wheat, 4 of rye, 4 of oats, 2 of clover, 7 of cowpeas, and 60 varieties of potatoes; of fertilizer experiments on meadows, barley, clover, wheat, and hops; of plant breeding work with potatoes and barley, and various other experiments, some of which have not yet been completed. Many of these experiments were in progress for several seasons.

Colossal Ladino, a sport variety of white clover, yielded 7,050 kg. of hay per hectare, as compared with 5,120 kg. of ordinary white clover. Inoculating land with soil from American cowpea fields resulted in a marked improvement in the yield of cowpeas, but neither the plants on inoculated soil nor those on uninoculated soil arrived at the blossoming stage. Of the varieties of potatoes tested 42 were new, and among them Kastellan and Badera were the richest in starch, containing 21 per cent. The fertilizer experiments on meadows consisted of applying different combinations of nitrate of soda, superphosphate, kainit, and lime at the rate of 150, 300, 400, and 250 kg. per hectare, respectively, and the use of compost at the rate of 30,000 kg. Liquid manure was applied at the rate of 160 hectoliters per hectare. The results were in favor of the complete fertilizer, the compost, and the liquid manure. During the three years of the experiments all the plats, except the one which had received lime alone, gave an increase in the yield of hay greater in value than the cost of the fertilizer applied. Harrowing the meadows was not as effective as anticipated.

Barley was grown with different applications and combinations of Thomas slag, kainit, and barnyard manure. Thomas slag and kainit were applied at the rate of 800 kg. per hectare, and the barnyard manure at the rate of 30,000 kg. per hectare. The object of this experiment was to test the effect of a slow-acting nitrogenous fertilizer like barnyard manure, in conjunction with mineral fertilizers. It is stated that a quick-acting nitrogenous fertilizer, like nitrate of soda, affects the growth of the plant in its early stage, but that the supply of nitrogen is exhausted or insufficient when the grains are developing. The results of this test showed that the addition of mineral fertilizers and barnyard manure materially increased the yield, and that the development of the grains took its normal course.

Plats which had received Thomas slag and kainit the preceding year, when a crop of barley was grown, produced from 400 to 1,050 kg. of clover hay more per hectare than plats which had received no fertilizer. Martellin, a prepared tobacco and hop fertilizer, consisting of powdered potash and finely ground peat, applied with barnyard manure for hops, decreased the yield as compared with the use of barnyard manure alone. Pruning largely increased the yield of hop plants. The unpruned plants developed too many leaves and underground stems for proper cultivation and profitable production.

Work with field crops at the experimental farms in Bombay Presidency in India, J. W. Mollison (*Ann. Rpt. Deputy Dir. Agr. Bombay Presidency, 1900, pp. 1–22, 23–36*).—This report records the results of experiments with field crops at the Poona and Surat experimental farms for the years 1898 to 1900, inclusive. The work included cultural tests with forage and fiber crops and with wheat, sugar cane, rice, and tobacco; a series of fertilizer and rotation experiments; improvement of seed by selection; and irrigation tests. Among a number of sorghums grown experimentally a variety known as Sundhia is considered as probably the best variety under cultivation in that region. Mauritius water grass proved an excellent plant for damp and even wet situations, and the successful cultivation of Guinea grass (*Panicum jumentorium*) is reported as fully established. Alfalfa gave good returns when conditions were favorable, but a mixed crop of alfalfa and Guinea grass is recommended as safer than alfalfa alone. Experiments with Egyptian and Brazilian varieties of cotton led to the conclusion that the conditions are unsuited to exotic varieties and that improvement must be along the line of developing indigenous sorts.

Rhea (*Bœhmeria tenacissima*), grown for 3 years, did not give encouraging results. *Hibiscus cannabinus* and *Crotalaria juncea* yielded 973 and 520 lbs. of fiber per acre, respectively, while Rhea produced only 56 lbs.

Five varieties of Bájri (*Pennisetum typhoideum*) are described and their value noted. Twenty-three varieties of wheat (*Triticum æstivum*) were tested, but no conclusions were drawn, and no individual varieties are mentioned. Gram (*Cicer arietinum*) was found to be an excellent rotation crop, requiring light irrigation only. Tur (*Cajanus indicus*) was grown as an intercultural forage crop with sorghum. The work in seed selection was undertaken with cotton and sorghum, and the progress of the experiments is discussed. Rice as an intercultural crop with cotton in rows wide apart proved a failure.

Sumatra tobacco was one of the earliest to mature among 10 varieties tested, and it produced a finer and softer leaf than indigenous sorts. The different varieties of tobacco are briefly described.

Agricultural experiments (*Rpt. Dept. Agr. Northwest Territories, 1900, pp. 22–28*).—The experimental work conducted in the Northwest Territories in 1900 is outlined, and the results at the Calgary Experiment Station in variety tests with wheat, barley, oats, rape, and potatoes are briefly reported. Short notes are given on culture experiments with grasses and forage crops. The meteorological record for the last 5 months of the year is shown in a table.

Crop experiments, W. T. Lawrence (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 162–171*).—The experiments were carried out at the Cumberland and Westmoreland County Council Farm in 1900. The work consisted of fertilizer experiments on meadows, potatoes, mangolds, swedes, and oats, and the results obtained are here briefly summarized.

Rotation experiments at Kimblesworth, Chester-le-Street (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 37–48, figs. 2*).—The experiment was made with a 5-year rotation, namely, potatoes, barley, hay, hay and oats. The work was carried out on 22 fifth-acre plats with suitable soil. Heavy dressings of barnyard manure were unusually profitable. Commercial fertilizers applied alone gave poor results, but as a supplementary application to 12 tons of barnyard manure per acre a mixture of 1½ cwt. of sulphate of ammonia, 5 cwt. each of superphosphate and kainit produced a profitable increase in the crops. The most important ingredients of the mixture applied with barnyard manure were the nitrogenous substances. Superphosphate was the best phosphatic fertilizer.

Rotation experiment at Rose Bank, Dalston (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 49–65, figs. 4*).—This experiment was conducted on poor moorland soil recently broken up from pasture. The succession of crops was swedes, oats, hay, hay and oats. On this soil barnyard manure proved much less effective than commercial fertilizers. Kainit, in the absence of barnyard manure, greatly benefited the crops, especially the oat crop. In general, applying all the commercial fertilizers to the root crop proved to be a better practice than using a certain portion for each crop in the rotation.

Suggestions for the manuring of various crops (*Reading Col., Agr. Dept. Rpt. 1900, pp. 44–47*).—Brief notes on the manuring of peas, beans, swedes, turnips, rape, mangels, potatoes, cabbage, cereals, rye grass, clover, and meadow and pasture lands.

The importance of the selection cf varieties in plant culture, EDLER (*Hessische Landw. Ztschr., 71 (1901), No. 9, pp. 88, 89*).

The utilization of the agave plant in Mexico (*Mitt. Deut. Landw. Gesell., 16 (1901), Sup. to Nos. 7, pp. 51, 52; 8, pp. 55, 56*).

The production of barley for brewing purposes, VON RÜMKER (*Fühling's Landw. Ztg., 50 (1901), Nos. 2, pp. 53–58; 3, pp. 95–104*).—A paper discussing the profits in the culture of the crop and the requisite quality of barley for brewing purposes. Special attention is given to the use of fertilizers.

The influence of the fertilizers application and the water content of the soil upon the form and composition of the barley plant, VON SEELHORST and N. GEORGS (*Jour. Landw., 48 (1900), No. 4, pp. 325–347*).—This work includes studies of the influence of plant food and soil humidity on the relation of root development to the rest of the plant, on the development of the parts of the plant above ground, on the total yield of straw and grain, and on the yield of grain alone. The plants were grown in pots containing 20 kg. of soil, which was fertilized with quantities of potassium carbonate, sodium nitrate, and monocalcic phosphate furnishing 1 gm. of potash, nitrogen, and phosphatic acid, respectively. These fertilizers were applied in different combinations. Grains of barley of uniform weight were sown March 28. The soil of all the pots was kept equally moist at first to insure uniform germination. April 20 the water content of the soil was differentiated and the pots divided into three series, namely, the first series with a low water content of 49 per cent of the water-holding capacity of the soil, the second series with a medium water content of 62 per cent, and the third series with a high soil humidity of 76 per cent of the water required to saturate the soil. The results were similar to results obtained in this kind of work with oats. (E. S. R., 13, p. 125.) The conclusion is that supplying the element or elements of plant food which are present in the soil in only minimum quantities, favors the development of the roots as well as the parts of the plant above ground, and that the increase of organic substance in the soil due to the development of the roots has a beneficial effect on the succeeding crop. It was noticed that the low water content of the soil induced a greater development of the root system, and attention is called to the fact that an increase in root development means a withdrawal of plant food from the other parts of the plant. The application of nitrogenous fertilizers when only a small amount of nitrogen was present in the soil, together with a high soil humidity, favorably influenced the stooling of the plants. The increase in the number of the internodes due to a higher water content was not quite regular, but nevertheless quite perceptible. The influence of fertilization in this respect was less evident. In every case where the humidity of the soil was increased without the application of nitrogen the strength of the culm decreased, while under the same conditions with the use of nitrogen in the fertilizer the strength of the culm increased. Increasing the soil humidity and furnishing nitrogen in the plant food increased the length of the culms and of the different internodes, the increase being greatest in the 2 upper internodes. The length of the third, fourth, fifth, and sixth internodes agreed with the length of these parts as laid down by Nowacki's law, but this was never so in the case of the second internode from above. The length of the heads and the strength of the culm were effected by the same factors. The increase of soil humidity with no nitrogen shortened the heads, while with the use of nitrogen the increase in the water content of the soil lengthened them. The results further show that in general both the increase in soil humidity and the use of nitrogenous fertilizers slightly reduced the number of undeveloped spikelets. The increase in the weight of the heads was especially noticeable when the application of nitrogen in the fertilizer accompanied an increase in soil humidity. The percentage relation of the grain to the entire plant was somewhat decreased by the high degree of soil humidity. This decrease was greatest when the plants received no nitrogen, otherwise it was much less perceptible. The authors state that so long as nitrogen is present in insufficient quantities the use of nitrogenous fertilizers will increase the percentage of gain, rather than decrease it as is often believed. The average weight of the heads of plants grown under conditions of a low and high soil humidity, was as 100:125, while the weight of their grains was as 100:121. Nitrogenous fertilizers increased the number and percentage of poorly developed grains. From the results obtained upon investigating the mealiness of the grain and determining the content of nitrogen and nitrogen-free extract, the authors conclude that on dry soils nitrogenous fertilizers tend to increase the nitrogen content of the grain, but that there is less danger of producing barley too rich in nitrogen for brewing purposes by the use of nitrogen in fertilizers when the soil is moist.

Culture and improvement of field beets, A. Kirsche (*Deut. Landw. Presse, 28 (1901), No. 20, p. 167*).—A report on culture and selection tests.

Cotton production of European and Asiatic Russia (*Mitt. Deut. Landw. Gesell., 16 (1901), Sup. to No. 11, p. 73*).

Forage plants for Kansas, A. S. Hitchcock and J. M. Westgate (*Kansas Sta. Bul. 102, pp. 179–220, figs. 30, pls. 16*).—This bulletin describes briefly a large number of forage plants considered valuable for the State, including those giving promise of success at the experiment station grass garden. Directions are given for the culture of millets, sorghum, timothy, red clover, mammoth clover, and native grasses. The renovation of worn-out native pastures is also briefly discussed. The following forage plants are described: Soy bean (*Glycine hispida*), white clover (*Trifolium repens*), mammoth clover (*T. medium*), red clover (*T. pratense*), alsike clover, Swedish clover (*T. hybridum*), buffalo clover (*T. reflexum*), crimson clover (*T. incarnatum*), Egyptian clover (*T. alexandrinum*), Bokhara or sweet clover (*Melilotus alba*), alfalfa (*Medicago sativa*), hairy vetch (*Vicia villosa*), spring vetch (*Vicia sativa*), Dakota vetch (*Lotus americanus*), bird's-foot trefoil (*L. corniculatus*), white lupine (*Lupinus albus*), blue lupine (*L. hirsutus*), yellow lupine (*L. luteus*), flat pea (*Lathyrus sylvestris wagneri*), Japan clover (*Lespedeza striata*), serradella (*Ornithopus sativus*), sainfoin (*Onobrychis sativa*), chick-pea (*Cicer arietinum*), beggar weed (*Desmodium tortuosum*), Scotch broom (*Cytisus scoparius*), furze (*Ulex europæus*), velvet bean (*Mucuna utilis*), green gram (*Phaseolus mungo*), timothy (*Phleum pratense*), orchard grass (*Dactylis glomerata*), meadow fescue (*Festuca pratensis*), Kentucky blue grass (*Poa pratensis*), Canadian blue grass (*P. compressa*), Texas blue grass (*P. arachnifera*), redtop (*Agrostis vulgaris*), tall oat grass (*Arrhenatherum avenaceum*), Bermuda grass (*Cynodon dactylon*), goose grass (*Eleusine indica*), Johnson grass (*Andropogon halepensis*), awnless brome grass (*Bromus inermis*), foxtail millets (*Setaria viridis*), barnyard millet (*Panicum crus-galli*), shama millet (*Panicum colonum*), sanwa millet (*Panicum frumentaceum*), broom-corn millets (*Panicum miliaceum*), pearl millet (*Pennisetum spicatum* or *P. typhoideum*), teosinte (*Euchlæna luxurians*), sorghum (*Andropogon sorghum* or *Sorghum vulgare*), corn (*Zea mays*), rye (*Secale cereale*), rape (*Brassica napus*), Australian saltbush (*Atriplex semibaccata*), giant spurry (*Spergula maxima*), and common morning-glory (*Ipomœa hederacea*).

The botanical composition of native pastures was studied by laying off a typical square rod within the pasture, removing the entire vegetation and separating, drying, counting, and weighing the different species represented. Upland pastures in good, average, and poor conditions were chosen, and the results for each are recorded. A few brief notes on the grazing capacity of native pastures and their care and management are given. A table shows the weights in pounds per bushel of seed of 24 different grasses and forage plants.

Forage crops (*Texas Sta. Bul. 59, pp. 45–98, figs. 11*).—This bulletin contains reports of stockmen and farmers from 71 counties of the State of Texas, by whom a number of different forage crops were given a cooperative trial. The crops which entered into these tests were: Alfalfa (*Medicago sativa*), Japan clover (*Lespedeza striata*), melilotus or Bokhara clover (*Melilotus alba*), crimson clover (*Trifolium incarnatum*), white clover (*T. repens*), velvet bean (*Mucuna utilis*), giant beggar weed (*Desmodium tortuosum*), cow peas (*Vigna catjang*), rescue grass (*Bromus unioloides*), red Kafir corn (*Sorghum vulgare*), field corn (*Zea mays*), and chufas (*Cyperus esculentus*).

Brief cultural directions for each crop are given. The average annual precipitation for the State and the distribution of the cooperative tests are shown on maps and the plans of other forage-crop work pursued by the station are briefly outlined.

Pastures and meadows of Iowa, L. H. Pammel, J. B. Weems, and F. Lamson-Scribner (*Iowa Sta. Bul. 56, pp. 385–621, figs. 82*).—This bulletin describes native and introduced species of Iowa grasses, with reference to their history, distribution, and value, and presents in tabular form the chemical composition of most of the described species based on the original and water-free substance. The conditions of Iowa pastures and meadows are considered, and directions are given for sowing grass seed and maintaining grass lands. A number of weeds commonly troublesome in meadows and pastures are described, and the conditions favorable to their growth are pointed out. The chemistry of foods and feeding is discussed and the average composition of feeding stuffs, American digestion coefficients, and other data bearing on the subject of feeding are shown in tables. A number of pages are devoted to lawns and lawn making under Iowa conditions.

Brome grass and timothy compared, E. F. Ladd and Adele Shepperd (*North Dakota Sta. Bul. 47, pp. 711–721*).—These two grasses were grown to compare the yields of green grass and to study their relative value for hay, considering their yield and chemical composition. In 5 cuttings during the season brome grass yielded 5,537.6 lbs. of green grass or 1,628.3 lbs. of dry matter per acre, and timothy, 4,681.6 lbs. of green forage or 1,422.8 lbs. of dry matter. The results were decidedly in favor of brome grass for permanent pasture. Analyses were made of both crops as green forage and the results are set forth in tables. Brome hay contained about twice as much protein as timothy and no more fiber than the average for timothy grown in different parts of the country. Owing to its larger root system, brome grass is considered a better humus producer and soil improver than timothy.

Seed mixtures for hay and pasture, D. A. Gilchrist (*Reading Col., Agr. Dept., Rpt. 1900, pp. 36–43*).—Brief reports on tests of different grass mixtures for permanent and temporary meadows and pastures, and on trials with sainfoin and alfalfa.

Very intensive forage culture, San Bernardo (*Jour. Agr. Prat., 1901, I, No. 7, pp. 212–214, fig. 1*).—A report on the intensive culture of maize, barley, and oats for forage in Spain. The crop was grown under irrigation on a field of 3 hectares which had received 50,000 kg. of barnyard manure, 666 kg. Thomas slag, 500 kg. nitrate of soda, and 170 kg. of superphosphate per hectare. The corn grew to an average height of 4.30 meters and yielded 90,000 kg. of forage per hectare during a favorable season. The corn was sown early in April and cut about August 1. The second crop of corn was then grown and harvested by November 1. Following this, barley or oats was sown, which was cut for green forage the following spring, before the preparation of the land for the first corn crop. The average yield for the three years was 75,000 kg. of green forage per hectare for the first crop of corn, 65,000 for the second crop, and 27,000 kg. for the crop of barley or oats. The experiment was a financial success.

Fertilizer requirements of meadows, Clausen (*Landw. Wchnbl. Schleswig-Holstein, 51 (1901), Nos. 7, pp. 103–106, figs. 2; 8, pp. 118–120, fig. 1*).—A report on experiments with rye grass on marshy and ordinary soils.

Fertilizer experiments on clover and rye grass (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 30-36*).—The results of cooperative fertilizer experiments on clover and rye grass at six different centers are reported. The application found most profitable consisted of 1 cwt. of nitrate of soda and $\frac{3}{4}$ cwt. of sulphate of ammonia per acre. Two hundredweight nitrate of soda gave almost as good results, the nitrate proving more generally useful than the sulphate of ammonia. Superphosphate was profitable in two cases only.

Experiments upon hops, 1900, A. D. HALL (*Jour. Southeast. Agr. Col. Wye, 1901, No. 10, pp. 21-32*).—The experiments here reported include a study of the effect of cutting the hop vine at picking time, a comparison of different systems of training as to the yield and observations on the effect of stripping the plants of their lower leaves and laterals. The data obtained through a series of chemical analyses, the results of which are tabulated, show that a valuable amount of nutritive material is retained by the root if the vine and leaves are allowed to ripen before their removal. The training experiments this season resulted in the best yields from the closely-planted systems. The previous season, when a much heavier crop was obtained, the results favored the widely-planted systems. Stripping materially reduced the yield, while in 1899 it caused no loss. These results were to some extent effected by the character of the seasons.

A report on tests with sport varieties of oats in 1899, K. KITTLAUSS (*Deut. Landw. Presse, 28 (1901), Nos. 18, p. 149; 19, p. 158*).

Potato growing experiments, J. S. GORDON (*Jour. Roy. Hort. Soc. [London], 24 (1900), No. 3, pp. 283-298*).—This is a report on experiments with potatoes with especial reference to seed, methods of planting, and the use of fertilizers. The selection of seed potatoes, the origination of new varieties, and the importance of tilth in potato culture are discussed. The results of tests with cuttings or whole tubers and different sized cuttings for seed and of experiments with commercial fertilizers and barnyard manure applied alone and in different combinations are presented in tabular form. The average yield of 5 varieties from cuttings and from whole tubers was 12 tons 5 cwt., and 13 tons 3 cwt. of salable potatoes per acre, respectively. Cuttings of 6 different sizes, the diameter varying from 1 to $2\frac{1}{8}$ in., were compared and the results showed that fairly large sets produce heavier yields than small sets, but they are not so profitable. It was further noticed that the yield of small tubers increases with the number of stems a potato produces, and that the varieties with the strongest stalks were the most drought-resisting. Barnyard manure was more effective than commercial fertilizers, owing to a large extent to its beneficial influence on the mechanical condition of the soil. Superphosphate in connection with barnyard manure decreased the yield. Sulphate of ammonia gave better results than nitrate of soda. An application of 15 tons of barnyard manure, 1 cwt. sulphate of ammonia, and 3 cwt. of superphosphate per acre, yielded $11\frac{1}{2}$ cwt. of salable potatoes less than the same application with the addition of 1 cwt. of muriate of potash, but the percentage of salable tubers was about the same. Muriate of potash was more effective than kainit. The use of 1 cwt. of potash gave better results than double that amount.

Experiment on potatoes (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 21-29*).—The results of a cooperative experiment on potatoes conducted on 5 different farms are reported. An application of $1\frac{1}{8}$ cwt. sulphate of ammonia, $1\frac{3}{4}$ cwt. of superphosphate and $\frac{3}{4}$ cwt. of sulphate of potash per acre, in addition to 12 tons of barnyard manure, gave better results than the use of double this quantity of commercial fertilizers. The most profitable dressing of commercial fertilizers alone consists of $2\frac{1}{4}$ cwt. sulphate of ammonia, $3\frac{1}{2}$ cwt. superphosphate, and 3 cwt. sulphate of potash, but the results on other plats indicated that if $\frac{1}{2}$ cwt. of nitrate of soda and 1 cwt. of fish meal had been substituted for 1 cwt. of the sulphate of ammonia, the returns would have been still more profitable. Copious dressings of sulphate and muriate of potash were found profitable, but heavy dressing of kainit decreased the yield. The use of kainit on all farms lowered the percentage of dry matter in the tubers, the average reduction amounting to 2.88 per cent. Barnyard manure for potatoes is recommended when the crop follows a fallow, but when such is not the case commercial fertilizers are considered best.

Potato-growing experiments at Abbey Holme, Cumberland (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9* (*1900*), *pp. 176–178*).—A report on variety tests made in 1900.

Potato experiments in 1900 at Kloster-Hadmersleben, K. KITTLAUSS (*Deut. Landw. Presse, 28* (*1901*), *No. 21, pp. 173–178*).—A report on extensive variety tests with potatoes.

Report on the variety tests conducted at the German potato experiment station in 1900 (*Sächs. Landw. Ztschr., 49* (*1901*), *No. 9, pp. 161–166*).—The results in yield of the tubers and starch of 18 varieties of potatoes are recorded.

New varieties of potatoes, A. DUBOIS (*Jour. Agr. Prat., 1901, I, No. 11, pp. 343, 344*).—A description of several new varieties of potatoes is given.

Producing a new potato by grafting, J. R. LAWRENCE (*Amer. Agr.* (*mid. ed.*), *67* (*1901*), *No. 16, p. 568*).—The author claims to have produced a new variety by grafting the eye of Scotch Rose on a tuber of Maule Commercial.

Fertilizer experiments, KUHNERT (*Landw. Wchnbl. Schleswig-Holstein, 51* (*1901*), *No. 11, pp. 166–168*).—A report on cooperative fertilizer experiments with beets and potatoes, the results of which led to the conclusion that lime must be used on marsh soils in conjunction with commercial fertilizers if these are to be fully effective.

Culture of ramie and other fiber plants in China, M. SCHANZ (*Tropenpflanzer, 5* (*1901*), *No. 3, pp. 126–136*).—Twelve of the most important Chinese fiber plants are described, and the culture of ramie, as it is carried on in China, together with a description of the process of decortication and the methods of exportation, is discussed.

Progress in the beet-sugar industry in the United States in 1900 (*U. S. Dept. Agr. Rpt. 69, pp. 178*).—This is the customary annual report on the progress of the beet-sugar industry in the United States, and is similar in character to the reports previously noted (E. S. R., 12, p. 742).

Report of the special agent, C. F. Saylor (pp. 5–122).—This report discusses in a general way the consumption of sugar in the United States, the forces which are educating the people in regard to the beet-sugar industry, American-made machinery and implements, bounties and other methods of promoting the industry, distribution and production of seed, the utilization of wastes and by-products of factories, and the cultivation and fertilization of the soil. The crop conditions and factory operations during the year are noted in detail for each State. Factories are now in operation in California, Colorado, Illinois, Michigan, Minnesota, Nebraska, New Mexico, New York, Ohio, Oregon, Utah, and Washington. New factory enterprises are reported from Colorado, Indiana, Iowa, Michigan, North Dakota, Oregon, Utah, South Dakota, and Wisconsin. Short discussions by different investigators and beet-sugar manufacturers on insect enemies and diseases affecting the sugar beet are presented, and reports from directors of experiment stations regarding culture, sugar content, and purity of beets grown at the stations and throughout the corresponding States are reproduced. These data have largely been published in the station bulletins.

Report of the chemist, H. W. Wiley (pp. 123–171).—This report presents the results of analysis of sugar beets grown on the experimental grounds of the Department of Agriculture and on trial plats of individual growers throughout the country, to whom seed were furnished by the Department. The tabulations show the number of samples received from each State and Territory, the variety of each sample, the weight of the beets, their sugar content, the purity coefficients of the juice, and other data of interest in connection with the production of beets for the manufacture of sugar. The average results for each year since 1897 are summarized and discussed by States.

Twelve years of sugar beet tests in the United States (*Beet Sugar Gaz., 3 (1901), No. 2, pp. 29, 30*).—A summary of the results of work with sugar beets at the agricultural experiment stations of the United States during the past 12 years.

Sugar beets, 1891–1900, J. T. WILLARD and R. W. CLOTHIER (*Kansas Sta. Bul. 103, pp. 275–286*).—The results of experiments with sugar beets in 1900, together with the analyses of samples containing over 14 per cent of sugar in the juice and representing all previous sugar-beet work within the State in connection with the station, are tabulated. The average sugar content of the juice in 1900 was 9.89 per cent, with an average purity coefficient of 72.7. In the opinion of the authors only the western part of the State, where the natural rainfall is entirely insufficient and the moisture required by the crop is supplied and regulated by irrigation, offers real climatic advantages for sugar-beet production.

Experiments in the culture of the sugar beet in Nebraska, H. H. NICHOLSON and T. L. LYON (*Nebraska Sta. Rpt. 1900, pp. 29–48*).—The results here reported at some length have been noted from a previous bulletin (E. S. R., 12, p. 846).

The sugar beet in North Carolina, W. A. WITHERS (*North Carolina Sta. Bul. 180, pp. 91–106, maps 2*).—This bulletin gives the history of experimental sugar-beet culture in the State, and reports the results of cooperative culture experiments conducted by the station in 1898 and 1899. The sample beets from several counties showed over 14 per cent of sugar. The opinion is that while the State in general is not well adapted to sugar-beet culture, there are certain sections in the western part of the State where the profitable culture of the sugar beet is feasible.

Regeneration of the seed beet, F. BUBÁK (*Deut. Landw. Presse, 28 (1901), No. 22, pp. 183, 184, figs. 3*).—A report on observations in beet seed culture. The author concludes from his observations and those of other investigators that the beet which yields seed during several vegetative periods develops each year one or more branch roots which contain the reserve material, and that the life of these roots depends largely upon the successful wintering of the adventitious buds.

The sugar industry of Louisiana, R. DYKERS (*Tradesman, 44 (1901), No. 9 (22 Ann.), pp. 144–146*).—A general article on the culture of sugar cane and the present condition of the sugar industry in the State.

Culture of sugar cane (*Bol. Agr. Min. é Ind. [México], 10 (1900), Nos. 5, p. 39, pls. 2; 6, p. 39; 7, p. 64*).—This article treats of the history, classification, composition, and culture of sugar cane.

Sugar production in Mexico (*Mitt. Deut. Landw. Gesell., 16 (1901), Sup. to No. 10, pp. 65–72*).—A description of the sugar industry from an agricultural standpoint in different Mexican States.

Seedling canes (*Sucr. Indig. et Coloniale, 57 (1901), No. 11, pp. 340–342*).—The degeneration of varieties of sugar cane during the last century is considered in this article and circumstances are described which indicate that the borer, so destructive to the crop, first appeared in Guadeloupe in 1785.

Experiments on the manuring of swedes (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 9–20*).—Cooperative experiments were made to determine the effects of commercial fertilizers used alone and with barnyard manure, and further, to test the soils on which the work was carried out. The average results show that where $2\frac{1}{2}$ cwt. of slag, $\frac{1}{2}$ cwt. of nitrate of soda, $\frac{3}{8}$ cwt. of sulphate of ammonia, and 2 cwt. of kainit were applied with 12 tons of barnyard manure, the increase in crop just paid for the commercial fertilizers. Considering the results of rotation experiments, it is believed that the effects of commercial fertilizers on subsequent crops would give a profit. The nitrogenous fertilizers produced the greatest increase in crop.

Sweet potato, F. S. SHIVER (*South Carolina Sta. Bul. 63, pp. 37*).—This bulletin sets forth the results of 3 different lines of observations, namely, the effect of fertilizing with different forms of potash on the starch content of the sweet potato, the effect of storing upon the composition, and the relative value of several generally used methods of storing. The results with different forms of potash as a fertilizer are presented in the following table:

Results of experiments with different forms of potash as a fertilizer for sweet potatoes.

Fertilizer.	Original material.		Water-free material.		Yield of sweet potato per acre.	Yield of starch per acre.
	Water.	Starch.	Dry substance.	Starch.		
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Pounds.*	*Pounds.*
Compost and kainit	63.81	22.86	36.19	63.16	11,403	2,607
Compost and muriate of potash	63.77	22.21	36.23	61.31	9,006	2,000
Nothing	62.07	24.58	37.93	64.80	7,986	1,963
Compost and sulphate of potash	64.97	21.63	35.03	61.75	9,576	2,071
Compost and silicate of potash	65.87	20.70	34.13	60.66	9,744	2,017
Compost	65.26	20.80	34.74	59.88	8,103	1,685

Compost was used at the rate of 1,000 lbs. per acre while kainit, muriate, sulphate, and silicate of potash were applied at the rate of 400, 100, 100, and 250 lbs. per acre, respectively. The variety used in this test was Horton yam.

The study of the effects of storing on the composition of the sweet potato was conducted with the same variety. The sweet potatoes fertilized with the different forms of potash mentioned above were stored November 28 and analyzed at that time and at different periods later.

The figures for all plats for the different periods are given in the following table:

Analyses at different periods of storing of sweet potatoes fertilized with different forms of potash.

Fertilizer applied.	November 28, 1898.				March 1, 1899.				April 17, 1899.

a Tubers spoiled.

After a storage of 140 days, the roots fertilized with kainit had lost 30.7 per cent of the starch originally present; those fertilized with muriate of potash, 34.4 per cent; the roots which had received no fertilizer, 32.1 per cent; and those fertilized with sulphate of potash, 14.8 per cent. The sweet potatoes from the other plats decayed.

"It would appear from these particular experiments that the loss of starch, which the sweet potato sustains on storing, is to be attributed very largely, but not wholly, to the increased formation of sucrose or cane sugar in the same. There may be possibly formed some other intermediate products, such as dextrin, but this has not yet been established."

In connection with this work the effect of storing upon the composition of different varieties of sweet potatoes was studied. The highest content of starch, 19.58 per cent, was found in the Bunch yam and the next highest in the Georgia yam. It was noticed that a high percentage of starch was usually accompanied by a low percentage of sucrose and that the glucose content of sweet potatoes is not subject to great variations. These roots were stored November 28 and an analysis made January 7 showed an average decrease of about 19.8 per cent of the starch originally present. This rapid loss of starch is attributed to storing the roots in a damp condition. The sucrose content showed an increase from 4.95 to 8.87 per cent for the same period of time. The Hanover yam preserved its starch content better than any other variety, being followed closely by the Georgia Buck varieties.

During the author's absence this work was continued by C. C. McDonell, with 4 varieties: The Pumpkin yam, Bunch yam, Georgia sugar yam, and Tennessee yam. The results of analyses made on different dates are given below:

Analyses of several varieties of sweet potatoes stored for different lengths of time.

Date of analysis.	Pumpkin yam.			Bunch yam.			Georgia sugar yam.			Tennessee yam.

Feb. 15, 1900..	10.08	1.45	7.12	8.18	1.64	9.48	13.76	1.45	8.78	13.25	1.18	9.05
Mar. 15, 1900..	11.12	1.04	11.59	8.83	1.68	11.70	13.42	1.10	11.96	9.94	1.15	9.75

The average content of starch decreased from 16.27 per cent to 10.92 per cent during storing, while the average percentage of sucrose increased from 5.21 to 11.31 during the same period of time. It was further observed in these different experiments that the sweet potato loses very little water while in storage. The results of work along this same line conducted at the Texas Station and previously reported (E. S. R., 7, p. 684) are reproduced for comparison.

For the purpose of determining the relative value of different methods of storing, roots of the Georgia Buck variety were stored in a covered building, in straw, sand, cotton-seed hulls and cotton seed, and in the ordinary way in piles covered with straw, cornstalks, dirt, and a shelter of boards. According to an analysis of a large composite sample, the roots on November 28, before storing, contained 75.35 per cent of water, 13.13 per cent of starch, 0.77 per cent of glucose, and 4.31 per cent of sucrose. The results of analysis after storing are given below:

Analyses of sweet potatoes stored by different methods.

Method of storing.	January 7, 1899.				March 1, 1899.			
	Water.	Starch.	Glucose.	Sucrose.	Water.	Starch.	Glucose.	Sucrose.
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
In straw, covered house..............	73.59	7.20	3.46	7.51	....	....	....	....
In sand, covered house	74.32	11.59	1.23	6.71	73.97	9.07	1.33	7.98
In cotton-seed hulls, covered house.	72.81	12.99	1.41	6.02	71.26	15.82	.68	5.12
In cotton seed, covered house	71.46	11.86	2.30	6.59	69.68	15.68	.55	6.04
In usual way (straw, cornstalks, etc.)	69.52	13.51	1.74	7.66	75.80	9.88	3.21	3.77

The method of storing largely influenced the changes in composition. The best results were obtained with the use of cotton-seed hulls, dry sand, and cotton seed, in the order named. Storing in straw is not considered advisable.

Climatic studies with wheat, oats, and corn, E. F. Ladd (*North Dakota Sta. Bul. 47, pp. 704-710*).—In 1899 Fife wheat was sown on April 25 and 27 and May 5 and 15. The number of days, the number of hours of sunshine, and the number of heat units required to mature the crops were observed and recorded. The results for the different sowings gave an average of 98.5 days, 779.5 hours of recorded sunshine, and 6,214.7 heat units necessary to mature the crops. The heat units represent the mean temperature of the growing period multiplied by the number of days of the growing period. In 1900 Fife, Blue Stem, and Preston wheat required an average of 103 days, 908.4 hours of recorded sunshine, and 6,560.1 heat units to mature. For the two years the average number of heat units was 6,387.4, as compared with 8,500 for all parts of Europe as given by Cooke. The period of growth averaged approximately 100 days, as compared with 115 to 184 for Europe. The author considers this difference to be due to other conditions of soil and climate, such as soil temperature, radiation, evaporation, rainfall, moisture-holding capacity of the soil, quantity of available plant foot, etc. Soil temperatures taken during the two seasons at depths of 1 and 6 inches are shown in tables. In 1899, oats required 89 days and 5,525.9 heat units, and in 1900, 92 days and 5,847.3 heat units, to complete maturity. Corn required 113 days and 7,423.3 heat units in 1899 and 114 days and 7,812.1 heat units in 1900 to ripen.

The wheat crop of 1900 grown under different methods of farming (*North Dakota Sta. Bul. 48, pp. 735–742, figs. 2*).—The results for 1900 of a series of rotation and cultivation experiments with wheat, in progress for several years, are reported. Three plats on which wheat had been grown continuously for 5 years received different cultural treatment. The first was plowed 3 to 4 in. deep and given ordinary cultivation; the second was plowed 6 to 7 in. deep, but otherwise treated as the first; the third was given better cultivation and was spring plowed 6 to 7 in. deep in 1900. The yields for the three plats were 4.7, 7.1, and 13.2 bu. per acre, respectively. Plat 4 in this experiment had been treated like the foregoing plats until 1899, when a crop of corn was grown. The grain on this plat stooled well, stood 34 in. high, and yielded 25.4 bu. per acre. Plat 5, which produced potatoes in 1899 and which had annually grown a cultivated crop since 1890, yielded 24.3 bu. per acre. Plat 6 had been treated as plat 5, but was summer fallowed in 1899. This plat yielded the longest straw and the most grain, the yield per acre being 29 bu. Plat 7, which has grown corn, wheat, flax, and corn, in the order given, during the 4 preceding years, produced 23.8 bu. of wheat in 1900. The yield on plat 8, which had grown wheat annually since 1883, was but 4 bu. per acre. In previous experiments harrowing after fall plowing, rolling and harrowing after spring sowing, and harrowing again when the wheat was 6 in. high, increased the yield 4½ bu. per acre as compared with cultivation necessary to put in the crop. It is concluded from these tests that good cultivation must be accompanied by a proper rotation of crops for the profitable production of wheat. A test of growing flax on soils treated like those above mentioned gave results similar to those of the test with wheat and led to the same conclusions.

Variety tests of wheat, G. C. Watson and E. H. Hess (*Pennsylvania Sta. Bul. 55, pp. 8*).—This bulletin is a report on a test of 23 varieties of wheat largely grown throughout the State. The work of testing varieties of wheat has been in progress at the station since 1890 (E. S. R., 11, p. 731). Attacks of the Hessian fly reduced the stand to 55 per cent of perfection, and the average yield was only 13.40 bu. per acre. The average yield of the 11 bearded varieties was 14.42 bu. and of the 12 smooth varieties 12.47 bu. per acre. The yields of grain from the different varieties varied greatly. The bearded varieties were injured less by the Hessian fly and gave a larger yield of grain and straw and a heavier weight of grain per measured bushel than the beardless or smooth varieties. The differences in yield of the smooth varieties are considered due to the differences in the damage done by the insect. Late-sown wheat was injured less by the insect pest than early-sown wheat and consequently gave better yields. In 1899 Reliable, a bearded variety, was sown on September 2 and 23, but the results in this case, owing to an early winter, were decidedly in favor of the earlier sowing. It is concluded from these results that the season governs the time of sowing, and that hence no definite date can be given. Of the varieties under test for 3 years, Reliable has produced the most grain. In 1900 this same variety was again the leader in productiveness, followed by Dawson Golden Chaff, the yields being 22.29 and 17.64 bu. per acre respectively.

The comparative values of Ontario wheats for bread-making purposes, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Bul. 115, pp. 6*).—For the purpose of making this comparison 37 ten-bushel lots of wheat were gathered from different sources. All lots were grown in Ontario in 1900, with the exception of a lot of Turkey Red imported from Kansas. These lots were ground and the flour saved from the last part of the run to assure the accuracy of all samples. The results of the work are set forth in the following table:

Average results of a comparison of the quality of flour from different varieties of wheat.

Varieties.	Number of samples.	Weight per measured bushel.	Flour.					
			Protein (N×6.25).	Crude wet gluten.	Crude dry gluten.	Water absorption.	Yield of bread per 100 lbs.	Quality of bread.
WINTER WHEATS.		*Pounds.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Pounds.*	*Per cent.*
Turkey Red	3	62.8	10.77	40.12	12.35	62.6	157.6	95.0
Michigan Amber	5	62.1	9.90	33.73	11.61	60.1	147.9	88.6

SPRING WHEATS.								
Fife	1	61.0	11.92	43.35	13.98	60.0	154.2	100.0
Herison Bearded	1	63.0	9.44	28.58	10.13	57.0	140.5	80.0
White Russian	3	60.6	9.65	34.15	11.82	58.3	145.6	83.0
Thickset	2	62.5	9.71	30.04	10.60	57.5	140.6	77.5
Colorado	2	61.2	9.33	31.68	10.85	57.0	140.0	75.0

In connection with this report the value of heavy and light wheats, the importance of gluten, the effect of baking, and the yield and quality of bread from flour are discussed, and notes on environment, season, soil, fertilizer, locality, and change of seed, so far as these factors influence the bread-making value of wheat, are given.

Varieties of winter wheats, C. A. ZAVITZ (*Ontario Agr. Col. and Expt. Farm Bul. 115, pp. 7, 8*).—This report presents the results of tests with 40 varieties of winter wheat, the most promising of 94 kinds tested for 5 years or more on about 800 different farms. These include 20 bearded and 20 beardless varieties, 32 of which are red and 8 white sorts. The average results of these different groups are given in the table below.

Average results by classes of 40 varieties of wheat grown in cooperative tests for 5 years.

	Bearded (20 varieties).	Beardless (20 varieties).	Red wheat (32 varieties).	White wheat (8 varieties).
Average height (inches)	46.2	47.1	46.5	47.3
Per cent of crop lodged	34.4	28.2	34.1	19.9
Per cent of rust	14.9	18.0	15.3	20.8
Comparative hardness of grain	80.0	76.0	80.0	69.8
Weight of grain per measured bushel (pounds)	61.2	60.7	61.2	59.8
Bushels per acre	45.7	45.8	46.1	44.5

The detailed results for each individual variety are also tabulated. Dawson Golden Chaff leads the list, with an average yield of 55 bu. per acre, followed by

Imperial Amber, Egyptian Amber, Michigan Amber, Early Genesee Giant, Golden Drop, Reliable, Early Red Clawson, and Russian Amber, in the order mentioned. All of these varieties yielded over 50 bu. per acre. Helena, the least profitable sort, gave a yield of 36.3 bu. per acre.

A new wheat industry for the semiarid West, M. A. CARLETON (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Circ. 18, pp. 8, fig. 1, map 1*).—This publication is an advance circular of a bulletin on macaroni wheats, by the same author. The main facts concerning the characteristics of macaroni wheats, their adaptation to the region of the Great Plains, varieties, and methods of cultivation are briefly presented.

Investigation of the wheat of southern Russia, P. MELIKOV (*Zhur. Opuitn. Agron., 1 (1900), No. 3, pp. 256–267*).—On the basis of analyses of different varieties of wheat of the crops of the years 1885–1899, the author finds that the wheat of southern Russia is rich in nitrogenous substances, the proportion of the latter varying with the weather from 14 to 21.2 per cent, being highest in dry years, while in years of good crops it falls to 14 per cent.—P. FIREMAN.

Sulphate of ammonia as a top-dressing for winter wheat, KIRCHNER (*Deut. Landw. Presse, 28 (1901), No. 21, p. 171*).—This article records the results of fertilizer experiments with sulphate of ammonia and nitrate of soda as a top-dressing for winter wheat for the years 1898 to 1900, inclusive. In general the results were favorable to the nitrate of soda, but in 1900 the results were about the same for the two fertilizers.

Winter cereals and fertilizers applied as a top-dressing, GRAND (*Jour. Agr. Prat., 1901, I, No. 11, pp. 338, 339*).—An article discussing under what conditions top-dressings can be profitably applied in growing winter cereals.

Breeding of wheats rich in gluten, E. SCHRIBAUX (*Jour. Agr. Prat., 1901, I, No. 9, pp. 274–277; Semaine Agr., 21 (1901), No. 1033, pp. 68, 69*).—A discussion of this subject, in which the author states that the nitrogen content of wheat is very variable, and that it depends much more upon the conditions under which the plants develop than upon the variety. He points out that all circumstances tending to shorten the period of growth favor the formation of nitrogenous substances in the grain, and that the differences of structure in the plant and of richness in gluten between grains of the same variety are not hereditary. Grain from hard and highly glutinous seed may be the same in composition as grain grown from soft, starchy seed. A further conclusion is that the industrial value of productive varieties of wheat is not well enough known to originate varieties which satisfy both the producer and the consumer.

HORTICULTURE.

Book of gardening; a handbook of horticulture, W. D. DRURY ET AL. (*New York: Charles Scribner Sons; London: L. Upcott Gill, 1900, pp. 1198, pls. 15, figs. 720*).—This work aims to cover the whole field of horticulture, including landscape gardening and the growing of fruits, vegetables, and all the more usual outdoor and indoor flowers and plants. The 27 chapters on the various phases of these subjects have been prepared by 13 different authors. Within the chapters on the various groups of plants, like ferns, bedding plants, rock plants, orchids, stove plants, greenhouse plants, cacti, aquatics, florists' flowers, trees and shrubs, etc., the matter is arranged alphabetically; the various plants are described, and concise directions given for their culture. A chapter is devoted to each of such subjects as forcing, landscape gardening, roses, chrysanthemums, pests generally, and manures. The book is well indexed and illustrated and will be found valuable as a condensed reference work on horticultural subjects.

The century book of gardening, E. T. COOK ET AL. (*London: Country Life, 1901,* *pp. X + 610 + XIII, figs. 575*).—This is a comprehensive popular work, prepared particularly for the home gardener. It treats of all the cultural operations of the flower, fruit, and vegetable garden, and of growing and handling fruits under glass. Especial attention has been given to details and illustrations of the laying out and arrangement of larger pleasure grounds, the planting of shrubs, trees, and flowers, the arrangement of rock and water gardens, management of lakes and running water, and planting of hedges and wild gardens. Under the different subjects the various fruits, flowers, shrubs, vegetables, etc., are arranged alphabetically, thus making reference easy. Chapters on insect enemies and diseases of garden plants, fruits, and vegetables are included. An abundance of good illustrations of all the different subjects considered is one of the special features of the work.

The art and craft of garden making, T. H. MAWSON (*London: George Newnes & Co., Ltd., 1901, 2. ed., pp. 252, figs. 178*).—Garden designing and all the elements that enter into garden making, like fences, entrance gateways, terrace and flower gardens, lawns, garden walks, summer houses, trellis work, garden furniture, conservatories, greenhouses, vineries, fruit houses, fountains, lakes, streams, ponds, kitchen gardens, orchards, hedges, trees, shrubs, hardy climbing plants, roses, hardy perennials, aquatics, ferns, etc., are considered in 15 different chapters. More than 130 plans and details are given of gardens designed by the author. He believes that while formal treatment of gardens is most likely to give satisfactory results, nothing is gained by slavish adherence to style or tradition. A short history is given in the opening chapter of the several styles of laying out gardens in England, the qualities commendable in each being pointed out.

Cabbage, cauliflower, and allied vegetables from seed to harvest, C. L. ALLEN (*New York: Orange Judd Company, 1901, pp. 125, figs. 27*).—Concise and practical directions are here given for the commercial and garden culture of cabbage, cauliflower, collards, Brussels sprouts, kale or borecole, and kohl-rabi. Types and varieties of each are described, and the great value of selected seed and intensive culture pointed out. The two final chapters deal with injurious insects and the fungus diseases of the different plants.

Vegetable tests for 1900, L. R. TAFT and M. L. DEAN (*Michigan Sta. Bul. 190, pp. 123–155*).—This bulletin is similar in character to those of preceding years (E. S. R., 11, p. 250). Descriptions and data are given for tests of 23 dwarf and 12 pole varieties of beans, 34 varieties of cabbage, 16 of sweet corn, 24 of cucumbers, 40 of lettuce, 17 of peas, 130 of potatoes, 25 of radishes, 22 of squash, 4 of pumpkins, and 85 of tomatoes. An outline is given of some fertilizer experiments with potatoes, and the amount of the different elements or combinations used on the different plats. The season of 1899 was rather dry for the use of commercial fertilizers, and from a strictly cash basis the increase in yield of potatoes was not sufficient to warrant their use. In 1900 the results were contradictory.

The influence of night shelter on vegetable production, A. PETIT (*Jour. Soc. Nat. Hort. France, 4. ser., 2 (1901), Mar., pp. 196, 197*).—Various mats, screens, canvas, and other contrivances are frequently used for protecting plants at night from frost. The author investigated the value of such shelter in vegetable production aside from frost protection by selecting a number of plants which are resistant to frost. In these experiments the screens were stretched horizontally on a framework about 12 cm. above the plants at night and a record kept of the growth as compared with similar plants not thus treated. The following table shows the difference in yield of cabbage, gilliflower, and lettuce between sheltered and unsheltered plants per unit of surface (1 are):

Effect of night shelter on vegetable production.

	Period plants were sheltered.	Yield.		
		Sheltered.	Unsheltered.	Increase in favor of shelter.
		Kg.	*Kg.*	*Kg.*
Cabbage	Mar. 2-June 21	1,103	900	203
Lettuce (Blonde)	Mar. 21-June 2	613	517	96
Lettuce (Grise)	Mar. 22-May 31	969	693	276
Gilliflower	Oct. 30-May 23	349	257	92

Strawberries sheltered from October 15 grew more vigorously, developed more rapidly the following spring time, were in the neighborhood of 8 days earlier, and the crop was sensibly heavier than where not sheltered. It is believed that these experiments show that the shelter has a certain value in vegetable production besides that of protection from frost.

Report of the experiment station at Charles City, C. G. PATTEN (*Rpt. Iowa Hort. Soc., 35 (1900), pp. 156-159*).—This report is on apples, apple seedlings, plums, and pears. Four seedling apple trees obtained from crossing Pound Sweet and Briar Sweet fruited during the season. The author states that only one tree of the four is at all like the Briar Sweet in form, though all are quite markedly stamped with the size, color, texture of the leaves, and color of the bark of the Briar Sweet. Three of the seedlings have the color and bloom of the Briar Sweet, while the fourth is in its first fruiting very similar in color to the Pound Sweet. It is a pure sweet apple, more tender in flesh than the Pound Sweet, and it has the appearance of becoming a good-sized apple. The apples of the smallest seedling are nearly two sizes larger than the Briar Sweet. All are of good quality and all are fall apples, the largest one being the latest. A number of other apple seedlings of promise are noted. Some very satisfactory results are being secured in the growing of plums and pears.

A study on fruit bloom, W. GREENE (*Rpt. Iowa Hort. Soc., 35 (1900), pp. 222-227, dgms. 2*).—Diagrams are given showing the temperature and date of blooming of apples, pears, and cherries in the different sections of Iowa during the two seasons of 1899 and 1900, as reported by observers in the different parts of the State.

Peach culture, S. B. VOORHEES (*Proc. New Jersey State Hort. Soc., 25 (1900), pp. 148-159*).—The author summarizes his 15 years experience in peach culture. In an orchard of 25 acres containing about 3,000 bearing trees, the number of baskets marketed has averaged 5,160; gross receipts for same, $2,800; average gross per basket, 54 cts.; average receipts net per basket, over 29½ cts. The average cost of baskets, picking, carting, and marketing was 25 cts.

Plums and plum culture, F. A. WAUGH (*New York: Orange Judd Co., 1901, pp. 371, figs. 115*).—This gives a very complete discussion of the botany and horticulture of plums. It is intended primarily for use east of the Rocky Mountains. California plum culture is not discussed. The book is divided into 2 main parts. Part I classifies, describes, and gives the names of practically all the cultivated native plums, and all the more important European, Japan, and hybrid sorts grown in this country. Under Part II the culture and management of plums are considered. This part includes chapters on propagation, varieties for planting, orchard and garden management, pollination, geography and climatology, diseases of plums, insects affecting them, cooking plums, and the use of plum trees as ornamental plants. The book is well illustrated and is especially opportune in view of the rapidly increasing attention given to plum growing by horticulturists in this country.

Fruit culture in Russia. II, Fruit culture in the government of Kazan, V. V. PASHKEVICH (*St. Petersburg: Min. Agr. and Imp. Domains, Dept. Agr., 1899, pp. XVI + 276, figs. 56, map 1; rev. in Selsk. Khoz. i Lyesov., 199 (1900), Oct., pp. 245-247*).

The breeding of native northwestern fruits, N. E. HANSEN (*Rpt. Iowa Hort. Soc., 35 (1900), pp. 455-457*).—Some 27,000 seedlings of different orchard and small fruits have been grown by the author and some comments are made on the results obtained. The author states that the most promising of the new types of fruits grown is the sand cherry (*Prunus besseyi*). At the present time this makes a good fruit for culinary use and it is believed that but little remains to make it a choice table fruit.

The washing of cider fruits, A. TRUELLE (*Mem. Soc. Nat. Agr. France, 139 (1900), pp. 303-337*).—This paper gives the history of this phase of cider making, includes the results of the author's experiments along the same line, and discusses at some length the advisability of washing apples and pears intended for cider making. In the author's experiments 15 samples, representing 7 varieties of apples, were washed and the wash water analyzed for total impurities, tannin, pectins, albuminoids, acid, and ash. Each sample was made up of 20 kg. of apples and was washed separately. In washing, the apples were not all put in the water at once but were washed quickly one at a time by hand so that all impurities were removed. By this method only a little distilled water was required for washing each sample. The apples had been gathered according to the usual methods of harvesting for cider. The water in which the samples were washed always assumed a dirty black color, and often had a disagreeable odor. The analysis showed the total impurities for the different samples to vary from 2.05 to 26.85 gm., averaging 7.24 gm. for each 20 kg. of apples washed. The total sugar content of the wash water from 20 kg. of apples varied from 0.121 to 14.905 gm., averaging 4.63 gm.; pectins and albuminoids from 0.3 to 3.68 gm., averaging 1.412 gm.; acid from 0. to 1.153 gm., averaging 0.191 gm.; total ash from 0.19 to 2.032 gm., averaging 0.708 gm. The number of grams of soluble and insoluble ash in 9 of the samples is also worked out.

A review of the literature since 1804 on washing cider fruits shows that of the 13 writers who have investigated this subject, all are agreed that the washing of dirty fruits is essential to the production of a first-class cider product. Ten of these authors are not opposed to washing clean fruits, three are; though this dissension is believed to be due largely to a difference in the interpretation of the term "clean fruit." The author shows that it is practically impossible to obtain really clean cider fruit and that, therefore, all cider fruit should be washed. In washing, fruit should be put in a loosely woven basket, constantly agitated up and down in water for a few minutes, then lifted out and spread on clean racks to dry in the open air. Violent streams of water should not be used.

The usual objections to washing cider fruits are (1) the removal of the yeasts disseminated over the surface of the fruit, causing a delay in fermentation of the juice; (2) a dilution of the cider, and (3) a loss of aroma. Relative to these objections, the work of Behrend, as given by the author, shows that the quantity of juice yielded by washed fruit is less than when not washed; also that the yeast is as plentiful in one case as in the other. The chemical composition of the juices of washed and unwashed fruits is also practically identical. The amount of material removed by washing 1,000 kg. of fruit is calculated by the author from his analyses to be as follows: Total sugar, 231.5 gm.; tannin, 1.15 gm.; pectins, 70.6 gm.; malic acid, 9.55 gm.; dry matter, 362.9 gm.; ash, 35.4 gm. These amounts are considered too small to harmfully affect the product by their removal.

The outcome of crossing fruits and shrubs in the Northwest, J. L. BUDD (*Rpt. Iowa Hort. Soc., 35 (1900), pp. 176-178*).—A summary is given of some results secured during a series of years in crossing plums, gooseberries, roses, crab apples, and strawberries.

The cultivation of oranges, ALIÑO (*Jour. Roy. Hort. Soc. [London], 25 (1901), No. 3, pp. 341-352*).—The feature dealt with especially in this article is the fertilizing of oranges. Formulas appropriate for young trees, trees in full bearing, old trees, and trees affected with gum disease and otherwise out of the normal, are given. As a basis for calculation the author gives the average analysis of the parts of the orange tree, as determined by himself, as follows:

Analysis of orange trees.

	Total ash.	Nitrogen.	Phosphoric acid.	Potash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Fresh fruit	3.21	0.38	0.40	0.38
Leaf	6.00	.70	.10	.38
Wood	7.00	.70	.50	.73

On the above basis, it is calculated that a hectare of oranges containing about 250 trees and yielding, when in full bearing, 30,000 kg. of fruit, would remove from the soil 114 kg. of nitrogen, 120 kg. of phosphoric acid, and 114 kg. of potash. If these elements are returned to the soil the equivalent of 760 kg. of nitrate of soda, 705 kg. of superphosphate of lime, and 225 kg. of sulphate of potash will be required. This formula is intended for soils composed mainly of siliceous sand with some lime and clay, having a good depth, and capable during the summer of receiving copious irrigation. This is considered by the author the ideal soil for oranges. On other soils this formula can not be strictly adhered to.

The evil effects attributed to an excess of nitrogen are that it produces an exuberant growth of wood and foliage, while the resulting fruit is very coarse and thick skinned, with little sugar or aroma, and of bad keeping quality. The time of ripening is also retarded. With an excess of phosphoric acid the fruits are small, numerous, well flavored, and aromatic, with thin skins and poor pulp. "When potash is superabundant, the tree does not grow very large, but the fruit is juicy, sweet, and of pleasant flavor."

As to the most desirable forms of fertilizers, the author prefers sulphate of ammonia in light soils and in those charged with organic matter; nitrate of soda is better applied to heavy soils. Superphosphate of lime is considered the best of the phosphate fertilizers. "Only in gypseous soils and those humid and rich in organic residues should the phosphate 'Thomas' be employed." The sulphate and chlorid of potash may be used indifferently, though the sulphate appears to give more delicacy and fragrance to the fruit. In rather limy soils the use of sulphate of iron is considered beneficial. In those with a little lime, and especially if inclined to be rough and clayey, the use of gypsum is advised.

In fertilizing young trees materials furnishing about one-half the nitrogen and phosphoric acid and one-fourth the potash required for an orchard in full bearing, as noted above, are required. For old trees the following is one formula recommended: Sulphate of ammonia, 300 kg.; nitrate of soda, 400 kg.; superphosphate of lime and manganese, 800 kg.; sulphate of iron, 300 kg.; chlorid of potassium, 25 kg., per hectare. In the case of orange trees which produce an abundance of wood, leaf, and flowers with but little fruit, the author believes the defect due either to a deficiency of nutrition or to a deficiency of the phosphates which promote the fecundation of the ovary of the flower, or to a superabundance of nitrogen, "which by excessively expanding the sexual organs of the flower produces its abortion." The following formula is suggested for such trees: Sulphate of ammonia, 75 kg.; nitrate of soda, 75 kg.; superphosphate of lime, 1,000 kg.; kainit, 300 kg.; sulphate of lime, 300 kg., per hectare. With orange trees suffering from gumming the use of organic fertilizers, and especially horse manure, should be avoided. The only manure required for trees in the seed bed is the free use of horse manure.

In orange fertilization the manures should be plowed under after the crop is gathered. If applied later or at blossoming time, the sap rises hastily and the "generating organs obtain an unequal or disproportionate growth, and the fecundation is bad or else noneffective; consequently the flowers prove abortive." Where phosphatic and potash fertilizers are applied to the orchard in February, nitrogenous fertilizers like nitrate of soda and sulphate of ammonia should be applied in June. The author considers it a mistake to apply manures to oranges in August, for the same reasons that apple orchards are not fertilized at this time of year.

Where it is desirable to hold the oranges on the trees for spring sales, the author considers it necessary to use a formula of mixed fertilizers, applied as follows: The superphosphate, the organic manure, and half of the potash salt should be applied in February; half of the nitrogenous mineral fertilizers and the remainder of the potash salt in July; the other half of the nitrogenous fertilizers, together with 400 or 500 kg. of gypsum, should be applied in September; and 10 or 12 days after the sulphate of iron. "The gypsum and the sulphate of iron tend to fix the fruit on the tree, and at the same time, by repressing the excessive growth of the wood and leaf, direct a great part of the fertilizing elements which might have been monopolized there to the fruit."

It is believed that the formulas recommended for oranges will apply equally well to lemons, citrons, and limes on similar soils, adding in each case from 10 to 12 per cent more of nitrogenous fertilizers, since under similar conditions these fruits require greater amounts of nitrogen than do oranges.

Notes on strawberries, L. R. Taft and M. L. Dean (*Michigan Sta. Bul. 189, pp. 111-119*).—This is a report on varieties of strawberries, similar in character to those previously rendered (E. S. R., 11, p. 931). The blooming and ripening periods, vigor, hardiness, percentage of bloom killed by frost, productiveness, size, form, color, quality, and firmness of the fruit are tabulated for 144 different varieties grown at the station. Fifty-three of the varieties are described in brief paragraphs. Frost affected a number of varieties. The loss was greatest with those varieties whose flowers were not protected by foliage, and whose petals were open. As a rule, only one flower upon a fruit stock was affected. Of the newer sorts fruited in 1900, H. and H., Echo, Emma, Gamage, Gladstone, Stouffer, Johnson Early, and Wooll are considered the most promising. Some of the older varieties which have stood at the head of the list for a number of years at the station, and which still maintain their position, are Excelsior, Haverland, Warfield, Clyde, Bubach, and Brandywine.

Modern cranberry culture; essential principles of the business (*Rural New Yorker, 60 (1901), Nos. 2684, p. 465; 2685, p. 482; 2686, p. 499*).—A popular presentation of all the details of modern cranberry culture, from the clearing of the land to picking and shipping the crop.

The grape in Oregon. I, Western Oregon, E. R. Lake et al. (*Oregon Sta. Bul. 66, pp. 63-84, figs. 10*).—A popular bulletin on grape culture in western Oregon, the purpose of which is to encourage grape growing for home consumption. The varieties growing at the station are described and cultural directions given for growing grapes in the different sections of the Willamette Valley.

"Among the best of the varieties that have been thoroughly tested in Oregon are Concord, Worden, Moore, and Eaton for black grapes; Niagara, Diamond, and Green Mountain for white grapes, and Delaware and Brighton for red grapes. All of these varieties will yield well and ripen perfectly in a favorable season and can not fail to give satisfaction, except that Worden will be found too soft for shipment. Do not attempt to grow such varieties as Black Hamburg, Sweetwater, or Muscat; they are not well adapted to this climate."

Grapes and wine: The grape in vineyards, gardens, and grape houses; wine, its preparation, distillation, and diseases, P. Jamain, G. Bellair, and C. Moreau (*La vigne et le vin. La vigne dans les vignobles, les jardins et les serres; le vin, sa préparation, sa distillation, ses maladies. Paris: Octave Doin, 1901, pp. 956, figs. 857*).—This comprehensive volume purports to be a complete study of the vine, considered from the quadruple standpoint of vineyard culture, the production of wine, distillation, and the production of table grapes in gardens and graperies. The first part of the work contains chapters on and discusses at length such subjects as varieties of grapes, propagation, grafting, plantations, cultivation, pruning, unfavorable conditions, diseases and insects affecting, trellising, grape houses, espalier culture, forcing, retarding growth, commercial culture, preservation of grapes, packing and selling, etc. The second part takes up harvesting and wine making, pasteurization, diseases of wines, distillation, wine making in Algiers, and a study and classification of the wines of France and her colonies.

The vine; notes on its intensive culture, E. L. Guardiola (*La vid; notas sombre su cultivo intensivo. Valencia, 1899, pp. 198, figs. 62*).—This is a popular work on vine growing, describing in detail intensive cultural operations, including methods of protection from insect pests and fungus diseases.

Viticulture, its processes and materials. Viticulture at the Exposition in 1900, P. Andrieu (*La viticulture, ses procédés et son matériel. La viticulture à l'Exposition universelle de 1900. Montpellier: Coulet & Sons, 1901, figs. 88*).—Part 1 of this work discusses the vineyard, stocks, French and foreign wines, reconstruction of vineyards on American stocks, culture and protection of vines, diseases and insects affecting. Part 2 takes up the subject of wine making in its various phases, such as fermentation, extraction of the marc, wine handling, analysis of musts and wine, extraction of tartaric acid, etc.

On the rational pruning of vines, F. Kövessi (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 15, pp. 923–925*).—The author holds that the ripeness of the wood materially influences the production of fruit the following season. This is true not only of vines but of fruit trees. The influence of ripeness is felt in two ways: It modifies the number and the position of the fruit buds and also the number of fruits. With well-ripened wood the fruit buds begin close to the base of the shoot on which they are borne, say the third bud, while on shoots of poorly matured wood the fruit buds commence to form only with the fifth bud. Besides, the shoots in the first case will carry 2 or 3 bunches, while in the second there will be only one. The production of a fruit crop, therefore, is subject to the influence of the meteorological conditions of 2 seasons: The year preceding, which determines the degree of ripeness of the shoots, and thus the position and number of bunches; and that of the same year, which affects florization, fructification, and the maturing of the crop. An examination of the weather record and of vintage production over long periods of time showed that dry years, which permit of the thorough ripening of the wood, are usually followed by abundant harvests; while wet years, which favor a late, immature growth of wood, are followed by small harvests.

These facts are susceptible of practical application, and furnish a rational basis for the pruning of different varieties in different localities. If the season has been such that the vines are well matured, pruning should be short. If rainy and conducive to the production of poorly matured shoots, the pruning should be longer than otherwise. It is the condition of the shoots themselves rather than rules which must govern in pruning.

Anatomical researches on the ripening of vine shoots, F. Kövessi (*Compt. Rend. Acad. Sci. Paris, 132 (1901), No. 10, pp. 647–650*).—In the reconstruction of the European vineyards on American stock, it has been found that much greater success has been attained with well ripened than with poorly ripened graft wood. For the purpose of gaining some light on this subject the author made a study of the thickness of the cell walls and of the starch content of the two woods. The vines consisted of a number of varieties of *Vitis riparia*, *V. rupestris*, *V. berlandieri*, and *V. vinifera*. The data obtained show that the cell walls of the well-ripened wood were much thicker than those of the poorly ripened, and that the cells inclosed more starch.

The quality of the wood of vines, L. Ravaz and A. Bonnet (*Prog. Agr. et Vit. (Ed. L'Est), 22 (1901), No. 12, pp. 360–369, figs. 12*).—In pruning vines it is desirable to reserve always the more mature wood. The authors have made some investigations as to the means of determining with certainty, by a simple process, how this can be done by the vineyardist. A review is given of the investigations of earlier workers, showing that the specific-gravity method of determining the maturity of vine wood is unreliable, besides being difficult of application with the crude scales found on most vineyard plantations. Microscopic examinations of longitudinal and transverse sections of mature and immature wood showed that the starch content of the mature wood is much greater than in the immature wood, with proportionate gradations between; hence by applying the tincture of iodin test to the freshly cut wood the intensity and extent of the blue color reaction with the starch of the wood will indicate the degree of maturity. This is a simple test, requiring no special knowledge or apparatus for its application, and is considered practical.

An old rubber plantation, A. H. Berkhout (*Indian Forester, 27 (1901), No. 4, pp. 184, 185*).—A brief account is given of a rubber plantation in Java, in which the trees, *Ficus elastica*, were planted in 1864. The estimated cost of planting and cultivation was about $7 per acre, and the plantation embraces 72½ acres, and contained, when planted, 5,200 trees. The first tapping of the trees was made in 1886 and the yield of rubber from that time to 1898 is shown in tabular form. An average of the figures shows the annual net profit of $39.30 per acre, with a maximum profit of $58 for the last year.

Caoutchouc from the Kongo, L. Gentil (*Gard. Chron., 3. ser., 29 (1901), No. 748, pp. 262–264*).—This article discusses protection and forest conservancy of caoutchouc, preparation of the juice, propagation, multiplication, and planting.

Sander's orchid guide (*St. Albans, England: F. Sanders & Co., 1901, pp. 330*).—This book gives in tabular form the native country, description, season of flowering, and cultural classification of nearly all the species and hybrids in cultivation at the present time.

Report of the committee on school gardens and children's herbariums, 1900, H. L. Clapp (*Trans. Massachusetts Hort. Soc., 1900, II, pp. 248–259, figs. 6*).—This report covers the methods and work of the children of several schools in herbarium and garden making, with list of prizes, etc.

The educational status of horticulture, F. W. Card (*Amer. Gard., 22 (1901), No. 326, pp. 213, 214*).—A paper read before the Section of Botany and Horticulture at the New Haven meeting of the American Association of Agricultural Colleges and Experiment Stations.

FORESTRY.

A forest working plan for Township 40, Totten and Crossfield Purchase, Hamilton County, New York State Forest Preserve, R. S. Hosmer and E. S. Bruce (*U. S. Dept. Agr., Division of Forestry Bul. 30, pp. 64, pls. 11, maps 4*).—This working plan was prepared at the request of the Forest, Fish, and Game Commission of the State of New York, under the provisions of Circular No. 21 of the Division of Forestry of this Department, and is the first instance of cooperation in practical forest management between this Department and a State government. The main purpose of this working plan is to outline a method of management under which the merchantable timber may be cut in such a manner that successive crops may be obtained and the condition of the forest constantly improved. A general description of the township and its chief topographical features are given. The forest consists of a mixture of coniferous and deciduous trees, the principal species, in order of occurrence, being as follows: Spruce, yellow birch, balsam, hemlock, beech, hard maple, and white pine. With these are associated arbor vitæ, commonly known as cedar, black spruce, tamarack, red or Norway pine, soft maple, and white birch, with scattered white ash and black cherry. Aspen, commonly known as poplar, and bird cherry are found on the burned-over land. The underbrush is mainly witch hobble, striped maple or moosewood, and mountain or spotted maple. Spruce predominates, forming as much as 46 per cent of the mixture. The different forest areas are divided into swamp, spruce land, and upper spruce slopes, and the characteristic species of the different forest types are enumerated. The species to be lumbered are spruce, balsam, and pine, and estimates are given of the merchantable volume of these different species. The remaining species of trees should not be lumbered at present, the demand for them not being sufficient to warrant the expense of lumbering these trees at this time.

The influence of forests on water (*Chron. Agr. Canton Vaud, 14* (*1901*), *No. 11, pp. 300–305*).—This article contains a summary of investigations which have been made on the relationship between forests and rainfall. According to the author it seems probable that forests increase the volume of the total hydrometeors. The actual demonstration of this statement is difficult, and it rests mainly upon theoretical deductions. The forest cover is said to retain a considerable portion of the total moisture. Spruce and fir retain the largest amounts, while deciduous trees—such as beech, oak, and hornbeam—retain the least. It is stated that an average of 25 per cent of the total precipitation during the year is retained by the forest cover. Some of this ultimately reaches the ground, running down the larger branches and trunks, so that the soil of the forest receives about 20 per cent less water than is deposited upon an equal area in the open. The forest cover is said to greatly diminish the evaporation of water from the soil, about one-fourth less evaporation taking place from forest soil than from a similar soil in the open. Upon plains and elevations up to 500 meters forests tend to increase the volume of soil water, while from 800 to 900 meters and above they diminish it. Forest trees are said to require only a small amount of water as compared with the amount used by agricultural crops occupying an equal area.

The mechanical effect of forests is shown in the increased permeability of the soil by the penetration of the roots to considerable depths. Upon a mountain side the forest, by its influence in carrying water deep into the soil, has the same effect as would be shown by a reduction of the slope. The total effect of this influence is unknown, but is now being investigated at two of the Swiss forest stations. The proportion of subterranean water is increased and the superficial moisture diminished under a forest cover, and in general more streams have their origin in wooded areas than in cleared ones. Streams having their origin between 400 and 800 meters' elevation are usually more numerous, larger, and more constant by reason of the greater total moisture at that elevation. The effect of forests in preventing erosion is pointed out. Forests likewise tend to repress floods by reducing the superficial soil moisture and by indirectly diminishing the slope, causing water to spread more evenly. As a result, in wooded areas local floods are less frequent and less destructive than in denuded ones. However, floods due to cosmic influences are but little affected by forests.

Extermination of oaks at Lake Geneva, Wisconsin, J. Jensen (*Forester, 7* (*1901*), *No. 3, pp. 63–65*).—An account is given of the gradual death and disappearance of oak trees in the vicinity of Lake Geneva, Wisconsin. An examination made of the leaves, branches, and trees failed to reveal the presence of any fungus or other external cause of injury, and it was suggested that doubtless the trouble was due to a lack of moisture. The seasons of 1893, 1894, and 1895 were noted for their extreme drought, and the winter of 1898–99 for its extreme low temperature and light fall of snow. These factors acting together are supposed to have been the cause of the destruction of many of the trees in question. As a means of preventing further injury the author recommends covering the ground with shrubbery or herbaceous perennials, or permitting the grass to grow among the trees. This would hold the fallen leaves and snow, and form a blanket which would prevent the frost from going deep into the ground, as well as protect it against excessive evaporation during the winter.

The plane trees, W. J. BEAN (*Gard. Chron., 3. ser., 29 (1901), No. 754, pp. 363, 364, fig. 1*).—Notes are given on some of the plane trees, which are said to include the most useful and important town and street trees. Of the species of Platanus the author describes 3, *P. orientalis*, *P. acerifolia*, and *P. cuneata* as of European and Asiatic origin, and *P. occidentalis* as of American origin.

Studies concerning the genus Platanus, F. JAENNICKE (*Abhandl. K. Leopold. Carolin. Deut. Akad. Naturf., 77, No. 2, pp. 111–226, pls. 10; abs. in Bot. Centbl., 85 (1901), No. 8, pp. 257–259*).—The author gives results of 5 years' study on the genus Platanus, and among his conclusions he states that there are 6 species and 11 varieties, as follows: *P. orientalis*, with 4 varieties; *P. occidentalis*, with 6 varieties; *P. acerifolia*, which he believes may prove to be either a variety of *occidentalis* or possibly a hybrid between *P. occidentalis* and *P. orientalis; P. racemosa; P. mexicana*, with 1 variety, and *P. wrightii*. The second and last 3 species are of American origin.

The conversion of home-grown timber for estate and other purposes, D. F. MACKENZIE (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 13 (1901), pp. 134–148, figs. 8*).—Suggestions are given for the conversion of timber into various manufactured products, by which the value of the forest products may be increased. Lists are given of the more common forms and purposes for which different kinds of wood are utilized, together with the average price that the material brings in the markets. Suggestions are also given for the utilization of the so-called waste products, derived during the manufacture of the timber, into different forms of lumber, etc.

Improvement felling as a financial success, F. E. OLMSTED (*Forester, 7 (1901), No. 4, pp. 85–88, figs. 2*).—The value of improvement cuttings in forest management is shown by examples drawn from the management of the Sal and Sain forests of India, in which crowded groups have been thinned out and a better quality of timber secured.

Colorado forest fires in 1900, H. MICHELSEN (*Forester, 7 (1901), No. 3, pp. 56–61, fig. 1*).—During the season covered by this report the forests of Colorado suffered severely by reason of fires. A cold spring was followed by a hot summer, almost rainless, and the first heavy snow fell on October 30. Between May 15 and the middle of September numerous fires swept over portions of the State. While no actual measurements were made of the losses, estimates are given, based upon statements of forest rangers, surveyors, and others, from which it appears that about one-tenth of the timber lands of the State were destroyed by forest fires during the summer of 1900. A list is given of the area of forest and brush lands, by counties, together with an estimate of the burned-over tracts. The area covered by the fires is estimated at 758 square miles, and the timber lands remaining at the end of 1900 at 6,407 square miles. The effect of this serious destruction of forests is expected to be shown in the coming season in the reduced amount of water for irrigation purposes late in the season, as some of these tracts were situated upon the headwaters of some of the important streams of the State.

Destruction of timber by the Galveston storm, W. L. BRAY (*Forester, 7 (1901), No. 3, pp. 53–56, figs. 3*).—The author gives an account of the extensive damage done to forests of Texas at the time of the famous Galveston storm. The forests which sustained the heaviest damage constituted an area of about 2,000 square miles, and were composed mostly of pines and oaks, the most valuable so far as lumbering is concerned being the white oak and loblolly pine. The effect of the storm was to prostrate at least 50 per cent of the merchantable pine and oak and in many cases all of the merchantable timber was overthrown. Of this amount of timber, it is estimated that not more than 10 per cent will be saved on account of the absence of mills, inaccessibility of forest tracts, etc.

A "snowbreak" for the protection of timber plantations, G. L. Clothier (*Forester, 7 (1901), No. 3, pp. 61, 62, fig. 1*).—The author states that the usual form of windbreak planted in prairie regions is almost invariably located too close to the buildings, and, if there is no natural or artificial protection beyond the grove to check the moving snow, in some cases these windbreaks are a positive damage. In order to protect forest plantations against this injury it is suggested that snowbreaks be formed on their exposed sides by planting 4 or 5 rows of trees and shrubs 8 or 10 rods to the windward. This protective belt should usually take the form of an L and the trees planted upon it should consist of species which may be broken or bent without serious injury to the plants. For such a snowbreak the author recommends the planting of white or bull pine which would be on the windward side of the belt. The next row should consist of red cedar or laurel-leaved willow; the third of Russian wild olive or chokecherry; and the fourth and fifth rows of the common wild plum. Such a snowbreak is adapted to all the requirements of either of the Dakotas or similar localities.

The forestry agitation in New Hampshire, E. M. Griffith (*Forester, 7 (1901), No. 4, pp. 79–81*).—A brief review is given of a bill which was presented to the State legislature but failed to pass. The author points out some of the most important features of the bill and calls attention to the impracticability of one section which relates to the shipment of logs under 10 in. in diameter. This requirement, which was intended to cover the size of trees cut, if applied to the logs of the upper part of the tree, would necessitate either a great amount of waste in lumbering or the selection of only a limited number of trees. The effect of forests on the water supply of the State is said to have aroused an interest in the general subject of forestry, and beneficial results are hoped to follow the inquiries that have been recently begun.

The forest laws of New York, T. Cleveland, jr. (*Forester, 7 (1901), No. 4, pp. 81–85*).—A brief review is given of the forest laws of the State of New York from 1650 to the present date.

Dictionary of German and English forest terms, K. Philipp (*Deutsch-Englisches Forstwörterbuch. Neudamm: J. Neumann, 1900, pp. 107*).—This dictionary is primarily intended for foresters, and gives technical definitions of the terms employed in forestry.

SEEDS—WEEDS.

An attempt to estimate the vitality of seeds by an electrical method, A. D. Waller (*Proc. Roy. Soc. [London], 68 (1901), No. 443, pp. 79–92, figs. 2*).—The author has conducted a series of experiments to test the possibility of the utilization of "blaze currents" in determining the vitality of seeds. By blaze current the author denotes the galvanometrical token of an explosive change locally excited in living matter. An unequivocal blaze current is in the same direction as the exciting current and can not be a polarization counter-current. The investigation is limited to the unequivocal blaze current as a criterion between living and nonliving seeds, from which the author concludes that "if the after-currents aroused by single induction of both directions are in the same direction, the object investigated is alive." His experiments were conducted with beans. The seeds were tested electrically and germination tests were carried out upon the same beans in 3 series, conducted at different laboratories under the supervision of well-known investigators. Whole beans which had been thoroughly soaked and seed which had the cotyledons removed were electrically tested, after which they were germinated, and in general the results closely coincided. The correspondence in the results was so close as to establish the fact that the blaze current reaction is a sign of life and its magnitude is in some degree a measure of the vitality of the seed. Fresh, vigorous seed manifested a large blaze response and germinated strongly. Older and less vigorous seed showed a smaller current and less active germination, while still older seeds, incapable of germination even under the most favorable conditions, manifested a still smaller blaze and finally gave such weak currents that they could not be distinguished from the counter effect due to polarization.

Vitality of seeds, H. H. DIXON (*Nature, 64 (1901), No. 1654, pp. 256, 257*).—The various experiments which have been lately conducted to ascertain the effect of low temperatures upon the vitality of seeds have led the author to investigate the effect of high temperatures upon the vitality of a large number of seeds. The author has found that by drying seeds in an oven at 65 to 75° C. for a day, and then at 90° C. for a day, a great many seeds will resist temperatures of 100° C., or even more. His experiments were made with oats, rye grass, lettuce, sunflower, musk flower, alfalfa, rape, California poppy, and poppy. Of these alfalfa proved the most resistant. After an exposure of 1 hour to 110° C. and then 1 hour to 121° C., 10 per cent of the seed germinated. Of other seeds investigated the maximum temperature was for poppies 100° C. and *Schizopetalon walkeri* 105° C. The effect of exposure to the high temperature was noticeable in all cases by the marked retardation of germination and by the extremely slow growth afterwards. The young plants were weak and there seemed to be a loss of sensibility to geotropic stimulus. Whether the plants would become normal or not was impossible to say, as the conditions of the experiments were such that they could not be grown to maturity.

The author also reviews the experiments of Giglioli (E. S. R., 7, p. 406), in which the action of both liquid and gaseous poisons to seeds was shown. In these experiments prolonged action of oxygen, chlorin, nitric oxid, alcohol, and an alcoholic solution of corrosive sublimate on seeds did not entirely destroy the power of germination. The author repeated a number of these experiments. Alfalfa seed exposed from 10 to 30 days to the action of methyl alcohol, saturated solution of corrosive sublimate and picric acid, did not have the powers of germination noticeably affected. Seeds of different kinds of poppies resisted the action of alcohol but were killed by corrosive sublimate solution. An experiment by the author seems to show that resistance to the poison is not due to a quiescent state of the protoplasm of the seed, but to the imperviousness of the seed coat. A large number of seeds of alfalfa were selected, half of them punctured, all dried, and after drying immersed in the various solutions mentioned above. The uninjured seeds were not affected by the poisonous fluids, while the punctured ones had their vitality entirely destroyed.

The effect of hydrocyanic-acid gas upon grains and other seeds, C. O. TOWNSEND (*Maryland Sta. Bul. 75, pp. 183–198, figs. 5*).—This is the completed paper, a preliminary notice of which has already been given (E. S. R., 12, p. 959). The author has investigated the effect of different strengths of hydrocyanic-acid gas upon the germination of dry and moist seeds, as well as the effect upon the edible properties of the same seeds when submitted for a considerable time to this gas. It was found that dry seeds may be fumigated with the usual strength of hydrocyanic gas for the length of time required for the destruction of animal life without in any degree interfering with the germinative power of the seeds. Dry seeds may be subjected to the influence of the gas for several months without entirely destroying the ability of the seeds to germinate. When subjected to the influence of the gas derived from 1 gm. of potassium cyanid per cubic foot the seeds lose their germinating power at the expiration of about 8 months, while the same seeds subjected to the gas from one-third the quantity of potassium cyanid will retain their vitality for at least 12 months. If exposed for from 15 to 60 days to the influence of hydrocyanic acid from $\frac{1}{3}$ to 1 gm. of potassium cyanid per cubic foot the germination of dried seeds is accelerated, although the degree is not sufficient to be of any practical value. Damp seeds are much more sensitive to the influence of gas than dry ones, and seeds soaked for 24 hours or more will not germinate in gas stronger than 0.003 gm. of potassium cyanid per cubic foot. The seeds soaked for 24 hours and then left for

7 days in the atmosphere of hydrocyanic-acid gas will remain inactive while in the gas, and for from 7 to 12 days after removal, but will eventually germinate to some extent if the strength of gas used does not exceed 0.05 gm. per cubic foot. Washing seeds immediately after treating with the gas greatly removes the injurious effects of the treatment. Dry seeds treated for several days with hydrocyanic-acid gas of any strength will not be injured for food, while damp seeds treated even for short periods of time should not be used for food until several hours after removal from the gas. The effect of the gas appears to pass off and the grain may be eaten with safety, although long exposure seems to render it unpalatable. Grain and other seeds may be fumigated with hydrocyanic-acid gas for the destruction of insect pests without injury to the germinating quality of the seeds and without rendering them injurious as foods.

The data upon which this bulletin is based are also published in *Botanical Gazette, 31 (1901), No. 4, pp. 241–264.*

Report of the seed control station at Gratz, 1900, E. HOTTER (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 4, pp. 337–345*).—A brief report is given on analyses of 913 miscellaneous articles and 337 samples of seed, 257 of which were samples of clover seed.

Report of the chief inspector of noxious weeds, T. N. WILLING (*Rpt. Dept. Agr. Northwest Territories, 1900, pp. 34–45*).—A report is given of inspection trips made by the chief inspector, as well as his assistants, and the weeds observed in various parts of Manitoba, Assiniboia, etc. The inspection work of the season was carried on at considerably less expense than usual, owing to the dry season which prevailed. It was found that many farmers did not recognize the various proscribed weeds, and when their attention was called to them they were willing to comply with the regulations requiring their destruction. A beneficial effect is noted in the attitude of managers of mills and elevators throughout the territory. As usual in the prosecution of such work the educational features must be given prominence.

Destruction of charlock by spraying (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 108–110*).—A tabular report is given of the results obtained by spraying with copper sulphate solutions for the destruction of charlock at 5 different places. Strengths of solution varying from 1½ to 4 per cent were employed, the amount of solution used varying from 25 to 100 gal. per acre. The results obtained show that, if properly applied, copper sulphate solutions may be depended upon for the destruction of charlock without seriously injuring fields of growing grain. The application should be made when the weeds are about 2 in. high during calm dry weather. If properly applied the 1½ per cent solution at the rate of 50 gal. per acre is sufficient. If the weed is exceedingly abundant or well covered by the grain the quantity of solution may be increased. When applications are made late in the season the amount used should be greater than when earlier sprayings are given. When the herbicide is used in damp or threatening weather it is recommended to increase the strength of solution rather than the quantity.

On the destruction of cuscuta in alfalfa, M. BAILLE (*Rev. Vit., 15 (1901), No. 372, pp. 130, 131*).—The ordinary means of combating the cuscuta, which consist of burning over the infested patches and exercising care in seed selection, are reviewed. Where this parasite has become especially troublesome, the author states that it may be absolutely destroyed by the application of powdered sulphate of iron to the soil. This will not only destroy the cuscuta but the alfalfa also, its action being due, according to the report, to the formation of a tannate of iron in the inner tissues of the plant. This does not act as a poison, but obstructs the vessels of the plant in such a way as to destroy it. The roots of the alfalfa are not injured and the plants quickly regain their normal condition. The cuscuta, however, is said to be completely destroyed. As a cheap source of iron sulphate the author recommends the utilization of the mixture which is used in purifying illuminating gas. This mixture is said to be composed of 30 kilos of iron sulphate, 15 liters of calcium hydrate, and 10 liters of wood sawdust. During the process of purification of the gas the sawdust takes up a large amount of the iron of sulphate, and, being a refuse in gas manufacture, is very cheap, costing less than one-fifteenth of the price of iron sulphate. Where this mixture is used it must be allowed to stand for some days, and stirred, to allow the gas which had been absorbed to escape.

DISEASES OF PLANTS.

Report on the fungus diseases studied at the botanical laboratory of the agricultural institute of Gembloux during 1900, E. MARCHAL (*Bul. Agr.* [*Brussels*], *17* (*1901*), *No. 1, pp. 4–18, figs. 5*).—A report is given of a number of fungus diseases which were investigated during the season Among the prominent ones were tomato rot, mildew of cauliflower, rust of currants and white pine, a mold on the stems of potato, witches' brooms of cherries, damping off or rot of young pea seedlings, a sclerotium disease of onions, a leaf spot of currants, scab of tomatoes, and a bacterial disease of beets.

The tomato rot was caused by *Phytophthora infestans*, and proved very destructive, the conditions during the ripening season having apparently been favorable for the rapid development and spread of the fungus. It was controlled, however, where Bordeaux mixture had been thoroughly applied to the plants for some time preceding and during the ripening period.

The mildew of cauliflower, which is caused by *Peronospora parasitica*, has proven of considerable loss to market gardening, and it is stated that the market gardeners in the vicinity of Paris, upon the recommendation of Maxime Cornu, successfully combated this disease by spreading about the plants wood sawdust saturated with copper sulphate as a mulch. Where this was used, it is said there was no loss by this disease.

The relation between the rust of gooseberries and that attacking the white pine is pointed out. The fungus, to which the name *Cronartium ribicolum* is given, is described in its different phases on the 2 host plants. The fungus is quite destructive on pine seedlings, and its suppression is recommended by the burning of all diseased parts of both pine and currant.

The mold of potatoes described is said to be an unusual one and due to the fungus *Hypochnus solani*. The lower part of the petioles and sometimes the lower leaves, and occasionally even the stems, of the potato are covered with ashy splotches. While giving the plants an unsightly appearance, it has so far been of little appreciable injury. It is superficial in its attack, and if serious injury is threatened could be prevented by the use of any of the better fungicides.

The disease of pea seedlings reported is due to *Thielaria basicola*, and the fungus was particularly abundant upon plants in water cultures which were being grown to study the subject of root development. It spread quite rapidly, destroying one-fourth of the plants in a very short time. It is thought to have been an unusual occurrence that this fungus should have developed in the water cultures, as it is ordinarily of terrestrial growth.

The scab of tomatoes described is caused by a new species of fungus, to which the name *Dendrodochium lycopersici* is given. A technical description of the fungus is given, and its method of attack upon the fruit is mentioned. It first appears upon the immature fruit, causing large grayish blotches which spread rapidly and running together envelop more or less of the fruit. Underneath these spots the fruit will be found to be in an advanced stage of decomposition. It is believed that the conditions under which the tomatoes were grown were largely responsible for this disease, it having developed in a shady situation. The author believes that growing tomatoes in well aërated and well lighted situations, especially in the autumn, would prevent the occurrence of this disease.

The bacterial disease of beets made its appearance in June, at which time the outer leaves became wilted and fell to the ground, the heart leaves being unaffected. The roots, when examined carefully, were found to have their extremities brownish black and decaying. This decay spread rapidly, enveloping more or less of the root. So far it has been observed in Belgium only upon garden and stock beets, but a somewhat similar trouble is reported upon sugar beets in Germany.

Investigations of the botanical section of the experiment station of the Pomological Institute, Proskau, R. ADERHOLD, (*Centbl. Bakt. u. Par., 2. Abt., 6* (*1900*), *No. 19, pp. 620–633, pl. 1*).—Notes are given on a number of fungus diseases that have been under investigation at the station for several years. A root disease of young fruit trees has been studied for some time. The trees are attacked in their roots while in the nursery. The cambial layer becomes brown and the whole root invaded by the mycelium of the fungus, resulting in the destruction of the young trees. The wood of the roots becomes softened into a gummy mass. The cause of this disease is said to be *Septocylindrium radicicolum*, n. sp., the technical characters of which are described. It is found to attack the roots of *Pyrus malus* and *Prunus avium*. The fungus grows readily upon several media, and inoculations were successfully made, which showed that the disease was due to this cause only.

A test was made of a new fungicide called Propolisin. It seems to be some sort of oil, and was added in a 1 per cent solution to a weak soap solution. This mixture was sprayed on the apple and pear leaves and upon chrysanthemums. It was without injury to the foliage, but had no practical value as a fungicide.

Miscellaneous notes are given on an attack on apple twigs of *Monilia cinerea;* the occurrence of a number of fungi upon apple leaves, among them species of Cladosporium, Phoma, and Hendersonia; the parasitism of *Cytospora rubescens* on pear shoots; a disease of plum trees somewhat similar to black rot, but in which no organism was found; descriptions of the maple woolly louse; the destruction of white pine trees by attacks of *Rhizoctonia strobi* upon the roots of the trees; diseases of violets, hydrangea, and erica; an attack upon *Acer platanoides* by *Cytospora acerina*, n. sp., the fungus being described; a leaf spot and nematode disease of lily of the valley, the fungus causing the leaf spot being described as *Septoria majalis*, n. sp.; and a new disease of narcissus caused by the parasitism of *Phyllosticta narcissi*, n. sp.

Report of botanist, P. H. ROLFS (*South Carolina Sta. Rpt. 1900, pp. 21–28*).—The author mentions the occurrence and briefly describes a number of diseases of economic plants, including cotton-boll rot, corn rust and smut, wheat rust and leaf blight, rice-leaf spot, oat smut, hop-leaf spot, asparagus rust, tomato bacterial blight, a disease of Irish potatoes probably due to a species of Fusarium, apple rust and scab, apple canker, pear-leaf scald and blight, black knot, and peach yellows.

Investigations concerning the distribution of parasitic fungi by the wind, C. VON TUBEUF (*Arb. K. Gesundheitsamte, Biol. Abt., 2* (*1901*), *No. 1, pp. 175–177*).—The wind as a means of distribution of fungus diseases is discussed, and numerous instances cited in which the spores of the fungi have been borne by the winds to distances of from 30 to 500 meters.

A reply to Alfred Fischer relating to plant diseases due to bacteria, E. F. SMITH (*Centbl. Bakt. u. Par., 2. Abt., 7* (*1901*), *Nos. 3, pp. 88–100; 4, pp. 128–139; 5–6, pp. 190–199, pls. 11*).—The author reviews some of the literature relating to bacterial diseases of plants, and describes at length his experiments in which he worked out the nature of the cucurbit wilt, due to *Bacillus tracheiphilus* (E. S. R., 7, p. 311); the cabbage brown rot (*Pseudomonas campestris*) (E. S. R., 9, p. 849); and the bacterial rot of potatoes, caused by *Bacillus solanacearum* (E. S. R., 8, p. 895).

The cultural characters of Pseudomonas hyacinthi, P. campestris, P. phaseoli, and P. stewarti, four one-flagellate yellow bacteria parasitic on

plants, E. F. Smith (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 28, pp. 153, figs. 2*).—The morphology and pathogenic properties of these species of bacteria have been previously described by the author and others. The first, known as Wakker's hyacinth bacterium, was described in a previous bulletin (E. S. R., 13, p. 63); the black rot of cabbage (E. S. R., 9, p. 849); the blight of beans (E. S. R., 10, p. 1058); and the bacterial disease of sweet corn (E. S. R., 10, p. 1056). In the present report the behavior of these organisms in a large number of different kinds of media, their sensitiveness to various reagents, and other cultural characteristics whereby they may be definitely distinguished, are given.

Bean diseases and their remedies, B. D. Halsted (*New Jersey Stas. Bul. 151, pp. 28, pls. 4, figs. 9*).—The author has been engaged in a study of the diseases of beans for a number of years, and the present bulletin describes those which are most common on the kidney and Lima beans. Among the more important of these are the anthracnose, bacteriosis, and downy mildew. The anthracnose has been previously described by the author (E. S. R., 4, p. 52) and suggestions given for its prevention. This disease produces the brownish spots upon the pods afterwards developing into sunken ulcers. The infection of young seedlings through the seed is shown and the treatment of the seed when planted is commented upon. Conflicting testimony is given relative to the value of seed treatment. Experiments in which the plants were sprayed with Bordeaux mixture, ammoniacal copper carbonate, and other fungicides, have shown that the disease may be to a great extent controlled by their use. The effect of mulching and distance in planting was studied, and the plats which had been mulched bore a considerably increased amount of diseased pods over the unmulched checks. The effect of distance of planting on the production of disease shows that where the plants are widely separated there is less tendency to the production of diseased pods.

The bacteriosis of the bean, due to *Pseudomonas phaseoli*, is described at some length, together with the organism (E. S. R., 9, p. 1058). The foliage, stems, and pods are subject to attack, and the disease may be readily distinguished from any other to which they are subject. Measures tending to check the ravages of bean insects, it is thought, will also prevent the spread of the bacterial disease. A number of investigations have been conducted upon bean plats, the results of which apply to both of the preceding diseases. Irrigation was found to largely increase disease, and planting on old soil seemed to have the same effect. Mulching appears to increase the tendency to disease to some extent, while ridging the land was without any apparent effect. Considerable difference in susceptibility of varieties has been noted, the Green Flageolet being most susceptible and Early Refugee the least.

The downy mildew of Lima beans, which was first described by the Connecticut State Station in 1889 (E. S. R., 2, p. 482), is described at considerable length, and quotations are given from Connecticut State Station Report for 1897 (E. S. R., 10, p. 261). Various precautions are mentioned for the prevention of the downy mildew, and from the Connecticut experiments the conclusion is drawn that even in unfavorable seasons a thorough treatment of the vines with Bordeaux mixture will insure a crop.

In addition to the foregoing, the author reports the occurrence of Lima bean pod blight, due to *Phoma subcircinata;* the bean rust, caused by *Uromyces appendiculatus;* a bean-leaf spot, caused by *Isariopsis griseola;* and a bean-leaf blotch, caused by *Cercospora cruenta*. These diseases are briefly described, and so far as known suggestions given for their prevention.

On Trichosphæria sacchari; a fungus causing a disease of the sugar cane known as rind fungus, A. Howard (*Ann. Bot., 14 (1900), No. 56, pp. 617–631*).—The author reports studies conducted under tropical conditions, with a view of ascertaining the effect of local conditions upon the life history of the fungus, the investigations being designed to supplement those of Massee, who has described the disease. Three distinct phases of the disease were investigated—the Melanconium, micro-, and macroconidial stages. Extensive cultures were made with the Melanconium stage of the fungus in which its parasitism was definitely established, but all attempts to produce the micro- and macroconidial phases of the fungus, in sterilized media, failed. Later specimens of diseased canes were found which, being split open, showed an abundant development of spores which, from their size and origin, agreed with the micro- and macroconidia described by Massee. Cultures made with these spores readily developed the Melanconium phase of the fungus. Spores of this kind are seldom met with in Barbados, the Melanconium stage being the predominant form. So far, all attempts to inoculate a healthy cane with the spores, without wounding the plant, failed. However, the tunnels of the moth borer provide means of entry for the spores, and infection speedily takes place. It is said that little attempt is made in Barbados to keep the fungus under control. Large piles of rotten cane are left in the fields to serve as centers from which the disease may be widely spread. Inoculation experiments were made in the field with the micro- and macroconidia, in which precautions were taken to prevent the entry of other spores, with the result that the tissues of the canes became infested in 8 to 10 days, while control specimens showed no infection. An extended search of diseased canes has so far failed to reveal the presence of any perithecia, and as a result the ascigerous stage of the fungus in this region is as yet unknown.

Fungus diseases of sugar cane, A. Howard (*West Indian Bul., 2 (1901), No. 1, pp. 46–56*).—An account is given of the rind and root rot of sugar cane. The effect of the diseases is described, and it is stated that there is probably a very close connection between the fungi causing them. Whether they are identical remains to be determined. Various suggestions are offered for their control, among them that all rotten canes be burned, and that a rotation of crops and a selection of healthy plants and disease-resisting varieties be practiced.

Powdery mildew of the apple, L. H. Pammel (*Contrib. Dept. Bot. Iowa State Col. Agr. and Mech. Arts, 1900, No. 17, pp. 177–182, pls. 3*).—A review is given of some of the literature and synonymy of the powdery mildew of the apple. The species most prevalent and probably the only one in Iowa is said to be *Sphærotheca mali.* The fungus is characterized, and spraying trees with Bordeaux mixture or ammoniacal copper carbonate is recommended as a treatment.

On a bacterial disease of the turnip, M. C. Potter (*Proc. Roy. Soc. [London], 67 (1901), No. 440, pp. 442–459, figs. 6*).—In a previous publication (E. S. R., 11, p. 1061) the author called attention to the occurrence of the bacterial disease of the turnip. In the present paper it is more fully described, the organism causing the disease is characterized, and its methods of attack are stated. In the autumn, when the activity of the turnip plant is devoted mainly to the storage of reserve material, it is said to be very common to find among plants still growing in the fields some whose roots are quite rotten and with a highly offensive and peculiar smell. The plants thus affected can be recognized by the drooping yellowish leaves, the older leaves being the first to show any indications of disease. The leaves next in age exhibit the signs of premature decay, and this proceeds until finally the young leaves are attacked. The time taken for the collapse of the leaves varies with different individuals, but it is about 2 weeks from the time of the first infection.

The roots of the plants examined present a very characteristic appearance. The decaying portion may be of grayish white or a dark brown color, and quite soft to the touch. In the particular disease under investigation the infected portion always remains white and on this account the disease is characterized as "white rot." It can be readily communicated to sound roots, it being sufficient to make a slight incision and add a small portion of the rotten mass upon the injured surface to immediately set up a decay. Within 24 hours the previously healthy cells around the inoculated surface will show the characteristic changes of form and color to the depth of ¼ in. or more.

The author conducted a series of cultures in which he finally succeeded in isolating a bacterium which liquifies gelatine and which, when sown on sterile specimens of living turnips, produced the characteristic white rot. Pure cultures of the bacterium sown upon plants growing in the garden gave identical results. The characteristics of the organism, to which he has given the name *Pseudomonas destructans*, are described.

The organism can live for many generations as a saprophyte without losing its virulence as a parasite. In 1898 the author isolated and passed the organism through several cultivations, and in August, 1899, sound turnips were inoculated with the old cultures and in 5 days the rot was found to have penetrated deeply into the tissues with all the distinctive characteristics of the white rot.

In order to ascertain the action of the bacterium and to determine whether it produced any ferment capable of acting upon the cell wall, cultures were precipitated with alcohol, filtered and digested with distilled water, after which the solution was passed through a Pasteur-Chamberland filter. In this manner a clear, pale, straw-colored liquid was obtained free from bacteria. Thin sections of turnips were subjected to the action of this liquid, with the result that the middle lamella was attacked and dissolved, proving that the bacterium secretes an enzym which dissolves the middle lamella and causes the softening and swelling of the cell wall. The author tested the juice expressed from a rotten turnip and obtained, on the addition of calcium chlorid, a precipitate of calcium oxalate. Cultures were undertaken which showed the presence of oxalic acid as a product of the organism causing this disease. The oxalic acid acts upon the cell, dissolving the calcium pectate which enters largely into the composition of the middle lamella. In this characteristic the action of the bacterium is said to be precisely similar to that of certain parasitic fungi; in both cases the organisms produce oxalic acid which acts as a toxin to the protoplasm and decomposes the calcium pectate, furthering the dissolution of the cells. There is also secreted a cytase which has a destructive action upon the cell wall and intercellular substance.

From numerous observations made in the field, the author concludes that *P. destructans* is introduced at a wounded surface. Except in cases where the disease has proceeded to a large extent, the point from which the decay spreads is indicated by a wound in the epidermis and adjacent tissues. This observation is further supported by failures to infect sound roots except by first making a small incision. Wounds caused by snails, slugs, and larvae would furnish the bacterium a means of entrance, and it is probable that the attack is made in this way.

Studies of some shade tree and timber destroying fungi, G. F. ATKINSON (*New York Cornell Sta. Bul. 193, pp. 198–235, figs. 39*).—The author gives the results of several years' study on the injuries produced by some of the higher fungi upon shade and timber trees. A number of the more prominent species are selected and the relation between the fungus and its host traced. The species described are *Polyporus borealis*, occurring on living or dead pines, spruces, and hemlocks; *P. sulphureus*, which occurs on the living trees of the apple, walnut, butternut, locust, oak, ash, pine, hemlock, spruce, etc.; *P. igniarius*, which occurs on the apple, oak, alder, beech, birch, maple, and other species of broad-leaved trees; *P. pinicola*, which has hitherto been considered as confined to various conifers, although the author reports having observed it on the beech, birch, and maple; and *Trametes abietis*, common on spruces and balsams. The effect of these different fungi, as shown in the wood and timber of the different trees, is described, and the importance of proper pruning in order to prevent means of entrance of the mycelium is shown.

The dry-rot fungus (Merulius lacrymans), E. HENRY (*Bul. Soc. Sci. Nancy, 3. ser., 1 (1900), No. 6, pp. 214–227*).—After describing the botanical character of the fungus, a résumé is given of its physiology, conditions for its existence, action on wood, and suggestions for preventing its attacks.

A Fusoma disease, C. VON TUBEUF (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901)*, *No. 1, pp. 167, 168, figs. 2*).—A report is given of a disease which attacked and destroyed many young pine and spruce seedlings which were growing in pots. The fungus causing the trouble was isolated and cultivated. Inoculation experiments were conducted and it was found that a species of Fusoma, which is as yet undetermined, was the cause of the disease.

Infection experiments with Æcidium strobilinum, C. von Tubeuf (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901), No. 1, pp. 164–167, figs. 5*).—A report is given of inoculation experiments with the æcidial spores taken from cones of a spruce, upon *Picea excelsa*, *Prunus padus*, various species of Campanula, Betula, Epilobium, Tussilago, and Carex, and upon *Salix purpurea*, *S. caprea*, and *Sorbus aucuparia*. The infections were successful only upon *Prunus padus*, upon the leaves of which uredo- and teleutospores were formed, showing that the alternate generations of this fungus were spent upon the spruce and this species of Prunus.

Infection experiments with the rust of white pine, C. von Tubeuf (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901), No. 1, pp. 173–175*).—An account is given of a number of experiments conducted by the author and others, in which the relationship between *Peridermium strobi*, the rust of the white pine, and that occurring on various species of Ribes, is shown by inoculation experiments.

Concerning Tuberculina maxima, a parasite of the leaf rust of white pine, C. von Tubeuf (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901), No. 1, pp. 169–173*).—A brief review is given of the literature of the genus Tuberculina, and the systematic position of *T. maxima*, a parasite of the rust fungus of white pine, is discussed.

Infection experiments with Gymnosporangium juniperinum from the leaves of Juniperus communis, C. von Tubeuf (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901), No. 1, pp. 177, 178*).—Infection experiments upon a number of plants are reported, in which it was shown that the Rœstelia stage of *Gymnosporangium juniperinum* occurs on *Sorbus aucuparia* and upon *Amelanchier rotundifolia;* and the same stage of *Gymnosporangium tremelloides* is found upon *Pyrus malus*, *Sorbus aria*, and *S. chamæmespilus*.

Further investigations on the abnormal outgrowths of Hibiscus vitifolius, Elizabeth Dale (*Bot. Centbl., 85 (1901), No. 11, pp. 372–375*).—Experiments were undertaken to determine the cause of the formation of outgrowths upon this plant. The outgrowths consisted chiefly of greatly enlarged epidermal cells, with very thin walls. Sometimes the underlying parenchyma was also affected. The cells concerned were always in the immediate vicinity of stomata so that the guard cells were lifted up as the outgrowth developed. Experiments were conducted to test the effect of moisture, temperature, and light in favoring the growth of these swellings. Most of the experiments were made in the open air, as the occurrence of the outgrowths is very common on plants growing in greenhouses. Various combinations of dry and damp air, and soil, were investigated, with the result that outgrowths were always formed in damp air, provided there was sufficient light and heat, while damp soil had no effect. The effect of light upon their production showed that outgrowths were developed upon plants under clear glass, and under red and yellow glass, but not under blue or green glass, in poor light, or in darkness. The formation of outgrowths was found to be favored by increased temperature, when the other necessary conditions were favorable. The immediate effect of damp atmosphere is to check transpiration, and the swellings were only produced where transpiration was reduced. They occur only in plants in which there is an accumulation of starch. The formation of the outgrowths was accompanied by the production of oil, not found in normal leaves. It is considered probable that these outgrowths are due to the local accumulation of osmotically active substances produced under abnormal conditions, such as reduced transpiration, and consequent lack of minerals, while carbohydrates are developed in excess. In addition to the experiments made upon the Hibiscus, similar observations were made upon *Ipomœa woodii*.

ENTOMOLOGY.

Report of injurious insects in Finland for the year 1899, E. REUTER (*Landbr. Styr. Meddel.* [*Helsingfors*], *1900, No. 32, pp. 44*).—Experiments were made in combating *Charæas graminis*. These experiments included the use of lysol, "lila," and Paris green. Lysol was obtained from several firms, some samples being strongly alcoholic, others slightly alcoholic, and still others being crude lysol. It was found that a thorough spraying with a 2 per cent solution of lysol and water quickly killed all the larvæ which were touched by the fluid. A careful application of the 2 per cent solution had a better effect than a less thorough spraying with a 3 or 4 per cent solution of lysol. Lila is described as a violet colored fluid of unknown composition. When used in a 5 per cent solution it had no effect in destroying the larvæ. The use of Paris green in combating this insect proved also unsatisfactory. Experiments with Paris green were conducted on a large scale. It was found that the larvæ continued to feed upon grasses which had been sprayed with Paris green and that only a small percentage was killed. Detailed statements are given of the prevalence and injurious attacks of this insect in various localities. When the species occurs in unusually large numbers it is recommended that rotation of crops be adopted and that the remedies which are in common use against the army worm should be adopted.

Further observations were made on the insects which cause the silver-top condition of various grasses. These observations were made for the most part on the same species of insects which were studied and reported upon in a previous publication by the same author (E. S. R., 12, p. 970). Brief notes are given on a few insects which are injurious to cereals, including *Hadena secalis*, *Chlorops tæniopus*, *Oscinis frit*, and *Physopus tenuicornis*. Garden crops were depredated upon by a large number of insects; and notes are given on the habits and life history of *Athalia spinara*, *Meligethes æneus*, *Cassida nebulosa*, cabbage-root maggot, and scales. Brief notes are also presented on some of the insects which feed upon fruit trees, berry bushes, conifers, deciduous trees, and roses.

Injurious insects, F. SHERMAN, JR. (*Bul. North Carolina State Bd. Agr., 22* (*1901*), *No. 6, pp. 3–29, figs. 16*).—The author gives brief descriptive biological and economic notes on the harlequin cabbage bug, cabbage plusia, cabbage butterfly, white grubs, Hessian fly, tobacco flea-beetle, bagworm, imported elm-leaf beetle, San José scale, scurfy scale, oyster-shell bark louse, woolly aphis, codling moth, peach-tree borer, and plum curculio.

The variegated cutworm (Peridroma saucia), R. W. DOANE and D. A. BRODIE (*Washington Sta. Bul. 47, pp. 16, figs. 5*).—The authors give a brief account of an unusually extensive outbreak of this species in the State of Washington in 1900. The insect attacked all sorts of plants, including field crops, garden crops, and fruit trees. Some young orchards were completely ruined and hop fields suffered severely. A description is given of the insect in its various stages. The authors did not determine whether the species was single or double brooded in the State. It may pass the winter in the larval, pupal, or adult stages, but probably hibernates as a rule in the pupal condition. Two parasites were reared from the cutworm and are identified as *Ichneumon maurus* and *Meteorus indigator*. The artificial remedies which are recommended for the control of this insect include clean cultivation, ditching, banding of trees, protecting small plants by paper wrappings, spraying with Bordeaux mixture, spraying with arsenicals, and hand picking. Potato vines which were sprayed with Bordeaux mixture were well protected against the attacks of the insect, while unsprayed vines in the same field were entirely destroyed.

Two new wheat pests, W. W. FROGGATT (*Agr. Gaz. New South Wales, 12* (*1901*), *No. 3, pp. 350–356, pls. 2*).—The grain aphis is reported as having injured wheat near the base of the stems to such an extent that the stems broke down when the grain was coming into head. The grain was attacked when about 6 in. high and the work of the grain aphis caused bending of the stems, which later led to their breaking.

The Rutherglen bug (*Nysius vinitor*) is similar in habits to the chinch bug, but has a great variety of food plants, attacking wheat and other field crops, as well as various fruit trees and garden crops. In combating the insect on fruit trees, the author had good success with the use of a tray 3 by 2½ ft., containing water covered with a film of kerosene into which the insects were jarred in the early morning. Experiments with hydrocyanic-acid gas indicated that this method could be used to advantage in destroying these insects.

The grain aphis, W. G. Johnson (*Weekly Mod. Miller, 26 (1901), No. 44, p. 13, figs. 3*).—Brief notes on the damage caused by this insect, especially in Texas, together with an account of the parasitic insects and fungus diseases which help to keep the grain aphis in check.

The Hessian fly in Minnesota, E. B. Forbes (*Farm Students' Rev., 6 (1901), No. 9, pp. 133, 134*).—It is reported that the Hessian fly occurred in unusual numbers during the season and that the wheat crop was damaged in some localities to the extent of 50 per cent. The insects seemed to be present in all parts of the State. Brief notes are given on the life history of the insect, and it is recommended that in combating the attacks of the Hessian fly attention should be given to the burning of stubble, rotation of crops, and plowing.

Insects that attack grains and meals, A. M. Lea (*Jour. Dept. Agr. West. Australia, 3 (1901), No. 3, pp. 183–188, figs. 6*).—Notes on the habits, life history, and means of combating *Sitotroga cerealella*, *Tribolium ferrugineum*, *Gnathocerus cornutus*, *Silvanus surinamensis*, *Lasioderma serricorne*, *Tenebrio molitor*, *Carpophilus dimidiatus*, and *Tyroglyphus siro*.

Observations on insects injurious to sugar beets in Italy, G. del Guercio (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1900, No. 3, pp. 371–409, figs. 6*).—The author describes *Melolontha vulgaris* in all its stages and gives details of observations concerning the life history of this insect. An investigation was made to determine the periods during which the species is most active and most injurious, and the results of this study are presented in tabular form. The injuries from this species during certain seasons reach great proportions. Conditions which are favorable to the development of the cockchafer are temperate climate, protection from strong winds and heavy rains, and against severe and sudden changes of temperature. The life history of the species occupies about 3 years in France and countries of the same latitude, but is somewhat shorter in Italy. Although the larvæ are usually found near the surface of the ground, they occasionally penetrate to the depth of a meter or more. The means usually recommended for the destruction of this species include infection with the spores of *Botrytis tenella*, the collection and destruction of the larvæ and adult insects, and the use of carbon bisulphid in the soil. The author believes that the last 3 methods promise the best success, and recommends the use of bisulphid of carbon in quantities of from 300 to 500 kg. per hectare.

Pentodon punctatus is described and illustrated in its various stages and brief notes are given on its life history and habits. The conditions which are most favorable for the rapid development of this species are similar to those which favor the spread of the cockchafer, and the artificial remedies which promise the most success are the same as those already recommended for the latter species. The use of cylinders made of reeds, tin or other metal, is said to have been attended with considerable success. Such cylinders prevent the attacks of this insect upon the young plants.

Some insects injuring market garden crops, H. T. Fernald (*Massachusetts State Bd. Agr. Rpt. 1900, pp. 322–335, figs. 5*).—Descriptive, biological, and economic notes are given on the asparagus beetle, imported cabbage butterfly, squash bug, root maggots of onion, cabbage, and turnip, flea-beetles, and cutworms.

Insects injurious to fruit, A. H. SNYDER (*Agr. Student, 7 (1901), No. 9, pp. 171–175*).—Brief notes are given on the codling moth, apple-tree borers, tent caterpillars, plum curculio, rose chafer, currant worms, cankerworms, May beetles, etc.

Insect enemies of the stone fruits, L. BRUNER and W. D. HUNTER (*Rpt. Nebraska Hort. Soc., 31 (1900), pp. 51–116, figs. 71*).—A list is given of all the insects which have been reported as injuring stone fruits in the United States. Economic and biological notes are presented on the more important of these insects, including the peach-tree borer, apple-twig borer, bark beetles, plant lice, oyster-shell bark louse, scurfy bark louse, San José scale, leaf crumpler, cankerworms, May beetles, rose chafer, grasshoppers, plum curculio, and plum gouger.

San José scale, with a few suggestions for its treatment, and rules and regulations adopted by State board of entomology, M. L. DONALDSON ET AL. (*South Carolina Sta. Bul. 65, pp. 12*).—Brief notes are given by way of description of the San José scale, and an account of its present distribution in South Carolina. The authors present a summary statement of remedies which may be recommended for summer and winter treatment against this insect. The text is given of an act of the South Carolina legislature creating a State board of entomology, defining its powers, and providing for the inspection of fruit trees, vineyards, and vegetable farms in the State. A copy is also given of the rules and regulations adopted by the State board as created by this act.

The cottony cushion scale (Icerya purchasi), H. A. GOSSARD (*Florida Sta. Bul. 56, pp. 309–356, pl. 1, figs. 6*).—A historical account is given of this scale in Australia and other foreign countries, as well as in California and Florida. It is stated that the insect was introduced from California into Florida in 1893, near Clearwater, and that it has subsequently become distributed more widely in the immediate neighborhood of the first point of infestation. The insect was sent from California in the same packet with specimens of *Novius cardinalis*, so that this important enemy of the scale is also present in Florida to hold it in check. The town council of Clearwater, and later the board of commissioners of Hillsboro County, appropriated money for the extermination of this pest, and the efforts in this direction were partly successful. During the summer of 1899 the scales decreased in number, but they increased again in 1900, reaching a maximum about July 1. At this time all the orange groves in Clearwater seemed to be infested. Then the pest began to decrease rapidly in numbers on account of the attacks of its natural enemies, especially the Australian ladybird. Since this time the insect has been held in check to a large degree by the ladybirds. An extensive list of food plants of the cottony cushion scale is given, and descriptions are presented of the insect in all its stages. The larvæ are most active during the hotter parts of the day and remain almost stationary at night. Badly infested leaves have a black or smutty appearance on account of the growth of a black mold in the honeydew which is excreted by the scales. The natural methods of dissemination of this insect are discussed and a detailed account is given of the appearance and habits of the Australian ladybird and of its introduction into Florida. A number of scales were destroyed by a fungus disease which proved very effective on some trees. The nature of the fungus has not been determined. Experiments show that the scale may be effectively held in check by persistent application of resin wash or kerosene preparations. Fumigation with hydrocyanic-acid gas is considered very efficient but rather expensive.

Report of the gypsy moth commission, A. PRATT ET AL. (*Massachusetts State Bd. Agr. Rpt. 1900, pp. 355–370*).—A brief report is made, containing a summary of the observations of F. C. Moulton on the condition of the infested territory during 1900. Since the lapse of the regular appropriation for carrying on the work of fighting the gypsy moth it is reported that the insect has increased somewhat in numbers in nearly all infested localities. Attention is called to the discovery of the value of arsenate of lead as an insecticide and to the improvement in spraying machinery which were incidental to the work in exterminating the gypsy moth.

Pineapple mealy bug (Dactylopius bromeliæ), H. TRYON (*Queensland Agr. Jour., 8 (1901), No. 4, pp. 297, 298*).—This insect, although widely distributed in pineapple plantations of Southern Queensland, is seldom especially injurious. In the northern districts the insect is more extensively attended by ants and causes more damage. It increases rather slowly and is usually kept somewhat in check by its natural enemies. Fumigation with hydrocyanic-acid gas is recommended in combating this insect.

Animal enemies of coffee in Java. II, J. C. KONINGSBERGER and A. ZIMMERMANN (*Meded. 'S Lands Plantentuin, 1901, No. 44, pp. 125, pls. 6, figs. 59*).—The authors present detailed biological and economic notes on the worms, mites, insects of various orders, birds, and other animals which are recognized as injurious to coffee in Java. In connection with the discussion on each pest, the approved artificial remedies for combating it are mentioned, together with notes on its insect enemies and fungus diseases.

Cockchafer grubs destroying strawberry plants, W. W. FROGGATT (*Agr. Gaz. New South Wales, 12 (1901), No. 4, pp. 473-476, figs. 5*).—Descriptive and biological notes are given on *Anoplognathus analis* and *A. porosus*. The larvæ of these species feed upon the roots of strawberries, sometimes completely destroying them, so that the plant falls over or is readily pulled out of the ground. As a treatment for badly infested strawberry fields, it is recommended that top-dressing of kainit or nitrate of soda be applied. As the adult beetles sometimes occur in large numbers in trees, they may be captured by jarring into collectors.

The redwood mealy bug (Dactylopius sequoiæ, n. sp.), G. A. COLEMAN (*Proc. California Acad. Sci., 3. ser., Zool., 2 (1901), No. 11, pp. 407-420, pl. 1*).—A detailed description is given of this insect in all its stages. The species is considered as new, and is reported as occuring on *Sequoia sempervirens* throughout the Sierra Morena Mountains. An undetermined species of parasitic fly was bred from certain of the specimens. The young larvæ crawl about over the leaves and twigs within a few days after hatching. Various stages of the insect were carefully studied in the laboratory.

Monophadnus elongatulus as an enemy of the rose, D. VON SCHLECHTENDAL (*Allg. Ztschr. Ent., 6 (1901), No. 10, pp. 145-147*).—The literature relating to this species is briefly reviewed and especial attention is devoted to a discussion of the process of egg laying and the entrance of the larva into the vegetable tissue. The eggs are deposited in the petiole of partly developed leaves, the puncture being made on the under side of the petiole.

Note on the respiration of Aleurodes citri, C. W. WOODWORTH (*Canad. Ent., 33 (1901), No. 6, pp. 173-176*).—A study was made of the respiratory organs of this insect for the purpose of determining their relationship to the reaction of the insect toward fumigation with hydrocyanic-acid gas. The spiracles of this insect are located on the ventral side of the body, and since the body is cemented to the leaf it is necessary that breathing folds should be developed in the epidermis which admit air from the outside to the spiracles. The breathing folds are highly specialized grooves in the outer skin of the insect and are armed with minute scattered elevations, together with a pair of combs at the outer opening. A detailed description is given of the structure of the tracheæ through the interior of the body of this species.

Respiratory organs of botflies, G. ENDERLEIN (*Sitzber. Math. Naturw. Cl. K. Akad. Wiss. [Vienna], 108 (1899), No. 5, pp. 235-303, pls. 3*).—The botflies which have thus far been found in the stomachs of herbivorous animals belong to 16 species, and the host animals are elephant, horse, zebra, ass, and rhinoceros. A general account is given of the anatomical and histological characters of the various parts of the respiratory system of these insects, with especial reference to the peculiar conditions under which they live. One feature of the spiracles by which the botflies are distinguished is the presence of an apparatus for closing the openings and thus preventing the entrance of the digestive fluids by which the insects are surrounded. The openings of the spiracles are long and narrow and can be closed so as to be water tight. A bibliography of the subject is appended to the article.

Notes on Cerrococcus, ROSE W. PATTERSON (*Proc. California Acad. Sci., 3. ser., Zool., 2 (1901), No. 9, pp. 385–394, pls. 3*).—Of the 3 species which are recognized as belonging to this genus, 2 are commonly observed in California on oaks and were studied. These are *C. ehrhorni* and *C. quercus*. Detailed descriptive and biological notes are given on these species and brief notes are also presented on *C. corticis*.

The rearing of hymenopterous borers in pruned branches, W. BAER (*Allg. Ztschr. Ent., 6 (1901), No. 11, pp. 161–163, figs. 4*).—Two species of boring wasps were found in the twigs of *Fraxinus excelsior*. Detailed notes are given on the structure and course of the burrows. The species concerned were *Psen atratus* and *Crabro capitosus*.

Monograph of the Sesiidæ of America north of Mexico, W. BEUTENMÜLLER (*Mem. Amer. Mus. Nat. Hist., 1 (1901), No. 6, pp. 217–352, pls. 8, figs. 24*).—This monograph contains an elaborate discussion of the characters of the family and genera, with analytical tables for the determination of genera and species and also tables for the determination of the larvæ from their food habits. In connection with the discussion of each species a detailed bibliography is presented, and a general bibliography of the literature concerning the family of moths and including 542 titles is appended to the article.

Smerinthus quercus, L. VON AIGNER-ALBAFI (*Allg. Ztschr. Ent., 6 (1901), No. 9, pp. 137, 138*).—The larvæ of this moth feed from July until September upon a species of oak, especially *Quercus robur*. The moths appear from March until June. They are readily attracted to electric lights and may be taken in large numbers in such situations.

Syrphus flies and colors of flowers, F. PLATEAU (*Mem. Soc. Zool. France, 13 (1900) No. 4, pp. 266–285*).—The author has previously investigated the relationship of the color of flowers to the visits of insects and a number of other crops, and from these results in connection with the study of the Syrphidæ concludes that insects are influenced in no way by the color of the flowers which they visit.

Trapping insects on fruit trees (*Landmandsblade, 34 (1901), No. 36, pp. 432–434, figs. 2*).—A description is given of a band for use in catching the larvæ of the codling moth. The band is made of coarse cloth with narrow strips of pasteboard attached to the cloth at frequent intervals in vertical planes. The band is fastened to the tree so as to bring the strips of pasteboard next to the bark. Good success is reported from the use of these bands.

Hints on spraying (*Jour. Jamaica Agr. Soc., 5 (1901), No. 4, pp. 145, 146*).—This article contains brief notes on spraying apparatus and a few of the common insecticides.

Catalogue of collections of pests and insecticides (*Com. Agr. Parasit. Secy. Pub. Prom. Mexico, 1901, pp. 6*).—Brief notes on *Trypeta ludens*, *Anthonomus grandis*, *Termes castane*, various species of bark lice, mosquitoes, bean weevil, etc., with brief notes on plant parasites and insecticides. The cucaracha herb is reported as being an effective remedy for destroying lice and fleas on dogs, cockroaches, mosquitoes, and other insects. The fresh plant costs 1 ct. per kilo and may be used in infusion. *Microsechium helleri* is useful in destroying plant lice and underground insects. The root of the plant costs $40 a ton.

How to get rid of fleas, J. A. MOFFAT (*Canad. Ent., 33 (1901), No. 6, p. 172*).—The effect of tarred paper in the construction of houses upon infestation by fleas was perhaps first reported from New South Wales. A similar experiment was tried at the suggestion of the author, and was found to be an effective means for ridding houses of these pests.

Fleas, W. W. FROGGATT (*Agr. Gaz. New South Wales, 12 (1901), No. 5, pp. 535–542, *pl. 1*).—A general account is given of the classification and economic relations of fleas, with especial reference to the possibility of transmission of infectious diseases by means of these insects. Special notes are given on *Pulex irritans*, *P. serraticeps*, and *P. fasciatus*. An extensive list of fleas is given, together with the host animals upon which they live.

An experiment in the importation of beneficial insects, F. M. Webster (*Canad. Ent.*, *33* (*1901*), *No. 6*, *pp. 183, 184*).—Specimens of *Exochomus nigromaculatus* were shipped from South Africa to Ohio in good condition. It is expected that these lacy beetles may be of service in checking the multiplication of mealy bugs in greenhouses.

Animal parasites, IV, E. P. Niles (*Virginia Sta. Bul. 111*, *pp. 39–50*, *figs. 6*).—Brief descriptive and biological notes on the horn fly, screw-worm fly, forest fly (*Hippobosca equina*), and sheep tick.

Animal parasites, V, E. P. Niles (*Virginia Sta. Bul. 112*, *pp. 51–68*, *figs. 14*).—Brief notes on the appearance, habits, and life history of *Sarcopsylla penetrans*, dog flea, bedbug, crab louse, head louse, body louse, *Hæmatopinus phalanges ovis*, *H. piliferus*, *H. eurysternus*, *H. vituli*, *H. urinus*, and *H. asini*.

Animal parasites, VI, E. P. Niles (*Virginia Sta. Bul. 113*, *pp. 69–80*).—Brief biological and economic notes on *Goniocotes abdominalis*, *Gonoides stylifer*, *Lipeurus polytrapezius*, *L. squalidus*, *Trichodectes subrostratus*, *T. latus*, *T. sphærocephalus*, *T. asini*, *T. scalaris*, and *Menopon pallidum*.

Animal parasites, VII, E. P. Niles (*Virginia Sta. Bul. 114*, *pp. 81–96*).—Brief popular notes on the poultry tick, cattle tick, wood tick, *Ixodes ricinus*, *Argus americanus*, sheep-scab mite, and *Sarcoptes scabiei*. A brief statement is also given on the common insecticide methods which are used in combating these pests.

Annual report for 1900 of the zoologist, C. Warburton (*Jour. Roy. Agr. Soc. England*, *3. ser.*, *11* (*1901*), *pt. 4*, *pp. 742–750*, *figs. 4*).—Biological and economic notes on scaly leg of fowls, tapeworms in dogs, mosquitoes, Hessian fly, *Chlorops tæniopus*, *Oscinis frit*, *Hylemyia coarctata*, wheat midge, wheat sawfly, and other insects.

Influence of the honeybee on the fruit crop, L. D. Stilson (*Rpt. Nebraska Hort. Soc.*, *31* (*1900*), *pp. 226–228*).—A brief general discussion of the agency of the honeybee in fertilizing the flowers of fruit trees.

The method of artificial swarming in frame hives for preventing natural swarming, maintaining the apiary, and increasing the yield of honey, R. Pincot (*L'Apiculteur*, *44* (*1901*), *No. 6*, *pp. 247–254*).—In an experience of 6 years with this method the author has had complete success in preventing natural swarming and in securing a larger yield of honey. A young and vigorous queen is selected for the portion of the swarm which is removed artificially, and by having the matter in control the most favorable time for the establishment of a new colony may be selected.

The relation of honey to beeswax, L. Moupy (*Rev. Internat. Apicult.*, *23* (*1901*), *No. 4*, *pp. 68–71*).—This is a controversial article, in which the main problem is discussed concerning the question of what substances contribute to the formation of wax and what quantity of honey is necessary to produce a given quantity of wax. The author believes that wax is formed almost exclusively from honey and that about 375 to 400 gm. of honey are required for the formation of 100 gm. of wax.

Twenty-first annual meeting of the Ontario Bee-Keepers' Association (*Ann. Rpt. Bee-Keepers' Assn. Ontario*, *1900*, *pp. 64*).—At this meeting, held in Niagara Falls, Ontario, on December 4–6, 1900, a number of papers were read, a few of which are mentioned here.

Moving bees to fall pasturage, R. H. Smith (pp. 10, 11).—It is recommended that large colonies of bees should not be moved during hot weather without allowing plenty of ventilation, by covering the super with a wire screen so as to allow the bees about 2 in. space above the frames. The author believes that where bee pasturage becomes poor in the fall in the immediate neighborhood of the apiary, profitable returns may be obtained by moving the colonies into the vicinity of more abundant honey plants.

Brief notes are given on wintering bees in and out of the cellar, by H. G. Sibbald (pp. 19, 20). It is recommended that bees should be left on their summer stands until from November 20 to December 1 before being placed in the cellar.

The production of extracted honey is discussed by A. Dickson (pp. 27, 28). Brief notes are given on the construction of a room for this purpose, and on the size, form, and material of tanks for use in extracting honey.

W. McEvoy reports finding foul brood in 33 out of 100 apiaries which were inspected during 1900.

M. B. Holmes reports on some practical experience with queen bees. Attention is called to the great difference in productiveness in different queens and to the necessity of inspecting hives in order to determine whether a sufficient number of eggs are being laid.

Notes on experiments with foul brood are given by F. C. Harrison. This is a brief form of another paper by the same author (E. S. R., 12, p. 966).

J. Fixter reports on experiments in wintering bees. Eight experiments were tried on wintering bees in the cellar, in a pit dug in the side of a hill, in a root house, in a house apiary, and out of doors. The average loss in weight of honey and bees was greatest in the colonies which were wintered out of doors and least in those which were wintered in the cellar.

J. Fletcher gives an account of the value of bees in fruit orchards. In this paper the author discusses the general relationship of bees to fruit trees, including the question whether bees eat fruit or not and their value in fertilizing flowers. It is believed that it is practically impossible for bees to puncture the skin of uninjured fruits.

FOODS—NUTRITION.

The functions and uses of food, C. F. Langworthy (*U. S. Dept. Agr., Office of Experiment Stations Circ. 46, pp. 10*).—A brief discussion of some of the principles of nutrition, together with a summary of the composition of the more common food materials, and a method for calculating the results of dietary studies and the digestibility of different foods.

Science in the daily meal, A. Broadbent (*Manchester, England: Author, 1900, 2. ed., pp. 45, fig. 1*).—A number of menus which the author considers suitable to special conditions are proposed. The volume also contains brief discussions of food.

The chemist-cook, E. J. David (*Le cuisinier-chimiste. San Francisco: Author, 1901, pp. 50*).—Foods, nutrients, preserving food, cooking, and similar topics are treated of.

Piedmont peasant bread, E. Bertarelli (*Riv. Ig. e San. Pubb., Roma, 11 (1900), Sup.; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 16, pp. 758, 759*).—A comprehensive study of the bread eaten by the peasants in the Piedmont region.

Sandy bread, B. Fischer and C. Grunhagen (*Jahresber. Chem. Untersuchungsamtes Breslau, 1899–1900, p. 9; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 16, p. 757*).—A chemical and microscopical examination of sand in bread.

Patent oat breakfast foods; their chemical composition and nutritive value, G. W. Chlopin (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 11, pp. 481–488*).—According to the author a number of brands of American oat breakfast foods are on sale in Russia. Analyses of such foods and similar products of Russian or other European manufacture are reported, and also digestion experiments in which the author was himself the subject. It was found that 87.43 per cent of the dry matter and 71.83 per cent of the nitrogen was digested when the diet consisted of oatmeal porridge (made with water), a little butter and sugar. When the diet consisted of porridge made with milk, the following average coefficients of digestibility were obtained: Dry matter, 92.49; nitrogen, 86.43; fat, 92.0, and carbohydrates, practically, 100. The comparative digestibility of oatmeal and other foods is discussed. According to the author, oatmeal and milk furnish the body with somewhat more energy than a like amount of bread and milk. This, however, is not considered a sufficient basis for the extravagant statements made by manufacturers concerning the nutritive value of such goods.

Eggs in cold storage, M. COOPER (*Chicago: H. S. Rich & Co., 1899, pp. 88, figs. 10*).—The theory and practice in preserving eggs by refrigeration are discussed. Much of the information given was received in answer to requests addressed to individuals and companies commercially interested in the subject of preserving eggs by refrigeration. The author also reports the results of experiments on the effects of low temperatures on eggs.

The danger attending the increased consumption of sugar, G. VON BUNGE (*Ztschr. Biol., 51 (1901), No. 2, pp. 155–166*).—In the author's opinion there is a possible danger in consuming considerable amounts of sugar, due to the fact that this material is lacking in calcium and iron salts. These salts are present in honey and sweet fruits and the author believes their use is not attended with harmful results. A detailed ash analysis of honey is reported as well as estimations of the calcium and iron in figs, dried plums, dates, fresh pears, and dried malaga grapes.

Food and the principles of dietetics, R. HUTCHINSON (*London: Edward Arnold, 1901, pp. XVIII + 548, col. pls. 3, figs. 34*).—The general topic of food, its composition and digestibility, theories of nutrition, etc., are treated of extensively. A noteworthy feature of this volume is the large amount of analytical and other data regarding patent and commercial foods and food products, a class of goods in regard to which it is difficult to secure reliable information. The volume is provided with a full index, and references are uniformly given for the large number of investigations cited.

Food supply [during the siege of Mafeking], R. S. S. BADEN-POWELL (*South African Dispatches, Vol. I. London: Harrison & Sons, 1901, pp. 106, 107, 110*).—A detailed account is given of the food supply during the siege of Mafeking. The foods consisted generally of canned meats, horse flesh (largely used for making sausages), bread from ground oats, sowens (a form of porridge made from oat bran), and fresh vegetables (largely grown within the defenses), with some condiments. The daily ration per man, at first, was made up of 1 lb. meat, 1 lb. bread, 1 lb. vegetables, $\frac{1}{3}$ oz. coffee, $\frac{1}{2}$ oz. salt, 2 oz. sugar, and $\frac{1}{2}$ oz. tea. Later in the siege the amounts were reduced to $\frac{3}{4}$ to 1 lb. meat, 5 oz. bread, 6 oz. vegetables, $\frac{1}{3}$ oz. coffee, $\frac{1}{2}$ oz. salt, and 1 qt. sowens. [The first ration has been calculated to furnish 142 gm. protein and 2,500 calories; the latter, 149 gm. protein and 2,700 calories.—ED.]

The theory and practice of military hygiene, E. L. MUNSON (*New York: William Wood & Co., 1901, pp. XII+971, pls. 8, figs. 389*).—The water supply for troops and the ration under different conditions of peace and war are treated of at length, as well as the numerous other topics pertaining to military hygiene. In every case, in addition to original material, the author has given a careful summary of the work of other investigators on the topic, and in this and other ways the work is a very complete manual of the subject treated.

Food products: A manual for traders and others, C. J. HIGGINSON (*London: E. Wilson, 1900, pp. XVI + 179*).—As the sub-title states, this is a consolidation of the "Sale of food and drugs act, 1875" (of Great Britain); "Sale of food and drugs act amendment act, 1879;" "Margarine, 1887;" and "Sale of food and drugs act, 1899." The general orders issued by local authorities regarding the registration of manufactories and premises and the regulations as to the competency of public analysts are also included.

The difference between light and dark meat for invalid diet, J. R. Offer and E. Rosenquist (*Berlin. Klin. Wchnschr., 36 (1899), pp. 937-939, 968-970, 1086, 1087; rev. in Sci. Amer., 82 (1900), No. 18, p. 276*).—The total nitrogen, nitrogen of extractives, and nitrogen of meat bases, were determined in different kinds of fish, fowl, fresh meat, and preserved meat. The total nitrogen and nitrogen of extractives were also determined in raw and fried veal. Light meat is often said to be preferable to dark meat in special diets, but no constant difference in the kind or amount of nitrogenous materials present was observed which would in the author's opinion warrant this belief.

The effect of light and dark meat in cases of chronic kidney disease, A. Pabst (*Berlin. Klin. Wchnschr., 37 (1900), pp. 547-550*).—Both sorts of meat were found to be equally satisfactory under the conditions studied.

On the behavior of olive oil in preserving fish, O. Klein (*Ztschr. Angew. Chem., 1900, pp. 559, 560; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 14, p. 646*).—A study of the specific gravity, iodin number, etc., of oil used for sardine manufacture and taken from old and freshly prepared cans.

Concerning the extractives in muscles, W. Gulewitsch and S. Amiradzibi (*Physiologiste Russe, 2 (1900), No. 26-30, pp. 114-118*).—Analytical work on a body which the authors call "carnosin" is reported.

Lectures on the physics of organic metabolism, E. Du Bois-Reymond (*Vorlesungen über die Physik des organischen Stoffwechsels. Berlin: A. Hirschwald, 1900, pp. 208, figs. 26*).—These lectures, which are edited by E. Du Bois-Reymond, treat of the physical processes involved in the metabolism of living things—transfusion, emulsion, capillarity, osmosis, and similar topics being considered.

Experimental investigations with man on the effect of muscular work upon the consumption of food material, and the value of different nutrients as sources of muscular energy, H. N. Heineman (*Arch. Physiol. [Pflüger], 83 (1901), No. 10-12, pp. 441-476*).—Using the respiratory quotient apparatus and the methods elaborated by Zuntz and his associates, a study was made of the different nutrients as sources of energy, the special object being to determine whether the nutrients replace each other in direct proportion to their heat of combustion. In connection with the work, the hourly excretion of nitrogen was studied.

Investigations on the source of muscular energy, J. Frentzel and F. Reach (*Arch. Physiol. [Pflüger], 83 (1901), No. 10-12, pp. 477-508*).—A number of experiments which are similar in purpose and method to those noted above.

Concerning protein cleavage and gain during muscular work, W. Caspari (*Arch. Physiol. [Pflüger], 83 (1901), No. 10-12, pp. 509-539*).—The income and outgo of nitrogen was studied with a dog, with special reference to the question of protein in relation to muscular work. It was found that when the diet was constant and a considerable amount of muscular work was performed there was a continual gain of nitrogen in the body.

Muscular work and over-feeding with protein, K. Bornstein (*Arch. Physiol. [Pflüger], 83 (1901), No. 10-12, pp. 540-556*).—The author was himself the subject of experiments similar in purpose to those noted above. The respiratory quotient was studied as well as the income and outgo of nitrogen. According to the author the experiments show that the normal body when overfed with protein and at the same time performing muscular work, is capable of gaining protein without gaining fat.

Concerning the value of different nutrients as sources of energy, N. Zuntz (*Arch. Physiol. [Pflüger], 83 (1901), No. 10-12, pp. 557-571*).—A theoretical discussion based on the 4 preceding investigations.

Ureine, W. O. Moor (*Physiologiste Russe, 2 (1900), No. 26-30, pp. 128-131*).—The author believes he has isolated a new compound from urine, for which the name "ureine" is proposed.

Concerning Moor's ureine and its physiological properties, A. Kuljabko

(*Physiologiste Russe, 2 (1900), No. 26–30, pp. 131–132*).—The body called ureine, according to the author, is a mixture of several substances and not a new chemical compound.

ANIMAL PRODUCTION.

Analyses of fodders from forage crops cut at different stages of growth, R. W. THATCHER (*Nebraska Sta. Rpt. 1900, pp. 73–80*).—To learn the effect of the time of cutting upon the composition of forage crops, analyses were made of oats and peas, field corn, millet, sorghum, Kafir corn, and cowpeas. In every case the second sample analyzed was cut three weeks later than the first. The results of the analyses follow:

Composition of feeding stuffs at different stages of growth.

Feeding stuffs.	Water.	Protein.	Albuminoids.	Ether extract.	Nitrogen-free extract.	Crude fiber.	Ash.
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Oats and peas:							
Pea pods beginning to form, oats beginning to head	12.67	16.19	9.66	2.90	30.24	28.15	9.85
Pea pods all filled out, oats in full bloom.	11.32	16.27	12.54	2.40	35.99	25.41	8.88
Field corn:							
Tassels beginning to appear	13.03	8.08	6.17	1.37	40.43	27.09	10.00
Corn full grown, some ears formed	13.85	6.69	5.49	1.38	45.74	24.04	8.30
Millet:							
Heads just appearing	10.24	8.41	5.79	2.54	32.03	35.86	10.92
Headed out, seeds nearly ripe	10.47	6.12	4.49	1.52	43.33	29.10	9.41
Sorghum:							
Heads just appearing	13.50	8.65	5.24	2.97	34.56	30.62	9.70
Headed out, seeds beginning to form	11.23	6.27	4.65	1.90	41.69	30.05	8.86
Kafir corn:							
Heads just appearing	11.37	8.53	6.00	1.76	35.94	32.74	9.66
Headed out, seeds beginning to form	12.95	6.98	4.86	2.06	37.42	31.38	9.21
Cowpeas:							
Vines 16 in. high, no heads formed	11.76	19.77	11.10	2.70	28.64	21.68	15.45
Well developed, some pods formed	12.60	19.09	12.82	2.71	30.25	21.33	14.02

"The conditions of growth of the crops this season were about equally favorable for each of them and some tentative conclusions may hence be drawn from the results of this season's work. . . . The mixed crop, oats and peas, improves in composition as it grows older and should probably be allowed to stand as long as the pea vines will remain fairly erect. The proportion of flesh-forming to fat-forming constituents in the fodder obtained from this crop is very nearly the correct one for a well-balanced ration for most classes of animals and it would probably be found unnecessary to supplement this fodder with grain or other foods.

"Field corn, millet, sorghum, and Kafir corn decrease rapidly in protein content while heading out. The percentage of crude fiber also decreases somewhat. Both of these changes are probably due to the rapid accumulation of starch and sugars in the plant juices at that time, as shown by the increased proportion of nitrogen-free extract. In order to obtain a fodder having as narrow a ratio of flesh-forming to fat-forming foods as possible the crop should be cut at as early a stage as it can be well cured. For 'roughage' to be fed in connection with highly nitrogenous foods, it may well be allowed to grow until seeds are formed. After that period, however, the stalks rapidly become woody and the proportion of waste is greatly increased.

"No very significant change in composition of the cowpeas is apparent. This year's experience would seem to indicate that the consideration of chemical composition is of minor importance in the selection of the proper stage for harvesting this crop for fodder. As compared with the other fodders analyzed this year, this one is by far the most desirable, on account of its high proportion of nitrogenous material and small percentage of difficultly digestible fiber."

The composition of cotton-seed meal, W. A. WITHERS and G. S. FRAPS (*North Carolina Sta. Bul. 179, pp. 77–86*).—A number of analyses of cotton-seed meal are reported. In addition to the constituents usually determined, the authors report determinations of betain, cholin, gossypein, organic acids, and several members of the carbohydrate group. The principal conclusions follow:

The average amount of betain and cholin in 7 samples of cotton-seed meal is 0.28 per cent. The ratio of betain to cholin in 2 samples is 79:21 and 78:22. Gossypein, if present, is in minute quantity.

Of the nitrogen-free extract in 9 samples, 29.2 per cent is composed of pentosans, and 47.4 per cent of raffinose. The pentosans of cotton-seed meal are not soluble in diastase, and are contained entirely in the nitrogen-free extract, unless an unusually large quantity of hulls is present. Cotton-seed meal contains no starch. No appreciable quantity of sucrose or reducing sugars is present.

Small quantities of organic acids are present, the average of 5 samples being 0.48 per cent.

Concerning blood molasses, a new feeding stuff, F. STROHMER (*Oesterr. Ungar. Ztschr. Zuckerind. u. Landw., 29 (1900), p. 161; abs. in Centbl. Agr. Chem., 30 (1901), No. 9, pp. 596–598*).—Molasses proved a valuable addition to blood feeds, since it improved the feeding value and acted as a preservative. Analyses of a number of blood molasses feeds are reported.

Analyses of feed stuffs sold in Maryland (*Maryland Agr. Col. Quart., 1901, No. 12, pp. 2–19*).—The State feeding-stuff law is quoted, and analyses reported of a number of samples of cotton-seed meal, flaxseed meal, pea meal, middlings, gluten feed, germ-oil meal, gluten meal, mill feed, hominy chop, shipstuff, old-process oil cake, bran, ground corn, corn fodder and hay, distillery grains, linseed meal, cereal breakfast food by-products, mixed rations, and poultry feeds. Three samples of insecticides were also examined. Brief directions are given for mixing rations, and condiments and condimental feeds are discussed.

Analyses of concentrated commercial feeding stuffs, H. J. WHEELER and A. W. BOSWORTH (*Rhode Island Sta. Bul. 77, pp. 173, 174*).—Analyses of 19 samples of gluten meal, 1 of gluten feed, and 2 of linseed meal.

Analyses of feeding stuffs, H. J. WHEELER and A. W. BOSWORTH (*Rhode Island Sta. Bul. 78, pp. 177–181*).—In compliance with the State feeding-stuff law, analyses were made of hominy meal, chops, damaged whole wheat, spring-wheat bran, winter-wheat bran, middlings, cotton-seed meal, linseed-oil meal, gluten meal, animal meal, oats, ground beef, beef scrap, and a number of commercial feeds for poultry and stock, mostly by-products from the manufacture of cereal breakfast foods.

Feeding stuffs, A. HALENCKE and N. KLING (*Jahresber. Thät. Landw. Kreis Vers. Stat. Speyer, 1900, pp. 5–8*).—A number of analyses of feeding stuffs and molasses are reported.

Digestion experiments with Kansas feeds, J. T. WILLARD and R. W. CLOTHIER (*Kansas Sta. Bul. 103, pp. 253–275*).—The digestibility of a number of feeding stuffs was tested with steers, with the results shown in the table below. These included alfalfa hay of different cuttings, Buffalo-grass hay, prairie hay, Kafir-corn stover, Kafir-corn meal and soy-bean meal. Kafir-corn stover was fed with the last two materials, the digestibility of the concentrated feeds alone being calculated.

Digestibility of a number of feeding stuffs by steers.

Feeding stuffs.	Total dry matter.	Protein.	Fat.	Nitrogen-free extract.	Carbohydrates.	Crude fiber.	Ash.
Alfalfa hay:	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
1st cutting, 10 per cent plants in bloom	59.49	78.52	60.00	75.31	62.05	46.10	63.49
2d cutting, 50 per cent plants in bloom	58.29	75.14	30.39	71.99	61.74	50.44	56.91
3d cutting, plants in full bloom	60.03	76.70	51.65	75.24	62.65	50.63	60.94
Buffalo-grass hay	50.08	54.39	62.41	61.71	62.75	64.65	6.04
Prairie hay	51.45	17.67	56.57	61.25	61.07	61.18	25.30
Kafir-corn stover	57.74	49.81	60.00	66.53	66.68	66.64	43.40
Kafir-corn meal fed with Kafir-corn stover	61.23	54.78	....	80.32	77.97	....	18.31
Soy-bean meal fed with Kafir-corn stover	71.79	89.79	98.49	68.27	56.57	....	63.27

Studies on the nutritive value of asparagin, F. ROSENFELD (*Ztschr. Ver. Deut. Zuckerind, 1900, pp. 1055–1079; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 13, p. 602*).—The special object of the investigation was to determine whether the influence of asparagin on the nitrogen metabolism of flesh-eating animals was changed when a definite quantity of crude fiber (hay) was added to the ration. In tests with a dog the nutritive value of asparagin and of albumin was compared, hay being mixed with the ration in one case. The conclusion was reached that the favorable effect of asparagin, and that of other amids also, was dependent upon the feeding of materials containing crude fiber at the same time.

Concerning experiments on artificial feeding, F. STEINITZ (*Inaug. Diss., Breslau, 1900, pp. 46*).—A number of artificial food mixtures were studied with dogs. In the rations the protein was furnished by casein, edastin, or vitellin; the carbohydrates by milk sugar or rice starch, and the fats by olive oil, margarine, or bacon. A salt mixture appropriating the ash content of meat was added to the ration when necessary. From the experiments the author believes that it is possible to nourish animals satisfactorily for a long time on artificial food mixtures if properly prepared. Among other points attention is drawn to the desirability of supplying a nucleoproteid containing iron.

Feeding of farm animals, M. E. JAFFA and L. ANDERSON (*California Sta. Bul. 132, pp. 55, figs. 3*).—Tables are quoted showing the composition and digestibility of a considerable number of feeding stuffs, especially those of local importance. The analyses not previously reported include marsh (Briston) grass, peas and oats, oat silage, orchard-grass silage, beet-pulp silage, olive pomace, pie melon, hay from mixed cereals, wild-oat hay, alkali weed, gourd or mock orange vines, Lima-bean straw, plump wheat, shrunken wheat, crushed barley, blood meal, dried blood, meat meal, and a commercial poultry feed. A number of the feeding stuffs are discussed at length. Special attention is given to sugar-beet pulp. Silos for storing the pulp are described and information gathered from California feeders on the value of this material for farm animals is summarized, showing, according to the authors, "that beet pulp should not be depended upon as the sole diet either for producing milk or meat, the chief reason being that it does not adequately nourish the animal. When fed in connection with other and dry feed it not only serves to keep the digestion in a healthful condition, but adds materially to the store of actual food substance. The amount of pulp which can be fed profitably is reported by all who feed for meat to be all the animals will readily consume in addition to the portion of hay or straw and grain, as already mentioned. In the case of the profitable quantity to feed for milk production there seems to be a wide difference of opinion. It may be that 25 or 30 lbs. per day of pulp will induce as large a flow of milk as 80 lbs. per day when the rest of the feed is dry, the notion being that the lesser quantity gives the cow all the succulent food and change of diet which she really requires for the best production. Where the pulp must be hauled a long distance and the cost of transportation is therefore great, it would undoubtedly be unwise to feed it in larger amounts than would give the necessary succulence to the ration, and 25 lbs. is probably sufficient for this purpose. But where the dairy is situated adjacent to the sugar factory . . . it might pay to feed the pulp in much larger quantities."

The feeding value of fruits is also discussed at some length. It frequently happens that owing to an overabundant crop, fruits (fresh or dried) have a low market value. Windfalls are more or less abundant on fruit farms and of little commercial importance. Regarding the feeding value of such materials the authors point out that green fruits have a high water content, while dried fruits constitute a fairly concentrated feed. In general, fruits supply little nutritive material except carbohydrates, and should be combined with concentrated feed to make a well-balanced ration.

A feeding test with a sow weighing 260 lbs., from which a litter of pigs had just been taken, is reported. After a preliminary feeding of barley and dried figs she was fed all the dried figs she would consume for 9 days. The average daily gain was 3⅓ lbs., the amount of figs consumed per pound of gain being 7.3 lbs. The author points out that the conditions were unusually favorable for gains in weight. Rating pork at 4½ cts. per pound live weight, the figs eaten were worth $1.35, or at the rate of $12.50 per ton. As regards the economy of feeding fruits the authors state:

"It may be a difficult question at times to decide, when prices are extremely low, which would be the better economy, to feed the fruit to cattle, or to receive whatever small returns might be offered for it in the market. In such emergencies a short soliloquy and a little arithmetic will decide the whole matter.

"When there is no market for the fruit there is sometimes nothing left to be done but to feed it to stock. Under any circumstances, when stone fruit is used as fodder for hogs, it is to be feared that when the animals crack large quantities of pits, poisoning may occur from the oil of bitter almonds and prussic acid present in the kernels. Precaution in this direction is unnecessary for stock, as they do not crack the pits. The stones or pits can be used to great advantage as fuel in the economical management of the farm."

Feeding wheat, H. M. COTTRELL (*Industrialist, 28 (1901), No. 1, pp. 3–6*).—A discussion of the subject with citations of station work.

Shelled corn vs. corn chop for calves, D. H. OTIS (*Agr. Expts., 1 (1901), No. 3, p. 63*).—A brief account of a test at the Kansas Station, which showed that better gains were made on shelled corn than on corn chop.

Sheep-feeding experiment, W. T. LAWRENCE (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 172–175*).—In continuation of previous work (E. S. R., 11, p. 1077), a test was made at Newton Rigg, Penrith, on the value of yellow turnips and pasture, 3 lots of 20 crossbred sheep each being used. Lot 1 was hurdled on yellow turnips and lot 2 grazed for 10 weeks. Both lots were fed in addition ½ lb. linseed cake and ¼ lb. oats per head daily, as well as hay *ad libitum*. Lot 3 was hurdled on turnips and given hay *ad libitum* in addition for 7 weeks. For the next 3 weeks the sheep were given the same grain ration as lots 1 and 2. They were then pastured on grass for 3 weeks longer and the grain ration was continued with turnips *ad libitum*. The average weekly gain per head of lot 1 was 1.53 lbs.; with lot 2 it was 1.26 lbs. While on turnips and hay only the average weekly gain per head of lot 3 was 0.55 lb.; when fed linseed cake and oats in addition it was 1.52 lbs., and when pastured on grass and fed grain, hay, and turnips in addition it was 1.07 lbs. The financial returns are discussed. The author believes that pasturing sheep on turnips is more profitable than on grass, and that there is an advantage in feeding grain and hay in addition.

Feeding experiments with sheep (*Jour. Bd. Agr. [London], 8 (1901), No. 1, pp. 17–20*).—A brief account of experiments noted above from another publication.

The influence of soil and manure on the feeding value of swedes, and influence of manures on the composition and feeding value of seeds hay, T. H. MIDDLETON (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 111–127*).—The influence of manure and the effect of soil on the chemical composition and feeding value of Swedish turnips was tested. The turnips were fed to sheep. The author also studied in a similar way the composition and feeding value of hay (clover and rye grass) manured in different ways. All the animals in the first test and half of those in the second were fed under cover. The work is summarized as follows:

"Between swedes grown with farmyard manure alone, farmyard manure and artificials, and artificials alone, very slight differences in feeding value were found. If an artificial manure grows and ripens a good crop of swedes the feeding value is not likely to suffer.

"Swedes grown on a good soil in East Lothian proved not quite equal to swedes of the same variety grown with the same manure on an inferior soil at Cockle Park; but the latter were quite up to the average quality of the district, whereas the former were not.

"Of four qualities of clover and rye-grass hay tested, hay grown with 1¼ cwt. nitrate of soda, 7 cwt. of slag, and 4 cwt. of kainit per acre proved inferior to a sample grown with slag and kainit only, and also to hay grown with ⅞ cwt. and 1¾ cwt. of sulphate of ammonia with slag and kainit. In this particular case the chemical and botanical analyses of the hay indicate that the inferiority was due to overripeness.

"Twenty sheep fed under cover left 4½ cts. per head per week more for their keep than 20 similar animals fed outside.

"When sheep were fed on a diet consisting chiefly of swedes it was found that 69 per cent of the live-weight increase in passing from a 'store' to a moderately fat condition was carcass. When sheep were fed on a limited ration of swedes and a full supply of hay 77 per cent of the live-weight increase was mutton.

"The feeder who fattens cattle under cover appreciates the swede. At Cockle Park it was found that for sheep fed under cover the swede is a valuable food. Sheep fed in the house for a period of 35 days were allowed as many swedes as they would eat; they consumed about 15 lbs. per head per day; they gained 6.25 lbs. per head upon this diet, although it contained less nutriment than is usually assumed to be necessary for maintenance. Twenty similar sheep fed in the same house and for the same period were allowed 8 lbs. swedes per day and as much seeds hay as they would eat; they consumed about 1⅐ lbs. per head of the latter; they gained only 1.64 lbs. per head in 35 days, although the diet from a chemical standpoint was more liberal than the other. This result is explained by the fact that it takes more digestible food to supply the animal's needs when the food is presented in a form difficult to digest—as in hay—than when in a form easy to digest—as in swedes."

The improvement of pasture as tested by the effects on sheep, W. Somerville (*Dept. Agr. Cambridge Univ. Rpt. 1901, pp. 9–16*).—The value of different fertilizers for pasture grasses was tested by grazing sheep on plats manured in different ways. The tests were made in Essex, Cambridgeshire, Norfolk, and Northampton. In the experiments at Cambridgeshire, plat 1 was not manured but the sheep were fed daily 0.86 lb. linseed cake per head. Basic slag was used on plats 2 and 4, and superphosphate on plat 5, while plat 3 was unmanured. A botanical analysis of the hay from the different plats is given. The principal conclusions follow:

"The live-weight gain, per acre and per sheep, was distinctly greater on the 3 manured plats (Nos. 2, 4, 5) than was the case on plat 1, where the sheep got daily considerably more than ¾ lb. per head of linseed cake. A similar result was got in Northumberland in 1898.

"Plat 2, receiving ½ ton of basic slag, carried nearly 2 sheep more than plat 4, which was dressed with half the quantity of slag, but the gain per head per week in the latter case was somewhat higher.

"When equal amounts of phosphoric acid were used in the 2 forms of basic slag and superphosphate, the latter produced the larger live-weight gain. A similar result was got in the first year of the Northumberland experiments.

"The unmanured plat gave decidedly the lowest yield of animal increase."

The other tests are very briefly reported, as they are not ended.

The influence of manures on the feeding value of pasture grasses, T. H. Middleton (*County Councils Cumberland, Durham, and Northumberland, Tech. Education, Rpt. 9 (1900), pp. 128–149, fig. 1*).—Abstracted from another publication (E. S. R., 13, p. 175).

California Angoras; a few chapters on the practical side of the Angora industry (*San José: C. P. Bailey & Sons, 1899, pp. 31, figs. 9*).—The care of Angora goats and similar topics are discussed in a popular way. Persian fat-tailed sheep are also briefly mentioned.

Home pork making, A. W. FULTON (*New York: Orange Judd Co., 1900, p. 124, figs. 36*).—The author points out the advantage of making pork on the farm, and gives directions for slaughtering, dressing, and curing pork, the preparation of ham and bacon, etc. The book also includes a large number of recipes for cooking pork and pork products.

American breeds of fowls. I, The Plymouth Rock, T. F. MCGREW (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 29, pp. 32, col. pls. 6, figs. 10*).—The topics discussed in this bulletin include, among others, the origin of the Plymouth Rock breeds, descriptions of the Barred variety, White Plymouth Rocks, Buff Plymouth Rocks, the Pea-Combed variety, as well as the Jersey Blue and Rhode Island Red breeds which are allied to the Plymouth Rocks. Information is given regarding mating, breeding, and related topics.

Farm poultry: A popular sketch of domestic fowls for the farmer and amateur, G. C. WATSON (*New York: The Macmillan Co., 1901, pp. 341, figs. 95*).—Poultry raising as a business, the breeds suitable for the production of eggs and meat, fancy breeds, poultry buildings, incubators and brooders, poultry feeding, preparation for the market, and related topics are treated of.

Practical poultry keeper, L. WRIGHT (*London: Cassell & Co., 1901, pp. 311, pls. 8, figs. 37*).—A new and revised edition. The volume treats of poultry houses, poultry rearing, and the different breeds of domestic poultry.

New egg farm; or, the management of poultry on a large scale for commercial purposes, H. H. STODDARD (*New York: Orange Judd Co., 1900, pp. 331, figs. 145*).—A general treatise on the subject.

Incubators and chicken-rearing appliances; how to make and use them (*London: Cassell & Co., 1899, pp. 64, figs. 36*).—Directions are given for making incubators of different sizes, and making brooders, and for operating incubators. Heat regulators for incubators are also described and discussed.

DAIRY FARMING—DAIRYING.

Hand feeding of cows for milk and butter production, G. S. THOMSON (*Jour. Agr. and Ind., South Australia, 4 (1901), No. 12, pp. 945–968, figs. 6*).—Under the above heading the author discusses a number of subjects connected with dairying. The benefits of feeding during the dry season in South Australia are brought out, and the rations used are discussed. One of the foods employed was copra cake, the residue from crushed cocoanut kernels. It is highly recommended as a part of a ration for milch cows, but must be given sparingly at first, or cows will not eat it. A quarter of a pound to a ration is sufficient in the beginning and may be increased to 2 lbs. daily. The cream from cows fed copra is said to require a higher temperature for churning. The butter grains are firmer and the melting point of the butter is higher. Heavy feeding of copra injures both the texture and the flavor of the butter.

Rations for milch cows, H. J. WHEELER and J. A. TILLINGHAST (*Rhode Island Sta. Bul. 77, pp. 131–172*).—Sixty-one rations for milch cows as reported by different feeders throughout the State are given, with modifications and comments by the authors of the bulletin. The principles of feeding are briefly discussed, and notes are given on methods of feeding and on the relative manurial value of several feeding stuffs. A table for use in calculating rations is reproduced from Vermont Station Bulletin 81 (E. S. R., 12, p. 877).

Domestic pasteurizing methods and the care of milk in the home, J. NELSON (*New Jersey Stas. Bul. 152, pp. 22*).—The author discusses in a popular manner the souring of milk, relation of milk fermentations to health, disease germs in milk and their destruction, the use of ice and heat in preserving milk, pasteurization and sterilization, etc. Methods of pasteurizing adapted to home use are described and suggestions given for pasteurizing infants' food. The bulletin is summarized at some length.

A study of the pasteurization of milk, H. Weigmann (*Milch Ztg., 30* (*1901*), *No. 27, pp. 417–419; No. 28, pp. 433–434*).—An experimental study of different systems and makes of apparatus.

Influence of pasteurization upon the properties of milk and the processes of butter making, R. Steiner (*Milch Ztg., 30* (*1901*), *No. 26, pp. 401–403; No. 28, p. 435*).—The author made a study of the effect of pasteurizing upon the viscosity and the specific gravity of milk, and also its effect upon the action of rennet. Milk to be tested was divided into two portions, one left at room temperature for 3 hours and the other heated 15 minutes at 70° C. and rapidly cooled.

It was found that pasteurizing lowered the viscosity of the milk. This result seemed to depend somewhat upon the concentration, for when water was added to replace evaporation the effect was lessened. The specific gravity was influenced but little and that not constantly. The coagulation was made with 0.1 cc. of rennet in 100 cc. of milk. In all cases the time of coagulation was increased with the pasteurized milk.. The time varied with different milks, apparently depending upon the composition. The completeness of the coagulation was also hindered by pasteurization. The following table shows the effect of pasteurization upon duplicate samples of similar milk:

Effect of pasteurization upon coagulation.

Treatment.	Loss of albumin.	Time of coagulation.
	Per cent.	*Min. sec.* *Min. sec.*
Not pasteurized		5 37 to 6 15
Heated at 60° for 25 minutes		14 22 to 15 ..
Heated at 70° for 20 minutes	6.90	20 .. to 22 30
Heated at 80° for 15 minutes	55.74	27 30 to 30 ..
Heated at 90° for 10 minutes	76.55	No coagulation in 1 hour.
Heated at 95° for 5 minutes	78.64	
Heated at 100° for 3 minutes	82.54	

A study was also made of the influence of pasteurization upon butter making. In this the fat content of the whole milk, skim milk, and buttermilk was determined and the total fat of the cream and butter estimated. The cream from the separator was divided into two portions, one cooled to 10° and the other heated to 75° for 15 minutes and cooled. Both portions were kept in the usual manner for from 20 to 24 hours and churned. From the results two points were clear: First, that the time of churning was shorter with the pasteurized milk, and second, the fat content of the buttermilk was lessened. Taking the average of 6 trials the buttermilk from the unpasteurized milk contained 1.2297 per cent of fat, while that from the pasteurized milk contained only 0.8819 per cent. The quality of the pasteurized butter was higher than that of the unpasteurized, the former scoring an average of 96.60, while the latter averaged 94.91. The average duration of the time of churning with the pasteurized cream was 73 minutes; with the unpasteurized, 92 minutes.

Why cream tests vary (*Creamery Jour., 11* (*1901*), *No. 143, pp. 6, 7, 30, 31*).—Statements from several creamery men as to the causes of the variations of the tests of cream from farm hand separators.

The mechanical introduction of water in butter, E. Sergeant (*Public Health, 14* (*1901*), *No. 1, pp. 10–12*).—The author discusses the adulteration of butter in Great Britain by the addition of water. The amount which may be added by mechanical means is stated to range between 18 and 36 per cent.

The manufacture of hard cheese from pasteurized milk, H. Tiemann (*Milch.

Ztg., *30* (*1901*), *No. 25*, *pp. 386, 387*).—After a discussion of the subject of making cheese from pasteurized milk, the author gives the following method as practiced at the Dairy Institute at Wreschen: After heating to 90° C. for about 15 minutes the milk is rapidly cooled. To 50 kg. there is added 20 gm. calcium chlorid and 750 cc. of a pure culture of lactic acid and peptonizing bacteria. This pure culture is made in sterilized skim milk and is added for the purpose of incorporating in the cheese the proper bacteria for assisting in the ripening. The whole milk is then brought to 40° and the rennet added. After putting into form the cheese is first pressed lightly and later hard, and salted. The finished cheese is placed in a somewhat dry cellar for 4 months and then in one containing more moisture—from 90 to 95 per cent.

After a period of 9 months the cheese is described as follows: Ripening normal, porosity good, taste sharp and pleasant, although the cheese is somewhat dry.

From 100 kg. of milk there was obtained 22 lbs. of ripened cheese, while the same amount of unpasteurized milk made only 18 lbs., a gain of about 18 per cent with the former. It required only 1½ hours from the addition of the rennet to the pasteurized milk to the pressing of the cheese into form.

Experiments in curing cheese, G. L. McKay (*Iowa Sta. Bul. 57*, *pp. 14*, *pl. 1*, *figs. 2*).—Experiments were conducted for the purpose of testing the feasibility of central curing rooms, and the effect of climatic conditions upon the curing of cheese. Cheese fresh from the press was shipped from the Iowa Station to the Guelph Dairy School and a factory at Stratford, Ontario, to be cured, and both of the latter shipped new cheese to the Iowa Station for curing. Cheese from the same lot in each case was cured where made. The scorings are tabulated. The results are considered as showing that "shipping the cheese 750 miles by express during the heat of summer did not affect the flavor." Central curing rooms which could be better constructed for controlling temperature and moisture are therefore considered desirable in warm and dry climates.

Other results of the experiments at the station are summarized as follows:

"Cheese cured in musty ice box at temperature of 55° F. compared favorably with cheese cured in well-ventilated room at a moderately low temperature during the month of October. Cheese cured in ice box scored 2¾ points higher on flavor and ½ a point higher on texture.

"Cheese can be exposed the first 5 days to a temperature as high as 90° without injuring its flavor if sufficient acid has been developed to make a firm-bodied cheese and it is cured at 60° afterwards.

"Cheese cured at a temperature of 60° F., with a high percentage of moisture, scored higher than cheese cured at a temperature above 65°.

"Adding artificial moisture through pine shavings in a box worked very satisfactorily in the curing room and left no bad odors.

"Fumigating with formaldehyde gas to destroy the mold-producing bacteria gave good results."

The ripening of cheese and the rôle of micro-organisms in the process, F. C. Harrison (*Trans. Canad. Inst.*, *7* (*1901*), *I*, *No. 13*, *pp. 103–134*).—The author reviews the work done on cheese ripening during the past 25 years and calls attention to the difficulties in the investigation, owing to the many different kinds of cheese, methods of manufacture, and other factors. A bibliography of the work is appended.

The work of the author is given, in which he sought to determine the causes of the ripening of cheese. He made a study of the acid content, and especially of the micro-organisms, and carried out an experiment similar to that of Russell and Weinzirl (E. S. R., 11, p. 487), except that his work was on Canadian Cheddar cheese and the culture media used were somewhat different. It was found that the bacteria developed in the curd and cheese with the greatest rapidity up to the age of 2 or 3 days. This was followed by a period of rapid decline until about the thirteenth day. From this period the decrease was gradual, up to 130 days, when only 1,400 bacteria per gram were found. The results agree with Russell as to the enormous development of lactic-acid bacteria, but differ somewhat as to the period of increase and decline. The greatest increase in acidity occurred between milling and salting. From this point until the cheese was 40 days old there was a gradual increase. The prevailing species of lactic-acid bacteria was the *Bacterium acidi lactici*. Next in numbers was *B. lactic ærogenes*, or a closely allied form. When cultures of these two organisms were introduced into sterilized milk a firm curd was produced, with little or no gas.

The gas-producing bacteria belonged usually to either the *B. coli* group or the *B. lactic ærogenes* group. In the presence of the former the cheese was sometimes mottled.

The liquefying bacteria were not numerous in the Canadian cheese examined, and they decreased in numbers as the cheese ripened, being seldom found after 3 weeks. In one instance the presence of a large number of digesting bacteria was associated with a bad flavor in the cheese. Two or three forms closely related to *B. fulvus* were found in young cheese. This group gave rise to bad flavor or odors in milk.

Yeasts were quite commonly found in Canadian cheese and frequently in large numbers. The experiments indicate that they are the only micro-organisms that actually increase in cheese. While the name yeasts is applied to this class, most of them were species of Torula, as they formed no spores. Some were beneficial, acting somewhat like lactic-acid bacteria, while others were injurious, causing undesirable fermentations. One species produced a mottled appearance in the cheese. These yeasts show a remarkable tolerance to acidity, so that it is difficult to overcome their action by the addition of a vigorous lactic-acid starter. Some grew in peptone solutions containing 2.25 per cent of lactic acid.

The author discusses at some length the causes of the ripening of cheese, as shown by his own work and that of others. He gives the following as important facts which are well supported by the evidence of careful experiments: (1) The enormous number of lactic-acid bacteria in hard cheese, and the very small numbers of liquefying or digesting bacteria; (2) the existence of galactase, a natural enzym inherent in fresh milk; and (3) the ability of rennet to cause the change of nonsoluble nitrogenous products to soluble ones."

The author's experiments with Canadian cheese indicate that the amount of acid present is sufficient to inhibit the action of galactase in cheese ripening, and that this enzym is therefore of little importance. On the contrary, rennet acts more quickly and with greater power in acid solutions. It would therefore seem that the rôle of the lactic-acid bacteria is to create a requisite acidity, so that the pepsin of the rennet can exercise its digestive action on the cheese.

"Summarized, the ripening of cheese may be said to be caused by the digestive action of the rennet on the insoluble nitrogenous matter of the cheese, in the presence of acid formed by the lactic-acid bacteria. The large amount of acidity also prevents or inhibits the growth of other (and perhaps undesirable) species of bacteria."

Danish trade in dairy produce in 1900 (*Jour. Bd. Agr.* [*London*], *8* (*1901*), *No. 2, pp. 233–234*).—Report to the foreign office from the British consul at Copenhagen.

Siberian butter trade (*Jour. Bd. Agr.* [*London*], *8* (*1901*), *No. 2, pp. 230–233*).—Report of H. Cooke, commercial agent of the board in Russia.

VETERINARY SCIENCE AND PRACTICE.

Report of the veterinarian, W. H. DALRYMPLE (*Louisiana Stas. Bul. 64, 2. ser., pp. 595–624, figs. 11*).—The station undertook to encourage the importation of highbred cattle from the North, and for this purpose volunteered to immunize such cattle without expense to the owners. Among the cattle sent to the station for this purpose the following breeds may be mentioned: Polled Durham, Hereford, Shorthorn, Red Poll, Jersey, grade Hereford and Shorthorn, and grade Hereford and Holstein. About 50 cattle were artificially immunized by blood inoculation and all passed through the 60-day period during which they were under observation without any mishap or without the necessity of medical treatment. The blood used in inoculations was from a steer imported from Missouri which had previously passed through an attack of fever. All the animals passed through a primary and secondary attack of fever. It is considered that the best time for inoculation is in the late fall or winter, for the reason that when the animals are turned out to pasture for the first time after immunization the ticks will not be numerous enough to cause a relapse. The author believes that the operation of blood inoculation is so simple that it can be successfully carried out by practical stockmen without the assistance of a trained veterinarian. All of the cattle which were inoculated at the experiment station were later shipped to their respective owners in different parts of the State and were placed on tick-infested pastures. A few of these animals had relapses and some died, but the history of the different cases indicates that the relapses and deaths could largely have been prevented by careful attention to the animals when they were first turned out to pasture. Recently inoculated animals should not be turned into pastures where the ticks are exceedingly numerous for the reason that an excessive infestation of ticks may overcome the partial immunity which is already produced in the animals.

An outbreak of anthrax occurred in 1900 on the experiment station grounds. A cow died rather suddenly from the disease and the carcass was thoroughly burned. The remainder of the cattle on the pasture were changed to other grazing ground and later were inoculated with the first and second lymph of anthrax vaccine. About a month after the outbreak of anthrax the vaccinated cattle were turned on the pasture where the first case occurred, but no further cases of the disease were noticed. One mule and one horse became affected and died. It is believed that the infection which caused this outbreak came from a bull which died in a neighboring farm 3 or 4 weeks before the outbreak on the station grounds occurred. Anthrax was not so prevalent during 1900 as during the 2 or 3 previous years, and it is believed that this was due to greater sanitary precautions being taken by stock owners throughout the State. Several outbreaks of blackleg occurred and were reported to the station. Inoculation with blackleg vaccine was recommended and the spread of the disease was checked. A serious outbreak of glanders occurred as a result of the importation of diseased animals from Kansas City. Of 223 animals which were inspected, 39 were found to have glanders. Of these, 11 died and 28 were killed on account of clinical symptoms of glanders or after reacting to the mallein test. It is stated that there is no law in Louisiana requiring shippers to give any guarantee as to the healthfulness of horses and mules which are shipped in from other States. It is urged that a law be passed by which the stock owners of the State may be protected against unscrupulous stock dealers who might otherwise ship in glanderous horses and mules. A nervous disease of cattle, characterized by trembling of the head, neck, and other portions of the body, was investigated, and the author believes that the disease was due to slight poisoning from eating unwholesome weeds. All cases recovered, the treatments recommended including a change of grazing ground, purgation with Epsom salts, and administration of bromid of potash.

A disease is reported among cattle as due to eating rotten sweet potatoes. The chief symptoms were difficulty of respiration and groaning. The sweet potatoes were probably affected with the black-rot fungus. Brief notes are given on the nodular disease of the intestines of sheep. This disease is reported as prevailing throughout the State, and it is stated that experiments are in progress which are designed to discover means for eradicating it from pastures so far as possible.

Annual reports of proceedings under the diseases of animals acts, etc., 1899 (*London: Board of Agriculture, 1900, pp. 102, pls. 2*).—The report of the chief veterinary officer, A. C. Cope (pp. 7–22), contains an account of rabies, foot-and-mouth disease, pleuro-pneumonia, hog cholera, glanders, anthrax, and sheep scab. Tables are given showing the decrease in the number of cases of rabies since the Board of Agriculture undertook the eradication of this disease in 1897. It is believed that rabies has been completely eradicated in Great Britain, the last case having been observed in November, 1899. In order to prevent the reintroduction of the disease, orders have been issued restricting the importation of dogs from abroad and subjecting them to quarantine for a period not to exceed 6 months.

During 1899 reports were received of 11 suspected outbreaks of pleuro-pneumonia. The investigation showed that in each case the animals were suffering from tuberculosis or some disease other than pleuro-pneumonia. It is reported that hog cholera occurred on premises where it had never been known before. In one instance 33 fresh premises were infected as a result of exposure of some infected but not evidently diseased animals in a certain market. Glanders has increased in the number of cases during the year, and its distribution has become wider. It is suspected that certain horsemen are using mallein as a diagnostic agent for glanders and then selling the horses which react on the public market. This might account for the spread of the disease. Brief notes are also added on the extent and distribution of anthrax and sheep scab.

The assistant secretary, J. T. Tennant (pp. 23–41), gives a statistical report on trade in foreign animals, animals brought from Ireland, and cattle markets and fairs. A copy is given of the order relating to the importation of dogs into Great Britain, and a brief account is presented of the measures which have been taken by the board for preventing the further distribution of hog cholera. Statistical tables are given showing the various orders issued by the Board of Agriculture regarding animal diseases, the international trade in animals, the number of animals of various species in Great Britain, and the number of cases of various diseases among these animals.

Report of the cattle commissioners, A. Peters (*Massachusetts State Bd. Agr. Rpt. 1900, pp. 395–482*).—The work of the cattle commissioners with reference to tuberculosis included the maintenance of the quarantine and testing herds at the request of owners. A paper is reprinted on obstacles to enforcing regulations requiring the tuberculin test in interstate cattle traffic (E. S. R., 13, p. 390). During the year 3,249 cattle were quarantined, and of these 1,178 were killed and paid for as being tuberculous. Statistical tables are given showing the number of cattle inspected in various towns of the State. Glanders prevailed to a greater extent than ever before, being reported from 128 cities and towns. In 1900, 699 animals were destroyed as glanderous. Detailed notes are given on some especially interesting cases of glanders with which the cattle commissioners had to deal. Blackleg is reported as having caused the death of a number of young cattle in parts of Worcester County. No cases of Texas fever were discovered during the year. A few cases of rabies were reported, and 11 outbreaks of hog cholera required investigation.

Report on animal diseases, W. H. Kelly (*Rpt. New York State Dept. Agr., 7 (1899), I, pp. 486–513*).—Brief notes are given on the occurrence and extent of actinomycosis, verminous bronchitis, blackleg, infectious mammitis, tuberculosis, and rabies. In one dairy 39 out of 92 cows were found to be tuberculous, and the owner was forbidden to sell the milk without previous sterilization. A number of cases of rabies were reported in cattle and horses, and the most of these were traced definitely to bites of mad dogs.

Report of veterinarian, G. E. Nesom (*South Carolina Sta. Rpt. 1900, pp. 18–21*).—Texas fever is reported as occurring in isolated localities throughout the State. The cattle ticks are especially abundant in low country, large swamps, and pine forests. The station proposes to undertake the immunization of cattle which are shipped into the State from north of the quarantine line. Brief notes are given on the occurrence of glanders and milk fever. It is reported that experiments in the use of arecoline as a remedy for colic and acute indigestion in horses indicate that this substance is fairly effective.

Eleventh annual report on the veterinary service in Hungary, F. HUTYRA (*Jahresbericht über das Veterinärwesen in Ungarn. Budapest: Agr. Dept., 1900, pp. 180*).—This volume contains a general account of the personnel and extent of veterinary service. Brief notes are given on the losses caused by animal diseases during the year. A detailed account is presented of the outbreaks and extent of cattle plague, anthrax, rabies, glanders, foot-and-mouth disease, pneumonia, sheep pox, mange, hog cholera, swine plague, tuberculosis, etc. Statements are made concerning the extent of traffic in domesticated animals during the year and the results of protective inoculation against anthrax, hog cholera, and blackleg. Copies of some of the veterinary regulations are also given.

The infectious diseases of domestic animals, N. V. ELMANOV (*Besyedui o zaraznuikh bolyeznyakh nashikh domashnikh zhivotnuikh. Moscow: K. I. Tikhomirov, 1900, pp. 67, figs. 15; abs. in Selsk. Khoz. i Lyesov, 199 (1900), Dec., p. 754*).—A general account of anthrax, glanders, cattle plague, contagious pleuro-pneumonia, tuberculosis, rabies, cowpox, and scabies.

The suppression of tuberculosis, R. KOCH (*Nature, 64 (1901), No. 1656, pp. 312–316*).—This is a paper read at the British Congress on Tuberculosis, July 23, 1901. The author presents a general discussion of the problem concerning the possibility of transmission of tuberculosis from animals to man and from man to animals. Numerous experiments indicate that human and bovine tuberculosis are two quite distinct diseases. Young cattle, which were shown by the tuberculin test to be free from tuberculosis, were inoculated hypodermically, intravenously, or in the peritoneal cavity, with pure cultures of tubercle bacilli from cases of human tuberculosis, or with the tubercular sputum of consumptive patients. In addition to these experiments, 6 animals were fed with tubercular sputum almost daily for a period of 7 or 8 months, and 4 were made to inhale great quantities of bacilli from the same source by means of a spray from an atomizer. In all, 19 cattle were used in these experiments, and none of them developed any symptoms of disease; on the contrary, they gained considerably in weight, and after from 6 to 8 months a post-mortem examination showed no trace of tuberculosis in any organs. When similar experiments were conducted on cattle with pure cultures of tubercle bacilli, or tubercular material of bovine origin, the result was entirely different, and all inoculated animals showed symptoms of generalized tuberculosis within a few weeks. Some of them died at the end of a month.

With regard to the other phase of the problem, the possibility of the transmission of tuberculosis from animals to man, the author believes that while the question is not absolutely decided, the infection of human beings from this source is of rare occurrence. It is stated that the transmission of infection by milk from fresh tuberculous animals is probably not greater than that by heredity, and it is therefore considered unnecessary to take any measures against possible danger to human beings from such sources. Attention is called to the reports of older experiments by other writers, in which it was found that calves, pigs, and goats fed with milk and tubercular material from cattle always contracted tuberculosis, while those which received sputum from human patients did not become infected. It is believed by the author that tuberculosis in man is transmitted only from tuberculous human patients, and that the disease in animals is transmitted only from one animal to another.

Report of the tuberculin committee, J. MCFADYEAN ET AL. (*Jour. Roy. Agr. Soc. England, 3. ser., 11 (1900), pt. 4, pp. 708–723*).—The experiments recorded in this paper were conducted for the purpose of determining the effect of repeated doses of tuberculin and the length of time after infection before a reaction to tuberculin takes place. For this purpose apparently healthy animals were selected and tested with tuberculin. If they failed to react they were inoculated with the tubercle bacillus and tested at intervals afterwards, in order to determine how soon they would react to tuberculin. One animal which gave a decided reaction when tested on October 9 subsequently failed to react, or reacted alternately. For 2 months it received large quantities of tuberculin and entirely ceased to react. The animal was inoculated with tubercle bacilli on February 6 and reacted to tuberculin 8 days after inoculation. The animal was then treated with large doses of tuberculin without reaction. When killed on May 22 no trace of tuberculous lesion was found except a casefied and inert tubercle in a mesenteric gland. In other experiments it was found that in many cases reaction to tuberculin did not occur until from 40 to 50 days after the animals were inoculated with tuberculosis. In several cases which reacted decidedly on the first test, a complete failure to react was noted if the test was repeated within a short time. The authors believe that repeated injections of tuberculin may have some curative effect, or may retard the progress of the disease to some extent, and that this matter is largely influenced by the individuality of each animal. A few animals could not be inoculated with virulent tubercle bacilli, although they had not been previously treated with tuberculin, and appeared to be entirely resistant to tuberculosis. The facts elicited with regard to reaction of animals to a second or later test with tuberculin were so variable that no attempt was made to tabulate them. From the numerous experiments the author concluded that with few exceptions tuberculosis may be recognized in a post-mortem examination of animals which give a decided reaction to tuberculin, and that no such lesions are found in animals which fail to react or react only slightly to the tuberculin test.

Is the Bacillus tuberculosis of cattle permanently different from that of man? J. Law (*Rpt. New York State Dept. Agr., 7 (1899), I, pp. 513–554*).—The author gives a general review of the literature of this subject, dealing especially with the possibility of transmission of tuberculosis from man to animals and from animals to man, and also with direct experiments in infecting animals with tubercle bacillus of human origin. A general account is also given of the nature, value, and reliability of tuberculin.

Tuberculosis in calves, Rabus (*Wchnschr. Thierheilk. u. Viehzucht, 45 (1901), No. 9, pp. 97, 98*).—A brief discussion of the literature of this subject, together with notes on a case observed by the author which was apparently of prenatal origin. The percentage of tuberculosis in calves in Bavaria, as shown by statistics based upon several million calves, is from 0.02 to 0.05.

Contribution to tuberculosis in the horse, F. Hendrickx (*Ann. Méd. Vét., 49 (1900), No. 10, pp. 575–584*).—Detailed description is given of the symptoms and pathological lesions of 2 cases in horses. The disease is quite easily distinguished from glanders. The lungs in both cases were affected, and caseous tubercles were found in the liver and kidneys. The spleen was somewhat enlarged and contained pathological structures which were probably tubercles in the process of formation.

Historical and bibliographical study on the use of raw meat in the treatment of tuberculosis, C. Richet (*Ann. Méd. Vét., 49 (1900), No. 8, pp. 410–427*).—A critical review of the literature of the subject, with numerous bibliographical references. It is concluded from this study that the evidence for the value of raw meat in the treatment of tuberculosis is very strong, and that raw meat or muscle plasma is not only a nutritious food, but has also the effect of an antitoxic agent.

Arrangements for inoculation against tick fever (*Agr. Gaz. New South Wales, 12 (1901), No. 4, p. 497*).—Since the cattle tick appears to be making only a slow progress in its distribution from Brisbane as a center, the stock inspector has deferred the general preventive inoculation of cattle. In order to be prepared, however, for the sudden appearance of ticks among cattle outside of the infested area, arrangements have been made to secure immune cattle from which blood may be obtained for inoculation.

Tristeza, J. LIGNIÈRES (*Ann. Inst. Pasteur, 15 (1901), No. 2, pp. 121–128, pl. 1*).—Tristeza is the name for a cattle disease in Argentina, which is identical with Texas fever. The author quotes the results of investigations upon this disease, during which the results already obtained by American students are largely confirmed. It is stated also that the examination of blood, although the most important element of diagnosis ante-mortem, is not an infallible test. An atypical form of the disease is occasionally observed, in which the destruction of red blood corpuscles is not very pronounced, or takes place slowly, and in which the corpuscles in general circulation are not attacked by the blood parasite until shortly before death. It is maintained that this form of the disease does not correspond to the benign form already described by the American writers. The author succeeded in making cultures of *Pyrosoma bigeminum* in a round form, and showed by experiment that the administration of quinin and arsenical compounds has no effect in preventing or curing the disease.

Tristeza or Texas fever in the Argentine Republic, J. LIGNIÈRES (*La "tristeza" ou malaria bovine dans la République Argentine. Buenos Ayres: Jacobo Peuser, 1900, pp. 172, pls. 16*).—A preliminary account of work on this subject has already been noted (E. S. R., 12, p. 885). The present volume contains a detailed account of the author's observations and experiments on this disease.

Parturient paralysis and the Schmidt treatment, J. J. REPP (*Iowa Sta. Bul. 58, pp. 17–30*).—A general account is given of the history, distribution, cause, pathological anatomy, symptoms, diagnosis, course, and treatment of parturient paralysis. The author considers this name preferable to either parturient paresis or milk fever.

In order to determine the effectiveness of the Schmidt treatment, as applied by the practicing veterinarians of Iowa, a circular letter was sent to 150 veterinarians requesting a report on the number of cases treated and the history of those cases. In all, 166 cases were reported to the author by 33 veterinarians, of which 119 cases were reported as successful, while 47 were fatal. The majority of the affected cows were between the ages of 6 and 9 years, and at the birth of the third to the sixth calf. Most of the cows were reported as being fat and at pasture, not receiving any other food. As a rule, the affected animals were heavy milkers. The disease developed usually within 24 hours after parturition. The infusion of potassium iodid was repeated in from 8 to 12 hours in 22 cases, and in 2 cases was repeated twice. In 6 cases the disease was complicated with pneumonia and resulted fatally in each case. The author believes that pneumonia may be the result of attempting to give medicines by way of the mouth when the animal is unable to swallow. The material might under such circumstances be carried into the lungs and produce an infection of these organs. In 7 of the cases which were treated a more or less serious affection of the udder was produced, probably from the use of instruments which were not properly sterilized. Allowing for cases which were complicated with pneumonia and other trouble, the author considers that 76.5 per cent of cures is to be placed to the credit of the Schmidt treatment. This treatment is recommended as being the most effective one which has yet been devised.

Parturient paresis, S. S. BUCKLEY (*Maryland Sta. Bul. 76, pp. 199–201*).—The author presents a brief account of the Schmidt treatment for milk fever, together with formulæ for solutions to be used and directions for applying the treatment. The usual symptoms of milk fever are mentioned, and statistics are given on the percentage of cures effected by the Schmidt method. Of 7 cases treated by the author, 6 recovered. In 2 cases which recovered severe attacks of mastitis subsequently developed.

Milk fever, E. W. HOARE (*Veterinarin, 74 (1901), No. 879, pp. 138–140*).—The author had good success in the treatment of milk fever by administering chloral hydrate in doses of 1 oz. and treacle in doses of 1 lb., followed by ammonium carbonate. In one case the cow received in all 7 oz. of ammonium carbonate and 9 lbs. of treacle.

It is stated that since the Schmidt treatment is based on empirical grounds, further investigation is needed to elucidate the nature of milk fever.

Effects of iodid of potash as an injection in the mammary gland, P. COUREMANS (*Ann. Med. Vet., 49 (1900), No. 5, pp. 240–243*).—A description is given of the usual method for making intramammary injections of this substance. Experiments were conducted for the purpose of determining whether oxygen compounds of iodin were contained in the commercial iodid of potash. It was found that such compounds were not present.

Infectious pneumonia of calves, SAUER (*Wchnschr. Thierheilk. u. Viehzucht, 45 (1901), No. 12, pp. 133, 134*).—Brief notes on outbreaks of this disease. After thorough disinfection of the premises no more cases of the disease developed.

Thrush in cattle, HAJNAL (*Berlin. Thierärztl. Wchnschr., 1901, No. 9, pp. 153–155*).—The author calls attention to the difficulties of differential diagnosis between infectious foot-and-mouth diseases and other forms of cattle diseases which are included under the term thrush. It is stated that stomatitis aphthosa, oidica, and diphtheritica are readily distinguished from infectious foot-and-mouth disease when a number of cases are to be had for observation and when the history of cases can be obtained; but that diagnosis is uncertain when based upon a brief inspection of an infected animal.

Foot-and-mouth disease and sanitation, E. THIERRY (*Jour. Agricole [Paris], 12 (1901), No. 131, pp. 29–32*).—A general discussion of the efficiency of various sanitary methods in preventing the spread of this disease.

Suspicion of infection with foot-and-mouth disease in the sense of the inspection regulations, REUTER (*Vrtljschr. Bayer. Landw. Rathes., 5 (1900), No. 4, Sup., pp. 641–653*).—The author presents a general discussion of the requirements of the law concerning this disease and of the accuracy of phraseology.

Analyses of hog-cholera remedies, R. W. THATCHER (*Nebraska Sta. Rpt. 1900, pp. 70–72*).—Analyses are reported of 5 preparations sold in the State as remedies for hog cholera.

Diagnosis of rabies in dogs by microscopic examination of the nerve ganglia, G. HEBRANT (*Ann. Med. Vet., 49 (1900), No. 6, pp. 302–309*).—Changes in the nervous tissue were especially well marked in the gasserian ganglia in cases of rabies. The ganglia of the left side were rather more acutely attacked than those of the right.

The agglutination of Staphylococcus aureus by the serum of vaccinated and infected animals, J. NICOLAS and C. LESIEUR (*Compt. Rend. Soc. Biol. Paris, 53 (1901), No. 4, pp. 87–89*).—The authors studied the influence of serum from an immunized goat upon cultures of this organism which were already developed and upon those which were in the process of development. Other experiments were also made in the agglutination of other species of Staphylococcus. The serum of rabbits and guinea pigs was tested with reference to the agglutinating power. From their experiments the authors conclude that the serum of goats immunized by means of repeated hypodermic injections of cultures of *Staphylococcus aureus* causes an agglutination of this organism, but that the serum of animals suffering from an acute infection from the same organism possesses no agglutinating power.

The histogenesis of malignant tumors, SCHÜTZ (*Ztschr. Veterinärk., 13 (1901), No. 3, pp. 101–117*).—An elaborate discussion of this subject, with a critical review of the literature and a bibliography.

On disinfection, W. L. MACKENZIE (*Vet. Jour., n. ser., 3 (1901), No. 15, pp. 141–150*).—The use of formalin for disinfection is discussed in detail, and notes are given on methods of applying disinfectants to surfaces, including disinfection by free gas, by moist brushing or rubbing, jet, or shower, and by spray.

STATISTICS—MISCELLANEOUS.

Biennial Report of Idaho Station, 1899 and 1900 (*Idaho Sta. Bul. 29, pp. 35*).—Reports of the director and heads of departments on the work of the station, and financial statements for the fiscal years ended June 30, 1899 and 1900. The report of the chemist contains analyses of 4 samples of baking powder, 1 sample of watermelon sirup, and 6 samples of water. The report of the meteorologist is noted elsewhere.

Fourteenth Annual Report of Nebraska Station, 1900 (*Nebraska Sta. Rpt. 1900, pp. 80*).—A report of the director on the staff, work, and publications of the station during the year; a financial statement for the fiscal year ended June 30, 1900; and several articles abstracted elsewhere.

Annual Report of South Carolina Station, 1900 (*South Carolina Sta. Rpt. 1900, pp. 32*).—The different lines of station work are reviewed at some length in departmental reports, parts of which are noted elsewhere. A financial statement is given for the fiscal year ended June 30, 1900.

Twelfth Annual Report of Texas Station, 1900 (*Texas Sta. Rpt. 1900, pp. 287–308, pls. 3*).—The report of the director reviews the different lines of station work during the year and summarizes some of the results obtained by the station during 12 years. Resolutions adopted by the Texas Farmers' Congress and by the Texas Live Stock Association relative to experiment station work in the State are given. Reports of the heads of departments are included, one of which states briefly the results of some experiments in marketing peaches. A financial statement is given for the fiscal year ended June 30, 1900. A subject list is given of station publications, those still available being indicated. The front elevation and first and second floor plans are given of the agricultural-horticultural building erected in 1900.

Sources of the agricultural imports of the United States, 1896-1900, F. H. Hitchcock (*U. S. Dept. Agr., Section of Foreign Markets Bul. 24, pp. 120*).—Tables are given showing in detail the quantities and values of all the agricultural products imported into the United States from the several countries of supply during each of the five fiscal years 1896–1900. A similar report for the fiscal years 1894–1898 was published as Bulletin 17 of the Section (E. S. R., 12, p. 98). The average annual value of the agricultural imports during the 5 years was $376,369,368. Of the articles imported sugar constituted over 23 and coffee 18 per cent. Brazil supplied 12.99 per cent of the total imports, the United Kingdom 8.96, Germany 6.88, and Cuba 6.10 per cent.

Distribution of the agricultural exports of the United States, 1896-1900, F. H. Hitchcock (*U. S. Dept. Agr., Section of Foreign Markets Bul. 25, pp. 182*).—Statistical tables show the quantities and values of all the various agricultural products exported from the United States to each country of destination during the 5 fiscal years 1896–1900. A similar report for the fiscal years 1894–1898 was published as Bulletin 16 of the Section (E. S. R., 12, p. 98). The average annual value of the agricultural exports during the 5 years was $752,120,133. The United Kingdom received 51.77, Germany 14.20, France 6.08, and the Netherlands 5.22 per cent of the total exports. Breadstuffs, cotton, and meat products constituted, respectively, 32.17, 29.38, and 20.02 per cent of the total exports.

Apprenticeships in agriculture (*Maryland Agr. Col. Quart., 1901, No. 13, pp. 61, 62*).—A brief statement regarding the apprenticeships offered in the dairy and horticultural divisions of the stations.

Nature teaching, F. Watts (*London: Dulau & Co.; Bridgetown, Barbados: Bowen & Sons, 1901, pp. XII + 109*).—This book treats of the general principles of agriculture and is intended for the use of schools. A chapter is devoted to each of the following subjects: The seed, the root, the stem, the leaf, the soil, plant food and manures, flowers and fruits, weeds and insects.

Industrial progress in North Carolina (*Bul. North Carolina State Bd. Agr., 22 (1901), No. 8, pp. 3–23*).—Gives lists of cotton, woolen, and silk mills and other industries, and cattle, horse, swine, sheep, goat, and poultry registers.

NOTES.

Connecticut Storrs Station.—W. A. Stocking, jr., has been appointed dairy experimenter, and W. M. Esten, assistant in dairy bacteriology at the station. George S. Palmer, of Norwich, and B. C. Patterson, of Torrington, have been elected members of the governing board in place of T. S. Gold and S. O. Bowen, and appointed on the executive committee of that board.

Hawaii Federal Station.—The first bulletin of this station has just been issued. It describes chicken diseases in Hawaii, which have prevailed to such an extent as to very seriously interfere with chicken raising in the islands.

Hawaii Sugar Planters' Station.—Owing to ill health, R. E. Blouin has resigned from the position of director of the station and has returned to the Louisiana Station as assistant director, the position formerly held by him before going to the islands. C. F. Eckart, assistant chemist, has been appointed director and chief chemist of the station; S. S. Peck has been made first assistant chemist, and E. J. Lea appointed second assistant chemist. A new laboratory has been erected and thoroughly equipped for the execution of all kinds of chemical work bearing on the growing and manufacture of sugar.

Maine University and Station.—G. E. Fellows, Ph. D., assistant professor of history in the University of Chicago, has been elected president of the University of Maine. M. B. Cummings, B. S. (University of Vermont, 1901), has been appointed assistant in horticulture at the station and entered upon his duties January 1.

Minnesota College and Station.—Thomas Shaw, professor of animal husbandry and widely known as an agricultural writer, has resigned his position, to take effect April 1, to become editor of *The St. Paul Farmer*. The school of agriculture is taxed to its full capacity this winter, there being over 450 regular students, and 110 factorymen in attendance at the dairy school, some of the latter being there for the second or third time. A special course for farmers was begun January 14.

Missouri Station.—T. I. Mairs, assistant in agriculture, has been elected assistant in home reading courses at the Pennsylvania State College and entered upon his new duties January 1. R. B. Oliver, of Cape Girardeau, has been selected as a member of the board of curators during the absence of Walter Williams in Europe.

Nebraska Station.—At the November election, Elisha C. Calkins, of Kearney, and Carl J. Ernst, of Lincoln, were elected to membership on the board of regents to succeed H. L. Goold and C. H. Morrill, whose terms expired January 1.

New Jersey Stations.—William P. Allen has been appointed assistant chemist.

Cornell University.—The Forestry School of Cornell University will hereafter confer the degree of Forest Engineer in place of Bachelor of the Science of Forestry, the former being thought more appropriate and more expressive of the kind of work for which the student has been prepared.

Oklahoma College and Station.—T. B. Ferguson, of Watonga, has succeeded Wm. M. Jenkins as Governor and *ex-officio* member of the board of regents.

Oregon Station.—A note in *The Oregonian* announces experiments at the Oregon Station in preserving silage by a new method. Two silos were filled with corn in the usual way, which was then thoroughly cooked by steam, and the silos sealed up airtight. One silo has recently been opened. The experiment is thought to have been entirely successful. The silage is described as sweet, and contains only 0.27 per cent of acid.

Pennsylvania Station.—Thorne M. Carpenter has been appointed assistant chemist of the station.

Rhode Island College and Station.—The death is announced of J. A. Tillinghast, instructor in agriculture at the college and agriculturist to the station. A small glass house is being built, connected with the new house just completed for experiments in the rearing of incubator chicks. It will be used solely to supply green food to the young chicks.

South Carolina Station.—The experiments in the evaporation of sweet potatoes have been successful, and an exhibit will be made at the Charleston Exposition.

Tennessee Station.—A hog barn, 100 by 18 ft., is in process of construction on the university farm. It is designed as a breeding and experimental feeding barn as well. It will have the usual yards in the rear for exercise, and is so situated that grazing experiments of various kinds can be carried on in a most convenient manner. It is proposed to maintain two or three of the principal pure breeds best adapted to the South. The work in animal husbandry is being extended as fast as possible.

Texas College and Station.—Chas. H. Alvord, assistant professor of agriculture (dairying and live stock), will withdraw from college and station work at the close of the present college year. At a meeting of the board of directors December 9, 1901, Acting President R. H. Whitlock was made president *pro tem.* and treasurer of the college, *vice* L. L. Foster, deceased. The committee from the board of directors have located the new experiment station at Troup, in Smith County.

Wyoming College and Station.—Frank E. Emery, formerly director of the North Carolina Station, has been elected professor of agriculture and horticulture in the college and station, *vice* Luther Foster, who, as already noted, resigned to become president of the New Mexico College and director of the station. The station is continuing lamb-feeding experiments inaugurated a year ago, and is also carrying on an extensive cooperative sheep-feeding experiment, with 1,900 sheep, at Fort Steele.

Society of Official Horticultural Inspectors.—The first general meeting of the Society of Official Horticultural Inspectors for the United States and Canada was held in this city November 11 to 13, 1901, with S. A. Forbes as president and H. T. Fernald as secretary. At the majority of these sessions representatives from fifteen States were present. A circular had been issued by the president in which topics were suggested for discussion, and this served as the programme for the meeting.

With regard to the limits of time within which nurseries may be inspected, it was found impossible to decide upon any definite period for all States, and after considerable discussion a resolution was adopted leaving the time of inspection to the discretion of the inspector in each State. It was also resolved that the certificate should not extend beyond the time of the beginning of the breeding period of the San José scale for the next year. In case a part of a nursery is affected by a dangerous fungus or insect pest not likely to involve other parts of the nursery, it was decided that the certificate should be so worded that stock could be sold after objectionable stock had been treated as suggested by the inspector. It was declared to be the sense of the society that certificates should specify the date of the completion of the inspection, should be worded in an impersonal form, and should not mention specifically the name of any insect or fungus pest.

Discussion on the acceptance of the certificate of inspection beyond the boundaries of the State showed that it had been the quite general policy of inspectors to accept certificates from State inspectors and from experiment station entomologists from outside States, but no formal expression of opinion on this point was taken.

Considerable time was devoted to a discussion of the nursery pests which should be regarded as dangerous enough to influence or prevent the granting of a certificate. The pests which were mentioned by different inspectors as of chief importance included crown gall, peach yellows, pear blight, San José scale, woolly aphis, and sinuate pear borer.

A lengthy discussion was given to the question of the best insecticide programme for orchards infested with San José scale. The results of experiments with kerosene and crude oil in different States have not been uniform and in some cases have been somewhat contradictory. As a rule, no bad results were reported from the use of kerosene and crude oil on apples and pears, and other hardy trees; on peaches and plums more precaution has to be observed. Whale-oil soap, while effective and safe on all kinds of trees, was objected to on the ground of greater expense. A committee appointed to prepare recommendations regarding the best insecticides to use for the destruction of the San José scale in orchards and nurseries, reported as follows: For nurseries, fumigation with hydrocyanic-acid gas, after inspection; for orchards, treatment with dilute solutions of insecticide soaps, oils, or other insecticides to kill the young scales, in late summer and fall; winter treatment with insecticide soaps or oils strong enough to kill the scale and safe for application on all kinds of trees.

During a discussion of the question of the proper public policy with respect to the division of the costs of inspection between the State and the property owners, a variety of conditions existing at present and their advantages and disadvantages were brought out. It was argued, on the one hand, that the work of inspection was directly for the benefit of the nurseryman or property owner, and, on the other hand, that since the general extension of inspection, requiring all nurserymen to be inspected, the financial advantage of a certificate is largely destroyed. Several inspectors stated that they had experienced more or less serious difficulty in collecting the assessments against nurserymen and property owners, and others that the fee led small nurserymen doing a local business to avoid inspection. The society gave formal expression to the view that in States which require inspection of nursery stock, the expense of inspection be borne by the State.

A discussion was had on the question of the desirability of national legislation on nursery inspection, and the society indorsed the bill providing for national control of interstate commerce, already recommended by entomologists, nurserymen, and orchardists. It was voted to request this Department to publish a practical article on the principal nursery pests of the country, for distribution among horticultural inspectors and nurserymen. With regard to a practical definition of nursery stock, it was voted that strawberry plants, grape cuttings, and general ornamental stock grown out of doors be included in that term.

A committee appointed to consider the propriety of making a permanent organization of the society, recommended that no such action be taken.

The society adjourned to meet next year in connection with the Association of American Agricultural Colleges and Experiment Stations.

Ontario Agricultural and Experimental Union.—The twenty-third annual meeting of this organization was held at the Ontario Agricultural College at Guelph, Canada, December 9 and 10. An interesting programme of papers was provided, prominent among which were discussions of the cooperative experiments of the Union. During the season of 1901 cooperative experiments were carried on with 1,885 experimenters on grain crops, 222 on root crops, 146 on forage crops, 180 on field beans and sweet corn, 66 on fertilizer experiments, and 261 on miscellaneous experiments; there were also 309 experimenters testing small fruits and 21 testing different methods of preserving eggs. In all there were over 3,000 Ontario farmers conducting cooperative tests upon their own farms during the year. The number has grown steadily from 12 in 1886, the year the cooperative experiments were started. Prof. C. A. Zavitz, the director of this work, says: "Both the financial and the educational influences of this work throughout Ontario are great. The benefits are not confined to the experimenters themselves, but are shared by thousands of others who examine the growing crops, who attend the annual meetings, who read the annual reports, or who become familiar with the results through the columns of the public press, in the meetings of the farmers' institutes, and in various other ways."

Meeting of American Chemical Society.—The winter meeting of this society, which was its twenty-fifth general meeting, was held in Philadelphia December 30 and 31. It was one of the largest winter meetings which the society has had, and was attended by chemists prominent in general, theoretical, industrial, and agricultural chemistry. The sessions were presided over by Prof. F. W. Clarke, president of the society, who delivered the presidential address on the subject of the development of chemistry. In this he called attention to the limited opportunities for systematic research on the larger problems which were open to chemists connected with educational institutions, the Government laboratories, and industrial establishments, in all of which chemistry was to a large extent a means for the attainment of a desired end. He strongly emphasized, therefore, the great desirability of public or private endowment of research laboratories, whose main object should be systematic research in the science of chemistry, and through which cooperation in investigation might be arranged.

Dr. Hale, the secretary of the society, briefly reviewed the growth of the society since its meeting in Philadelphia 11 years ago. During the past year 344 new members have been added to the society, making the total membership at present about 2,000, with 13 local sections aside from the one now forming on the Pacific coast.

F. W. Clarke presented the report on atomic weights, noting the more important work in that line during the year. The international committee on atomic weights had not been able to make a report on the standard of values to be used—whether O=16 or H=1. A communication from the new U. S. Bureau of Standards proposed cooperation with the society in fixing methods of testing glassware apparatus and in adapting the work of the Bureau to the needs of chemists. A resolution urging Congress to make the use of the decimal system compulsory in all departments of the Government except the Public-Land Surveys, and to provide for its immediate adoption in the Mint and the Post-Office, was referred to the council of the society.

The programme of the meeting contained a list of 37 papers, only 20 of which could be read, aside from the address of the retiring president, on account of lack of time. The papers presented dealt quite largely with analytical and industrial phases of chemistry, although there were several on general and theoretical chemistry. Among those which were not reached on the programme were several on subjects relating to agricultural chemistry.

A long list of excursions to various industrial establishments was provided for the afternoons. These were quite generally participated in by the chemists, and, with the purely social features, made the meeting one of unusual interest and profit.

Dr. Ira Remson, president of Johns Hopkins University, was elected president of the society for the coming year, and Dr. Albert C. Hale was reelected secretary. The editor of the journal of the society, Edward Hart, having resigned, W. A. Noyes was elected to that office, and the edition of the journal was increased to 3,000 copies. The next meeting of the society will be at Pittsburg in June, in connection with the meeting of the American Association for the Advancement of Science.

Necrology.—Thomas Meehan, long one of the most prominent horticulturists and botanists in this country, died of heart trouble in Philadelphia November 19, 1901, at the age of 75 years. Mr. Meehan was a recognized authority on the broader lines of botany, a prolific writer on botanical and horticultural subjects, and one of the most prominent nurserymen of eastern United States. Of English birth, he inherited a love of plants from his father, who was a skillful gardener. At 19 he entered the

Royal Gardens at Kew, where he remained until 1848, when he came to America. In 1852 his present extensive nursery business in Germantown was founded in partnership with the late William Saunders, afterwards superintendent of the experimental gardens and grounds of this Department. Mr. Meehan was editor of *Gardeners' Monthly Magazine* for nearly 30 years, and in 1890, in company with his younger sons, established the present *Meehan's Monthly Magazine*, devoted to general gardening and wild flowers. His published writings include The American Handbook of Ornamental Trees, an octavo volume of 257 pages, published in 1853; The Native Flowers and Fruits of the United States in their Botanical, Horticultural, and Popular Aspects, published in 1879–80, and more than 1,000 shorter scientific articles.

In his public life his name was closely allied with the movement for the establishment of the smaller parks in Philadelphia, and it is largely to his foresight and efforts that their number and beauty are due.

Prof. Dr. Robert Hartig, professor of botany of the University of Munich, died on October 9, 1901. He was born at Brunswick May 30, 1839, and began service as forester to the Duke of Brunswick in 1865. In 1867 he became attached to the Prussian Academy of Forestry at Eberswalde, and in 1877 became professor of botany in the University of Munich. The principal works which he has published are Investigations on the Growth and Production of Oak and Beech; Principal Diseases of Forest Trees, which has gone through a number of editions and been translated into English, French, and possibly other languages; The Decomposition of Wood; Report on the Investigations of the Forestry Institute of Munich; A Manual of Anatomy and Physiology of Plants; A Monograph of the Wood of German Conifers; and The Beech considered from an Anatomical, Physiological, Chemical, and Forestry Basis.

The death of Henry Settegast, director of the agricultural institute of the University of Jena, occurred December 4, 1901. He was born October 12, 1853, at Ragnit in East Prussia. During his life he held important positions in agricultural institutions and made valuable contributions to the science of agriculture.

Personal Mention.—D. W. May, a graduate of the Missouri Agricultural College and for two years past an assistant in this Office, has been appointed animal husbandman at the Kentucky Station and entered upon his duties January 1.

W. J. Spillman, agriculturist of the Washington College and Station, has succeeded F. Lamson-Scribner as agrostologist in this Department. Professor Scribner, as previously announced, has become chief of the newly established Bureau of Agriculture in the Philippine Islands and will sail for Manila about the middle of February.

Marcus L. Floyd, tobacco expert in the Bureau of Soils of this Department, has resigned to accept the position of manager with a company formed to grow wrapper tobacco under shade in the Connecticut Valley.

Miscellaneous.—According to a note in *Science*, taken from the London *Times*, the National Association of British and Irish Millers has decided to institute an inquiry into the whole question of the relative strengths of English and American wheats, and have secured the cooperation of the Southeastern Agricultural College at Wye. The question has arisen in consequence of complaints of English farmers that the millers give the preference to American wheat, though they have to pay a higher price for it. The millers reply that they can not sell for bread-making purposes flour made from English wheats because they lack the strength of the American sorts. The coming season the Southeastern Agricultural College will grow the same wheats on different soils and with different manures, and milling and baking tests will be made of the grain in each case. New varieties are being obtained from Canada and the United States, and an attempt will be made to improve the yield of the old varieties by selection and cross breeding to increase the number of grains in the ear.

A note in *Nature* gives the results of experiments in hop culture carried on at the Southeastern Agricultural College at Wye. These experiments have in some cases been going on continuously on the same plats since 1895. Training experiments are favorable, on the whole, to the system of wide planting and broad alleys. The umbrella system of training has generally given the maximum yield per acre, but is thought to have various disadvantages as compared with the Butcher system. Cutting the vine at picking time is found to result in a considerable loss of material to the hop plant and weakening and loss of crop in the succeeding year. Stripping off the lower leaves and laterals is found to be harmful in seasons of short growth, but without effect when the plant is vigorous. The growth of hops continuously on the same plat for 7 years without any cultivation beyond surface hoeing has aroused considerable interest, and the trial is to be extended to other soils. Fertilizer experiments at a number of places were chiefly with mineral fertilizers.

The Agricultural Education Committee [English], a committee formed in 1899 and composed of members of Parliament and others interested in the promotion of agricultural education, passed the following resolutions at its December meeting, which, according to *Nature*, have been confirmed by the Agricultural Education Association:

"(1) That, if the Board of Agriculture retain their present educational work, it is essential that there shall be complete cooperation between that board and the Board of Education on all educational matters specially affecting the agricultural classes. (2) That for purposes of agricultural education the country should be divided into districts, and such inspectors appointed as may be necessary. (3) That groups of counties, not yet affiliated to any collegiate center, should be formed, each group being affiliated to some center. (4) That, after due inquiry, reports should be issued dealing with the most appropriate forms of agricultural education for each county. (5) That permanent demonstration stations should be organized in each county or group of counties. (6) That official information bearing upon all matters of agricultural interest, whether educational or otherwise, should be distributed to the public free of cost. (7) That to carry out the above objects it is essential that larger funds be placed at the disposal of the Board of Agriculture for educational purposes. (8) That the work of the Board of Agriculture might be facilitated by the appointment of a consultative committee on the analogy of those of the Board of Education and of the Department of Agriculture in Ireland. (9) That copies of the above resolutions be sent to the presidents of the Boards of Education and of Agriculture."

A general index has been issued to the first 25 volumes of *Biedermann's Centralblatt für Agrikulturchemie*, prepared by Konrad Wedemeyer. The period covered is from 1872 to 1896. The volume comprises over 300 pages, and contains author and subject indexes. As this journal covers a wide range of literature relating to agricultural science and experimentation and reviews many of the more important investigations in that field, the index will render a very large amount of literature available for reference and be a great convenience in gathering that on any particular subject.

The first number has recently appeared of a new periodical, *Biometrika*, a journal for the statistical study of biological problems. While published in England, the periodical is cosmopolitan, the editors inviting contributions in German, French, or Italian as well as English.

The Yearbook of the Scientific and Learned Societies of Great Britain, recently issued, contains, in addition to the list of the societies and other institutions, their officers, meetings, publications, and other information, and a list of the papers read before each society from January, 1900, to June, 1901.

With the completion of the first volume (13 numbers) *La Grêle*, published by the Viticultural Station of Villefranche and devoted mainly to the subject of hail prevention by cannonading, suspends publication.

EXPERIMENT STATION RECORD.

Vol. XIII. No. 6.

The death of Dr. William LeRoy Broun, of Alabama, removes one who has been a prominent figure in educational matters in the South for nearly a half century. His splendid career as president of the Alabama Polytechnic Institute for nearly twenty years stamps him as a man of rare wisdom in educational affairs, marked executive ability, and a strength of character which commanded the confidence and support of his colleagues and legislators alike. He maintained the individuality and integrity of the institution during a period which was fraught with many disruptive and formative changes in other colleges, guiding it along the lines of a well-conceived plan, and developing one of the foremost institutions of its kind.

A Virginian by birth and an honor graduate of the University of that State, Dr. Broun's entire mature life was devoted to educational work except during the period of the civil war. As an instructor he occupied successively the chairs of mathematics and of physics in a college in Mississippi, the University of Georgia, Vanderbilt University, and the University of Texas. He founded Bloomfield Academy in Virginia in 1856, which he conducted successfully until the outbreak of the war; and was for three years (1872–1875) president of the Agricultural and Mechanical College of Georgia. His connection with the Alabama Polytechnic Institute, formerly the Agricultural and Mechanical College, dated from 1882, when he was elected president, but remained only a year. He was recalled in 1884 and continued as the guiding hand of that institution up to the time of his death, retaining the details of administration very largely in his own hands. He was the executive officer of the experiment station from 1892 to 1897, and was president of the station council at the time of his death.

Although of late Dr. Broun had not been active in educational movements outside his State, there were many evidences of his continued interest in the progress of education. He was one of the pioneers in technical education, his interest being especially strong in that branch relating to the mechanic arts. He established the first manual training laboratory in the South, and the first well-equipped electrical engineering plant. He had a high appreciation of the study of the natural sciences, and encouraged the building up of a first-class biological laboratory. His high conception of the aims and purposes of the land-grant colleges was clearly set forth in his presidential address before the Association of American Agricultural Colleges and Experiment Stations at the New Orleans meeting in 1892. This was an earnest plea for that form of technical education which trains and develops the mind as well as the hand, and this, he urged, called for both breadth and liberality in the curriculum. The institution whose development he is so largely responsible for is a worthy exponent of his views on that subject.

The rapid development of agricultural education in this country during the past few years has rendered obsolete many of the notions regarding its possibilities which have hitherto passed current. Unfortunately this fact is not always recognized in discussions on the subject, even in educational bodies. Much stress has been laid, for example, on the great difficulty of getting students to attend the regular college courses in agriculture. Undoubtedly such difficulty has existed in the past, and in a way still exists. But in recent years it has been shown that much may be done to overcome this difficulty by proper provision for adequate courses, by special plans to excite interest in thorough training in the science and practice of agriculture, and by the creation of an atmosphere of cordial sympathy with agricultural education in the college community.

We have outgrown the notion that a farm and a professor of agriculture are sufficient means for the promotion of agricultural education in our colleges, and it were well that this should be universally recognized in practice as well as in theory. Data in considerable amount have accumulated, showing that where a strong faculty of specialists in different branches of agricultural science is organized, and arrangements are made to meet the varying needs of students by special agricultural courses or schools, it is not difficult to gather in a considerable number of students and to increase materially the number who will elect to take the complete college course in agriculture. It is also pretty well recognized that institutions for agricultural education have not done their full duty until they have strenuously endeavored to widen their base of operations by extension work through farmers' institutes, correspondence courses, etc., with a view to arousing their agricultural constituency to the importance of technical training in their art and the opportunities which such training opens up, and thus laying a broad foundation for successful college courses in agriculture.

It is idle for members of governing boards or college presidents to publicly profess interest in agricultural education unless they are actually pursuing modern methods in their own institutions to make their agricultural courses effective. It will not do to plead lack of funds or lack of interest among the farmers. It is the plain duty of the managers of agricultural colleges to secure funds and to arouse interest along agricultural lines, and until it is clear that they are making earnest and intelligent efforts in this direction they should not expect to escape criticism from the friends of agricultural education. "Where there's a will there's a way" is true in agricultural education as in other lines of human activity. The way has been pointed out in a number of States, and the success which has been achieved in attracting and training students for their life work and in broadening the influence of the institution along agricultural lines should stand as an inspiration to instructors and directing officers alike.

The initial report of the new Department of Agriculture and Technical Instruction for Ireland outlines the various plans which have been put into operation for the promotion of agriculture and the education and assistance of the small farmers in that country. The department was organized under the agriculture and technical instruction (Ireland) act of 1899, and intrusted with a variety of duties pertaining to technical education, lands, fisheries, control of animal diseases, etc., which had formerly been in the hands of separate boards and commissions. One of its chief objects is "to bring order and simplicity into branches of administration where correlated action was not properly provided for before." It is provided with an annual endowment of £166,000 (over $800,000), together with funds for maintaining a number of institutions turned over to it. It embraces six branches, i. e., agriculture, technical instruction, fisheries, statistics and intelligence, veterinary, and accounts.

The work of the department will be carried out very largely in cooperation with the different counties and boroughs, rather than as an independent government undertaking, and its financial assistance will be rendered in the form of subsidies to local enterprises of various kinds. In planning for this, two important principles have been laid down, namely, that the department will seek to evoke and fortify the self-reliance, enterprise, and sense of responsibility of local communities, and that in encouraging local initiative and responsibility it will guard against an indiscriminate multiplication of unrelated local schemes. The national as well as the local point of view will be kept in mind, and the attempt made to coordinate various undertakings and render expert aid, which are the most important functions of the central authority. To this end the department has established direct and personal relations with the local authorities, societies, schools, and other organizations of the people generally with whom its work has to do. Correspondence has not been relied upon for this purpose, but representatives have been sent out to aid local authorities in perfecting their "schemes" for agricultural education or improvement.

The distinctively agricultural features already inaugurated are along the lines of agricultural instruction, the improvement of live stock, and agricultural experiments and investigation. The facilities for regular instruction in agriculture have been provided in the Royal College of Science for Ireland, where a three-years' course has been established; in the Albert Institute (Glasnevin), which will serve as the chief center for training male students in higher technical and practical agriculture, and the Munster Dairy School and Agricultural Institute, which is to be given up entirely to the instruction of girls in dairying and domestic science.

Itinerant instruction is for the present to constitute a rather prominent feature of the scheme for agricultural instruction. These itinerant instructors will give practical and technical advice and lectures in each county on tillage, dairying, poultry raising, fruit culture, bee keeping, and other subjects. The plan is for the county to take the initiative in this matter, and on the acceptance of its scheme for the department to bear one-half the expense of carrying it out. Such instructors have already been appointed in a number of counties, and the lack of properly trained instructors is beginning to be felt. A number of "pioneer" lectures have been given with a view, for the most part, to showing the character of the work that might be done by itinerant instructors, in order to stimulate the counties to action.

The plans for the improvement of live stock are similar, in some respects, to those followed in a number of European countries. The best stallions to be found are registered by the department, and "free nomination tickets," good up to £3, are issued for mares which are judged of sufficient merit, entitling the owners to have them served by the registered males. During the year 1,700 of these nomination tickets were issued. Money is loaned to farmers at a low rate of interest for the purchase of registered stallions and premium bulls, which are to be insured and paid for in annual installments. The fact that sixty-one farmers took advantage of these loans the first year shows the interest which is felt in the improvement of the live stock. Premiums of £12 each were offered for approved pure-bred yearlings and 2-year-old bulls of any breed, but only about half of the 737 premiums offered were awarded, as there was not sufficient stock exhibited which came up to the standard. This, it is thought, will act as a stimulus to farmers to improve their stock, and thus have quite as great an influence as the premiums which were awarded. Premiums were also offered for approved rams and boars.

The benefits of these measures are confined to counties which adopt schemes for the encouragement of stock breeding, and all but two counties have already done so, the county usually bearing half the expense. The sum of £5,000 was loaned to cooperative creameries for the erection of plants for pasteurizing their skim milk, and a plan to organize and advance capital to agricultural credit associations, from which small farmers may obtain loans for purchasing separators and other expensive dairy utensils, in order to encourage home dairying, is under consideration.

A variety of cooperative experiments were carried out, mostly by cooperative societies and organizations formed for the purpose; and special experiments in tobacco growing were made in twenty-five counties, under the supervision of an expert from France, to determine the possibilities of successful culture of that crop. Flax culture, which has fallen off greatly in Ireland in recent years, will receive special attention from the department. Experts have been brought over from Holland and Belgium, and experiments inaugurated in growing flax and in improving the method of scutching. A dairy herd has been leased for experiments in cheese making, and experiments in calf-feeding with skim milk were made on a private farm. A seed-testing station has been established at the Royal College of Science, where seeds are tested for farmers at merely nominal charges.

It will be seen that, as regards the promotion of agriculture, the steps which have already been taken and those which are outlined are, for the most part, on a very practical basis, and are directed toward some of the most immediately important problems in Irish agriculture under present conditions. These facts, together with the cordial relations which have evidently been established and the interest which the first year's operations have aroused, bespeak a career of much usefulness for the new department.

The announcement has been received of the establishment of a new experiment station in England—the Aynsome Agricultural Experiment Station and Farm, located at Grange-over-Sands, Lancashire. The station is a private enterprise of J. S. and T. M. Remington, located on their joint estate, and "consists of a fully equipped experiment station of the latest continental and American type." The features of its equipment are a chemical laboratory, a laboratory for water analysis, microscopic work, and bacteriology, a greenhouse for pot culture experiments and researches in plant physiology, and a farm. The latter includes a model dairy, a special barn for experiments with cows, sheep, and steers, and about 12 acres to be used for plat experiments. The remainder of the farm will be conducted on a strictly commercial basis and not as a hobby.

Soil investigations will be made a prominent feature of the work, including physical and chemical investigations; but fertilizer experiments with different crops and feeding experiments will also receive much attention.

A rather unusual feature of the station is the provision for receiving pupils for instruction in theoretical and practical agriculture, general and agricultural chemistry, and other branches of agricultural science, making it a farm school as well as a station. As the announcement states, this is the first station to throw its doors open to pupils in scientific and practical agriculture; and it must be said that there is an element of doubt as to the wisdom of the combination of effort in this case. Usually the case is reversed, the institution for instruction having a department for experimentation. Whether the institution at Aynsome shall ultimately become an experiment station in the true sense or largely an agricultural school will depend upon the management and the conditions which develop.

CONVENTION OF ASSOCIATION OF AMERICAN AGRICULTURAL COLLEGES AND EXPERIMENT STATIONS.

The Association of American Agricultural Colleges and Experiment Stations held its fifteenth annual convention at Washington, D. C., November 12 to 14, 1901. The representation was a quite general one, the various sections of the country, including the far West, sending delegates. Several topics of importance at this time, such as providing opportunity for graduate study at Washington, the graduate summer school of agriculture, and cooperation between the stations and this Department, were freely discussed, and the convention again recorded its opposition to changing the name or the scope of the association.

A very enjoyable social feature of the meetings was a reception given to the members of the association by the Honorable Secretary of Agriculture and Miss Wilson on the second evening of the convention. A committee appointed to pay the respects of the association to the President was cordially received by him and given assurances of his interest and high appreciation of the work of the agricultural colleges and experiment stations.

The Association of State Universities met at Washington simultaneously with the association of colleges and stations, and a plan for formal cooperation between the two associations was considered by both. The project was, however, abandoned.

The Society of Official Horticultural Inspectors for the United States and Canada also held its first general meeting in Washington in connection with the association, as many of the inspectors are college or station men. An account of their meeting was given in the last number (p. 496).

GENERAL SESSIONS.

The general sessions of the association were held in the hall of Carroll Institute, and were presided over by President A. W. Harris, of the University of Maine, who delivered the presidential address on the first evening of the convention. This address set forth clearly the more important things for which the land-grant colleges stand, and summarized the results of their work. The land-grant act of 1862 was considered important not only in providing for agricultural education, but as the first sufficient recognition of study and investigation as the basis of the best success in the arts and industries. It also proclaimed the duty of the National Government to promote industrial education and in its results demonstrated the effectiveness of governmental cooperation. The most important of the direct results of this act to agriculture was the experiment station. "If the agricultural college did nothing more than to establish, maintain, and officer the experiment station it would be justified many times over." The establishment of the agricultural colleges also resulted in the strengthening and broadening of industrial education along all lines, and has culminated in a great system of technical education. "It is a great result of the land-grant college to have asserted and established the doctrine that education in all its forms, from the lowest to the highest, is a State function in which the State has the fullest rights and for which it must bear responsibility, sharing the privilege and responsibility with private corporations only as it thinks best." The speaker considered State aid and control in higher education as necessary, under present conditions, to the best national development, especially as the results of this higher education thus become the property of all the people. The address concluded with an eloquent tribute to the memory and worth of the late Justin S. Morrill.

The association expressed its appreciation of the address by a vote of thanks, and directed that the Secretary of Agriculture be requested to publish it as a separate.

The report of the executive committee, presented by its chairman, H. H. Goodell, called attention to the fact that the bill for the establishment of schools or departments of mining and metallurgy in connection with the land-grant colleges passed the Senate, but failed to be called up in the House of Representatives during the last session of Congress. The introduction of a similar bill into the present Congress was recommended. Efforts of the committee to have all land-grant colleges made designated depositories of Government publications were unsuccessful. The plan for holding a summer school of graduate instruction in agriculture during 1902, suggested by the Ohio State University, was approved.

The report of the bibliographer, A. C. True, noted the work of a bibliographical character being done by the Department of Agriculture, and enumerated, with explanatory notes, 44 general and partial bibliographies in lines relating to agriculture which had appeared during the past year.

The report of the treasurer, E. B. Voorhees, showed that the receipts during the year amounted to \$1,132.97 and the expenditures to \$1,105.40, leaving a balance of \$27.57.

The report of the committee on revision of the constitution called forth a vigorous discussion. The various proposals to change the name of the association, to extend separate representation to the departments of mechanic arts of the colleges, and to limit the number of sections to two, were voted down. Amendments were adopted striking out the provisions requiring a synopsis of the proceedings of each section to be presented to the association at the close of every convention, and requiring the chairman of each section to make at the annual convention a report of the progress during the year along lines pertaining to his section. An amendment was adopted providing for the election of officers by ballot upon nomination made upon the floor of the convention. An amendment relative to the program for the annual convention provides for the distribution of programs sixty days before the annual convention of the association, and contains the following provisions: "The program for a convention of the association shall designate the time and place of the convention, shall present a well-prepared order of business and of subjects for discussion, and shall provide an arrangement for the meeting of the general sessions and of the sections. The subjects provided for consideration by a section at any convention of the association shall concentrate the deliberations of the section upon not more than two main lines of discussion, which lines shall so far as possible be related. Not more than one-third of the working time of any annual convention of the association shall be assigned to miscellaneous business." The provision for amending the constitution was also made more specific. The executive committee was authorized to appoint, subject to the approval of the association, "an advisory committee on program, whose duty it shall be to prepare a program of topics to be discussed in general or sectional meeting at the next annual convention and to secure presentation of appropriate papers and engagement of suitable speakers under the provisions of the constitution and by-laws of the association, said program to be submitted to the executive committee for approval and distribution at least ninety days in advance of the annual meeting." The following were appointed members of this committee: E. A. Bryan, W. H. Jordan, H. W. Tyler, C. E. Thorne, and H. T. Fernald.

The committee on graduate study at Washington reported that no progress had been made in securing a bureau in Washington for the administration of graduate work since the last convention. The committee was directed to exhaust every effort to devise a plan whereby graduate study and research in the several departments of the Government may be efficiently organized and directed under Government control, and in the meantime to secure, if practicable, the same opportunities for study and research in other departments of the Government as are at present afforded graduate students in the Department of Agriculture. A resolution was also adopted by the association recording its appreciation of the action of the Government in making available the facilities for research and advanced work in the Department of Agriculture, and expressing a desire that these facilities be still further extended and that a national university devoted exclusively to advanced and graduate research be established.

A sixth report of progress was submitted by the committee on methods of teaching agriculture. Syllabi of courses in agrotechny, rural engineering, and rural economics, completing the outline of the college course in agriculture, were completed by the committee since the New Haven convention and published in the proceedings of that convention and also as Circular No. 45 of this Office. In surveying the progress of agricultural education in this country during recent years, the committee "found abundant evidence that the attitude of this association and the work of this committee as its representative have already borne good fruit in stimulating and aiding the movement for the specialization of agricultural instruction in our colleges, the strengthening of the agricultural faculties, and the bettering of the material equipment for agricultural education." The collation of information regarding courses in agronomy in our agricultural colleges and the facilities for instruction in this subject was undertaken by the committee during the year, and considerable progress was made. The nature of the work was explained and some of the material already accumulated was exhibited.

The committee on cooperative work between the stations and the Department of Agriculture made the following recommendations as supplementary to those embodied in the report submitted at the last convention: "(1) When cooperation is desired by the station, it is deemed advisable that the proposal for such cooperation be made to the Department by the director of the experiment station; where, on the other hand, the Department desires the cooperation of the station, it is deemed advisable that the proposal be made in the first instance to the director rather than to members of the staff. (2) While it is well understood that no financial obligations can be undertaken beyond the end of the fiscal year, yet it should be recognized that any arrangement for joint experimentation which requires some years to complete creates a moral obligation upon both parties to carry the work to conclusion. (3) Where a line of investigation has been in progress in any State under the auspices of either institution, it is, as a rule, unwise for the other party to undertake independently the same line of investigation, at least until after full consultation upon the subject." The committee was continued, with the addition of B. T. Galloway from the Department of Agriculture.

The report of the committee on indexing agricultural literature was submitted by the chairman, A. C. True. Attention was called to the fact that the Library of the Department of Agriculture would be able to do this work if an appropriation of not less than $2,500 could be secured for the purpose. A resolution was later adopted by the association urging such an appropriation. A paper on Agricultural college libraries, prepared and presented by Miss Josephine A. Clark, Librarian of the Department of Agriculture and a member of this committee, completed the report. This paper emphasized the great importance of libraries as aids to work of investigation and instruction, and pointed out the necessity of systematic arrangement and complete cataloguing of agricultural college libraries. Arrangements in progress by the Library of the Department for assisting agricultural colleges in classifying and cataloguing their libraries were explained. Of six libraries recently visited by the speaker, only two were considered well organized and administered. The functions of a library and a librarian were discussed. The paper also reviewed the work done in indexing agricultural literature during the past year.

The report of the section on horticulture and botany, by L. R. Jones, summarized rather fully the more important tendencies and results along these lines during the year. In the discussion of college work, facilities for instruction, courses of study, etc., were considered. The marked strengthening of advanced courses was noted. The demand for specially qualified men in horticulture was stated to exceed the supply. In the discussion of station work, progress in bacteriological and physiological investigations and in the selection and breeding of plants was reviewed. The relation of college to station work was discussed at some length.

M. V. Slingerland submitted the report of the section on entomology. The review of progress in this science during the year as presented touched upon the work of the colleges and stations as regards instruction, investigation, inspection, institute work, and correspondence. A plea was made for the continuance of the section, and its previous meetings were reviewed. Failure to publish a full account of the section meetings was thought to have been a drawback to the success of the section.

The report of the section on mechanic arts was presented by the chairman, H. W. Tyler. This reviewed at some length the progress of work in mechanic arts during the year. Data were given concerning the courses and attendance in the department of mechanic arts in the several colleges. A proposed outline for the work of the section, especially as regards the character of the papers to be presented at the conventions, was presented and discussed. This had been the subject of considerable correspondence during the year, the results of which were given in condensed form.

No reports were presented from the sections on agriculture and chemistry and on college work.

The general plan of the graduate summer school of agriculture as proposed by the Ohio State University at the last convention, and approved by the executive committee, was explained and discussed by W. O. Thompson and A. C. True. It was stated that sufficient encouragement had been received from the leaders of agricultural education and research to warrant a decision to hold the first session of the school at the Ohio State University at Columbus, Ohio, during the summer of 1902. It was announced that Secretary Wilson had cordially approved the plan for this school, and that acting under his advice, Dr. A. C. True, Director of this Office, had consented to act as dean of the school. The Ohio State University makes itself responsible for the general management of the first session of the school, but if it proves a success it is proposed to make it a cooperative enterprise, to be managed by a committee of control appointed by the association. The execution of the plan after the session of 1902 was referred to the executive committee.

The desirability of a collective college and station exhibit at the St. Louis Exposition in 1903, and plans for its preparation and care were considered at some length by the association. A committee, composed of W. H. Jordan, A. C. True, H. J. Waters, W. M. Hays, and C. F. Curtiss, was appointed to confer with the Secretary of Agriculture with a view to securing the assistance of the Department, and to prepare, if considered feasible, an exhibit setting forth the progress of education and research in agriculture in the institutions represented in the association. A similar committee, composed of W. E. Stone, J. K. Patterson, and J. H. Washburn, was appointed to consider the advisability and the preparation of an exhibit setting forth the progress of education and investigation in mechanic arts in the land-grant colleges.

The committee on animal and plant breeding submitted a report of progress. A tentative plan for securing cooperation in the study of different features of this work was adopted by the committee. C. F. Curtiss and H. J. Webber were appointed members of the committee in place of A. A. Brigham and H. P. Armsby.

The report of the committee on pure-food legislation, recommending the enactment of a national pure-food law, was submitted by the chairman, W. A. Withers.

The report of the committee on uniform fertilizer laws was presented by the chairman, H. J. Wheeler, and the subject briefly discussed.

The association was briefly addressed by Philippe de Vilmorin, of the seed firm of Vilmorin-Andrieux & Co., of Paris, who paid a high compliment to the activity of the American stations and especially the extensive publication and distribution of the results of their work.

Resolutions of respect to President George T. Fairchild and Dr. John A. Myers, who died during the past year, were unanimously adopted.

A report of a committee of the section of agriculture and chemistry on nomenclature of terms relating to nutrition was read, and on the recommendation of that section was adopted by the association.

A resolution, introduced by W. A. Henry, was adopted by the association, urging upon Congress "the necessity and wisdom of providing a building for the accommodation of the Department of Agriculture, which in magnitude shall be sufficient to provide for its future as well as its present needs, and which shall properly represent in its architecture the enormous importance of agriculture in this country, and which shall constitute a worthy addition to the Government buildings in this the capital of the United States."

A resolution was adopted urging upon the authorities concerned the fostering of the beet-sugar industry as far as consistent with public policy.

The dues for the ensuing year were increased to $15 for each institution represented in the association. Invitations were presented for the association to meet in Ohio, New York, and Illinois.

The following officers were elected for the ensuing year:

President, W. M. Liggett of Minnesota; vice-presidents, W. O. Thompson of Ohio, H. J. Waters of Missouri, J. H. Washburn of Rhode Island, J. H. Worst of North Dakota, and J. C. Hardy of Mississippi; secretary and treasurer, E. B. Voorhees of New Jersey; bibliographer, A. C. True of Washington, D. C.; executive committee, H. H. Goodell of Massachusetts, G. W. Atherton of Pennsylvania, Alexis Cope of Ohio, and H. C. White of Georgia.

Section on college work.—Chairman, J. L. Snyder of Michigan; secretary, W. E. Stone of Indiana.

Section on agriculture and chemistry.—Chairman, H. J. Waters of Missouri; secretary, C. G. Hopkins of Illinois.

Section on horticulture and botany.—Chairman, J. Craig of New York; secretary, A. Nelson of Wyoming.

Section on entomology.—Chairman, F. M. Webster, of Ohio; secretary, H. E. Summers, of Iowa.

Section on mechanic arts.—Chairman H. W. Tyler, of Massachusetts; secretary, F. P. Anderson, of Kentucky.

MEETINGS OF SECTIONS.

SECTION ON AGRICULTURE AND CHEMISTRY.

A prominent feature of the proceedings of this section was the discussion of the question as to the extent to which the Department of Agriculture and the experiment stations may profitably cooperate and what lines of work are likely to yield the most important results. The discussion was introduced by a paper by B. T. Galloway, of this Department, who outlined the cooperative forage plant work which is now in progress. He believed the success of the undertaking depended upon grouping the stations with reference to the problems to be solved in different sections of the country, and devising a working plan for each group, with one of the stations as a central agency, for the distribution of seeds and other assistance. As examples of what might be done in this direction he cited the range improvement work in the Southwest in cooperation with the Arizona Station, and the grass and forage plant investigations in the Northwest, with the Minnesota Station as a central agency. The following lines of work were suggested: (1) The introduction of crops from foreign countries, (2) the growth and dissemination of introduced crops after they have become in a measure established, (3) the dissemination of native crops of local value, (4) breeding crops for certain conditions, and (5) increasing production by improved culture methods.

R. H. Forbes described the grass and forage crop conditions of Arizona, and dwelt upon the ways and means of solving existing problems. For the improvement of the worn-out range the exclusion of grazing in connection with sowing and harrowing in seeds of native plants, the construction of small embankments for holding storm water, and the introduction of desert forage plants were recommended. Range reclamation conducted by the Arizona Station for two years along the lines mentioned, on a reserve of 350 acres, has given promising results. *Lippia repens*, an Egyptian lawn plant, was reported as having made a very good growth during the dry summer.

F. Lamson-Scribner, of this Department, described the arrangement and plans of cooperative work with the stations, the method of keeping records, and the work done by voluntary experimenters.

In a paper on Quantitative studies in the transmission of parental characteristics in hybrid offspring, W. J. Spillman presented the results obtained in breeding wheat with a view to originating a non-shattering winter variety for the Palouse country of Washington, the range of variation as observed in the first and second generations of hybrid plants being illustrated by specimen heads. The hybrids produced were the progeny of a variety of club wheat (*Triticum compactum*) and a variety of *T. vulgare*. In the first generation the hybrid plants of the same breeding showed little variation, but in the second generation they split up into many types, representing on nearly every plat the characters of the two parents and intermediate combinations. These types were classified into groups and the proportion of the different groups on each plat was presented graphically. W. M. Hays also presented a paper on wheat breeding, discussing the results obtained at the Minnesota Station. In the experience of the author, the distribution of seeds of new varieties on a commercial basis, rather than by sending out small packages, has given the best results.

Following a paper by B. W. Kilgore on the methods for determining the fertilizer requirements of soils, there was a quite general discussion of the subject, which brought out the difficulties in this work and the many factors which tend to vitiate results in practice as well as in field experiments. From this discussion it appeared that the problem of a suitable means or method for this work is far from solved, despite the large amount of investigation which has been directed toward it.

W. A. Withers and G. S. Fraps submitted a paper discussing the nitrification of various fertilizers in the soil and the favorable influence of lime upon this. The importance of the presence of nitrifying organisms was pointed out, and a further study of the question of liming was recommended as a subject worthy of more extended study.

The question of the practicability of irrigation in humid regions, and the crops and circumstances under which it is likely to prove profitable, was discussed by Elwood Mead, E. B. Voorhees, and H. J. Waters. As indicative of the profitableness of irrigation in humid regions, Mr. Mead pointed to the highly successful results obtained in Louisiana and Texas with its use in growing rice, and to other results obtained in the Middle West during the past season. Efficient pumping machinery which may be operated without the attention of skilled labor was mentioned as an important factor in this connection. A great future was predicted for irrigation in the humid sections of the United States. E. B. Voorhees showed from the rainfall record for New Jersey for the past 60 years that in 3 out of every 5 seasons during that period all crops have been more or less injured by drought, while one or more crops, and usually the money crop, was injured every year. Experiments by the New Jersey Stations for the past 5 years have shown a gain every year from the application of water, notably with asparagus and blackberries. Irrigation plants established in New Jersey are paying investments in all cases, and in the majority of instances the equipment paid for itself the first year. H. J. Waters stated that he had found the irrigation of the compact clay soils discouraging at first, owing to the packing of the surface. This was obviated by mulching. Irrigation at the Missouri Station has been found very profitable with nursery stock. F. H. Newell, of the U. S. Geological Survey, submitted a paper on the work of the agricultural census on irrigation, indicating a great increase in the practice of irrigation under a variety of conditions. The irrigation work of the Geological Survey was briefly outlined, and a description given of early irrigation in Massachusetts and irrigation by sewage, as now practiced in the vicinity of Boston.

SECTION ON HORTICULTURE AND BOTANY.

In a paper on College or station work, E. S. Goff called attention to the condition existing in many institutions in which the workers are called upon to devote their attention to both college and station duties, and raised the question as to the advisability of such a combination of duties. He believed it desirable when sufficient men are provided to perform the proper functions of both teaching and investigating without allowing either to suffer. This paper called forth an earnest discussion of the relations of instruction and research in horticulture in the agricultural colleges, developing the general opinion that while a combination of teaching and investigating was often desirable, it would frequently prove more profitable to allow the horticulturist especially qualified for investigation to devote himself largely to that field, provided the conditions of the institution would permit, and by specializing to raise his work to a high order of excellence. A large amount of elementary teaching was generally held to be detrimental to thorough station work.

A paper by B. D. Halsted, on Observations concerning the first and second generations of plants, gave the results of the author's observations in crossing sweet corn, cucumbers, beans, tomatoes, eggplants, and salsify. A pink-colored sweet corn, obtained by crossing a white variety and the Egyptian, proved very unstable in the second generation, many of the ears reverting to the Egyptian type. Cucumber crosses were all exceedingly variable, and with beans no two varieties were obtained which were alike. In crossing tomatoes many of the plants were identical with or very similar to the mother plant, while a few were variable in foliage, habit, shape, and color of fruit. With eggplants some very satisfactory crosses were made. Crossing garden salsify with a wild species of the same genus gave true hybrids, which in the second generation proved very variable in the color of flowers, and showed a strong tendency toward reversion. The paper led to a quite general discussion of the subject of plant breeding, in which the experience and views of a number of speakers were recounted.

A paper by J. Craig, on Cooperation between the farmer and the experiment station, while favoring this line of work, called attention to some of its difficulties and recommended that it be confined to practical lines and that there be personal supervision of the work on the part of the station. The discussion developed the fact that at a number of stations cooperative work with farmers has been found both practicable and profitable, and that it is being undertaken by horticulturists to a considerable extent.

In a paper on the effect of light and heat on the germination of Kentucky blue grass, E. Brown, of this Department, reported a series of experiments covering a variety of conditions. The best results were obtained when the temperature alternated between 20 and 30° C., and light was found to be apparently without effect upon the germination of this seed. The effect of different degrees of moisture appeared to be of little consequence, provided the seeds were kept sufficiently moist for germination. Attention was called to the beneficial effects of alternation of temperature upon a number of varieties of seeds while others require a constant temperature; each particular kind of seeds seems to possess its own optimum temperature for germination. In another paper by the same author on The quality of some commercial samples of grass and clover seed, specimens from the Pan-American Exposition were exhibited illustrating the work of the seed laboratory of this Department.

L. C. Corbett described the Arlington Experimental Farm, conducted by this Department, together with its object and purpose. It is planned to plant extensive collections of varieties of fruit to furnish authentic new specimens for comparative studies, and by planting seed-growers' novelties to avoid duplication of varietal names. Tests of cultural methods for fruits and crops and phenological investigations are to be undertaken. The plan received the hearty approval of the horticulturists, and a number of suggestions were made of lines which it was hoped might be taken up.

J. S. Newman reported some observations on apple-twig blight, F. D. Gardner exhibited specimens of a number of kinds of fruit from Porto Rico, and H. J. Webber showed specimens of cowpeas which are believed to be resistant to the attacks of nematodes. The latter brought out considerable evidence of the possibility of obtaining fruits and grains which are resistant to various diseases and pests.

SECTION ON ENTOMOLOGY.

The convention brought together a rather larger number of entomologists than usual, due perhaps to the meeting of the Official Horticultural Inspectors in Washington at that time.

J. B. Smith gave an account of a year's experience with crude petroleum in New Jersey. This insecticide was used successfully on peach, apple, and pear trees, and all the scales which were touched by it were killed. Crude oil was considered most effective on pear trees, where under favorable conditions the San José scale can be entirely exterminated even in a large orchard. The scale is dying in large numbers on pear trees in the southern part of New Jersey and seems to be rapidly losing its economic importance.

H. T. Fernald discussed a few of the more important insects of Massachusetts; notably the gypsy moth and the brown-tail moth. The gypsy moth was reported from several new localities and in slightly increased abundance, and a colony was discovered during the year near Providence, R. I. The brown-tail moth is found quite abundantly in nurseries, and may become widely distributed from such sources.

In a paper on Notes and suggestions, M. V. Slingerland urged the continuance of the section, called attention to the desirability of greater uniformity in popular names of insects, and gave brief notes on the outbreaks of a number of insects.

A paper by F. A. Sirrine described a folding fumigator, which is perfectly gas tight and hinged in such a manner that it may be folded so as to occupy but little space. Unbleached sheeting of medium weight was used as the cover.

A brief account was given by C. B. Simpson of experiments with the codling moth in Utah, Idaho, Arizona, and Washington. In the Rocky Mountain States broods of this moth were reported as overlapping to such an extent that the determination of their number became a difficult matter. A combination of spraying with Paris green and banding the trees was found effective in reducing the amount of damage.

Other papers presented before this section were as follows: The time of emergence and oviposition of the spring brood of the Hessian fly, by H. Garman; The life history of the sugar-cane borer in Louisiana, by H. A. Morgan; Florida observations and experimental work, by H. A. Gossard; and Apple aphids, by E. D. Sanderson.

A committee, consisting of J. B. Smith, W. E. Britton, and S. A. Forbes, was appointed for the purpose of proposing topics for discussion by the section at the next annual meeting.

SECTION ON COLLEGE WORK.

The two main subjects considered by this section were the relation of the agricultural colleges to the proposed national university, and the value of short courses at the agricultural colleges. A paper on the first subject by W. O. Thompson opposed any official relation between the association and any private corporation, like the Washington Memorial Institution. He believed that "the relation of the agricultural colleges to a national university should be that of sympathetic cooperation and enthusiastic support, as against all other measures whether proposed as substitutes or stepping stones." This paper called forth a lively discussion, in which it appeared that there was a general sentiment in the section in favor of securing some agency under Government control for making the laboratories, museums, libraries, and other educational facilities in Washington available to advanced students. This sentiment was voiced by the convention as a whole in its instructions to the committee on graduate study at Washington, as noted above.

The discussion on the value of short courses was led by W. M. Liggett, who described briefly the longer courses in the college of agriculture and the school of agriculture in Minnesota, and then turned his attention to the farmers' course of 8 weeks for persons of mature age, given last winter for the first time, and to the short dairy course of 4 weeks, both of which he considered valuable adjuncts to the longer courses.

Honorable J. H. Brigham, Assistant Secretary of Agriculture, spoke of the short courses as a means not only of giving valuable instruction to farmers, but also of bringing about more cordial relations between the agricultural colleges and the farmers. In his judgment "the best way to secure the support of farmers is to let them come to the college even for a short time and see that you are trying to do good."

W. A. Henry pointed out the conditions which led to the establishment of the dairy course and the farmers' course in Wisconsin, both of which he described in detail.

The workings and advantages of the short courses in a number of other States were briefly discussed by other speakers.

SECTION ON MECHANIC ARTS.

The sessions of this section were occupied in discussing the future policy of the section as suggested by H. W. Tyler in his reports to the association for the year. The general policy advocated in Dr. Tyler's paper was that of giving more attention to the discussion of one or two broad engineering subjects in the section meetings, rather than encouraging the presentation of papers on isolated independent technical subjects. This plan was indorsed by the section. A decided sentiment in opposition to abolishing the section was manifested.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

A hydrolytic derivative of the globulin edestin and its relation to Weyl's albuminate and the histon group, T. B. Osborne (*Connecticut State Sta. Rpt. 1900, pt. 4, pp. 388–399*).—A continuation of work previously reported (E. S. R., 12, p. 512) on the proteids. The action of water or very dilute solutions of acids converts the globulin edestin into a substance insoluble in saline solutions of moderate concentration. This derivative of edestin is formed by hydrolysis and is the same substance as that designated "albuminate" by Weyl, which is the first product of the hydrolitic changes leading to the formation of so-called acid albumin. This substance the author terms edestan, and it is of the same composition, as determined by analysis, as that of edestin, from which it is formed. Edestan forms salts with hydrochloric acid, possessing an acid reaction; it is insoluble in water, less soluble in potassium hydrate than edestin, and insoluble in all except very strong ammonia solutions. The aqueous solution of edestan chlorid, when concentrated, has an acid reaction, and is precipitated by neutralization, the precipitate being soluble in strong ammonia. It gives a precipitate with nitric acid, which dissolves on warming and reappears on cooling; a precipitate with ovalbumen solutions, with the alkaloidal reagents, and with mercuric chlorid. These reactions agree closely with those given by Kossel as characteristic of histons. With the true histons, however, edestan has little in common.

The basic character of the protein molecule and the reactions of edestin with definite quantities of acids and alkalis, T. B. Osborne (*Connecticut State Sta. Rpt. 1900, pt. 4, pp. 399–441*).—From a large number of experiments the author draws the following conclusions: The proteins are basic bodies, and with acids form true salts. For example, the preparations of native proteins usually obtained from slightly acid or neutral solutions are salts of the basic protein substance. The acid of these salts can be separated from the proteins insoluble in water by neutralizing with potassium or sodium hydrate. The acid may then be identified by filtering, evaporating, and analyzing the alkali salt obtained. Preparations of edestin made in the usual way partake of the nature of the salts from which they are crystallized. Those obtained from sodium chlorid solutions dissolve to a considerable extent in washing, the soluble portion being twice as acid as that undissolved. From the reaction of the insoluble portion edestin must form salts corresponding to a mono- and a bi-chlorid. The crystals of edestin and its different salts are isomorphous, the small amount of combined acid not being able to effect a change in crystalline form.

The action of acids upon edestin is treated at some length. Ten times as much sulphuric acid as of hydrochloric acid is required to dissolve a given quantity of edestin, while the latter dissolves more nearly the calculated quantity than acetic acid. Phosphoric acid reacts with edestin as a mono-basic acid, and nitric acid forms a salt which corresponds to the bi-chlorid. Edestin is dissolved in centinormal potassium, or sodium hydrate solution, in an amount closely proportioned to 1 molecule of the base to 1 of protein. This solution after a time becomes turbid, depositing some of the dissolved protein. Edestin is soluble in a smaller amount of sodium hydrate than of sodium carbonate. It conforms strictly with the definition of a globulin, being insoluble in water, but readily soluble in neutral solution of sodium chlorid of sufficient strength. Edestin mono-chlorid is insoluble in water but soluble in saline solutions, while potassium and sodium edestin are soluble in water and insoluble in dilute solution of neutral salt, though soluble in more concentrated solutions. As edestin and its acid salts are soluble in neutral solution of sodium chlorid, it shows that the solution of globulin does not depend upon an alkali, as stated recently by Starke.

A type of reaction by which sodium carbonate and hydrochloric acid may be formed in the animal organism, T. B. Osborne (*Connecticut State Sta. Rpt. 1900, pt. 4, pp. 441, 442*).—From the examination of the resulting precipitate produced by carbonic acid in a dilute sodium chlorid solution of edestin, the author deems it probable that sodium carbonate and hydrochloric acid may be formed from sodium chlorid in the organism.

Sulphur in protein bodies, T. B. Osborne (*Connecticut State Sta. Rpt. 1900, pt. 4, pp. 443–471*).—The author sought to determine as accurately as possible the total sulphur in a considerable number of different proteids in order to learn if this element forms a definite constituent of these substances, and also whether the fraction of this sulphur converted into sulphid by heating with strong alkalis corresponds to a definite number of the atoms in the formulas calculated. Schulz's method of boiling in a reflex condenser and recovering the sulphur as lead sulphid was followed in obtaining the loosely-bound sulphur. These results were compared with those obtained by treating the proteids under pressure with strong alkalis at various temperatures. The total sulphur was also determined, the method followed being described. The various protein bodies from different sources were analyzed, the results being shown in the following table:

Sulphur content of protein bodies.

	Total sulphur.	Loosely-bound sulphur.
	Per cent.	*Per cent.*
Edestin	0.884	0.346
Excelsin	1.088	.350
Legumin	.385	.166
Vignin	.426	.214
Amandin	.429	.217
Glycinin	.710	.320
Gliadin	1.027	.619
Hordein	.847	.348
Zein	.60	.212
Oxyhæmoglobin from dog's blood	.5618	.335
Ovalbumin	1.616	.491
Ovovitellin	1.028	.362
Casein of cow's milk	.80	.101

From an examination of the figures, of which the above represents averages, it appears that those proteids which can be obtained in crystals, and therefore quite pure, show a uniform proportion of sulphur, and there can be no doubt but that this element is a definite constituent of their molecules. The substances, vicilin, phaseolin, and conglutin gave no constant proportion of sulphur, and average figures are not therefore reported. By using the simplest empirical formulas for a number of proteids the molecular weights are calculated. These are regarded as only approximate, since the methods of analysis precludes great accuracy. Carbon and nitrogen may be determined with sufficient precision, but a slight error in sulphur leads to serious differences in the formulas. A table is shown giving the composition and formula ot a number of vegetable, animal, and compound proteids.

On the proteid reaction of Adamkiewicz, with contributions to the chemistry of glyoxylic acid, F. G. HOPKINS and S. W. COLE (*Proc. Roy. Soc.* [*London*], *68* (*1901*), *No. 442, pp. 21–33*).—Adamkiewicz in 1874 described the now familiar reaction of the production of a violet color when strong sulphuric acid is added to the solution of a proteid in glacial acetic acid. Of late years this reaction has been employed in determining the presence of carbohydrate groups in certain proteid derivatives, though its uncertainty has been several times noted. The authors find from their investigations that the proteid reaction is not a furfurol reaction, but depends upon the presence of small quantities of an impurity in the acetic acid employed, and that this necessary substance is glyoxylic acid. A dilute aqueous solution of glyoxylic acid forms an admiral test for proteids, and may be substituted for the acetic acid of Adamkiewicz' test.

Nitrites in milk, H. W. BETTINK (*Nederl. Tijdschr. Pharm.*, *13* (*1901*), *pp. 67–70; abs. in Chem. Centbl., 1901, I, No. 15, p. 854; Jour. Chem. Soc.* [*London*], *80* (*1901*), *No. 464, II, p. 422*).—The method of Riegler (E. S. R., 9, p. 322) is recommended. To apply this method to milk, 20 cc. is coagulated with 12 drops of strong hydrochloric acid, filtered, and the filtrate examined in the usual way.

The examination of market butter, W. VON KLENZE (*Ztschr. Landw. Versuchsw. Oesterr.*, *4* (*1901*), *No. 2, pp. 77–80*).—In a comparison of methods of determining the Reichert-Meissl number of butter fat, the author obtained slightly higher results by the use of glycerol-soda solution over the use of alcoholic-soda solution in the saponification. As favorable results were obtained by the use of copper as with glass saponification flasks, while the loss from breakage was eliminated.

A simple, practical method for estimating the salt content of butter and at the same time indicating the admixture of margarine, B. ORZECHOWSKI (*Ztschr. Hyg. u. Infectionskrank.*, *37* (*1901*), *pp. 275–277; abs. in Chem. Centbl., 1901, II, No. 3, p. 239*).—The method is carried out by treating the butter fat with a solution of alcohol and ether, and allowing the salt to crystallize out from the solution. One gram of butter is rendered soluble in 3 cc. of a weak alkaline mixture of alcohol and ether in the proportion of 3:7. In testing for the presence of oleomargarine the fat is collected in a glass tube, and if clear is said to be unadulterated.

A study of the saponification number of fats, O. SCHMATOLLA (*Apoth. Ztg.*, *16* (*1901*), *p. 425; abs. in Chem. Centbl., 1901, II, No. 3, pp. 239, 240*).

Estimation of fat in fodders, M. JAHN (*Ztschr. Oeffentl. Chem.*, *8* (*1901*), *pp. 137–140; abs. in Jour. Chem. Soc.* [*London*], *80* (*1901*), *No. 464, II, pp. 431, 432*).—Instead of the usual paper cartridge the author used one made of tin, 70 mm. high and 19 mm. wide, the bottom consisting of brass gauze of 35 meshes to the cm. The gauze is covered inside with a piece of filter paper and a thin layer of cotton wool, upon which the material to be extracted (5 to 10 gm.) is placed and covered with another layer of cotton wool. The ether not being able to escape from the sides must find its way through the mass. With substances containing very little moisture and yielding only a small amount of soluble matter to water or alcohol the previous drying is unnecessary.

The determination of cocoanut oil in cacao butter and in chocolate, J. WAUTERS (*Bul. Assoc. Belge. Chim.*, *15* (*1901*), *No. 3, pp. 131, 132*).—The author states that cocoanut oil is often used to adulterate cacao butter and chocolate, and proposes a method for determining its presence in the articles named. This is accomplished by his method of determining the addition of cocoanut oil to oleomargarine and butter, *i. e.*, by the determination of the soluble and insoluble volatile acids.

The determination of sesame oil in chocolate, G. POSSETTO (*Gior. Farm. Chim.*, *51*, *pp. 241–245; abs. in Chem. Centbl., 1901, II, No. 3, p. 236*).—The determination is made by means of the Baudouin reaction.

Boiled linseed oil; analytical constants, M. Kitt (*Chem. Rev. Fett u. Harz-Ind., 8 (1901), No. 3, pp. 40–42; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 5, p. 484*).—A table is given in which the alterations in linseed oil on boiling are represented at 6 different stages, from a thin oil to the consistency of India rubber. The changes are represented by the variations in the acid value, saponification value, iodin number, iodin number of fatty acids, acetyl acid value, and acetyl saponification value.

A comparison between the bromin and iodin absorption figures of various oils, H. T. Vulte and Lily Logan (*Jour. Amer. Chem. Soc., 23 (1901), No. 3, pp. 156–159*).—A revision of the bromin and iodin figures of various animal and vegetable oils is offered. Of the 15 oils examined, only 6 were found to be at all capable of forming substitution products.

Kjeldahl method for the determination of sugar, R. Woy (*Ztschr. Oeffentl. Chem., 6 (1900), pp. 514–519; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 4, p. 395*).—The author indorses the Kjeldahl method with the Jessen-Hansen extension (E. S. R., 11, p. 614) in the estimation of sugar. The different reducing sugars are reduced under similar conditions, thus permitting comparisons by means of the copper values determined. Again, the method employed is so simple as to admit of closely agreeing results by different analysts. A source of great error, however, lies in the absorptive power of the alkali solution for carbon dioxid. The author suggests the working out of similar tables to those of Kjeldahl, but using sodium carbonate instead of caustic soda.

Influence of salts on the rotary power of sugars, J. de Kowalski and P. Tomartschenko (*Arch. Sci. Phys. et Nat. Genève, 11, No. 4, pp. 294–299; abs. in Chem. Centbl. 1901, I, No. 18, p. 984; Jour. Soc. Chem. Ind., 20 (1901), No. 6, p. 623*).—The authors found that the chlorids, bromids, and iodids of sodium, potassium, and ammonium at different concentrations lowered the rotation of cane sugar.

The coefficient 0.85 in the indirect analysis of sugar cane, L. Bonnin (*Bul. Assoc. Chim. Sucr. et Distill., 18 (1901), No. 7, pp. 465–467*).—In a test of 14 varieties of cane the author found that the coefficient for calculation to be exact should range from 0.789 to 0.882 and to average 0.843.

Scheibler's extraction method for the determination of the polarization of beets, A. Herzfeld (*Ztschr. Ver. Deut. Zuckerind. 1901, pp. 334, 335; abs. in Jour. Chem. Soc. [London], 80 (1901), No. 464, II, p. 426*).—A description of the method as carried out in the laboratory of the Verein der deutschen Zucker-Industrie.

Notes on sugar beets, P. F. Trowbridge (*Jour. Amer. Chem. Soc., 23 (1901), No. 4, pp. 216–223*).—The experiments reported were made in Michigan and represent the conditions at the various beet-sugar factories in that State. Tests were made of 2 methods of finding the tare on beets, in practice at Michigan factories, the sample in one case being well brushed with bristle brushes, and in the other washed in a revolving washer. The tare by the method of brushing was 10.14 per cent, while the tare by washing and draining for a few minutes was 10 per cent. Owing to the fact that there has been some controversy between the farmers and the factory managers, tests were made to determine the proper factor for estimating the sugar in the beet from the amount of sugar in the juice. From the analyses made during 2 seasons, the author found that the average factor should be 0.918, the range being from 0.875 to 0.956. He concludes that the average factor lies between 0.91 and 0.92. Attention is called to the necessity of taking similar portions of several beets for the sample.

A comparison was made of the German method of analysis by digesting with hot alcohol, and the French method of digesting with hot water. The percentage of sugar obtained by alcohol digestion averaged 13.41; by water digestion, 13.43; and in no case did the difference exceed the limit of error in ordinary duplicate analysis.

To determine the richest portion of the beet, samples were sliced transversely into 3 portions; the upper portion contained an average of 10.9 per cent sugar; the middle portion, 12.2 per cent, and the lower portion 11.7 per cent. Owing to these variations it is urged that longitudinal sections of fractional portions of several beets should be taken in sampling.

Sugar in swedes. I, Analytical methods, S. H. Collins (*Jour. Soc. Chem. Ind., 20 (1901), No. 6, pp. 536–538, figs. 2*).—The food value of any root crop depends upon the amount of dry matter, and the author states that of this the sugar is the most valuable part. As the sugars in swedes have very different rotary power, polarization is not applicable and they must be determined by reduction. For rapid work the author recommends colorimetric methods, and describes one depending upon measuring colorimetrically the unreduced copper of Fehling's solution. In applying this method to turnips it is necessary to remove other reducing substances and to hydrolyse any cane sugar present. Ten grams of swedes are ground with 100 cc. water and 1 cc. of a concentrated solution of lead acetate. After some hours, 50 cc. of the filtrate is inverted with 0.5 cc. of strong sulphuric acid, digested 20 minutes, cooled rapidly, and an aliquot added to the Fehling solution. The color of the supernatent liquid is judged by a comparison with standard tints.

Table for the determination of the degree Baumé with sirups at different temperatures, H. Nové (*Bul. Assoc. Chim. Sucr. et Distill., 18 (1901), No. 7, pp. 464, 465*).

Detection of artificial sweetening agents, saccharin, in foods (*Ztschr. Ver. Deut. Zuckerind., 1901, No. 541, pp. 95–97; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 4, pp. 393, 394*).—Three methods of detecting saccharin in foods and beverages, as set forth in a circular issued by the Russian customs authorities.

Estimation of saccharins in foods, H. Defournel (*Jour. Pharm. et Chim., 6. ser., 13 (1901), p. 512; abs. in Chem. Ztg., 25 (1901), No. 48, p. 184*).—In the described method the saccharin is found with ammonia as a salt very soluble in water. After separation the amount of nitrogen is determined and from this the amount of saccharin is estimated.

A generally applicable volumetric method for the determination of aldehydes, M. Ripper (*Monatsh. Chem., 21 (1900), No. 1079; abs. in Analyst, 26 (1901), No. 302, p. 131*).—A method based on the combination of alkaline bisulphites with aldehydes.

The occurrence and the estimation of lactic acid in wines, R. Kunz (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 15, pp. 673–683, figs. 3*).—The author finds lactic acid to be a normal constituent of wines, and in some instances present in an amount in excess of other acids. A method of making a quantitative estimation of lactic acid in wines is given, using a specially constructed apparatus which is figured and described.

The estimation of the volatile acids and the chlorids in wines, A. Kleiber (*Schweiz. Wchnschr. Pharm., 39 (1901), pp. 295–300; abs. in Chem. Centbl., 1901, II, No. 3, p. 240*).

Estimation of methyl alcohol in vinegar, Robine (*Rev. Internat. Falsif., 14 (1901), No. 3, pp. 72–75*).

A short method for the determination of thein and its practical application, A. Nestler (*Ztschr. Untersuch. Nahr. u. Genussmtl., 4 (1901), No. 7, pp. 289–295*).—The proposed method is especially applicable in determining the presence of spent leaves in teas. It depends upon the formation of crystals of thein by ground unextracted leaves when heated between two watch glasses over a small Bunsen flame. The formation of crystals is favored by placing a drop of water in the center of the upper watch glass. The crystals may be examined under a microscope, and by the method of Molisch, adding a drop of concentrated hydrochloric acid and a drop of a 3 per cent solution of gold chlorid. Two grams of Souchong boiled in half a liter of water for 2 minutes and dried gave no crystals of thein by this method. The method was also used with satisfactory results in testing coffee grains, both green and roasted, coffee leaves, kola nut, and guarana, and maté leaves.

The synthesis of indigo, J. M. MATTHEWS (*Jour. Soc. Chem. Ind., 20 (1901), No. 6, pp. 551–555*).—The methods for the preparation of artificial indigo and the influence of this manufacture upon the output of the natural product.

The relative leather-forming value of the different tanning materials; their speed of tanning and weight giving, with notes on the quality, J. YOCUM and R. W. GRIFFITH (*Jour. Soc. Chem. Ind., 20 (1901), No. 5, pp. 426–436*).—This article gives the results of a research carried out at Herold's Institute, London, under the direction and support of the Leather Sellers Company. The authors made a series of experiments to determine whether the hide-powder method of tannin analysis can be relied upon for giving the tanning value of an extract, and whether the results so obtained are borne out in practice. The test was carried out as follows: A large excess of tanning liquor of known strength was used with a given weight of hide powder. The leather thus obtained was weighed and the amount of nitrogen present in the leather determined by the Kjeldahl method. The weight of leather which should have been produced was calculated from the weight of the hide powder used; and by analysis the amount of soluble matter absorbed from the liquor was determined. The work covered a period of 2 years and represents many determinations. The results, the authors claim, go to prove that, within the ordinary experimental error, the hide-powder method is an accurate representation of the leather-forming quality of a tanning material. The excess of tannin makes no practical difference in the result except to increase weight, and throughout the work the results are proportionate. A number of tables are submitted showing, among other things, the amount of leather obtained from a definite amount of substance and the percentage gain in weight in leathers made with the various tanning materials.

Among the technical points brought out are the leather-forming and the weight-giving values of the various extracts tested, the color given to the leather, the quality of the product, its imperviousness to water, and its strength.

Report to the International Association of Leather Trade Chemists on results of comparative experiments with Freiberg hide powder, J. PAESSLER (*Ledermarkt, 2 (1901), No. 1; abs. in Jour. Soc. Chem. Ind., 20 (1901), No. 4, p. 395*).—This hide powder, prepared according to Cerych's prescription, was sent out together with samples of oakwood extract, quebracho extract (pasty and solid), and valonia, to 6 chemists. The object sought was to determine whether the results obtained by the same analyst with the different hide powders correspond and whether the mean values obtained by different analysts agree.

Only the non-tannin figures are given, and the results show that the differences between maximum and minimum results of the same analyst are not important. The differences between the results of different analysts with the quebracho extract are not important, but are somewhat greater with oakwood extract and valonia. The differences appear to be due largely to the different ways of packing the filter.

The conclusion is reached that the Freiberg hide powder is very suitable for tannin analysis, and it is recommended that the filter be so packed that the quantity of filtrate required will come through in about 2 hours.
