THE

TROPICAL AGRICULTURIST:

A

MONTHLY RECORD OF INFORMATION

FOR

PLANTERS

OF

COFFEE, TEA, CACAO, CINCHONA, RUBBERS, SUGAR, TOBACCO, CARDAMOMS, PALMS, RICE,

AND OTHER PRODUCTS

SUITED FOR CULTIVATION IN THE TROPICS.

ISSUED ON OR ABOUT THE 1ST OF EACH MONTH.]

"Step after step the ladder is ascended."—GEORGE HERBERT, *Jacula Prudentum.*

COMPILED BY

A. M. & J. FERGUSON,

of the "Ceylon Observer."

"It is both the duty and interest of every Owner and Cultivator of the Soil to study the best means of rendering that soil subservient to his own and the general wants of the community; and he who introduces, beneficially, a new and useful *Seed, Plant* or *Shrub* into his district is a blessing and an honor to his country."—SIR J. SINCLAIR.

A. M. & J. FERGUSON: COLOMBO, CEYLON.

AND SOLD BY:—*London*: TRÜBNER & Co., 57 & 59, Ludgate Hill; J. HADDON & Co., 3, Bouverie St., Fleet St., E.C.; GEO. STREET & Co., 30, Cornhill; HUTCHISON & Co., 4, Guildhall Chambers; F. MDCCCLXXXIV.

PRINTED AT THE "CEYLON OBSERVER" PRESS: COLOMBO, CEYLON: 1884

INTRODUCTORY NOTE.

IN closing the Third Volume of the "TROPICAL AGRICULTURIST," we have to direct attention to the increased amount of useful information afforded, and to the great variety of topics treated. From month to month we have endeavoured to lay before our readers the latest results of practical experience and scientific teaching in all that concerns tropical agriculture ; and our ambition has been to make this periodical not only indispensable to the planter but of service to business men and capitalists, never forgetting that agriculture trenches upon every department of human knowledge and science, besides being the basis of all human wealth. While directing our attention chiefly to the products most prominently mentioned on our title-page, we have never omitted to notice minor industries likely to fit in with tropical conditions ; and our readers have an ample guarantee in the pages before them that, in the future, no pains will be spared to bring together all available information both from the West and East, the same being examined in the light of the teachings of common-sense as well as of prolonged tropical experience in this the leading Crown and Planting Colony of the British Empire. A full and accurate Index affords the means of ready reference to every subject treated in this third volume which we now place in our subscribers' hands.

N.B.—The present volume derives special value from the fact that it includes a reprint in full of the elaborate and valuable Report on the Forests of Ceylon by Mr. F. D'A. Vincent. In describing the Forests of the Colony, Mr. Vincent deals with many details of the physical characteristics and meteorology of the Island, and brings in a vast amount of miscellaneous information regarding Ceylon, its people and products, not to be found elsewhere.

A. M. & J. FERGUSON

COLOMBO, 21st June 1884.

Yucca Gloriosa, Cultivation of 92

DR. TRIMEN ON LEDGERIANA.

We do not suppose any man of science will envy Dr. Kuntze's feelings, or, at least, his position with reference to the hybrid theory in regard to *Ledgeriana*, which he started on such grossly insufficient evidence, and which Dr. Trimen has now, after reference to Mr. Gammie and Mr. T. N. Christie, blown to the winds. There can be no doubt that Dr. Kuntze, as Mr. Gammie suggests, confounded with Ledgeriana the hybrid (*ignota*) which appeared in British Sikkim as well as in Ceylon. But this hybrid or variety stands midway between succirubra and officinalis, having no resemblance to the well-marked and distinct species (for such it is now acknowledged to be) to which the name of Ledger has been appropriately given. Its discovery by Mr. Ledger's agents, just in time to preserve to the world, apparently, the very richest of the quinine-yielding trees, is one of the most romantic incidents in the history of the Cinchonas since the period when the wife of the Viceroy of Peru was cured of fever by the bark.

CINCHONA LEDGERIANA.

BY HENRY TRIMEN, M.D., F.L.S.

[*Reprinted from the* "JOURNAL OF BOTANY" *for May* 1883.]

With reference to the remarks upon *Cinchona Ledgeriana* by Dr. Kuntze, printed in the January number (pp. 5-9), it does not seem necessary to do more than controvert the two statements upon which his hybridity-theory is based.

Firstly. On p. 6 it is said "*C. Ledgeriana* originated spontaneously in the Government plantations of Mungpo in Sikkim"; and "Mr. Gammie and the late Mr. Biermann assured me that '*C. Ledgeriana* had originated spontaneously there in the Calisaya-field.'" To settle this it seemed best to write direct to Mr. Gammie on the subject, and this is what he replies (20th Feb. 1883):—"Dr. Kuntze must have one of our hybrids in his mind's eye, and not *Ledgeriana*, as having originated spontaneously in the calisaya-field at Mungpo. Certainly I never told him so of *Ledgeriana*;" and he further adds, "You are quite right in thinking that *all* our Ledgerianas originated from the small packet of Ledger's S. American seed I got from the Nilgiris in the early part of 1866, and Moens is equally right in stating that I have never seen it from any other source. So that the Sikkim experience of it is identical with that of Java." This is conclusive, and I think it is pretty clear that if Dr. Kuntze ever knew *C. Ledgeriana* he does not know it now.

Secondly. Dr. Kuntze states (p. 7) "*C. Ledgeriana* is the only cinchona that suffers from sterility, and only ripens more fruits if it gets fertilized and hybridized by other cinchonas; that happens often, and therefore the descendants of *Ledgeriana* are mostly degenerated," &c. This being a practical matter I have requested the opinion of several cinchona-growers upon it, and I now give some portions of a letter (30 Jan., 1883) from Mr. T. N. Christie, who is a very trustworthy observer, and possesses one of the finest plantations of *C. Ledgeriana* in Ceylon. He says, "I find *Ledgeriana* loth to blossom compared with *officinalis* or *calisaya*, but in no way sterile. Climate and seasons affect the blossoming very greatly. The Yarrow Ledgers had a prolonged drought in 1881, many of them drooped and partially withered, and as a result were covered with seed the following season, so much so that many of the branches had to be propped up to bear the weight of the fruit. Last year they had a wet season and as a result they have not this year one-third of their last crop. There is no sterility about the blossom when it comes; I find it comes perfectly true from seed." This is our experience throughout Ceylon; the species flowers later in life than the others, is quite as fertile as other kinds, and when protected from cross-fertilization and carefully collected the seed is remarkably true.

The contention of this species being a hybrid is thus a singularly unfortunate one; it is I think also much to be regretted that such unfounded and careless statements as those of Dr. Kuntze's should have been published. Further acquaintance with more and older trees since the date of my former paper (Nov. 1881) has confirmed my opinion of the specific distinctness of *C. Ledgeriana* from *C. Calisaya*, and its "great variability" exists only in Dr. Kuntze's imagination.

In conclusion, I wish to insist again emphatically on the fact that there are no *C. Ledgeriana* trees in the East that have not descended from Mr. Ledger's seed from the Rio Mamore; the species is doubtless a very scarce one, and has not up to the present been re-discovered in S. America.

Peradeniya, Ceylon, March 8th, 1883.

BRAZIL AND ITS COFFEE PLANTING INDUSTRY.

The following descriptions are from a work recently published—"Wanderings South and East"—and they give a very vivid idea of Rio town and district. It will be observed that Darwin was as enthusiastic about Brazil as Haeckel was lately over Ceylon:—

. . . "Every form, every shade, so completely surpasses in magnificence all that the European has ever beheld in his own country, that he knows not how to express his feelings."—*Darwin.*

It is the calmest, stillest night in all the year, the loud rattle of our cable chain has just ceased, and we are at anchor in the bay of Rio de Janeiro. Across the harbour lies the great city, shining with a hundred thousand lights; here dotted among the hills, and there in long even rows down by the water's edge. Mountains loom vaguely in the starlight, blotting out a hundred constellations; there is a hushed rippling sound upon the water, and the lights shoot across its surface, now in bright spangles, now in waving lines towards us from the shore. We are on the eve of a great experience—the experience of beholding Nature's fairest handiwork.

The sun rises gloriously some hours later, and we are on deck again to catch the first glimpses of Rio's bay. What can I say of it in the early morning's sunlight as it breaks upon me? How beautiful a scene it is! Its rich green hills, its barren rugged peaks, its thickly clustered houses! What peaks! where are any else so fanciful? What hills! where are such slopes of green, so rich and varied? What groups of villas! hundreds and hundreds of them glistening amongst the green, now in great masses, now wandering away amongst the hills. See, away above the town, the strangely-shaped peaks and precipices one behind another. See again, amongst the islands of the bay, the same strange peaks and rocks. See once more, far off there in the west, that great wall of Organ Mountains, with their serrated crests, like organ pipes, cutting the blue sky. See near again, less striking hills and islands, but all as green; and forts and piers and palm-filled gardens, and low and fern-hung rocks. See, nearer still, the blue smooth water, and a hundred boats swarming around us, as all the world over, so at Rio. I recall memories of Sydney Bay, and Smyrna, and Stockholm and Stamboul, the Min river, too, in China and the harbours at Hobart Town and Wellington, and San Francisco's Golden Gate, and Turkey's Bosphorus and Naples' Bay. Enough surely there is in those of the beautiful in land and town and bay, but I can recall, charm I never so wisely, no bay like this Brazilian Rio, far or near. There are here the little coves and bays of Sydney, and green hills of that far east, and all the glories of the tropics, and the blue water of the Bosphorus, and the rugged peaks of Smyrna, and the quaint church domes and castle battlements of Genoa, and the broad open amphitheatre of hill walls of Wellington; but the magnificent completeness of no other place, for none other is there so exquisitely perfect. It is the monarch of all scenery, the greatest combination imaginable of Nature's wildest glories, this peerless bay of Rio in Brazil. There is such variety, as I have tried to say, the utter peacefulness at sunrise of the western end, where one might dream of paradise, and endless summer days, and lotus-eating lives and perfect rest. The grand and boisterous glory of the entrance, with Sugar Loaf and Gavia and Corcovado looming near, and affording endless temptation to mountain-climbing minds; the noisy, hurry-scurry wonders of the great city itself, from every street of which one has a view worth crossing Europe for; the less distracting suburb scenery all round the town; the great broad-spreading views from mountain ridge a dozen, twenty miles away; what have you not in Rio to delight the eye, where all of Nature's grandest work seem to converge in one sublime and mighty whole?

One must be excused for using strong superlatives in such a country as Brazil; the whole country is superlative, superlatively rich, and green, and beautiful. We rode some distance the next day, crossing the hills at a different point from the road of the night before, and, sending our horses back, walked down the range, and into the town by another route. The head of this pass is called the Chinese view,* on account of Chinamen being employed upon the road. It is thought to be the finest view near Rio, and certainly appeared to us quite unsurpassable:

"When for a mile or two we thus had gone,
The mountains opened wide on either hand,
And lo, amid those labyrinths of stone
The sea had got entangled in the land,
And turned and twisted, struggling to get free,
And be once more the immeasurable sea."

We reached Petropolis in the evening after the most delightful drive, and were very comfortably lodged at quite a pretentious hotel. Petropolis is the royal suburb. Here the Emperor flies from the summer of Rio. Here also the diplomatic people have their hot-weather houses. The air is keen and bracing, and the scenery in every direction superb. It is 2,600 feet above the sea, and the nights are cold, and even frosty. The town is most German in appearance, having, indeed, been founded by imigrants of that nationality; a stream runs down the centre of the Main Street, and trees are planted along its banks, and here and there a garden is laid out. Fuchsias sixty feet high, and the universal tree fern, and poinsettias a foot in diameter, however, remind us we are in Brazil. The Germans have given up settling in any numbers in this part of the country, but to the south, in the Rio Grande district there is still a very large annual immigration from Bremen, Hamburg, &c.

We started, literally at the first streak of dawn on the following morning, in a real old English coach drawn by four splendid mules, to drive along the great high road to Entre Rios. Our way lay through a very hilly country, not mountainous, but simply covered, if one may use such an expression, with hills all wonderfully alike. The road winds in and out amongst the valleys, and a capital road it is, comparable with any in Europe or elsewhere. We made the journey, seemingly with great ease, of forty-five miles in five hours, employing six teams. We were often as many as twelve outside, and yet the mules were always up to their work.

Coffee, coffee everywhere; whole forests cleared away to make place for coffee, whole hills close shorn for coffee; coffee above on the right, and again below on the left; coffee along the valley, and on the hill-brow, and down the slope, and up the rise; coffee drying in the sun on flat open floors in front of peasants' houses; coffee in little piles near the cottage doors, or in sacks ready for carting: waggon-loads of coffee being drawn toilfully along towards the railway; coffee too in little cups on the counters of the wayside inns; in fact, everywhere coffee! It is deplorable to see the awful destruction of vegetable life in the production of this berry. The virgin forest is burnt and the hillside disfigured with smouldering logs and stumps. The lovely valleys are stripped clean, and coffee reigns supreme over hill and dale. "Agassiz convinced himself that this rich country had been swept by glacial action, and that the most successful coffee plantations were found exactly where the movements of ice had most enriched the soil by transportation and mixture of its compound elements." The glaciers surely then worked to some purpose. The production of coffee in Brazil has now reached twelve millions sterling worth a year. Half the supply of the entire world comes from these hills, which are said to produce no less then 260,000 tons per annum.*

Pleasant hamlets line the road at intervals, and prosperity is generally observable. Now a village school, where are clean and neat children; now some rich planter's villa, large and barrack-looking; now, shaking off the coffee for a mile, we catch a glimpse of the old primeval forest glory, with some fine crag or bold hillside, untouched or even untouchable by the planter's destroying hand.

We took the railway when our coaching was done, and ran through more coffee country, and then changed on to the main line, known as the Pedro Segundo railroad, and commenced our journey over the mountains and back to the western side of Rio. The crossing of the "serra" is a great engineering work, abounding in sharp curves, steep gradients, tunnels, high bridges, and the like. We passed through quite indescribable marvels of forest scenery, ferns, shrubs, and trees, flowers and creepers, all mixed in wildest entanglement. Great open views, too, may be had from the Organ Mountains' crest, across the lower hills, beyond and away to the broad Atlantic.

* The engraving given might stand for a view in Trincomalee Harbour given by Tennent: the similarity is wonderful.—ED.

* An able-bodied man can cultivate 2,000 coffee-trees, on an area of five acres; these will give him an average crop of £6,000 worth about £80. With slave labour the produce is reckoned at £60 per head.

AGRICULTURAL SCHOOLS IN THE WESTERN TROPICS (EQUALLY REQUIRED IN THE EAST).

(*From the Demerara Royal Gazette.*)

The consideration we have of late given to the encouragement of new industries in the colony has, in a measure, been the means of directing our attention to the necessity of establishing a School of Agriculture. There is little good in telling even the more intelligent of the small landowners and labourers, that they can, by cultivating the many and various products this colony is blessed with, make for themselves and their children, not only an easy livelihood, but an ever increasing source of wealth and comfort. The fruits they know and understand, which grow, we may say spontaneously, requiring but little care and attention, they will, no doubt—a suitable market offering—cultivate and attend to in the manner their forefathers did before them. But we all know what an unsatisfactory system this has been. No care taken in the collection of plants, no attempt made, by grafting or otherwise to improve those already known to all, and no trial given to new varieties. As were the fruits of British Guiana—with the exception of a few plants got from India, Jamaica, and Trinidad, by the proprietors of one or two sugar estates—so are they still, and with this serious drawback—the natural deterioration due to old and worn out trees, and continuously planting from the same class of seeds. The consequence is, our oranges are stringy, our limes are reduced to a size not much bigger than a walnut, and other plants have degenerated in like proportions. In fact it is the unanimous verdict of all old colonists that none of the fruits of the colony have one half of the excellence they possessed in their younger days. The reason for this is not far to seek. The cultivators, few though these be, know nothing of the good results to be obtained from grafting or from change of seed, and have accordingly been satisfied to go along in the old grooves.

An ounce of example is worth many pounds of precept, and fortunately for the colony and its future well-being, that example can now be obtained. In the Botanical Gardens, under the able administeration of Mr. Jenman and his co-adjutor Mr. Waby, colonists have an opportunity afforded them of witnessing the results that can be procured from scientific cultivation. The difficulty that presents itself to our mind, however, is that due advantage will not be taken of the opportuities there afforded them, by farmers and small landowners, who would more particularly b enefit from the study of the work in the gardens. It is hard to move them off the beaten track, and we fear the gardens to them will only be a name. Were a school of Agriculture associated with them this would not long remain so. Our creoles, no matter of what colour or race, are not wanting in cuteness or adaptability; and parents, aware of the good they would drive from their children attending such a school as that indecated, would, we feel certain, gladly send their larger boys there. The example which would be set them of continuousindustry, and the knowledge they would obtain of plant life,—its conditions and proper mode of treatment,—could not but have the very best effect on the agriculture of the colony. That this is true has already been shown by the advancement which has, within the last few years, been made by several of the villages in cane cultivation. The fields cultivated there are, in the great majority of instances, quite as well tilled and maintained—the item of manure only excepted—as any on the best sugar estates, and the return per acre has been good accordingly. Here we have a notable instance of the force of example, and ti is but a natural deduction to add that given a like pattern like results would follow in other directions.

The Botanical Gardens are being, presumably, formed for the agricultural development of the colony, and for its ultimate benefit. Before they are completed ethree or four hund d thousand dollars will have been xpended on themn, amd from what we have seen w have no doubt that amount will have been spent judiciously. But when we consider the intelligence of the vast majority of the taxpayers who have contributed uumurmuringlv to this large outlay, we are inclined to ask *cui bono*? Onlya few hundred of the inhabitants are intelligent enough to take advantage of the lessons being taught them, or to appreciate the results to be derived from them. Without an Agricultural School, in connec'ion with the gardens, the colony taken as a whole, will from any many years to come derive no recompense from the expenditure. But given the school,—the pupils we mantain would shortly be forthcoming—their ebnefits would be open to all, and the lessons they are meant to teach would be, in a few years' time, spread through the length and breadth of the colony. Large reductions have this year been made in the estimates for education, and this because the Governor and members ot the Cmbiued Court considered there was no adequate result being obtained for the money expended. In this we have no doubt they were right. In a purely agricultural colony such as this is, we want the children to grow up to be useful members of th community, and this is the end that should be aimed at in their early training. Our children must be taught that all cannot be "preachers, aeachers, or stump orators." Agriculture is our sole maintenance and the teaching given to the children should be such as would contribute to its advaneement. The establishment of an Agricultural School would gradually pave the way to this desirable end, and to no better purpose could a portion of the saving which has been effected in our educational system be devoted, than in founding a public school for instruction in purely Agricultural Affairs.

The thousands of people who visited the Botanic Gardens yesterday afternoon, were struck with the vast improvement which has lately been effected in their appearance, and the more intelligent amongst them were keenly alive to the value of the work which had been, and was being, done; and showed n eager inquisitiveness as to the names and nature f the various plants. The warm interest they took in these, simply shews that the plan we urged a few months ago, of establishing an Agricultural School in connection with the Gardens, would be a perfect success; and its benefits would be highly appreciated by the better-to-do portion of the working classess. In many of the purely agricultural dependencies of the British Crown, these schools are already successfully established, and we can see no reason why, if the idea was properly taken up by the Government, a like success should not attend their establishment here. In Jamaica, for instance, quoting from Mr. Morris's report, referred to last week, although an actual School of Agriculture has not been established, still a system of employing eadets, and apprentices, under the trained managers and superintendents of the Government plantations has been begun, and with the happiest results. He reports that the cadets, who are received without salary for the purpose of being taught the details of the cinchona cultivation, and with the view of fitting them either to open plantations on their own account or to act as managers of cinchona plantations are "devoting themselves with zeal and energy to their work, and taking a keen interest in all that concerns the value and management of labor; details of nursery work: the minutiae of planting: and the various methods adopted for successfully harvesting cinchona bark. The knowledge and experience thus gained will doubtless prove ot great service to them in after life, and I look forward to a great impetus being given to cinchona planting by the introduction of men of capital and education, who intend to devote themselves to this important industry."

Mr. Morris is quite aware of the fact that the plantations in Jamaica are being worked for the future benefit of the Island, and he knows full well that the lessons he is striving to teach by lectures and pamphlets, will be still more effectually taught by the practical training of the young. Hence the encouragement he holds out to the sons of men of some eapital to attend at the plantations and learn the details of their working. But he does not restrict himself to cadets only. He is quite well aware that skilled guides also require the assistance of skilled laburers, and he has accordingly engaged a number of apprentices "in order to train the better class of native workmen in the details of nursery and propagating work connected with cinchona cultivation, where they undergo a systematic course, so as to fit them in due time to take charge of nurseries or act as foremen on private plantations The experiment, so far, has worked satisfactorily. The apprentice for the first three months receive only a nominas rate of pay, which however is gradually increasedl as they become more efficient. When applications are received for men to take charge of nurseries on private plantations, the best of these are recommended." Such is the system Mr. Morris is pursuing in Jamaica, and who can no doubt that it will be highly beneficial to the colony, as well as to the large class of young men it is specially designed to benefit, and who have been without the means of lucrative employment.

If an Agricultural School is ever to be started in the colony, now is the time to commence it. A large portion of the Botanic Gardens is still unreclaimed, and the lessons taught to students there now are much more valuable than these would be when the gardens are completed, and initiatory work finished. The cultivation of the smaller industries which the gardens are specially designed to encourage must first be undertaken on land in much the same condition, viz., undrained and abandoned. To put these in a fit state for the reception of young plants must be important work, requiring special knowledge, and that could never be better explained than by the practical illustrations the boys or others would now treceive at the hands of Mr. Jenman. In Canada, Ausralia, some parts of India, Ceylon, etc., these schools under thoroughly practical trainers are doing a great deal of good. It seems rather an anomaly here, when compared with other colonies, that the only section of the community being deliberately trained to agricultural pursuits are those juveniles who qualify themselves by some grave offence against the law for a lengthened period of confinement and teaching at the industrial school at Onderneeming. In some respects, therefore, the lot of these is preferable to the law-abiding boys who do nothing but play marbles, or fly kites until they reach man's estate. This subject is an important one, and well worthy the careful consideration of all parties.

PLANTING IN UVA, CEYLON: MONARAGALA FOR ITS COFFEE AND COCOA.

MADULSIMA, May 21st.

The coffee is fresh and vigorous looking with not a sign of leaf-disease or grub. I have not seen finer young coffee in the island—not even in Haputale. The lower half of the hill grows magnificent cocoa-finer than anything to be seen elsewhere for its age, and bears very heavily.

Cardamoms are also exceptionally good. I saw some six acres on Walton, two years old, and planted 8×8 feet, covering the ground and from 5 to 10 feet in beight,—and going to blossom. Where every estate is so good it would be invidious to mention any one in particular; yet, on the whole, Raxawa struck me as being the finest and most regular sheet of coffee. The whole hill is covered with immense boulders of magnesian rock, so large that on the top of one in Raxawa the coolies are mustered. The soil is rich and very deep and porous. The roads in the hill are rough, as one might expect where the ground is so uneven and some of the short-cuts in estates and in the jungle left standing are indescribable. Up and down ladders amongst a mass of rocks, and into holes that have never yet seen daylight, remind one of Bulwer Lytton's "Coming Race"—the journey into the land of the Vril! The Wihara rock on the hill is some hundreds of feet high and ascended by means of chains, but I had not the requisite time to visit it. If you wish to electrify your readers by a description of scenery, go and stand on the Kawdawa trig. in Monaragala and survey from thence the various mountain ranges of the island. The view is simply exquisite! The sea is clearly visible from Trincomalee to Galle almost, and with the naked eye vessels can be seen sailing along between Batticaloa and Hambantota. Would like to have stayed all night on this trip to see the sun rise, but, as it looked for rain, came down and met my companions at Maragalla bungalow to breakfast, and a Bett-er breakfast we could not have had. This bungalow is surrounded by immense banyan trees, and here you may also see a coffee tree bearing a ton an acre and growing on a bare rock! Such a thing was never before seen! Left the hill from the "Sirriagalla" end—an estate planted up alternately with Liberian and cocoa and promising well Experienced great hospitality on the hill, and came away delighted with everything we had seen. Rode back via Maddegama and Bibile, along a very pretty bridle path, and during the latter part of the journey, in torrents of rain, for it was on this day (13th) that so much rain fell all over the island. Every stream was a river, and one of our party was nearly carried away by an alligator which frequents a particular ford we had to cross. The ride from Bibile, or Yalkumbura completed one of the most enjoyable trips I have had in Ceylon.

POETT'S PLANTATION: "THE NORTHERN TERRITORY" OF SOUTH AUSTRALIA.

[By *S. A. Register* Correspondent.]

Rum Jungle, March 25.

Mr. Poett's driver kindly gave me a lift over in his buggy to the plantation, which has been largely invested in by Adelaide capitalists, and is a distance of four miles from Rum Jungle. And here let me say that there is but little doubt in my mind that the greatest industry of the Territory will eventually be the cultivation of tropical products, and it is consequently highly desirable and important that all matters connected with agriculture of this description should receive the fullest consideration at the hands of Parliament. That this has been done hitherto, I think, is seriously open to question. I do not believe in giving away the lands of the Territory for nothing, but still I think greater inducements should be held out to planters to settle amongst us. And I think that the clause in the old regulations for the disposal of the waste lands, which provides for the granting of quantities for this purpose at a nominal rental of 2s 6d, payable in five years, at the end of which time the ground would become the property of the licencee, was inserted for the purpose indicated. But, unfortunately, that clause has been found to be a dead letter through the introduction of the words "country lands," which by the interpretation of the regulations mean surveyed blocks, the said surveyed blocks having already been purchased, *i.e.*, those along the watercourses, the only land suitable. I hope that in the not distant future planters will be allowed to select lands suitable for their avocations in any part of the Territory, whether surveyed or not, care of course being taken that large tracts of land should not be taken up ostensibly for planting purposes, but in reality for other objects. The clause I refer to, 82 of the old regulations, provided for this contingency by making it necessary that the license should have a sufficient amount cultivated before the land became his property.

However, to return to the plantation, which is situated from Rum Jungle in a south-westerly direction: It stands at the head of a creek, as yet unnamed, which rises from a waterhole within a hundred yards of the homestead. This is fed by numerous tiny springs, which can be plainly seen bubbling up from the bottom of the hole, and the water finds its way by a channel, only five or six feet wide, but three feet in depth, running through the plantation, and onwards for fully six or seven miles till it joins the Finniss, of which river it is one of the most important tributaries. The estate contains a total area of 4,000 acres. The main road between Southport and Pine Creek runs through the estate about one and a quarter mile in an easterly direction from the bungalow, and the proposed railway line, which hereabouts is nearly parallel with the road, is not more than a mile and a half away. It is most likely that when the line is constructed a station will be built at Rum Jungle; so, as far as position is concerned, Poett's Plantation is magnificently situated. In fact, this feature had, in conjuction with the favourable character of the soil, much to do with Mr. Poett's selection of the site, which was made after three months' prospecting of the Territory by that gentleman and his assistant, Mr. McKinnon. The ground was taken up by Mr. Poett eighteen months ago, and it was formed into a Company in Adelaide in August last, when it was registered under the title of Poett's Northern Territory Plantation Company. All the shareholders are South Australian men, and I can, I am glad to say, sincerely congratulate them on their investment.

The work done on the estate up till the present has been purely of an experimental character. Mr. Poett, the manager, is qualified as an experienced tropical agriculturist by twenty-three years' experience on coffee and cinchona plantations in Ceylon, and Mr. McKinnon has been known to Mr. Poett, as a coffee-planter for the past eighteen years.

But neither is prone to boasting. "See for yourself; I will give you all information in my power," was the reply I received from Mr. Poett, when I asked him as to the success or otherwise of the experiments. Accompanied by that gentleman, who during my few days' stay treated me in a most hospitable manner, I first made a tour of the buildings, which consist of a nice homestead, or "bungalow," outhouses, &c., large shed 100+20, used for stabling and other purposes, cart-shed, toolhouse, European labourers' hut, and coolie quarters, which latter afford comfortable accommodation for 100 men, although as yet that number has not been employed, seventy being the largest total yet engaged at one time. During my visit an average of twenty-five coolies were daily employed, a white labourer, and white contractor for fencing. After making a tour of the buildings we proceeded to the nursery, which is the initiatory and convincing ground for all cultivation in connection with coffee and cinchona. This nursery, which takes in an area of 3½ acres, two of which are planted out, is laid out on the commencement of a long and narrow flat, composed of a narrow belt of black loam near the pool from which the creek flows, which alters into magnificent chocolate soil adjoining the forest land, which lies on the western boundary. It is immediately in front of the homestead verandah, so that when not actually employed in superintending, the manager and his assistant can have their eye on the labourers, a very necessary precaution, as I shall explain farther on. This closepile enclosure has been trenched, drained, laid out in beds, and planted with coffee arabica, coffee liberica and cinchona. All these plants have to be grown under cover, and Mr. Poett, in looking for the best means for building these shades, determined that he would not be guided by any set rule, but planted the coffee beans under sheds of all descriptions, of various heights, and various degrees of exposure, in addition to planting a number of beds in the open. All received the same treatment, with the result that those planted in the open proved utter failures, scarcely a seed being able to stand the exposure; others, planted under very slight shade, coming up thinly; whilst those under thick, flat shades, four feet in width by two in height, succeeded admirably, as did also that sown in long sheds with vertical roofs about five feet high, open at both ends to allow a free current of air. These latter sheds the manager has decided to use in future, as the grass which composes the roof is easy of removal as the plant increases in hardihood, and this exposure is worked gradually until the time when the young coffee-shrub is sufficiently strong to allow of its being planted in the clearing. Under the latter sheds and those with the flat roofs, the coffee plants, showing every indication of the most robust health, are growing as quickly as watercress, about four inches high. There are eleven of the larger sheds and fifty smaller ones planted with coffee arabica, and from them Mr. Poett calculates that, allowing for losses, he has 200,000 plants nearly ready for removing to the clearing. In addition to this a quantity of Liberian coffee seed has recently been received and planted, and it was at the time of my visit just showing above ground. Of this eighty beds have been planted, and these will, calculating roughly by the quantity of seed planted, give another 300,000 plants. In Ceylon, Fiji, and other coffee-growing countries a disease called Hemilia vesttatrix has attacked the leaf of the coffee plants. It is a fungoid which strips the leaves and blossoms, and an idea of its devastating effects may be gathered from the fact that in those countries it has lowered the rate of coffee production by fully 75 per cent. At Poett's plantation not a sign of this pest has yet made its appearance though young plants, such as those at this nursery, are generally its first victims. This is an interesting and perhaps significant fact that the climate or soil is antagonistic to the growth and propagation of the disease. The Arabica coffee was planted in December last, and as, at five months' growth, it is ready to plant out in the open, in two months sufficient will be ready to plant 100 acres.

From the coffee sheds we proceeded to those devoted to the growth of cinchona plants—a thing which Mr. Poett is very enthusiastic about. A great quantity of this seed was planted in October last, and it came up magnificently. It is planted out very similarly to the coffee beds in the larger beds, and in addition two much larger houses—40 × 20 feet—have been erected and thickly sown with seeds in January last. Through unfortuitous circumstances the seed in the latter has not thriven so well as in the October sowing, this being due to the fact that after it was sown a gale of wind swept the seed into heaps. But it is picking up again: and the manager has still great hopes of it. The earlier cultivation of cinchona is attended with very great difficulties. In the first instance the happy mean of light and darkness has to be hit off to a nicety, as has also the amount of water which the plants must receive. After the seed is first sown it has to be watered by sprinkling with a brush, as the rose attached to ordinary watering-cans throws much too great a quantity of water. In the first stage of growth the plants are kept in dark sheds, of course always allowing for free ventilation. When three months old they are planted—or "pricked"—out into beds at intervals of three by two inches, and four months from that time, when eight or nine inches high they are planted out into the clearing at intervals of 8 feet + 8 feet, or about at the rate of 700 trees to the acre. After they are thus planted out they require nothing but weeding, and in five years, the first stripping of bark takes place, when 1,600 lb of bark to the acre is considered an average crop. A "barking" follows every year if the grower wishes to get a quick return; though, if he can afford to wait, every alternate year is considered more profitable gathering. The bark which succeeds the stripping grows richer in alkaloids every year, and is consequently much more valuable. On this plantation the following varieties are grown:—The succirubra, the officinalis, and ledgeriana, of which the first-named is the least valuable, though it gives a much larger amount of bark per tree. The most of the plants grown are of the succirubra variety, though the success which Mr. Poett has had with plants of the officinalis, a much more valuable variety of the quinine-tree, leads him to hope much for the success of their growth, and he has ordered more seed to be forwarded him immediately. As showing the suitability of the soil and climate for the growth of this important product, I may mention that twelve months ago a few plants were sown, and that amongst these is one of the Officinalis variety which is now planted in the open, and has attained the enormous growth of four feet, a result which Mr. Poett has never seen equalled in Ceylon or anywhere else. He looks upon this as conclusive evidence of the future paying results of this crop. In addition to this I may mention that close to the bungalow is a plant which was not noticed till lately. Some seed was spilled near the spot when it arrived twelve months ago, and one of these, without care and attention, and as I have said unnoticed, has gained a height of two feet. Thus without the ordinary efforts which are made with this most delicate (in its earlier stages) plant, a seedling, self-sown, roots and flourishes. I think nothing more need be said after this of the suitability of the Territory for the growth of cinchona, a tropical product than which probably none more profitable obtains. The price of the bark varies from 2s to 15s per lb., according to the percentage fo quinine—at its lowest calculation, two shillings, 1,600 lb. per acre will give a bi-yearly return of £160 an acre. Think of this ye wheat-growers on the impoverished lands of your sunny South. The produce of a forty-acre clearing was sold by public auction in London, and realized £11,000. Outside the nursery is a clearing of about ten acres, which is under a fair crop of maize. It must not be thought from this that the Manager has any intention of growing maize for market, as he considers that the ground can be much more profitably employed. The crop is merely grown for home consumption, and Mr. Poett intends yearly growing a few acres to save the Company the great outlay which would otherwise be incurred in feeding the horse stock. A small patch of peanut, which perhaps, is the best fodder-plant grown in the Territory, will also be cultivated for the same purpose.

Tropical fruits, also, do as well here as in any other parts of the Northern Territory, and oranges, limes—in fact, all members of the *citrus* family-soursop, mangoes, bananas, jack, etc., are flourishing splendidly. The whole of the ground at present cleared is well-fenced, and another fence of post and four wires is being erected.

The most serious difficulty in connection with coffee and cinchona growing is undoubtedly that which exists in the employment of suitable labour. This plantation, when in full swing, will require fully 300 labourers. Let it be remembered that that number must be employed, or the ground return to its original state of unproductiveness. White men in the territory are paid £2 per week and cooked rations. It will be plainly seen that their employmentis out of the question. No cinchona, coffee, or other estate of 500 acres could afford a weekly outlay of £700, even if the supply of labourers could be obtained. And equally as impossible to meet would be the lesser expense of 300 Chinese at £1 per week, exclusive of rations. Labour of the cheapest is required and must be obtained if this important industry is to flourish. Are the resources of the country to be continually ruined by the clap-trap cry of—Australia for the whites? This will be the case assuredly if interference is offered to employers in getting suitable labourers at a suitable figure. This they can do easily by incurring the expense of bringing coolies from the coffee and cinchona countries. 300 Malabar coolies can be engaged at 1s. a day, which is an advance of 4d. on the sum they receive in Ceylon, and it is to this description of labour that Mr. Poett looks for the development of this industry. The Malabar coolies would be brought to the country under engagement for a term of years. They would live together on the plantation for which they were hired, speaking their own language, and working only at the work for which they were engaged, after which their passages would be paid back to their own country. They would know nothing of other work, and even if they did the law could step in to prevent employers of labour for other purposes than plantation work from importing them to compete with the whites. The case lies in a nutshell. With them a great industry is introduced and fostered, which will add an immense amount of wealth to the country : without them that industry cannot exist, and the land will again lie waste, or at most feed a few sheep or cattle. Mr. Poett condemns Chinese as a fraud—men who, beyond putting in the time necessary to ensure the wages, do nothing for them, and have not, and show that they have not, the slightest interest in common with their employers. Even if they were good workmen they cannot be relied on to remain on the place, and are as likely as not to desert *en masse* whenever their inclinations or interests prompt them.

I close this lengthy report of Poett's plantation with a few remarks on the grand field an industry, of which it is the pioneer in Australia, opens up to young Australians with energy and limited capital. Hundreds of young men have availed themselves of this magnificent field for investment, both in Ceylon and India, with profit to themselves and benefit to the countries in which they have invested them. There is no reason, in a grand country like ours, that the only outlet for the energies of young Australians should be the growth of meat and wool; and should, as they must do if no obstacles are thrown in their way, coffee and cinchona growing, prove profitable, there is a great field open for them on the vast plantations which will doubtless before another decade be opened in the hitherto despised Northern Territory of South Australia.—*Adelaide Observer.*

PROGRESS IN BRAZIL.

In Brazil, as in other tropical countries, the two great difficulties with which planting enterprizes have to contend have been labour and transport, and the Imperial Government has of late years earnestly striven to remove—or, at any rate, to mitigate—them both, though not, it must be confessed, with equal success. It is now generally admitted that the rapid development of the splendid resources of the country is in a great measure due to the enlightened policy of opening up the interior by means of railways constructed chiefly by British capital, interest on which at 6 or 7 per cent, has been guaranteed by the Government for thirty years. The routes of these trunk lines have been so well selected, and the traffic upon them is growing so fast, that in a very few years it is evident the net earnings will be sufficient to pay handsome dividends to the shareholders without reckoning on the state subventions. During last week the Minas Central Railway Company was brought out here, subscriptions being invited for 15,625 preference shares of £20 each bearing 7 per cent preference dividend, and there is no doubt that the capital will be forthcoming, as the shares of other Brazilian railways, similarly guaranteed, all stand at a high premium. The line will be 138 miles in length, and the contract for it has been taken at the exceptionally low rate of £8,600 per mile, owing to the easy gradients and the absence of engineering difficulties. The province of Minas Geraes which it will traverse is ones of the principal coffee-growing districts, and it is also said to be one of the most fertile in the whole empire. This line will bring it into direct railway communication with both Rio and Santos. The Government subsidy amounts to £60,500 per annum, and only a little more than a third of this is needed to provide 7 per cent on the shares now offered.

As regards labour, the Government has made several not very successful attempts to attract it from Europe and elsewhere, but it is now going to try a new field. A correspondent informs us that arrangements have been made between Brazil and China for the introduction into the former country of 20,000 Chinese indentured labourers. It is estimated that they can be landed at Rio for a little more than £2 per head, and it appears they are to receive wages at the rate of seventeen-pence per diem, and to provide their own food. They will therefore cost less than negro slave labour, upon which the Brazilians have hitherto relied. Our correspondent states that no guarantees are given for the fair treatment of the Chinese. In the interior of Brazil there is a total absence of any judicial machinery for the protection of the labouring class, and the Chinese possess no diplomatic or consular authority to secure redress for their grievances. It is said that the labourers are not to have pass-ports like other foreigners, that they will be prohibited from living in the towns, the intention being to employ them in coffee planting; and that they will be compelled to make their purchases in the truck shops, which are almost invariably owned by the planters. It is further stated that the ultimate importation into Brazil of from 400,000 to 500,000 Chinese is anticipated.—*Planters' Gazette.*

CINCHONA CULTIVATION IN JAVA.

Not very long ago a handbook was published on Cinchona Cultivation, by Herr van Gorkom, in which the most ample particulars were given of the history of the plant and the progress the culture has made in Java. Amongst the facts noted was one of great importance to the Netherlands-India Government, and that was the difference between the cultivation in British India and Java. In the former the species *ledgeriania* is hardly propagated, whereas in the Dutch East Indies it occupies a prominent place possessing as it does great yielding properties. The attention drawn to the subject by this work has no doubt been the cause of the articles which have appeared with reference to the proposed scheme for selling by auction the seeds of this variety. It is argued with a good deal of force that if the sales are conducted in the unchecked manner which has been in vogue that the future losses resulting will not be compensated for by the present gain of a few handsful of coin. Looking, therefore, on the transactions from this point of view, it is not surprising to find that the Dutch desire to go to the other extreme and stop the sale altogether. It is proposed even to go to the extent of making the recipients of cinchona seeds from the Government account for the same by a certain percentage of seedlings in the nurseries. Some one evidently means business when this exacting device is suggested, and it would not be at all astonishing to read a further suggestion that the seeds which cannot be used ought to be destroyed, so as to prevent their reaching British India. Probably long ere this the Indian Government on the alert now have acquired a good supply of *ledgeriania,* and will proceed at once to propagate wherever the existing trees are large enough to be operated on. Indeed, the great anxiety shown in Java will result in producing increased activity in this respect in India, especially as such wholesale doctrines of stoppage are enunciated. No one would for a moment object to the careful preservation of the species of which the Dutch are to such an extent the happy possessors, and if the Goverment will only foster the cultivation there need be no necessity, we imagine, for tho sales by auction. But on the other hand, there ought not to be such a spirit existing as is shown in the desire to absolutely prevent the export altogether. There can be no reason why the surplus stock should not be sold. Java, far ahead as the island is in the cultivation of cinchona, can hardly fear competition as yet, whereas no amount of stopping the supply of any particular kind will prevent it in the future. Our Dutch friends do not seem to be able to appreciate this, and in theirexcitement are quite willing to undergo a system of official supervision, to which the enforced labour, said to be abolished, was child's-play. No amount of checking by seedlings in the nursery or high charges for the missing percentage would check the export if the demand were great. It might, however, have the effect of reducing the local enterprize, for people would not care to run risks of fine if natural causes produced less than the required quantity. Let the Netherlands-India by all means preserve their *ledgeriania,* but let them go about the right way to do it.—*L. and C. Express.*

THE SUGAR DISTRICT OF QUEENSLAND.

MACKAY, March 26th.—The scarcity of labour for cultivation purposes is making itself more keenly felt from day to day. Since my last letter a further departure from the old method of recruiting has been made. Hitherto the labour vessels have chiefly confined themselves to the New Hebrides and the Solomon groups of islands as fields whereon to raise the labourers for the Queensland plantations, occasionally the Santa Cruz, Ellis, and other outlying groups were visited. A firm of merchants here who only lately embarked in the trade have, however, sent their schooner to quite a new district, one from which till now, as far as can be ascertained, no islanders as labourers have yet been obtained. Planters as a rule, have have an antipathy to recruits from new and hitherto untried islands. This is but natural. Among certain islanders the mortality is always greater than with others; some islanders are naturally good workers, others again can never be induced to work, and it frequently happens that some again are too quarrelsome to get on with their fellow labourers from a to them foreign island. With the natives of New Guinea, however, an objection will certainly arise which up to date has not been taken into sufficient consideration. The coastal climate of Queensland, even as far north as Cooktown, bordering, even that of a large continent, is subject to extreme ranges of moisture and temperature—a hot close day is commonly followed by a cold night, and *vice versa,* and in general the features of the climate are very different to those of an island in the tropics. Men coming from the humid and uniformly warm temperature of the Line islands sicken sooner or later of pulmonary complaints when brought to a country whose climate is characterised by this great range of temperature and moisture. Coolies from India would naturally not suffer. But planters are so pushed for a low class labour of any description that they cannot afford to go into questions of this sort, they are obliged to take what they can get, and what one planter may refuse there are always 20 planters willing to accept. During last session large sums of money were voted both to increase existing and to initiate new lines of railway on our coast. Mackay is to have railway on the south side of the Pioneer tapping the sugar plantations for a distance of 25 miles; the surveys for this line are almost completed. The planters on the north side of the Pioneer consider themselves equally entitled to a railway, and are now agitating accordingly. As the production of sugar is about equally divided by the plantations on the north and south side, the probabilities are that the Government will consider the matter favourably. These small coast railways will in time form the nuclei of a grand coast line from Brisbane to Cooktown.—*Australasian.*

THE CEARÁ RUBBER TREE.

(From the *Indigo Planters' Gazette.*)

In the year 1881, the Government of India, on the recommendation of the Chief Commissioner of the Andaman and Nicobar Islands, sanctioned the employment of Major Wimberley, the then Officiating Deputy Superintendent of Port Blair, on special duty in Ceylon, for the purpose of enquiring into the cultivation of Liberian coffee and other products, in view to determining which were the most suitable for introduction into these islands. The result of Major Wimberley's visit to Ceylon is a highly interesting report on the principal products of the island, and among these we find that he gives by no means an insignificant place to the Ceara rubber tree, the cultivation of which was attracting very great attention.

The peculiarity of the tree is that it grows equally well from seed or from cuttings, and, though a native of a tropical sea-level, it is said to thrive well in Ceylon up to at least 3,000 feet and on most barren soil. The seed-coat is of remarkable thickness, and the natural process of germination occupies a long period. All that is necessary to hasten this is, says Major Wimberley, to assist the seed-coat in splitting. This is effected by holding the seed firmly and rasping off with a file both edges at the root end. It is best not to file off the actual end, as it may thus easily happen that the rootlet of the embryo may be injured. After this treatment it is said that the young plants should appear above ground in two or three weeks. The seedlings do not, it appears, require any particular attention: they grow rapidly, and may be planted out at 20′×20′. Cuttings will take root as early as willow, and should be taken from the points of strong shoots, and may be a foot in length. In planting, Major Wimberley explains that each cutting may be put into the soil to a depth of six inches. If scarce, the entire shoot should be cut into pieces, each possessing a bud, all of which will grow if covered with half an inch or so of soil. Loose sandy soils and hard dry gravelly wastes are also suitable sites. It is added that "holes might be made in strong land with an iron jumper and a stout cutting put into each and filled with pebbles. On bare or thinly-covered portions of rock, the cuttings might be laid down flat and a little heap of stones or any kind of *debris* about the size of a mole-hill, piled over each, care being taken that the extreme point of each cutting with a bud is left uncovered."

COCA.

The medicinal properties of this remarkable plant have lately attracted considerable attention. Its well-known property of stimulating the action of the heart and digestive organs has recently been turned to account in the United States in the treatment of dipsomania, and of the habit of opium eating, laudanum drinking, or sub-cutaneous injection of morphia. There seems no reason, also, why it should not be used to cure the habit of taking chloral. In all these cases it is a stimulant action which is required, and this coca possesses, while it does not produce any deleterious after-effects. Some remarkable results have been obtained by its use, more especially cases of indigestion, which are entirely cured by this drug, and which lead to the hope that the leaves may soon be in extensive demand.—*Planters' Gazette.*

CINCHONA CULTURE.

As many of our readers are already aware, the planters of Ceylon and other portions of India who have been driven from coffee-growing by the ravages of leaf disease (*Hemileia vastatrix*) sought refuge from the calamity in the cultivation of Cinchona. This new industry has now flourished for the greater part of a decade, and continues, with few exceptions, to be as promising as ever. Different varieties find favour in different localities, owing to variations in soil, amount of rainfall, and height of temperature; but, on the whole, the plant seems to require a tropical heat, or nearly so, to thrive, and a moderate amount of rain—considerably less of the latter than the tea plant—to do its best. Several months ago we were favoured with a parcel of *Cinchona officinalis* seed for distribution. This kind is in favour with Ceylon planters for its quality, but si hardly as successful in Ceylon as *C. succirubra*, *C. ledgeriana*, and some other varieties, because the rainfall appears to be in excess of its requirements. It was on account of the climate of Queensland being known to be drier than that of Ceylon that the "crown bark" variety was selected for a trial here. Up to the present time, however, we have heard nothing from those who had seed from this office with reference to their success with it or otherwise; but they have only had sufficient time to raise a few seedlings, so cannot have much to report

It is gratifying to note that the Government have an eye on the probable requirements of the colony in the matter of cinchona culture, and are intending to take the initiative on the experimental farms now starting. The idea itself is good, though whether the sites selected for the experiments are at all suitable remains to be seen. Perhaps no one can say emphatically that cinchona trees will not thrive in the localities of Yeulba and Withersfield, but, so far as can be judged from experience elsewhere, they can hardly be expected to do well in either place. Will it be wise, then, to make much stir in the matter when failure would probably deter persons from giving it a trial in other parts of the colony? This is a question deserving of consideration. History abounds in illustrations of the mischief which has resulted from badly designed or indifferently executed experiments. Some years ago, before the sugar industry had taken good hold anywhere in Queensland, the owners of a selection on the Agricultural Reserve, eleven miles from Rockhampton, planted something like 40 acres of cane, which grew magnificently, and, sanguine of success, one of the firm started for Sydney to make arrangements for the necessary machinery. While away south, and before anything had been done, a telegram reached him saying that a heavy frost had destroyed the cane, and the consequence was that no machinery was procured, and the verdict was made public that sugar could not be grown successfully in the district, while, in fact, the cane was only slightly frosted. This hasty conclusion regarding a partially successful experiment was the immediate cause of preventing the industry being tried there again until recently, and a large amount of capital which was to have been expended upon it then in that neighbourhood was taken elsewhere. So far as possible, it is well to prevent history repeating itself after this fashion. A partial success is often more damaging than a complete failure, because it will first excite hope, to be eventually rudely dispelled. We write this not so much with the intention of preventing cinchona being tried on these experimental farms (for it would be well to try it everywhere) as of guarding against too much stress being laid upon trials in such localities. But the plant should certainly have a thorough trial somewhere north of Rockhampton or of Mackay, in ridgy coast country. Circumstances favourable for its perfect development will probably be found near Cardwell, or on the Herbert River; most probably not in any of our western country.

Cinchona trees of several varieties are on trial at the present time in the Brisbane Botanic Gardens and elsewhere. *Cinchona succirubra* so far looks exceedingly well in the Botanic Gardens, and in its foliage and general appearance wears so close a resemblance to the Leichhardt tree of the North (*Sarcocephalus cordatus*) that it might easily be mistaken for it. The bark and wood of the Leichhardt tree are also bitter—another remarkable point of resemblance between the two; and on account of these resemblances a strong suspicion lurks in the minds of some that an affinity will eventually be traced between them—a matter for our colonial botanists to determine. Mr. Brady, of silkworm notoriety, on the north branch of the Tweed River, has a thrifty plant of cinchona near his house, not making very rapid growth certainly, but apparently healthy. Bananas thrive in the same locality, and are never injured by frost, and it will probably be found that one essential condition for success with cinchona is the absence of any considerable degree of frost. Then, again, as profit will be resultant from a good yield of bark, it follows that only in localities where the maximum of growth can be secured will its cultivation prove reliable and satisfactory. It is not reasonable to expect strong growth with a minimum and precarious rainfall, and yet this condition, together with c rtainty of plenty of frost, is what the cinchona will have to contend with in both the localities selected for the experimental farms. To make the trial complete, a third experiment should be conducted simultaneously with the others somewhere in the northern coast districts, and a comparison of results could then be made after a certain time between the different localities. It would thus be definitely shown where it could and where it could not be grown profitably; and also what might reasonably be expected from it. In Ceylon at the present time the question is often put—"What ails our cinchona trees?" A new trouble in the form of canker is dangerously affecting the trees and damping the planters' ardour in its cultivation. Those on the spot who have experience of the coffee-leaf disease and also of this new trouble say—"What disease or what insect is so fatal to coffee as canker is to cinchona?" So far as experience in cinchona culture in Ceylon goes, it apparently establishes the fact that some varieties of the tree will not do well with an excessive rainfall, and probably the rest would be better with less. If so, this points the more decidedly to Queensland as being better suited for it than Ceylon, and if reasonably fair chances are afforded it in the coast districts of Central and Northern Queensland there is good reason to believe that it will thrive and prove remunerative. Something more than sugar and different to coffee will be wanted before long, and cinchona should be thoroughly tried before it is passed over as unsuitable.—*Queenslander.*

NEW INDIGO [AND COFFEE, TEA AND CINCHONA] COUNTRIES.

(*Indigo Planters' Gazette*, May 22nd.)

The southern portion of Burmah called Tenasserim, which includes the Moseos and Mergui Archipelago, lies along the coast between 17° and 10° north latitude, and is bounded on the east, from thirty to forty miles inland, by a chain of hills in some places 5,000 feet in height. The breadth of this chain at Martaban has never been ascertained, but near Tavoy it appears to be about 40 miles wide, whence it gradually narrows to 10 miles near Mergui. The coast line is very irregular and low for some miles inland, beyond which the surface of the country is mountainous, thinly populated, and much intersected by streams. The chief rivers are the Tavoy and the Tenasserim. The Tenasserim, named after the town, rises in about 15 north latitude, flows through a valley scarcely broader than its bed, and is navigable for about 100 miles. The mouth of the Tavoy river affords an excellent anchorage, for ships; and vessels can anchor along the coast at all times during the north-east monsoon. The soil of the northern portion of Tenasserim is alluvial; stratified sandstone is the prevailing rock interspersed with veins of quartz, in which crystals of great beauty are sometimes discovered. The chief formation of the small hills is laterite.

In the Arakan Division tobacco cultivation is attracting notice. According to native calculation the average production of tobacco in Arakan is 370 lb. to an acre, but experience has shown that the yield of properly cultivated ground would be 800 lb. to an acre. The tobacco-producing soil is so rich that no rotation of crops is necessary, and beyond a little weeding the plantations require only occasional manual labour. The crop is sown in November and reaped in April.

Experiments have been made in tea and coffee. Though the soil and climate are no doubt favourable, the *labour question has hitherto proved insuperable.* Chinese immigration is the thing for Tenasserim; and looking at the numbers now moving towards Borneo, there is no doubt that with a very little encouragement from Government they would readily come to Tenasserim.

Tenasserim Division consists of six districts, of which Tavoy is one. The chief town of the Tavoy district is Tavoy, with a population of 14,795. The other centres of population are mere villages :—

TAVOY DISTRICT.

Latitude N, 14°·71
Longitude E, 98·18.

Area in square miles ...	7,200
Number of villages ...	308
Population ...	79,122
Population per square mile ...	11
Land revenue ...	98,006
Average rainfall in inches ...	195

The population is chiefly composed of Buddhists and Jains. In this district and Mergui are found metalliferous minerals such as lead, iron copper, and antimony. Coal of an inferior quality is found in the Tenasserim river near Mergui.

The population in Mergui district for 7,809 square miles is 52,175, giving a population of only seven to the square mile. The rainfall is 151 inches in the year.

Tenasserim came into the possession of the Burmese in 1793, and was ceded to the English by the Treaty of Yandaboo, February 24th, in 1826. Tavoy surrendered to the English in 1824.

The area of Tenasserim in square miles is 46,776, and the population about 700,000. Its length is something over 500 miles and its breadth about 90 miles. The mountains run in parallel chains N.-N.-W. and S.-S.-E., and are 3,000 to 5,000 feet high. From the base to the summit they are covered with dense brushwood, which extends in some places to the edge of the sea. The temperature is variable on account of the mountains being so close to the shore, and cold and heat alternate rather rapidly. The peoples are Talians, Karens, Siamese with a sprinkling of Hindus and Mahomedans. The religion is Buddhism.

W. M. R.

MODERN ARTIFICIAL HATCHING AND HATCHING APPARATUS.

I am frequently asked the following question:—Are chickens hatched in an incubator as strong as those hatched by hens? My reply is that those which are *properly* hatched artificially are not only as strong, but if separated from older fowls, are not nearly so liable to disease, and may be kept till far beyond marketable size *entirely without vermin*—a thing which, in California, is almost unknown among hen-hatched birds. If vigorous eggs are hatched with too little moisture or too much heat, weak chickens and poor hens may be counted upon every time; the same results could be looked for from an incubator varying greatly in heat, one portion with another (if eggs are changed about) or one time with another over the whole; such would also result from the hatching of chickens in an incubator supplied with too little fresh air. Among the thousands of broilers that I have raised for market I have never had a contagious disease. I have invariably kept my chickens from all chance of contact with hens in any manner, and not a blemish or trace of vermin has ever been seen among them. I believe that these things originate spontaneously among fowls after passing a certain stage of their development only. This season I am hatching almost exclusively from eggs laid by hens which were hatched from my incubators last spring, and I verily believe that in all California no more clean, hardy, or vigorous fowls or better layers could be found. They are of mixed breeds—Plymouth Rock, Light Brahmas and Dominiques predominating. Their progeny, hatched in my incubators, have long been going to market at the ratio of 90 out of every 100 hatched. If any raisers of chickens by the natural way can beat this in midwinter, I may be persuaded to consider whether I have been altogether correct in my statement as to the strength of incubator-hatched birds; until I hear of a better result, extending into the thousands, I may be permitted to differ with anyone who questions the results of good artificial incubation.

In the matter of economy, as compared with natural hatching:—Exclusive of the little time consumed, and which is scarcely missed, a good incubator will hatch at the rate of about one half cent per chick. In producing numbers of chickens, the incubator can beat the hen "out of sight;" for a few chicks, I am free to admit that the hen would lead. The care of a small incubator (though well enough if used as a plaything) is as great as that of a sizeable machine, and I do not consider one of any practical value which will not accommodate at least 200 eggs, as a few hens would win every time on small numbers. But when we come to the consideration of the room, care, feed, attention, and uncertainty in many respects of, say, twenty sitting hens, the incubator, according to my experience, distances the hen; double the number, and still greater results go to the credit side of the artificial plan. On the other hand, I do not advise the use of very large machines, as I consider medium-sized ones far more convenient in starting or hatching. If a person desires greater capacity, a duplication of such machines is much better. I leave out of the consideration the difficulty of making perfect uniformity of heat in large egg-chambers. An advantage over the hen lies in the fact that the machine is always "broody," and taking advantage of this, we may produce chickens for market at a time of year when hens could scarcely be brought to see the importance of it, and thus secure the best prices when chickens are not raised naturally. I am also frequently asked:—Do you make the business pay? My invariable answer is: I have been engaged in it three seasons nearly, and my plant is not for sale. Next year I shall double my facilities. Draw a very easy inference, please—one which is too palpable for disguise, did I desire concealment.—*Correspondent of the "Breeder."*

CINCHONA.

Calisaya Verde and Morada form the subject of a letter to a contemporary, from which we take an extract:—

I was one of the first to import Verde and Morada seed, and therefore, I fancy my plants are as large or larger than most plants in the island.

From the satin-like texture of the leaves (in the young plants), and their general appearance, they present the characteristics of Ledgerianas; but they are of a far more robust habit, and their growth at this elevation is very much quicker.

There are apparently several varieties which, although equally robust, yet shew differences on the leaves—some being large leafed, with a deep red underneath, others with longer leaves and a yellow or red midrib. From what one can judge at this stage the bark promises to be rich. The astringent properties are most marked on tasting. Mr. Christie says Ledgerianas lose the underleaf when they grow up, which would imply that young Ledgerianas have always the red underleaf. I am under the belief that many ledgers shew no red whatever in the underleaf and yet may be very rich in quinine*; and Howard gives several distinct types not only as to leaf, but as regards flowers.

As far as a mere outsider can judge, the divergent forms of Ledgerianas are numberless. At this stage, there is of course no Verde or Morada blossom to be got, or the matter might be more satisfactorily settled; but that these plants *are* of the Ledgeriana type, I do not think can be doubted, and I hace a great number of all kinds. I will forward various leaves to Dr. Trimen, who will no doubt be able to give a more pronounced opinion, and from what he says in his report, I incline to think he considers them. most likely to be the quite distinct from C. Ledgeriana —J. V. H. O.

We trust they will not be found to have any affinity to *C. micrantha*. It is evident that the enormous *C. verde* trees noticed by Markham were of great age. We add further extracts:—

Sir,—I have raised several thousand "Calisaya Verde" plants from the seed which, I received from Mr. Christie, (the first seed that came to the Island I believe) and I have no hesitation in saying that the growth of the "Verdes," both as seedlings and since being planted in the clearings, is at least double as quick as that of any other variety.

I have some "Verde" plants put out in the clearing 5 months ago, and they are more than double the size of Ledgeriana put out at the same time. Perhaps your correspondent "G," has planted them at too high an elevation? One of the great recommendations of the "Verde" is, that it is supposed to flourish at a much lower elevation than any other variety of cinchona, and if this proves to be the case in Ceylon, a large quantity of land hitherto found unsuitable for cultivation of this valuable variety of cinchona, and now that forest land at a suitable elevation for other varieties of cinchona is so scarce it would be very important to prove that "Calisaya Verde" *will* really flourish at an elevation where other varieties will not.—B. Fanshawe. Lunugalla, May 2nd.

'G' asks whether Calisaya Verde will grow in Ceylon to four times or ten times the size of Succirubras. How *can* any one answer that until they have grown them? Mr. Christie cannot tell him *that*, or Markham, or Holmes, or any other authority unless they are grown in Ceylon! All we have heard is that it grows to a "very large tree" in Bolivia. All I can say is that at this elevation, 5,200 feet, it grows very quickly indeed, but as to whether it is to be four or even *ten* times bigger than succirubra it is impossible as yet to say. As to what 'Markham' says, I refer 'G' to Peruvian Bark, chapter xvii. page 191. 'Gironda' was Governor of Sina, a village in Caravaya, between Peru and Bolivia, to whom Hasskarl referred in his travels through Peru, and with whom Markham stayed during his travels in the Caravaya country. Martinez was the Cascarillero who accompanied Weddell, in 1846, and later on Markham in 1860.

Regarding the Morada tree, Markham mentions one he saw which had been planted in a clearing taken from a root-shoot 12 inches high, and planted in January 1859. In May, 1860, it was seven feet high, six and four-tenth inches round the trunk! I think 'G' will gather *all* that is known of these varieties from the references here given him. Possibly if he asked Mr. Christie to refer more particularly to his agents they might tell him more concerning the growth of Calisaya Verde in Bolivia, but until, as I said before, *we* grow these trees, it cannot be said what size they will or will not grow to in Ceylon.—J. V H. O.

CINGHALESE LABOUR IN QUEENSLAND.

(*To the Editor of the "Mackay Standard."*)

Sir,—A considerable amount of misdirected sympathy, both at Bundaberg and Mackay, is being extended to the Cinghalese lately imported by the "Devonshire."

What that class of people hope to gain who are inviting the Cinghalese to break their agreements it is difficult to say: instead of allowing them to perform their five years' agreements as agricultural laborers on the plantations, this class of people are doing all they can to cause the agreements to be broken, and to let the Cinghalese loose in the town to compete with themselves—the very last thing one would think, which was desired by them, and which is certainly utterly opposed to the wishes of the planters.

A great deal has been said about their having been deceived in their agreements, about their remuneration being inadequate, &c., which deserves consideration.

In the first place what are their wages in their own country? We have several Ceylon coffee planters amongst us, and they say that the highest wages paid in Ceylon is £1 per month, or 8d per day, and find themselves. In Mauritius the authorized legal wages of identured immigrants is 10s per month, with rations, which is equal to 4d per day, and found; in India the rate is from 4d to 5d per day, and find themselves. Now, granting that there is a difference in value of rations between this country and Ceylon, no employer has, that I am aware of, declined to make up this difference, for an ample ration for Cinghalese can be given here at the rate of from 6d to 7d per day, as the following scale will testify:—

				s.	d.
Beef	1 lb. ꝑ diem	7 lb. ꝑ week,	@ 1¾d ꝑ lb.	1	0¼
Bread	1¼ lb. ꝑ diem	9 lb. ꝑ week,	@ 4½d ꝑ 2lb.	1	7¼
Rice	½ lb. ꝑ diem	3½ lb. ꝑ week,	@ 2½d ꝑ lb.		8¾
Tea		2 oz. ꝑ week,	@ 2s. ꝑ lb.		3
Sugar		1 lb. ꝑ week,	@ 2d. ꝑ lb.		2
			Total ...	3	9¼

This £9 16s 1d per annum deducted from the £20 per annum for which the Cinghalese contracted to come still leaves them £10 3s 11d or equal to 8d per working day, (within a fraction), which contrasts favorably with their own country, 8d a day and find themselves.

---

* Ledgerianas with specially red leaves were not in favour with Mr. Moens, and we saw a field of them separately planted so that their value might be tested.—Ed. C. O.

In practice, however, the planter takes upon himself the extra cost of the rations in the country, and the Coolie gets 18s a month in cash besides his rations, while the Kanakas only get 10s a month here, and 5s a month in Fiji.

With importation, exportation, and medical attendance, the total cost of each coolie to the planter is fully £26 per annum, or 10s. per week, the same as the Kanakas, while no one will deny the great superiority of the Kanakas in docility as well as in physical strength.

It is the most absurd thing in the world to treat these Asiatics (who are a servile race) as deserving of sympathy; they have ample rations and nearly double the pay they get in their own country, but they are encouraged by misguided men to leave their work, loaf about the towns, subsist on charity, and do nothing; this suits their characters down to the ground, as to have plenty to eat and nothing to do would suit many men who still have to earn their living by the sweat of their brow; but where the Government funds are prostituted by turning the immigration quarters into a depôt to harbour these idle loafers, and they are encouraged in their illegal desertion by Government officials, some protest should be made.

The acts of the Immigration agent are a regular laughing stock for them, and as a Cinghalese said to me the other day—"Me gentleman now, me sit down along table with knife and fork, white man wait on me, Government give me rations, by and by money, send me back along Ceylon." With such absurd treatment as this to men who are many of them well known gaol birds, is it a wonder that they should prefer leaving their employer and being supported in idleness to earning their living by honest work.

A point in the Asiatic character, with which we are as yet unfamiliar is, their utter disregard of truth, or the obligations of an oath, and their consequent unreliability as witnesses; it is notorious that a native advocate has only got to go into the bazaars at Colombo, and for a rupee each he can get as many witnesses as he wants There is also the well known story of the Calcutta judge summing up in an important case: "54 witnesses have sworn to certain facts, while 54 have sworn diametrically opposite. I am therefore forced to discard the evidence entirely, and decide the matter upon my own judgment."

Finally, unless these Cinghalese are to become a perfect nuisance hanging about the town, begging or stealing, they should be promptly banished, and sent back to their employers, where 18s. a month and rations, double the pay they have been accustomed to, awaits them.

Any sympathy with such men as these only encourages them to absent themselves from work and live upon the earnings of those who are really working men, does an infinity of harm, and unsettles those Tamils and Cinghalese who are disposed to work.

A MACKAY PLANTER.

SAND-BINDING PLANTS

have been reported on by Dr. Bidie to the Madras Government as follows :—

The utilisation of indegenous plants to bind the sands of this coast was apparently first attempted in 1849 on the suggestion of Colonel Worster, R. A,. to protect the beach road from sand. Subsequently Dr. Cleghorn devoted attention to the subject, the immediate object then in view being to consolidate the shifting sands thrown up by the sea near Sir A. Cotton's groyues, which still exist along the beach opposite the city of Madras. The chief plants employed on both these occasions were the Goats' foot creeper (*Ipomœa pes-capræ*) and the Spiny pink-like grass (*Spinifex squarrosus*).

In Europe and America the importance of conservative measures of this nature has long been recognized. On the shores of the Baltic, where numerous dunes exist, attempts to reclaim them date back several centuries, and in America the planting of sand-binding plants was enforced by law on the beaches of Long Islands as early as 1758. In France where operations to control dunes have been most extensive and successful, the first important experiments were apparently made in 1870 by Mons. Bremontier, who subsequently published an account of his method. "Memoire sur les Dunes," in 1796.

In dealing with aggressive sands, such as those of the south-west of France, the first step towards arresting their progress is to create a barrier to the drift. This is usually done by erecting a paling of boards about 4 feet high and with the sharpened ends driven into the sand. Each board is from 5 to 6 inches wide by 1¼ inches thick, and a space an inch wide is left between the boards. The sand gliding along the surface is piled up in front of the paling, and a portion passing, through is deposited behind. This goes on till the boards are buried, when they are raised by a mechanical contrivance without disturbing the consolidated sand. When the paling is first erected a space on the windward side, eight times wider than its height is planted with sand-binding plants, those used in France being chiefly *Arundo arenaria*, a *Triticum*, an *Artemisia*, *Cakile maritima* and a *Salsola*. The Dune thus secured rises higher and higher, and the plants, as they are buried, struggle upwards and bind the drifted heap with a network of roots. The best angles for security in a dune are one of 7° in front and 22° in the rear. The increase by drift to the height of a dune in France is about 12 inches per annum, and the top may be crowned with Tamarisk. These particulars are mentioned here because it seems probable that some such measures will be required to control the sands of some of the tracts referred to in the correspondence forwarded by the Government of India.

At various parts along our coast the phenomenon of natrual drifted heaps of sand may be seen, and these to a large extent owe their existence to the presence of sand-binding plants. The moving sand on a beach is not lifted up like dust by the wind, but is driven along near the surface, and thus plants in the course of the drift catch less or more of it, and in course of time a sloping bank or dune is formed. The chief local plants instrumental in thus arresting and consolidating sand are those mentioned by Dr. Cleghorn, viz., *Spinifex squarrosus*, *Ipomœa pes-capræ*, and *Launæa pinnatifida* (formerly *Microrhyncus sarmentosus*), and to these may be added *Cyperus arenaria* and other *Cyperaceæ*, and *Tridax procumbens*. The locality which these plants frequent on our shores is that of the loose shifting sands, and the names of the whole of the more common species growing there will be found in List A of appendix.

Immediately behind the dunes the flora is somewhat more extensive, the chief plants found in that zone being those enumerated in List B. Here also shrubs and trees begin to appear, amongst which may be noted *Carissa Carandas*, *Ehretia arenaria*, *Pandanus odoratissimus*, *Phœnix farinifera*, *Borassus flabelliformis*, a *Calamus*, *Anacardium occidentale*, *Solanum jacquini*, *Psidium pyriferum*, *Jasminum angustifolium*, *Memecylon tinctorium*, *Calatropis gigantea*, *Hoya viridiflora*, *Tylophora asthmatica* and *Hemidesmus indicus*. *Pandanus odoratissimus* is particularly useful when it is desirable to raise the sand drift in large heaps, and at the same time to afford shelter from the sea-breeze. The Alexandrian laurel (*Calophyllum inophyllum*) also thrives well when planted in such situations, and so does *Phœnix sylvestris*. If there is a back-water or canal *Avicennia tomentosa* will be found most useful for consolidating the bank and catching drift, as a dense minature thicket of shoots spring up wherever the roots extend, and catch debris of all kinds as well as sand. If the water is fresh the tall grass *Saccharum spontaneum* also becomes a most valuable protecting agent from the moving sand.

Other trees which thrive well near the coast, and might be used for planting up reclaimed tracts of sand, are *Eugenia jambolana*, *Albizzia lebbek*, *Sapindus emarginatus*, *Thespesia populnea*, *Paritium tiliaceum*, *Cordia myxa*, *Pongamia glabra*, *Odina wodier*, *Mangifera indica*, *Feronia elephantum*, *Mimusops hexandra*, *Dalbergia paniculata*, *Acacia planifrons*, *Acacia latronum*, *Pithecolobium dulce*, *Ficus indica*, *Ficus tsila* and *Casuarina muricata*.

Of the last-named tree, *Casuarina muricata*, extensive plantations exist for many miles along the coast north and south of Madras, and these have greatly improved the appearance of what was before a sun-beaten sandy waste. There can be no doubt also that the plantations have rendered the fields behind them more valuable by affording shelter, and in some cases have permitted land to be brought under cultivation, which would otherwise have remained in a waste state. The Casuarina is a very hardy plant near the sea, and will grow down to high water mark, even amongst loose sand. The secret of its flourishing in such situations is due to the fact that the sub-soil water is always near the surface, and that the sand, although apparently barren, is generally largely mixed with decayed organic matter. When the trees in a Casuarina plantation are left unpruned, they throw out decumbent horizontal branches which develop roots and thus fix the sand. If the trees are cut, these rooting branches, when left intact, throw up shoots, and thus the forest is naturally renewed. In the shade of an established Casuarina plantation the ground is littered with the minute twigs shed by the trees, and this top-dressing, if left undisturbed, shortly decays and fructifies the soil. The plants which grow in the shade of Casuarinas, when not too dense, are those which are marked with an asterisk in List B.

The importance of the Casuarina in the reclamation of waste sandy tracts on the coast can hardly be overestimated. Perhaps the better way to put it as regards this Presidency would be to say, that there should be no such waste lands. Their reclamation belongs, properly speaking, to the Forest Department, and to them the task should be entrusted.

ENCLOSURE, No. 1.

Appendix A.

Canavalia obtusifolia	Sesamum prostratum
Hydophilax maritima	Pupalia orbiculata
Launæa pinnatifida	Crinum *sp.*
Tridax procumbens	Cyperus arenarius
Impomæa pes-capræ	Spinifex squarorosus.

ENCLOSURE, No. 2.

Appendix B.

Polycarpæa corymbosa	Salicornia Indica
* Alysicarpus vaginalis	* Cyperus castaneus
Phaseolus trilobus	* Do. bulbosus
Desmodium gangeticum	* Do. distans
* Do. triflorum	Cyperus *sp.*
* Indigofera enneaphylla	* Fimbristylis ferruginea
Mollugo stricta	* Do. 2 *sps.*
* Spermacoce articularis	* Kyllingia triceps
* Hedyotis Heynei	* Isolepis gracilis
Impomæa pes-tigridis	* Do. 2 *sps.*
Ipomæa tridentata	Trachyozus muricata
Lippia nodiflora	Aristida setacea
Asystasia coromandeliana	Eleusine ægyptiaca
Pedalium murex	* Chloris barbata
* Leucas diffusa?	* Perotis latifolia
* Chammissoa aspera	Imperata arundinacea
* Ærua monsoniæ	* Panicum 2, *sps.*
Chenopodina Indica	Eragrostis 2. *sps.*
Salsola Indica	

(Signed) G. BIDIE, M.B., Brigade-Surgeon,
Supt., Govt. Central Museum.

Madras, 27th March 1883.

[Most of the plants mentioned are the same as our littoral sand-binding plants in Ceylon, the goats-foot ipomœa, the *Canavalia obtus-folia*, and *Spinifex squarrosus*, being the most abundant and best for binding the sands on sea-shores. These are often torn up by the waves, but take root at once and grow out towards the sea as soon as the waves allow them. I understand that several years ago attempts were made to grow casuarinas on portions of our coast near the pearl banks at Silavatturai and elsewhere, and if those have succeeded they should be planted everywhere in Ceylon where there is waste ground which is required to be reclaimed and on which nothing else of value will grow. That avenue of casuarinas on Torrington Place from the Edinburgh Crescent to the new Lunatic Asylum was planted in 1880, so that in about 3½ years these trees have grown to a height of 25 to 30 feet in sandy soil with some cabook on the surface.—W. F.]

A PINE TREE cut in Amos Bailey's camp, Indian River, Cheboygan county, Mich., measured 22 ft. in circumference, and was sound from butt to top; and a tree was recently cut in Hemstead county, Ala., that measured 26 ft. in circumference. It took six men. working constantly, half-a-day to fell it.—*Forestry.*

NORTH BORNEO.—Mr. L. B. von Donop, in a letter of this mail, writes:—"I am just off up the Segama river to search for gold and see the country. The propects of this country could not be brighter everything is swinging along right merrily."

POLISHED SATINWOOD.—The cases and ornaments of the pianofortes are in many instances extremely beautiful, in others merely curious and extravagantly expensive, in none so tasteful as the old-fashioned spinnet and harpsichord cases of polished satinwood, painted with wreaths of flowers and knots of ribbon. —*From an Exhibition Report.*

GROUND NUT TRADE.—The ground nut trade in Pondicherry was recently a very large one, and thousands of bags were shipped from that port to France. The demand for storing space was so great, that every available dwelling house was rented by the merchants. The trade in ground nuts in Madras is pretty large. Last month the shipments to Great Britain, France, Bombay and Calcutta aggregated 15,926 cwt. valued at 63,719 rupees.—*Madras Times.*

CARDAMOM DRYING.—An Indian planter writes:— "Can you inform me whether Mr. Shand's patent tea drier will do for drying cardamoms. By doing so you will oblige me." We believe Shand's patent drier is admirably adapted for drying cardamoms, as well as cinchona bark, cocoa seeds and tea, and, being so cheap comparatively, it should be a very useful article on estates.

EURYA SERRATA.—This is a plant which is met with in all tea districts of India. It has considerable resemblance to the tea leaf for which it is often mistaken, and coolies have been known often to pluck it by mistake. It is desirable, therefore, to direct attention to the matter.—*Indian Tea Gazette.* [We suppose this is the plant called wild tea in Ceylon. A few plants appear occasionally in nurseries, but unless they were planted out amongst the true tea bushes how could coolies pluck the leaves?—ED.]

NEW INVENTIONS.—No. 135 of 1882 Robbins Thomas Cook., of Sylhet, Tea Planter, for an improved method of sifting tea and other produce or materials. No. 1 of 1883.—Andrew Charles Guy Thompson (Engineer), of Windsor Tea Estate, Darjeeling, for firing or drying tea or other substances and, when required, reducing and sorting the same into kinds or qualities while passing through the machine, or the several processes may be performed separately if desired, and is also applicable to withering leaf prior to manipulation.—*Indian Tea Gazette.*

CINCHONA.—The Earl of Kimberley, writing to the Madras Government, on the 15th March says:—"I have to inform you that cinchona seed was forwarded to you by the mail of the 23rd ultimo by letter post. The varieties and quantities of seed sent were as follows:—2 lbs. of Calisaya Verde, and Calisaya Morada seed in the husk, equal to 4 ounces of clean seed; 1 lb. of Calisaya Verde seed in the husk, equal to 2 ounces of clean seed; 1 lb. of Calisaya Morada seed in the husk, equal to 2 ounces of clean seed; and 2 ounces of Calisaya Zamba Morada, clean seed. None of the bark samples asked for by you have been received."—*Madras Mail.*

Correspondence.

To the Editor of the "Ceylon Observer."

TEA PLANTING: PRACTICAL HINTS.

18th May 1883.

DEAR SIR,—In your issue of the 16th inst. you mention a case where "150,000 two year old nursery tea plants were put out last season." It would be most interesting to know in what way the roots were treated, and if the trees were topped before planting.

My experience is against allowing the plants to grow to a greater height than 12 inches before planting in the field. This height tea plants will, under ordinary circumstances, arrive at in six to eight months from the date of putting the seed in the nursery. Six inch plants I consider preferable to those of a larger size, from the fact of the root being as a rule deeper than the height of the plant above the ground. Small plants, I find, scarcely cease growing when transplanted, whereas it is not unusual for those of more mature growth to remain in the ground for six months without making the slightest progress.

Germinated seed does uncommonly well in cleared land, but not where mana grass or weeds have been grown, poochies being frequently most destructive in the latter.

S. A.

[Windsor Forest was planted we believe with plants over 18 month old, but there is much in what "S. A." says about the readiness of six months' plants to grow after transplanting—that is, we suppose, provided they do not come in for the burst of the monsoon as they are put out.—ED.]

SILK CULTURE IN CEYLON.

Hope Estate, Deltota, 23rd May 1883.

DEAR SIR,—Mr. C. R. White may be able to obtain eggs of mulberry-feeding worms from the Indian Government. The eggs of *B. mori* that I was bringing from England began to hatch out on the 7th instant, about a week before we reached Colombo, and, though every effort was made to retard the hatching of the remainder, the young worms died soon after arrival. It is impossible to do more than experiment with *Bombyx mori* at present, as there is not a sufficiency of *mature* mulberry trees on any estate.—Yours faithfully,

P. N. B.

EXPERIENCE OF GROWING TEA FROM THE NURSERY IN CEYLON.

Ardallie, Agrapatana, 24th May 1883.

DEAR SIR,—As there seems to be a number of erroneous statements flying about the Windsor Forest tea, I may now try to put you right, as I put in the tea nurseries that supplied the first tea to Windsor Forest and Horagalla and Seaforth. In the first place, the tea seed was not from Assam: it came direct from Darjeeling, and first-rate seed it was. I had some 68 maunds, and on an average there was only about 6 per cent light. It was carefully packed in one maund boxes, mixed with charcoal, and the boxes lined with lead and inside the lead brown paper. The varieties of the tea seed were hybrid, and indigenous. The difference in the seeds I could not make out at the time, but directly they got above ground you could easily spot them, the leaf being a much lighter green than the hybrid and much longer. I finished putting in the seed into the nursery on the 30th December 1874. I planted over 9 acres of it by the middle of June 1875, and also supplied Windsor Forest and Horagalla with plants in July, the following month.

Plants grown down in a forcing climate like Yakdessa I consider would not be in good condition, 18 months old, for planting; and the great object in planting tea is to catch the first rains. This gives them a splendid start and they go on growing for ever. This is Ceylon experience.—Yours faithfully,

J. D. W.

SHAND'S PATENT* DRIER.

Colombo, 28th May 1883.

DEAR SIR,—I am much obliged to you for the reply you make to the "Indian Planter"'s enquiry as to whether my tea drier is also suited to drying cardamoms.

I had previously written to him to repeat what I wrote to you a short time ago, viz., that by putting a soup plate on a saucepan of water kept boiling, and placing on it some green cardamoms, he could ascertain whether the principle of my drier would answer the purpose or not. I also told him that, if the shells cracked in the process of drying, it would be owing to his own mismanagement and want of intelligence.

The fact is my tea drier will not answer for any purpose whatever in the hands of persons not gifted with an average share of intelligence, or who ignore the condition upon which successful results depend.—Yours truly,

C. SHAND.

PRODUCT OF A 17-YEAR OLD SUCCIRUBRA TREE.

Kalugala, Pussellawa, 28th May 1883.

DEAR SIR,—I am sending you under separate cover per today's post a sample piece of succirubra bark obtained from a tree which I have just uprooted on this estate, as I am well aware you take a great interest in all products. The following is the quantity of bark obtained from the tree, which was 17 years old. I may mention that the proportion of stem bark to branch and root seems small, but the tree many years ago got broken off, and consequently had not attained any great height:—

Stem bark ...	94 lb.	Net bark.
Large branch ...	143 ,,	
Small branch ...	42 ,,	
Root	100 ,,	

The monsoon burst here last night, but with little wind.—I remain, yours faithfully,

HENRY MANNERS.

[The specimen of bark is splendid and might well be mistaken for the finest yellow bark. The total quantity of wet bark is 379 lb., equivalent to about 126 lb. dry, which certainly ought to sell at 1½ rupee, if not 2 rupees on an average, considering the large proportion of stem and root bark. We should be glad to know the result. At 1½ rupee per lb. the result would be 189 rupees, or more than 10 rupees for each year of the tree's existence.—ED.]

IT is not as if the Tea Industry was an expansive one. Increased yield there will of course be as young gardens arrive at maturity; but new gardens will not for many years, if people are wise, be opened out. Men have already lost too much in tea to render this at all likely, besides which the supply even now exceeds the demand. What we say, then, to those who, for circumstances not arising from their own fault, find themselves stranded in India, is: Seek, while there is time, fresh fields and pastures new, and go hopefully and manfully to work to achieve there a success, or a livelihood even, unhappily at present denied to so many planters here.—*Indian Tea Gazette.*

WOOD FOR TEA BOXES.

TO THE EDITOR OF THE "INDIAN FORESTER."

SIR,—I notice in your Vol. IX. of January 1883, an article by Mr. Gamble, containing a list of tea box woods used in Darjeeling. He concludes his letter by asking some one to furnish a list of the woods used in Assam and Cachar. As the Tea Industry is not confined to Bengal and Assam alone, I would suggest a general list being compiled of all the woods used for making tea boxes in various Presidencies and Provinces througout India where it exists.

To further this suggestion, I send you a list of tea box woods used by the Planters of the Kangra District, Punjab—

Palampur Tehsil, Kangra District.

Chil...	...	*P. longifolia.*
Rai...	...	*A. webbiana.*
Tos...	...	*A. Smithiana.*
Oi...	...	*Albizzia stipulata.*
Tún...	...	*C. toona.*
Mango	...	*M. indica.*
Simmal	...	*B. malabaricum.*

Kullu Tehsil, Kangra District.

Kail...	...	*P. excelsa.*
Rai...	...	*A. Smithiana* (called Tos at Palampur)
Tos...	...	*A. Webbiana* (called Rai .. „).

These are chiefly used, though there are several other woods which I have no doubt would answer the purpose, such as Alder, Elm, Poplar (Phalse), Hill Tún and Chil. Deodar is not used for tea boxes owing to its strong smell of turpentine.

Hoping to see the general list added to.—L. GISBORNE SMITH.

THE NORTHERN TERRITORY AND COOLIE LABOURERS.

We have to acknowledge the receipt from the Minister of Education (Hon. J. L. Parsons) of a copy of a pamphlet just published by him upon the sugar-growing industry in Queensland, and the coloured labour question there and in the Northern Territory. The facts in this little work are so concisely stated, and in themselves are so interesting and so encouraging, viewed in relation to the prospects of our Northern Territory Plantations, that the wide circulation of the book can hardly fail to have a good effect in directing the attention of capitalists in various parts of the world to the rich fields which are waiting to reward their enterprise far away to the north of South Australia proper. Although a good deal of the matter of the pamphlet has been published already, it has never been given in such a connected form, or in such a way that it could be so easily available for reference. But whilst Mr. Parsons—ever warmly enthusiastic in his belief in the Territory's capabilities and prospects, and untiring in his advocacy of its claims as a field for investment—has, in commending the country to the consideration of moneyed men and sturdy working pioneers, marshalled many old facts and familiar figures, he has fortified them with news of late date. This interesting information, for example, had not previously been generally been generally circulated. A plantation has lately been started in the Rum Jungle District, with Adelaide capital, and it is cheering to find, on the authority of so experienced and reliable a planter as Mr. Henry Poett, that "Cinchona, with care and attention, does exceedingly well—better than in India. Some seed planted here only eleven months ago has given us a few plants whose growth for cinchona is splendid. I have never seen it equalled in Ceylon. On November 30 I marked these plants as 15 inches; today (February 12) they top a yard measure. This is a splendid growth for cinchonas, and I am much pleased with such success. I was very sanguine of their doing well, but they far exceed my most glowing anticipations. Of younger cinchona plants there are fully 10,000 promising splendidly, and probably 200,000 younger still. I never saw better prospects of the growth being successful than I now point to on this estate. *Coffee.*—There are from 150,000 to 200,000 young plants just putting out their fourth leaves, and a prettier, more successful, or more healthy nursery I challenge any one to show anywhere. *Cotton.*—There are thirty-five plants of this, it is the South Sea Island variety, and grows most beautifully. *Tobacco.—Indiarubber.*—A small parcel of seeds of both the above have been received and planted with due care. The latter will do well here, and I think tobacco will also, but of this plant I have not much experience."

Going from a direct advocacy of the Northern Territory, Mr. Parsons addresses himself to the task of proving that coolie labour will satisfy the necessities in this regard of the future planters. The practical fact is this. Apart from the opportunities afforded by the growth of rice, cotton, cocoa, coffee, tapioca, &c., the consumption of sugar in South Australia this year may be set down at 12,000 tons. The actual quantity imported last year was 11,373 tons. On sugar there is an import duty of £3 per ton, but when grown and manufactured in the Northern Territory it will enter free. There is room, therefore, for twenty-four mills, each producing 500 tons, or twelve mills producing 1,000 tons per annum, upon which the planters and manufacturers in the Northern Territory will be in a position of advantage to the extent of £3 per ton over foreign growers. According to the experience of planters in Queensland it requires an expenditure of £40 per ton on the milling capacity to produce merchantable sugar. There is room, therefore, for the investment of £480,000 in the sugar industry in the Northern Territory to supply the consumers of South Australia alone. The average total cost of all the sugar grown and manufactured in the Mackay district, laid down on the wharf at Mackay, is estimated at £14 per ton. The margin of profit, therefore, is sufficiently obvious. The percentage of profit of course will depend upon the care and skill of the planters, and the quality of the sugar manufactured. These facts, in addition to the advantages offered by the Indian Immigration Bill, should stimulate those who have the capital and enterprise to prosecute sugar industry with promptitude and vigour in the Northern Territory." When that devoutly to be wished for stimulation shall take place, as it assuredly will, the present Minister for the Northern Territory may lay the flattering unction to his soul that he has contributed in no degree to so satisfactory a result.—*Adelaide Observer.*

SUGAR GROWING IN THE PACIFIC ISLANDS.

The interesting letters which have appeared in our columns from correspondents in and connected with Fiji have touched upon the important question of the sugar-producing capacity of the Pacific Archipelagoes, and the importance the cultivation will assume in a not remote future, when the Pacific slope of Canada and the United States and the Australasian Colonies are more densely populated than they are at the present time. The most northerly of the many groups of islands dotting the surface of the wide Pacific, in which the sugar-cane is cultivated, comprises the Hawaiian kingdom, better known in Britain as the Sandwich Islands, whose cultured king visited these shores about eighteen months ago. There are eight islands in the group, and sugar is produced in five of these. Of these five, four—named respectively Hawaii, Maui, Oahu, and Kanai—produce so very largely, that the whole of the Pacific Coast of North America is chiefly if not almost entirely supplied with sugar from them. It is not yet twenty years since sugar was first exported from the Sandwich Islands, although sugar-cane is a native and had been grown for food by the people from time immemorial. It was found, however, that certain lands which had been considered desert were admirably adapted for the growth of cane, provided a means of irrigation could be devised; and a company was formed to construct an irrigating ditch that would bring a supply from a mountain stream about four miles distant to the land fixed upon for the pioneer plantation. The first venture succeeded so well and the plantation gave such large returns that plantations multiplied with great rapidity. In the year 1876 a reciprocity treaty was entered into between the United States Government and the King of the Sandwich Islands, whereby the latter agreed to receive all United States products duty free, provided the American Government allowed Hawaiian sugar to enter United States ports free of duty. This at once established the sugar industry of the Sandwich Islands upon a profitable basis. Capitalists from America crowded into the islands in quest of suitable lands, machinery of the best kind poured in from England and Scotland, and every one on these islands having capital was smitten with sugar fever. During the past six years the rate at which this industry has been extending is altogether unprecedented in sugar-cane cultivation anywhere. All the principal plantations have their fields irrigated by water led from streams distant in some cases as much as twenty miles. Very little rain falls on the leeward sides of the islands owing to the high mountains of their centres which drain the clouds as they pass. On these leeward slopes, however, wherever irrigation has been established, are the best sugar lands. The style of cultivation does not differ from that in New South Wales or Fiji except in the matter of irrigation, which forms a large item of expenditure. The cane fields on the islands are generally situated on the mountain slopes more or less elevated, say from 3,000 feet down to about 200 feet above sea level, the great object being to have a fall from a mountain stream, and a gentle slope for irrigation purposes. The soil of the field originally was a fine snuff-like dust upon which grew little else than cactus and a few weed-like bushes. The labour of clearing was consequently very small, and the fields are mostly unfenced, as no cattle or other animals are allowed to be in the vicinity of the crops. The great item of expense was the construction of irrigating ditches, and that in many cases has been very great. Most of the timber has to be brought from America, which is 2,000 miles distant.

The experience of the Sandwich Islands in sugar planting under such disadvantageous circumstances, and the success of the cultivation of sugar in Fiji, to which we have recently alluded, suggest an extension of the industry in other Pacific islands. The Island of Targatabu, for instance, one of the Friendly Group, measuring fifty-two miles by fifteen, is a natural home of sugar-cane, with a splendid soil and plenty of rain. If this fine island were annexed to the British Empire, plantations would soon cover it and prove very profitable. The other groups of islands, and New Caledonia, will also in time assuredly become great sugar lands, and will, in common with Fiji, find markets for their produce, not only in the States, but also in the ever-growing centres of population in the Australasian Colonies. At the same time, Australia itself, more particularly the Colonies of Queensland and New South Wales, and the Northern Territory of South Australia, are rapidly becoming producers, as well as consumers, of this important product.—*Colonies and India.*

BARK AND BARK-STRIPPING.

Data for ascertaining the weight of marketable bark from given quantities of timber of various sizes may be approximately obtained from the following figures, which are the result of calculations and observations extending over many years:—(1) When stripped out pretty closely, a well-grown and flourishing tree of large size may be calculated to yield 6 cwt. of bark for every ton of measurable timber. (2) Smaller trees averaging 10 ft. each will yield a ton of bark to 150 ft. of timber. (3) Hedgerow trees, well grown and in fairly open situations, sometimes give a ton of bark to three tons of timber. (4) In plantations, the proportions of the weight of bark to timber will vary greatly. Thickly growing trees may yield only 1 ton of bark to 4½ tons of timber. With ample space the same yield may be obtained from 4 tons of timber. Small blackrinds are generally found to yield 1 ton of bark to 5 tons of the wood. The age of the tree and the situation greatly influence the yield of bark. Short stems and spreading heads give the largest yield ; and long stems with slender heads the smallest.

The proper time to fell and strip a tree in order to obtain the largest weight of the most valuable bark is just as the buds are bursting into leaf. Afterwards there is both loss of weight and deterioration of quality. When the leaf comes fully out the loss is very great—often amounting to fully 10 per cent.

The less the inner side of the bark is exposed to the sun and to the elements the better. With proper curing under good protection or in a favourable season the bark will come to stack of a bright creamy colour inside. Injuries from hammering during the stripping or from undue exposure will give the inner layers a brownish hue. Wherever young persons or careless workmen are employed it will be necessarry to exercise a close supervision, or the smaller branches will not be thoroughly stripped. And it is well known that these yield bark containing the largest percentage of tannin matter.

A practised eye will generally tell at a glance when the bark of a tree will run freely. And it is of the greatest importrnce to ascertain this before felling. In a variable spring, with tolerably warm days and cold or even frosty nights stripping will be very uneven. Sometimes the upper branches yield freely while the body bark remains firm. In a mild or wet spring the work when once commenced generally proceeds uninterruptedly.

Open and airy spots should be selected for stacking and drying the bark, and these should be so situated that they may afterwards be approached without injury to the springs. A raised stage of peeled branches set up on forked sticks is preferable to placing the bark upon the felled trunks. With a proper but not too close a covering of the body bark a thorough harvesting may be expected in less than a fortnight in a dry season. The fitness of the bark for delivery can generally be ascertained by its brittleness, and by its snapping rather than bending under pressure. In this stage it has commonly lost about one-third of its green weight.

In districts where the bark is likely to suffer from excessive humidity it is well to be prepared with some kind of inexpensive covering which may be run up quickly when required. A light wooden framework covered with sheets of iron, either plain or corrugated, can easily be removed from place to place as required; and in wet seasons the outlay upon this will soon be repaid with interest.

The felling, flawing, cutting up oak-tops, delivering the bark, and clearing the falls cause a good deal of stir throughout the months of May and June in districts where Oak abounds and where thinnings are executed periodically. But the low price of bark, which seldom exceeds £4 5s. or £4 10s. per ton delivered, has left but a small margin of profit to the owners of woodlands.

The reproductive powers of the stools will depend very much upon the method of felling the timber and trimming off these. Whenever the bark is torn away down to the surface of the ground, or even below it, as is sometimes the case, the continuity of the dormant buds is destroyed, and no new shoots will spring up. But with comparatively young trees, whenever such are carefully felled and the edges of the stools are neatly trimmed off, a plentiful crop may be looked for.

The prices we have been paying for some years past are 32s. per ton of bark for felling, stripping, and stacking; 2s. per ton for tying up or binding in withes; and for loading and delivery on rail 3s. per ton and upwards, according to the distance from a station. The practice of chopping up the bark, which was once a common one throughout the district, and was paid for at the rate of 6s. or 7s. per ton, is now very generally discontinued.—A. J. BURROWS.—*Forestry.*

THE SUGAR-CANE IN AUSTRALIA.

Mr. Angus Mackay, the author of a book bearing this title, has enjoyed such special opportunities of studying the growth of the cane and the manufacture of sugar that he is entitled to speak on this subject as an authority. As a Special Commissioner of Queensland, Mr. Mackay has visited the sugar plantations of the West Indies and America, and there added largely to the knowledge and experience which he had already gained in the Australian plantations and factories. His book is divided into three parts, the first of which deals with the kinds of soil suited to the cane, and the best methods of cultivating it; the second part is devoted to the methods and experience of the most experienced and successful sugar-growers in Queensland as described by themselves; while the third division of the work treats of the various appliances and processes employed in manufacturing the sugar from cane juice. Mr. Mackay's style is lucid and straightforward, and his meaning is always easy to arrive at. The use of technicalities is avoided as far as possible, and numerous illustrations are employed to show the construction and use of the various mechanical appliances used in manufacturing sugar. The all-important question of the remunerativeness of sugar-producing in Australia is satisfactorily answered by Mr. Mackay. He decidedly affirms that it does pay, and will continue to do so if proper care and attention is devoted to the cultivation and manufacture. Sugar of the value of £30 per ton can now be produced in quantities at a cost of £15 and with the growth of experience and the use of improved machinery this cost will be lessened. The entire separation of the manufacture of the sugar and the cultivation of the cane has led to very beneficial results in the West Indies, and the author strongly recommends the adoption of a similar course in Australia. With regard to the cultivation of the cane, it is stated that it will not grow far from the sea, and thirty miles is the utmost distance from the coast at which it can be successfully cultivated. A free loose soil is required, rich in lime and vegetable matter, and a very open subsoil. Good sugar country is found in Queensland, in widely different conditions. Sometimes it is covered with dense scrub, sometimes with heavy forest, and occasionally it is open and lightly timbered. The latter, however, is rare, and the work of clearing is so expensive that cane-growing is an enterprise which requires a considerable amount of capital. The cost of clearing ordinary forest country is about £12 per acre, and when this has been done a further expenditure of £3 to £4 per acre is necessary in preparing the ground for planting. The average return per acre is about 30 tons of cane, from which 70 per cent of juice may be extracted when good crushing machinery is employed. This quantity of juice should yield from 3½ to 4½ tons of sugar, according to the quality of the cane and the skill and care employed in the manufacturing processes. From these figures it will be perceived that with sugar at £30 per ton a very handsome profit can be made on the first heavy outlay of capital in preparing the plantation. Full and minute particulars as to the proper method of planting the canes and keeping them in a healthy condition are given by the writer, who also describes and enumerates the various species of cane which have been grown in Queensland, and particularizes those which he considers the best. The exposure of the juice to atmospheric influences and excessive heat in boiling it are said to be the chief defects in the manufacturing process as it is generally carried on in Queensland. Mr. Mackay has employed with success a process in which vacuum pans are used and heat is applied by steam, and he believes that by this means the quality and yield of the sugar are greatly improved. The subjects of clarification and refining are extensively dealt with, and the opinions of many eminent authorities are quoted on the use of clarifying agents and machinery. The concluding portion of the volume is devoted to the consideration of other sugar-producing plants, and some interesting particulars are given with regard to the sugar beet which is largely cultivated in France, the American sugar maple, and the various species of palms which also yield the saccharine crystal. Various species of sorghum which have been introduced in different parts of Australia, and which yield an excellent syrup, may also be considered as sugar-producing plants. Mr. Mackay is of opinion that Australia will yet be a great sugar-producing country, and attributes the failure of some of the latest Queensland planters to want of care and knowledge, and waste of capital, through taking up larger areas than they were able to properly cultivate.

"The Sugar-cane in Australia" is an eminently useful work, and shows that its author has a good practical as well as theoretical knowledge of his subject, which is of very great importance to the future of Australia. The work, which contains several illustrations, is neatly got up, and reflects credit upon the publishers, is issued from the *Town and Country* Office, Sydney.—*Adelaide Observer*.

PICKLED TEA.

Mr. Hardinge's memorandum on the subject is as follows:—

"There is little doubt that the tea-leaf used by the Burmese, which is imported from Mandalay in its dry, as well as wet state, is obtained from the plant *Thea chinenis*, the tea of commerce growing in its wild state on the slopes of the hills in Upper Burmah, to the north and northeast from Mandalay to Bhamo. A leaf taken from a sample of the wet tea sold in the bazaar, has the same minute serrations, and is like the ordinary tea-leaf in shape, and possesses the aroma; moreover from reliable information received, I find that the Burmese tea-leaf is gathered from a bush or shrub never more than eight or ten feet in height, which grows on the slopes of hills, women and girls being employed in picking the leaf from the higher branches, and little children from the lower ones.

"The average price of Burmese dry tea in Rangoon compressed into balls (sample marked No. I) is from R85 to R90 per 100 viss (365 lb.), and is used by them (just as we do in infusion) sweetened with palm-jaggery, but is not used to a very great extent. It is said that the better classes of the Burmese here now prefer the cheaper China tea in infusion. It is noted that the Burmese tea can be purchased here by retail, at little over five annas per lb.

"Dry tea-leaf compressed into large cakes (sample No. 2) of a coarser description, is also imported into British Burmah from Mandalay, and sells here from R80 to R85 per 100 viss (365 lb.,) and is consumed by the poorer classes in infusion.

"But it is the *wet* tea-leaf which enters into all the domestic or religious ceremonials of the Burmese, which is the most consumed by them, for no marriage, or birth, or death, or ear-piercing, or feast, or any other event would be complete without the introduction of delicious morsels of the *wet* tea in (what is known) its pickled state, to be eaten by the guests invited thereat. It is also lavishly given to the Poongyees, who no doubt are its largest consumers. The information obtained is, that after the leaf has been gathered on the hills, it is packed in baskets and brought down to the waterside, damped, and sent down to Mandalay, where the following process of 'curing' or fermenting the leaf is practised. It is first steamed and then spread out on mats to dry; when dry, the leaf is deposited in a pit lined with bamboos or the large leaves of a tree common in Upper Burmah, and pressed down, layer over layer, until the pit is filled up, when it is covered over with the branches and leaves of trees and earth heaped over it. The tea-le f is left in that state for a month or six weeks, when it is considered fit for market use, being often sold on the spot while the leaf is in the pit, (each pit, according to size, being supposed to hold a certain number of viss), otherwise the leaf is tightly compressed into those curiously shaped bamboo baskets with two heads or knobs on the top (so familiar to travellers on the Irrawaddy); the baskets are then submerged for days in a creek near by, heavy weight being placed on them to prevent them floating up; they are then taken out and shipped into Lower Burmah, the great secret being always to keep the tea wet.

"The leaf as prepared above (sample No. 5) is eaten in its moist state, and undergoes no process of cooking. The addition of a little til-seed oil, a few slices of fried garlic, a sprinkle of salt and til-seed, and sometimes a little scrape of coconut, is all that is required to make it the most enjoyable zest a Burman cares to partake of.

"The wholesale price of the wet tea in Mandalay is from R159 per 100 viss, and the retail selling price in Rangoon is R2-8 per viss of 365 lb.

"One Pho Thoung, a wealthy trader of the Kyonktada quarter, and also Commissariat contractor, engaged a few Shans and Burmese, and sent them to Bengal, and from thence to certain Chittagong tea gardens, to manipulate the tea-leaf in its wet state (as eaten by the Burmese), and since that time similarly prepared *wet* tea, as received from Mandalay, has become an article of import into Rangoon by the sea-board from Chittagong. It sells in the bazaars here from R120 to R125 per 100 viss, or a little cheaper than the Upper Burmah leaf, but it is said the Burmese prefer the latter.

"One curious custom which obtains amongst the Burmese engaged in the wet tea-leaf trade, has been related to me with the greatest gravity and good faith. Should any person, male or female, living in the house of a dealer who may have a stock of, say, 50 or 100 viss in his house, get very sick, and if death is apprehended, he immediately removes his stock into another building, for were such person to die while the tea was in the house, the whole of it would turn bad and be completely spoilt. It appears this has happened over and over, and they implicitly believe in this incredible phenomenon.—*Indigo Planters' Gazette*.

POTASH AS A FERTILIZER.

The following letter appeared in a late issue of the *Mark-Lane Express*:—

TO THE EDITOR OF THE "ADELAIDE OBSERVER."

SIR,—Although an admitted fact that soils devoid of potash are incapable of yielding remunerative crops, it was considered, till quite recently, that very few soils were so deficient that the farmer need trouble about this substance.

For several years I have conducted numerous experiments with kainit with no marked results. During the last four years I have been working with muriate of potash of 80 per cent, and have obtained such very definite results that I consider them of sufficient importance to British agriculture to warrant me asking you to give them publicity.

From very many experiments I will cite but three, but these have so marked a character that they cannot but be of interest, even should they not lead many farmers to experiments for themselves.

1. In March, 1881, Mr. William Betts, of Flitcham, was induced, by previous year's experiments, to apply to a 40 acre field of new ley 10 stones per acre of muriate of potash, leaving unsown two strips each, of about 30 yards in breadth across the field. The salt was applied later than was advisable, and the small rainfall of the next two months was insufficient to wash it in. A poor crop of hay was reaped, so little better than the portions undressed that it was not deemed worth while to determine the difference in the yield of equal dressed and undressed portions. This year the field, being in wheat, showed so plainly where the potash was missed that it was generally admitted by the many farmers who visited it that, at least, there was from a quarter to one-and-a-half quarters of corn per acre more on the dressed land. Unfortunately this harvest time was so fickle that no time could be spared to cut out measured plots for an accurate determination of results.

2. Mr. Alfred Oldfield, of Grimston, applied in the early spring two cwt. of muriate of potash of 86 per cent to an acre of clover ley, leaving the remainder of the field undressed. Plots of 20 rods from the dressed and undressed portions were cut and made by themselves. Weighed as the crop was carted to the stack, the results were as follows:—The dressed portion gave equal to 3 tons per acre; the undressed, 2 tons 2 cwt. 4 lb per acre.

3. In April last I was requested by Mr. F. J. Cooke, of Flitcham Abbey, to give an opinion respecting three acres of barley, a portion of a 40 acre field. I found the three acres in question had been sown last year with white turnips, the rest of the field with swedes. The white turnips had been clean drawn for early lamb feeding; from about one-half of the three acres both bulbs and tops were carted off, from the other only the bulbs, the tops being left in rows. At barley sowing these three acres received per acre 2 cwt. nitrate of soda and $2\frac{1}{2}$ cwt. superphosphate of lime. Yet at the time of my visit, the barley was yellow and sickly to a degree, offering a most striking contrast to the adjoining barley on the swede land, which latter crop was fed on the land by fatteuing hoggets. I noticed strips where the tops of the white turnips had rotted in the autumn looked decidedly better than the spaces between, and then about one acre where both tops and bulbs had been carted off. The idea at once suggested itself that deficiency of potash in the soil was the cause of this unhealthiness. I advised an immediate application of from one to two cwt. of muriate of potash per acre. This was done on the worst acre. Rain immediately followed. At once a marked improvement took place, and which was more and more pronounced as the season advanced. Where the potash was not applied, the barley, a good plant, struggled to develop ears, but failed totally to perfect any corn; the stems were weak, very few able to maintain an erect position. When I went in August to assist Mr. Cooke to mark out plots for careful separation and estimation of bulks, he agreed it was quite useless to mark a plot on the portion undressed, as there was no corn; a few "shapes," probably a quarter per acre, certainly no more. A plot of 12 poles of the dressed plot was staked out, the barley stooked and afterwards carefully thrashed. The yield was 11 pecks or 40 qurs. 1 bush. per acre.

These experiments have been accompanied and preceded by numerous others, all teaching the same lesson with varying emphasis. The conclusions unmistakably forced upon me by them are—That the varying fertility of soils not only depends on the presence of available phosphates and nitrogeneous compounds, but in a very important degree upon the presence of available potash. The fact has been long established by M. Georges Ville, that with potash absent, no healthy growth is possible; but it is not yet generally conceded that a large proportion of our English fields have been by cultivation so robbed of potash as to be unable to yield maximum crops of clover, pulse, mangels, and even in some cases of corn, even when dressed by phosphates and nitrogen. How important this question is to agriculture in its present depressed condition it appears to me impossible to over-estimate. If, as my experiments declare possible, by an outlay of 8s. to 12s. per acre in potash, an increase can be obtained of three-quarters of a ton of hay, of one quarter of corn, of three tons of potatoes, of ten tons of mangels, it needs no philosopher to show the importance of experimenting at least on the various soils of other districts.

Soils themselves ought to be solicited to inform the cultivator whether potash is deficient or not. If by adding this substance to plots of potatoes, grasses, peas, beans, or mangels, no increased yield is obtained, the land replies that potash exists in sufficient abundance. If, however, a marked increase results, the land replies that it requires an addition of potash to acquire the power of building up maximum yields of these crops.

I would not advise any extensive experiment on wheat, barley, or oats, save on barley following white turnips, mangels, or vetches, where these crops have been removed from, not fed on, the land. On naturally poor land a marked result may then confidently be looked for.—I am, Sir &c., THOMAS BROWN King's Lynn.

ON IMPROVEMENT IN THE PREPARATION OF JAPAN TEA.

(Translated from the *Keizai Zashi* Correspondence.)

Political economy tells us that the variations in the prices of commodities are caused by their exchange for the labour required for producing them, and that the price of the former arises from the value of the latter. The labour is therefore the greatest factor of all those which regulate the prices of commodities. Now the sum of 10,000,000 *yen*, brought by the exportation of our tea, will have mostly to be put into the pockets of those who manufacture this staple article. How great a bearing has this branch of industry upon the welfare of many of our people! The time being near the tea season, affords me a fair occasion to allude a little to the improvement of the present tea manufacture, although it may only be like "looking at the heavens through a reed."

The recent fall in the price of tea is entirely due, it is said, to the bad manner in which this article is manufactured. "The lamplight goes out because the oil is all gone," and so there must be a certain cause that has brought about this depreciation. In my opinion it is due to the spirit of selfishness amongst our tea producers. According to the present system of our tea exportation, it is delivered equally to foreigners, without any distinction of good or bad, or any reference to the names of the producers. In America, as a matter of course, and even in our open ports, foreigners do not know the name of the producers, and therefore the latter have no means of making known their names by the good quality of their tea. It is therefore a natural result that they are not inspired with any wish to improve their productions. Their honesty and skill are also entirely unknown amongst the foreigners. The producers are not indiscreet nor lazy workmen, yet the aforesaid condition tends much to induce them to engage in dishonest practices in manufacturing this staple article. Moreover, a foreign gentleman well acquainted with the trade said a short time since, it is often the case that the more the capital, the less the profit, and therefore the producers dare not attempt to increase their profit by altering or improving the present system of manufacturing at the cost of their funds.

Now the only means by which we can get rid of such an evil is to establish a system of using trade marks to distinguish the qualities of the teas, or marking the different kinds according to the different system of preparing them for the markets. It is an easy task to prepare tea for market, inasmuch as in Yokohama, women and children are employed for the propose, and they are quite sufficient. Moreover, tea is quite free from any deterioration or change in color or quality for many months, if it be prepared a few days after picking, and be packed in boxes lined with paper. If it were so prepared, we should be enabled to exclude inferior qualities, and the taint on the leaf so often experienced by foreigners, and at the same time give buyers the satisfaction of drinking a good cup of tea. It is not good policy to prepare it at the open ports, for we can have it for half the cost that the foreigners have to pay, if we prepare it in the districts in which it grows, and where firewood, coals, &c., are cheaper, and wages, lower in comparison than those paid in Yokohama. The fact that the foreigners expend much money on their tea firing establishments, which number more than 50 in Yokohama and Kobe, clearly shows that they must make considerable profit. Our native growers expect to get a good profit out of a little labour. In India and China the producers go to considerable trouble in superintending the preparation of their tea, and in the former country the system of packing is carefully carried out. Should our growers take the trouble to see their tea properly prepared and packed, and have a distinguishing brand for good and bad qualities, so that the purchaser could know which quality he was buying, then it would be to the advantage of the producers, because if his tea was of a better quality than that of other merchants, he would, of course, sell more of it, and thus would endeavour to keep the quality always good.

Therefore, if the foreigners could buy the tea from our producers at a fair price and also good, there would be no occasion for them to keep up their tea-firing establishments. Should this come to pass, not only would it drive away bad tea from our market, but the foreigners would have no cause for complaint regarding the quality of their purchases, and the consumers of the tea would be perfectly satisfied. We think, therefore, that in order to do away with inferior teas it is necessary for the producers to prepare and pack the tea themselves, and have each box stamp with their trade-mark. Yet, of course, these improvements in the tea trade we have just spoken about, would be discountenanced by foreigners at first, who, not understanding them, would endeavour to thwart our objects. Such objections, however, are not to be feared, as long as we are honest enough to deliver them as good or better tea than heretofore. By these means also, the present foreign merchants would gain the advantage of being able to ship the article immediately after purchasing, and would find it to so much to their interest, that they would begin to wonder why they had never found out this system before. The success of such a brilliant undertaking as the foregoing, of course, depends entirely upon the producers themselves. In India and China we hear there is no such system of delivering tea as is adopted in our country. Even the Chinese who are such a mean, cunning people, have sufficient confidence in one another. I dare not ask the tea producers of this land, the land of the "Rising Sun," why they so mistrust each other?—*Japan Herald.* [Our readers will be interested in seeing the views of a patriotic "Jap" on the tea enterprise of his country. But if, as we imagine, tea is grown in Japan as it is in China, in small patches by the peasantry, we do not see how they can afford each to prepare and pack.—ED. *T.A.*]

INCUBATORS.

The Chinese and Egyptians have, for thousands of years, had the secret of hatching eggs without the intervention of the hen. Indeed, it would seem almost a matter of course that the inhabitants of tropical countries should early have learned this art, from watching the method by which the eggs of turtles, alligators, etc., are incubated, being simply buried in the warm sand of the river's bank. As early as 1750 the French scientist, De Réaumur, perfected a process of artificial incubation, which, though successful, was not practicable for ordinary purposes. During the past twenty years, however, the attention of poulterers has been freshly drawn to this question, and now the number of appliances for artificial incubation bids fair to equal the patent bee-hives.

"The essentials of a successful incubator are three: an equable heat of about 105 degrees; sufficient moisture in the atmosphere to prevent an undue evaporation from the egg; and ventilation." * * * *

"It has been found that the mercury may rise to 110 degrees without injury to the eggs, provided it does not remain at that point more than a very few minutes, or it may sink as low as 50 degrees, for a correspondingly short time; but should it remain below 100, or above 106 for many hours, all the labor expended upon the lot of eggs which the incubator may then contain will have been thrown away, while, as will be seen, it requires a very delicate instrument to quickly appreciate the difference between these degrees of heat. * * * *

"The practical difficulty about these machines is the extreme delicacy of their construction, rendering them liable to get out of order in inexperienced hands, and thus to cause a great loss of eggs. Of course the manufacturers of each machine claim that theirs is absolutely perfect, and that these objections pertain to all the others; but the testimony of disinterested parties who have given a large number of the best machines a thorough trial, is that not one of them is always reliable, and that all are sure to give trouble to beginners in their management, although one who has had experience in handling them may hatch a large proportion of eggs than is usually done by the average hen. * * * * * * *

He then gives a description of what may be termed a *home-made* incubator, except the galvanized iron tank which must be procured from a tinner, or worker in galvanized iron; and this is supposed to do as good work as the more costly and patented machines. As we have not the illustrations given in the book, we have made some verbal changes which refer to them. He says:—

"Have a pine case made somewhat like a common chest, say three feet square. About a foot from the floor of this case, place brackets, and on a level with these screw a strong cleat across the back of the case inside. These are to support the tank. The tank should be made of galvanized iron, three inches deep and otherwise proportioned to fit exactly within the case and rest upon the brackets and cleat. The tank should have a top or cover soldered on when it is made. At the top of this tank in the centre should be a hole an inch in diameter with a rim two inches high, and at the bottom, towards one end, a faucet for drawing off the water. When the tank is set in the case, fill up all the chinks and cracks between the edges of the tank and the case with plaster of Paris to keep all fumes of the lamp from the eggs. Fill the tank at least two inches deep with boiling water. To find when the right depth is acquired, gauge the water with a small stick. Over the top of the tank spread fine gravel a quarter of an inch thick; over this lay a coarse cotton cloth. Place the eggs on the cloth, and set a kerosene safety-lamp under the centre of the tank. The door of the lamp-closet must have four holes for ventilation, otherwise the lamp will not burn. The lamp-closet is the space within the incubator under the tank. Turn the eggs carefully every morning and evening, and after turning sprinkle them with quite warm water. Two thermometers should be kept in the incubator, one half-way between the centre and each end; the average heat should be one hundred and five degrees. If the eggs do not warm up well, lay a piece of coarse carpet over them. If they are too warm, take out the lamp and open the cover for a few minutes, but do not let the eggs get chilled. If they should happen to get down to ninety-eight or up to one hundred and eight degrees, you need not think the eggs are spoiled. They will stand such a variation once in a while; but, of course, a uniform temperature of one hundred and five degrees will secure more chickens, and they will be stronger and more lively. In just such an incubator as this one I have described, I hatched over two hundred chickens two years ago.'

"Several forms of artificial mothers, however, have been invented—and most of them, of course, patented—of which the inventors claim that they far surpass the natural mothers, in that they do not drag their chicks through the dew, nor trample them to death, nor cover them with, vermin; all of which, no doubt, are positive advantages, but in practice these advantages have been offset by the lack of the instinctive care of the mother hen. The artificial mother may frequently be used to advantage, however, in supplementing that care.

"The essential points of the artificial mother are a sheep-skin tanned with the wool on, or a piece of buffalo robe or similar material, fixed with the wool side down upon a frame which will hold it just high enough for the chicks to creep under, and which may be raised to suit their growth; and a system of pipes, or a water-tank similar to that used in the incubator, placed over the sheep-skin, and warmed as in the incubator. The 'mother' should also be placed in a room warmed with a stove, for the more easy regulation of the heat.

"While the incubator and artificial mother are certainly not what is claimed for them by some of the more sanguine of their advocates—especially those who have a pecuniary interest in selling them—there can still be no doubt that they may be made of great service in the poultry-yard, in the hands of persons who have the time and natural adaptitude necessary to give that close and judicious attention to the details of their management which is absolutely necessary to success."—*Southern Planter.*

ASBESTOS.

One of the most remarkable of all the products of Nature's mineral factory is that whose title heads this article. Everyone knows, of course, that asbestos possesses the strange and valuable quality of being indestructible by fire. Indestructible, that is, in the conventional sense of the word, for, strictly speaking, fire can destroy nothing—it can only decompose. But asbestos is the only substance which is not affected by any heat, however great or however long applied. It is from this fire-resisting quality that it receives its name, asbestos, or amianthus—the former signifying "indestructible," and the latter "the undefiled." Every schoolboy knows—or in these days ought to know—that the former title is derived from the Greek negative "*a*" and "*sbestos*," an inflection of the verb "*sbennumi*," to destroy; while the latter comes from the Greek "*amiantos*"—*a*, not and *miaino*, to pollute.

To give a history of this remarkable mineral product would be a pleasant task, and one which would, for its proper treatment, make considerable demands on the learning, research, and literary powers of the historian. On such a task—seductive though it be—we have no intention of entering. One or two points may, however, be briefly noted. Asbestos was certainly known to the ancients. The Egyptians made cloth of it; while napkins, as well as paper, and probably other articles, were made of it in the time of Pliny. But there is little doubt that the singular power of asbestos to resist heat was utilised in bygone times for the purpose of performing many so-called miracles. It is not improbable either that the ancient ordeal by fire was frequently accomplished in safety by the aid of asbestos, the fibres being imbedded in a kind of paste which adhered to the skin of the hands. About the year 1500 asbestos was manufactured at Venice, and from that date it has been applied to more legitimate purposes. Some half century ago, an Italian gentleman, the Chevalier Aldini, travelled through Europe for the purpose of demonstrating his method of utilising asbestos as a life-saving agent. Some of the public exhibitions given by the ingenious Italian were sufficiently astonishing and clearly showed the marvellous power of asbestos and its usefulness as a protection to firemen. One very striking incident occurred at some experiments which were conducted in Paris. A fireman bore on his back a wicker basket, which was covered with metallic gauze, and in which was a child, whose sole protection was a cap made of asbestos cloth. In opposition to all advice this man rushed with his little burden into a narrow place where the flames were raging twenty-four feet high, and whence a thick smoke issued, so that the spectators had to seek a "more removed ground." The man and child were absent so long that fears began to be entertained for their safety, but at length they issued from the fiery gulf uninjured; the man not a little proud of the success with which he had braved so great a danger. Some thirty years later a person calling himself the Fire King gave some similar exhibitions in London, but more as a public entertainment than as a means of showing the value of asbestos.

Since then asbestos has been somewhat spasmodically dealt with as an article of commerce and manufacture, and it is only quite recently that its marvellous adaptability to many different purposes has been fully recognised. What these purposes are and the means by which asbestos is applied to them would make demands on our space which could not well be met. Some of the principal may, however, be noted. Asbestos millboard is largely used as a material for steam joints, and for this purpose it must be manufactured not only from the best material, but in the best manner, for to produce a perfect material for steam joints it is necessary that special knowledge be applied to the selection of the right fibre for the purpose, and that this be manufactured in the proper manner. Another similar preparation is the Asbestos and Indiarubber Woven Sheeting. Hitherto whenever a joint has been exposed to much moisture, indiarubber sheeting has been largely employed, but by combining indiarubber and asbestos there has been produced a material which defies alike the influences of heat and moisture, and which affords in consequence absolute security to any joint. This is one of the most valuable and important of this class of productions, for every user of steam power knows the full meaning of the term "imperfect joints." Somewhat analogous preparations are the Asbestos, Indiarubber and Woven Tape, and Asbestos Fibre. The former is so constructed that it can be bent to any circle without puckering, and being composed principally of asbestos is practically indestructible. Manhole cover joints made with this material, after fifteen months' working, and having been lifted nine or ten times during that period, have been found to be as good as when first made. The fibre is for special engineering purposes, and is made from the long Italian variety, carded and combed by special machinery, without the intervention of any acids. One very valuable preparation of asbestos is the Patent Asbestos Covering for Steam Pipes. This is a combination of asbestos and hair felt, and is a simple, cheap, and effective means of preventing radiation, and of thus saving fuel. The *modus operandi* is as follows:—Flexible asbestos millboard, specially prepared so as not to tear, is wrapped round the pipe to be protected, and over this is put a layer of hair felt, the final layer being oil-cloth. The mention of this brings us to the Asbestos Boiler Covering Composition, an effective and economical coating for boilers. It is quickly and easily applied, whether the steam be up or not: it adheres readily, and preserves the metal from rust; while seven hundredweight will cover 248 square feet to a thickness of two inches. As a preventer of radiation and a consequent saver of fuel it has no superior.

The basis of nearly all of these productions is, of course, Asbestos Yarn, and this is manufactured without any admixture of vegetable fibre, and so strong that six folds possess forty pounds tensile strength. From this yarn is obtained Asbestos Cloth, which is much used in filtering acids and in some very excellent patent filters. It is also used as a protection against fire in theatres. The pure asbestos yarn is also made into a steam-tight rope, forming, without any covering, a most efficient and durable packing. This packing is prepared without the use of any chemicals, and, while of great strength, is as soft and flexible as silk. It is, and has been for the past three years, used in the British Navy, and has also been adopted by several foreign Governments, including that of Germany. Another similar production is the New Asbestos Yarn and Soapstone Packing. This is a combination of asbestos yarn and soapstone, which, after having been bound together, are plaited over with a covering of the yarn, thus forming a packing which will not harden as so many similar preparations do. Asbestos Fuel for gas fires is another and well-known preparation, but indeed the forms in which the famous mineral is prepared, and the purposes to which it is applied are not only numerous, but appear to be on the increase. It is satisfactory to know that modern science seems to be quite alive to the value of asbestos, and equally determined that the world shall enjoy the full benefit obtainable from it.—*Home and Colonial Mail.*

THE PROFITABLE DISPOSAL OF MANURE.

Under the ordinary system of agriculture the use and disposal of manure is perhaps the most important part of the farmer's business, and that in which experience and good judgment is the most called for. Its importances is shown in the wide differences of opinion in regard to the question, and the frequent discussions of it in farmers' meetings, as well in the changes of practice which occur from time to time. For if it were a simple matter that could be decided by a few experiments or a short experience, it would be easy to arrive at a satisfactory decision in regard to it. But to a great extent we are "all at sea" upon this subject, and there are great differences of opinion among farmers about it. Perhaps this is due chiefly to the habit of looking at a question from a single point of view, and of discussing it without keeping clearly in sight the objects aimed at. The means, of course, are always to be adapted to the end and purpose desired in all farm operations, but if these are not fully considered, one may easily be led astray and become disappointed in the result of his work. That there is great uncertainty in respect of the best methods of disposing of manure for various crops is shown by the frequent requests for advise and the constant fruitless discussions which appear in the agricultural journals and in the report of farmers' meetings. One of the points of difference is as to the effect of mixing manures; another is as to the manner of applying it—whether in the hill or drill or on the surface by plowing it in, and another as to the advantage of spreading it upon the surface as it is taken from the stables, or of putting it in heaps in the fields be to spread afterward. It might be well to go over each of these points singly and discuss each in turn.

Mixing manure or fertilizers is a laborious work, and if nothing is gained by it, it is labor lost. But something may be gained by it when the condition of the material can be changed for the better, and at the same time something may be lost when anything can be changed for the worse. In composting, for instance, such raw substances as swamp muck, leaves, tannery wastes, or other wastes, with manure, or in mixing various manures, as from the horse stable, cow sheds, pig pens, and poultry-house, valuable results may be obtained; while in mixing lime or wood-ashes with manure, and especially in making the common fertilizer with poultry manure and wood-ashes, harm may be done and valuable fertilizing matter may be wasted. In the one case the more actively fermenting horse or pig manure will serve to decompose more readily the colder cow manure, and to produce decomposition in the abundant litter or raw matter that may have been used. Besides, when the whole manure heap has been reduced to an even and homogeneous condition and quality, it is made more valuable for use in the field, and neither unduly or wastefully enriches one portion of it while in adequately fertilizing another portion. It is therefore a judicious and useful practice to mix these manures or these waste substances in the heap, either in the yard or the field, and so add considerably to the value of a part without detracting from the value of other portions. But in the other case much harm may be done by mixing any substances in the heap which may exert an injurious action upon the others. This may happen when lime or wood-ashes are mixed with the manure, or with the poultry manure; and the more harm is done, the richer in ammoniate manure may be. Lime and potash are alkalies, and when fresh are in a caustic condition. That is, they are free or nearly so from carbonic acid, which, when combined with an alkali, renders it neutral, or mild and inert. When fresh lime or wood-ashes are mixed with manure, they at once seek to combine with carbonic acid from whatever source they can procure it. Ammonia is an alkali, and manure is generally in combination with carbonic acid as carbonate of ammonia. The lime or wood-ashes take the carbonic acid from the carbonate of ammonia, and the ammonia escapes as a gas into the air, and so far as the owner of the manure is concerned this ammonia is lost, and as ammonia is the most valuable and costly fertilizing element in existence, the loss is very serious. It is easy, however, to avoid this loss by using the lime or the ashes by themselves on the soil, and not with the manure directly, in which way they will do as mu h good.

But sometimes it is advisable to mix lime or wood-ashes in a compostheap, and this may be done safely when this especial behaviour of these indispensable substances is understood. If the manure is quite fresh, there is very little ammonia in it, and if there is more, a large propotion of absorbent matter, as swamp muck, in the heap will absorb and hold it, and carbonic acid will be produced by its decomposition in sufficient quantity to saturate the alkali of the lime or ashes or to take up the ammonia as fast as it is formed or set free. In fact a farmer who understands the chemical decompositions and combinations which go on in a heap of decaying manure or compost may use lime or wood-ashes with safety and with advantage. With regard to the common mixture of ashes, hen manure, and plaster, too, this may be safely and beneficially made at the time it is to be used, but not if it is left to remain mixed for any considerable time previously.

The manner of applying manure in the field is a question that deserves special consideration. It goes without saying that top-dressing. Fall grain or grass land is a part of the question that settles itself, because it admits of but one manner of doing it. But the application of manure to stubbled land, or for such crops as corn, potatoes, or roots, may be made in so many ways, that it is reasonable to believe there will always be differences in regard to it while "many men are of many minds." Some advocate spreading the manure upon the surface and plowing it under; some would rather plow first and spread the manure by harrowing it, even when it is fresh and coarse, and is gathered into heaps under the harrow to be spread and spread again and again; others think it better to apply the manure in the hill or the drill, and plant the seed directly upon or under it. The first of these methods is easy, effective, and, on the whole, an excellent one, but the second has some palpable disadvantages which condemn it. It is troublesome and the reverse of neat farming. Moreover, it is not putting the manure where it will do the most good, which is clearly as near to the roots as possible. It is true that the soluble portions of the manure will be carried into the soil by the rains. But in such dry seasons has have occurred for the past few years, crops have suffered and starved for want of the food which has laid baking and roasting upon the surface. Again the roots of plants themselves are able to get considerable food from undecomposed organic matter by their own ability to reduce it to decomposition, and this may be seen very plainly in the case of a corn-plant which has grown in a hill that has been manured by a shovelful of half-rotted or even fresh manure. The roots have penetrated and embraced the manure completely, and have formed a dense mat in and about it, so that when the stub is pulled up the remains of the manure have come with the roots. So that it appears to be a waste of manure to spread it upon the surface unless it is so fine that the harrow will mingle it thoroughly with the soil to the full depth which the teeth penetrate. With coarse manure it seems clear that it is better to spread it before plowing and cover it, so that it is evenly mixed between the furrow slices, and can be afterwards intimately mingled with the soil. And, indeed, it might seem best to follow this method even with fine manure, for it is very certain that the young plant comes up all the stronger and more vigorously when its first roots are provided with an abundance of food as soon as they are ready for it, which is as soon as they begin to penetrate the soil in search of it. Indeed, for the clear understanding of the necessities of this part of farm practice, farmers must study and become acquainted with the facts relating to plant growth.

As regards the too prevalent practice of spreading the manure in small heaps on the field, and leaving them for months before it is scattered over the surface, too much cannot be said against it. It is waste both of material and labor. Heaps so left lose a largeportion of their soluble contents by the washing of rains or the melting of snow, and this goes into the soil under the manure, which is in fact manured in consequence of this at a rate equivalent to many hundreds of tons per acre, while the rest of the ground must necessarily be robbed of its share. Many years ago the writer, then a young farmer following the methods to which he had been used, thus spread the manure on a field for wheat, and left it for less than two months before it was spread. The next year the wheat grew enormously on the spots where the heaps had lain and rusted badly and the straw fell down, while the rest of the field showed the plainest evidence that it needed what had been wasted elsewhere. The lesson has remained, and it is recalled with much force when a field is seen dotted over with manure heaps too soon after the oats have been cut or when the snow lies upon the ground, or whenever this subject is discussed.—*New York Times.*

INDIARUBBER.

The last *European Mail* and the *Planters' Gazette* of the 1st ult., each contained short notices of the recent discovery made by Mr. Jenman, the Government Botanist and Superintendent of the Botanic Gardens, of two new India-Rubber, and Gutta-Percha trees in the interior, and his report on these has now been published in the *Official Gazette* by the order of His Excellency the Governor. Our readers may remember that Mr. Jenman wrote a previous report on the Hevea Spruceana, which was published last year, and the present one may be considered to be supplementary to that. Then the Essequebo and Mazzaruni Rivers, and the creeks connecting with these, were the localities described, now he takes us to the Pomeroon River, and gives a most interesting account of his operations there. From his description the Hevea, or Hatie,—the Arawack name of the tree, and the one most generally known by the River residents,—is very similar to the Para rubber tree, attaining about the same dimensions, and growing precisely under the same conditions. Low lying ground, frequently under water during the wet seasons, and densely shaded, seems to suit them best, as where these conditions most uniformly prevail, in the localities where they are found, most of the trees occur. The Hevea, at its best, is not a large tree, rarely exceeding twenty inches in diameter, and squaring for timber to about fourteen or fifteen inches. The bark is thin and smooth, and on trees, a foot or more in diameter, it is not more than a quarter of an inch thick. "When found in high forests, surrounded by others, the trees are quite straight and erect, and attain a height of sixty feet or more, with a few branches at the head." As to the rate at which the Hevea grows, Mr. Jenman can only adduce evidence gathered from the residents of the rivers and forests of the colony. An intelligent lad, a half breed, who has been acquainted with the tree from his youth estimated "speaking of it, of course, in its natives habitats, that it attains a diameter of eight or nine inches in five or six years." This Mr. Jenman considers must be its extreme rate of development under the most favourable conditions; still it is a sufficient guide to those who may entertain Mr. Jenman's advice to undertake the cultivation of the tree in some of the many localities suitable for its growth.

These will be found on all the rivers of the Colony below the falls, and will thus be accessible without difficulty or expense. "The cultivation might be successfully pursued, not only where the trees are found spontaneous, but, as well, on land of a similar or identical character, though in which, through other circumstances, they are not naturally established." The labour required would be very inconsiderable, and a few hundred acres, treated with care and intelligence, would prove, in the course of years, a source of considerable means to the proprietor. "If planters in Ceylon and India speak hopefully as they do, of the eventual success of Hevea cultivation in those countries, here possessing all the natural conditions, and the advantages derived from an intimate acquaintance with these under the actual occupation of the trees, the success should be assured. Wherever the tree is found, in the fruiting season—April to June—seed may be procured in fair abundance. If sown at once under the trees in nursery beds prepared from the lighter soil and leaf-mould which the forest affords in places, the plants would spring up rapidly, when they might be carefully lifted, with their rootlets unbroken, and planted at intervals under the other trees. Where the latter are too close to admit the amount of light required, they should be thinned out first; and it might be necessary to carry this on with care from time to time with the increasing requirements, both for room and light, of the planted trees. In some seasons and places it would be unnecessary to collect and sow seeds as natural seedlings may be gathered under the trees."

The Hevea cultivator should be prepared to wait for his crop, but meanwhile any trees already on the ground might be utilised, and the produce sold. Seeing the increasing demand for indiarubber, with the daily extension of its application, and particularly the value of Hevea rubber, as compared with other kinds, the results of the enterprize might be looked forward to with the utmost confidence. Manufacturers will take all they can obtain, and were it only more abundant in the market and cheaper, many new uses might be found for it. "To give an idea of the importance of the Brazilian trade in rubber, I may mention that the export from Para for the half-year ended June last reached the value of R12,350,000. It illustrates, as well, the value of the industry which is within our reach. The present market value of Para rubber is 4/6 per lb. The cultivation might be carried on in conjunction with woodcutting, plantain growing, or any other immediately remunerative industry which would enable the cultivator to tide over the time till the trees reached the age of production."

Having shown how the tree may be cultivated, Mr. Jenman next deals with the yield, and the method of collection. From experiments on good trees he has come to the conclusion that each cut may give half a cup-full of juice, there being 15 cups to the English imperial pint. The chief difficulty seems to be in the method and means for collecting the juice, and for this purpose he recommends cups that are round or flat, or slightly concave; the latter being the best as they fit more closely when pressed against the tree. They are made of burnt clay and can be readily obtained at a cheap rate from Caribisci Indians, being fastened to the tree immediately under the incision made by the collector's axe, by a small lump of well-wrought clay. In the Pomeroon where the tree grows, he found a very suitable clay which he employed in his operations. "Nothing is gained by making numerous cuts close together; the flow of juice should be allowed to take place by a few rather than several exudations. If it occurs from too many for a certain area, so little is obtained from each as to be a mere drop or two in a vessel, which, diffused over the large surface of the several receptacles, involves a proportionately large loss by surface, adhesion, in addition to the time and labour taken up by extra work. A circle of incisions is made each day, extending from as high as one can reach, and working downwards day by day to the base of the tree. They should be made about six or eight inches apart; the incisions in the circles being in quincunx order."

Mr. Jenman then goes on to describe the new tree which he discovered in the Pomeroon, and which he regards as of "great interest and importance." The tree appears to be a species of *Ficus* or *Urostigma*, but in the absence of flowers or fruit it can only be identified conjecturally, and he adds "the colony abounds in different plants of the above given, of which presumably other species to this are also valuable," some of them being known to attain large dimensions. The method of collection seems very simple. The bark is cut and then left, and the milk which oozes from the wound dries in a few days. This is then stripped from the bark, and rolled up in the shape of a ball, the rubber being exceedingly strong and tenacious. "This method of collecting is that pursued in Ceara, the province of Brazil, which produces *Manihot Glaziovii*. It is very economical of time, for it saves the tedious operation of catching the milk in a vessel as it issues from the wound, which is the most bothersome of all the operations. The principal objection to it is, that the rubber becomes soiled by the dirt adhering to the bark, a little of which it retains, and no doubt this would deteriorate its market value; but this cause of depreciation might be reduced to a minimum by carefully brushing the surface down prior to commencing collecting operations." "The Indians know the tree under two names, the *Carabisi* calling it Touckpong and the *Arawacks* Cumakaballi. Noble in all its proportions, spreading and lifting its massive head above its neighbours, it is one of the largest trees of the forests, and has a wide and general distribution over the deep belt of low country in the colony. Samples of the rubber of both this and the Hatie, I have sent to England to be tested as to their probable commercial value." An attempt was made by

Mr. Francis to extract indiarubber from the bark, but with no practical result, as the amount obtained was only three per cent of the quantity treated, and this quantity would never pay for the cost of extraction.

The Report concludes with a wholesale condemnation of "the nefarious acts of traders and others" who induce the Indians to cut down rubber-bearing trees for the purpose of obtaining their juice. The Indians should be held responsibl. for this on detection, and "much more should the men who instigate them to it, for their own profit, knowing that they could not do it with impunity themselves, be severely punished for their villany." From the products of our forests which are utilised, important as they undoubtedly are, the colony derives hardly any profit, while the forests are impoverished by wanton waste, and the depredations of the dishonest, and the trade is in the hands of a few merchants. As to the balata trade, unless some efficient method of utilising the whole of the bark be discovered, felling should be prohibited, and, if with this rule, an export tax were imposed, and every package containing the gum required to bear a special brand belonging to the grant on which it was gathered, which would show the production of each grant, a very salutary change would be effected in the trade." All right-thinking people will agree with Mr. Jenman in the above remarks, and heartily endores his proposals for improvement. It is not only in Indian-Rubber and Ballatta this is required. Large quantities of Locust Gum, Tonquin Beans, and other products of the interior are now being exported from the colony, collected principally on Crown Lands, and which do not contribute one cent to its taxation. Mr. Jenman deserves the thanks of the entire community for the discovery he has made, and for the valuable information his report contains.—*Demerara Gazette.*

CINCHONA BARK AND QUININE IN THE UNITED STATES.

From the annual review of the New York Drug Trade in the *Oil, Paint and Drug Reporter*, we quote as follows :—

The imports of Cinchona bark for the year ending December 30, 1882, were 29,200 bales, against 31,700 in 1881 and against 32,800 in the previous year.

Imports and Sales of Cinchona Bark from 1878 to 1882.

	Receipts. Bales.	Stock December 31. Bales.	Sales. Bales.	Exported. Bales.
1878	44,900	10,100	35,700	900
1879	46,700	16,000	26,650	4,400
1880	32,800	29,000	34,800	6,800
1881	31,700	11,800	26,600	4,400
1882	29,200	12,500	16.600	10.100

The stock on hand January 1, 1883, was 700 bales more than it was in January 1 of the previous year. The number of bales received was 2,500 less than in the previous year, while the number of bales exported was 5,600 in excess of the exportation in the year ending December 31, 1881. A comparison of the bark receipts in the United States with those of other countries shows that the foreign receivers of bark are more and more profiting by the unhappy position in which Congress has placed the receivers of bark and the quinine manufacturers in the United States.

Imports of Bark in London Market.

		Receipts.
1878	bales	45,250
1879	„	58,666
1880	„	78,257
1881	„	115,360
1882	„	117,571

Showing an increase of 2.210 bales. Of the total London receipts there were 6,312 bales Calisaya in 1882, against 7,017 in 1881, 6,580 in 1880, 9,187 in 1879, and 7,834 in 1878. 21,631 bales East Indian in 1882, against 15,388 in 1881, 20,692 in 1880, 13,460 in 1879, and 6,251 in 1878. 5,473 bales Carthagena in 1882, against 5,723 in 1881, 6,480 in 1880, 5,360 in 1879, and 5,771 in 1878. 84,155 bales of Colombian and New Grenadian in 1882, against 87,232 in 1881, 44,505 in 1880, 30,659 in 1879, and 25,394 in 1878.

The importation of bark into the French Market shows a still greater gain. There were imported into France during the year 1882, 39,657 bales, against 26,452 in 1881, 20,166 in 1880, 15,994 in 1879, and 11,995 in 1878. The year 1882 closed with a stock of bark in the English, French and American markets of 103,076 bales, against 59,743 in 1881, 48,369 in 1880, and 44,577 in 1879. The imports into the three markets were 186,428 bales in 1882 173,212 in 1881, 131,223 in 1880, and 121,360 in 1879. The number of bales sold in the London market were 84,471 in 1882, against 104,333 in 1881, 64,291 in 1880, and 43,775 in 1879.

There were sold in the United States 16,600 bales in 1882, against 26,600 in 1881, 34,800 in 1880, 26,050 in 1879, and 35,700 in 1878.

Considering the fact that the world's consumption of quinine is certainly increasing yearly, the decrease in the amount of sales of bark in 1882, in comparison with those in 1881, would seem rather anomalous ; but it is to be accounted for by the fact that the year of 1881 was one of great activity in the quinine interest. Combinations among the holders of bark and among the manufacturers of quinine were anticipated; the market for "futures" was very active; and there is no doubt but that the amount of quinine manufactured in the year 1881 was considerably in excess of the actual wants of the world.

During the year 1882 the manufacturers, with possibly two exceptions, have been buying only to supply their immediate wants. A feeling of great uncertainty has prevailed. The holders of bark, most of whom have made advances on the bark consigned to them, have felt that they should not sell at the price which quinine manufacturers could afford to offer, in order to produce quinine at the ruling rate.

The bark syndicate in London, refered to in last year's report, which controlled a large portion of the best barks in the London market, especially those of the Cuprea variety, came to an agreement in July last with the two largest manufacturers in Europe, whereby they agreed (separately) to take a large quantity of the bark at a price which was considerably above the ruling price today. It was supposed that these manufacturers would combine interests and advance the price of quinine, instead of which a competition was commenced, especially for the American market. The price was much depressed, and now rules lower in America than it does in Europe. What the outcome will be is very uncertain. There is certainly a large stock of bark in London and Paris, but it must be considered that a large percentage of this bark is of comparatively low grade.

The Cuprea district of Santander has, as was indicated in last year's report, become a small factor in furnishing a supply of rich Cuprea barks. The neighboring States, especially Tolima, have sent a very considerable amount of bark to the market, in general appearance the same as that from Santander; but this bark has proved to be of comparatively little value, and it is of these varieties that the London stock represents a large amount.

The noticeable feature of recent operations has been the large sales of Ceylon and East India cultivated bark, in comparison with those from South America. In recent auctions a very much greater quantity of these barks have been sold than the South American. Considering the amount of East India and Ceylon arrivals in comparison with those from South America, the proportional sales of East Indian and Ceylon are very large, and go to show the probable drift of the future.

Everything indicates that at some time in the near future our supply of bark will be derived from plantations where the cultivation of cinchona is thoroughly understood, rather than from the natural growth in the South American forests. Taking the ratio of the progress of the two countries into consideration, it will be possible for a grower in Ceylon to furnish bark at so much per unit of quinine, cheaper than could a shipper in South America, even should he have the land and natural growth free, and have only to pay expense of cutting and shipping.

The question has been considered by private parties and by our Government respresentatives as to whether the cinchona tree could not be cultivated with profit in the United States. It is possible that the proper conditions of latitude and altitude may exist in our territory, but it must be considered that it would take six years before any satisfactory experimental results could be obtained, and six years more, even should the experiments prove satisfactory, before bark in any quantity could be placed in the market.

The British Government, about twenty years ago, commenced the introduction of the cinchona tree into their colonies, where the conditions of the successful cultivation have gradually been learned, and the governments of the different colonies have offered great inducements to prospective planters in the way of cheap lands, seedlings, seeds, &c. It is stated that one hundred million trees are now in different stages of growth in the Island of Ceylon alone. The consumption of quinine must, in a general sense be limited, and the question of price has a small effect on the amount consumed. There is no doubt that great territories still remain where quinine should be more used, as for example in the greater part of China and South America. At the same time there is every prospect that the coming supply of bark will fully equal the demand for quinine, and should any one wish to engage in the cultivation of the cinchona tree, under existing circumstances in the United States, where no encouragement has ever been extended to the cultivation of the cinchona, and where the manufacturers of quinine have been handicapped by duties on the raw materials incidental to the manufacture, while the manufactured product is without compensating duty, it would be much more profitable to engage in the enterprise in a British province, for instance, Jamaica, where the conditions for successful cultivation have been thoroughly investigated, where land of known desirability for cinchona cultivation, at a distance of not over 30 miles from point of shipment, can be procured for one pound sterling per acre, where it is possible to obtain cinchona seedlings or seeds at a moderate cost, and where the cost of labor is about one-fourth of that in the United States.

The price for sulphate of quinine for the year ending June 30, 1882, has ranged as follows:—Manufacturers' quotation, January 1, 1882, was \$2·50. In February the price receded to \$2·40; then to \$2·30; in April the price was \$2·10; then, it advanced to \$2·20; in June it receded to \$2·00; then advanced in August to \$2·20; was reduced in October to \$2·10, then to \$2·00; in November to \$1·80; and the quotation at the beginning of the new year was \$1·70.

The importation of quinine for the year ending June 30, 1882 was 794,495 ounces, against 408,851 ounces in the previous year. The yearly import of quinine for the five years preceding June 30, 1882, was as follows:—1882, 794,495 ounces; 1881, 408,851; 1880, 416,998; 1879, 228,348; 1878, 17,549.

The quinine imported in 1882 was entered at an average price of \$1·96, the average paid for the four years preceding being—1881, \$2·57; 1880, \$2·66; 1879, \$2·75; 1878, \$2·90.

The year has been a remarkably uneventful one in regard to large operations or combinations. There have been three new factories started in Europe, which are sending their product to the American market, while one of the oldest and most respected manufacturers of quinine in America was obliged to place his affairs in the hands of his creditors, leaving but four manufacturers of quinine in the United States.

What the future of the business will be in this country is most uncertain. The manufacturers have all made large investments for their different plants, and it would be a matter of great loss to attempt to dispose of them. There is always a hope that they may receive fairer treatment at the hands of Congress, and by the public press, and that the claim they make that they are justly entitled to a compensating protection of 10 per centum for the disabilities imposed upon them by Congress, and the circumstances of the situation, may be met by reasonable arguments and not by epithets and abuse as in the past.

The following table from June 30, 1877, to June 30, 1882, have been compiled from statistics kindly furnished by Hon. Joseph Nimmo, Jr., Chief of the Bureau of Statistics at Washington.

Imports of Cinchona Bark during the Past Six Years.

Years.	Pounds.	Value in gold dollars.	Average gold value per lb.
1877	1,760,446	443,404	25·2
1878	4,826,290	1,423,502	29·5
1879	6,389,378	2,094,514	32·8
1880	6,013,877	1,679,472	27·9
1881	4,219,403	1,846,280	43·8
1882	5,010,547	1,846,375	36·8

Imports of Quinine during the Past Six Years.

Years.	Ounces.	Value in gold dollars.	Average gold value per ounce in bond.
1877	75,804	136,948	\$1·81
1878	17,549	50,858	2·90
1879	228,348	626,567	2·75
1880	416,998	1,111,254	2·66
1881	408,851	1,052,228	2·57
1882	794,495	1,554,350	1·96

Imports of Opium during the Past Six Years.

Years.	Pounds.	Value in gold dollars.	Average gold value per lb in bond.
1877	230,102	997,692	\$4·33½
1878	207,752	712,624	3·43
1879	278,554	929,894	3·34
1880	243,211	858,225	3·53
1881	385,060	1,791,415	4·65
1882	227,126	881,023	3·88

Imports of Opium for Smoking during the Past Six Years.

Years.	Pounds.	Value in gold dollars.	Average gold value per lb in bond.
1877	47,428	502,662	\$10·59
1878	54,805	617,160	11·27
1879	60,648	643,774	10·62
1880	77,196	773,796	10·02
1881	76,446	761,349	9·96
1882	106,221	1,038,305	9·78

THE RESOURCES OF MADAGASCAR:

A NEW FIELD FOR ENTERPRISE.

(From "Standard" Correspondent.)

TAMATAVE, Feb. 23.

The total amount of business transacted between British ports and Madagascar cannot fall short of a half-million sterling. Of exports, the chief articles at present are bullocks to Mauritius and Réunion; hides, indiarubber, beeswax, rice, fibre, spices, coffee, and sugar. There are many other articles, such as gums and dyes, but these are the principal. In imports, American cottons take the first place. American spinners turn out a kind of coarse brown sheeting, which exactly suits the Malagasy taste, and is rapidly becoming the basis of Malagasy clothing—at least, so far as the poorer classes are concerned—throughout the island. Lancashire supplies lighter goods, such as cotton prints and fancy cloths. The consumption of these is steadily increasing, especially among the Hovas of the interior; but the English spinners have failed altogether to compete with those of America in the production of the cheaper material. The fact is, there are no mills in England with machinery adapted to the weaving of this particular cloth, and there are apparently no spinners enterprising enough to lay in the special machinery required. Consequently, they have not succeeded in imitating the samples upon which the English merchants have based their orders, and the trade has been lost. This is to be regretted, as the American sheeting in question is rapidly coming into favour at Zanzibar and other ports on the African coast; and the trade would be certain to pay any English mill which chose to lay itself out to obtain a share of it. Hardware goods come almost entirely from England, and the trade in them is rapidly extending. The import trade of Madagascar, however, can only be expected to grow as the exports increase. At present the bulk of the population are extremely poor. They produce little more than is necessary to gratify the most simple wants of Nature; consequently, notwithstanding the magnificent advantages with which Providence has blessed the country—its prolific soil, its teeming forests, where year by year, for lack of a gathering hand, the richest products of the earth lie rotting; its minerals, and in many parts its numerous navigable waterways—the Malagasy does not as yet possess the means wherewith to purchase the goods of other nations. And although, on the coast particularly, the people show mere desire to work and to better their condition, the Hova Government has stood in the way of commercial and agricultural development. This cannot last long, however; even the Hova officials begin to realise that the change is close at hand, and that Madagascar is about to enter on a new era of her history—an era in which her advancement in the arts of civilisation promises to be as rapid and, perhaps, as astounding as has been the progress during the last thirty years of her people in the profession of Christianity.

At present live bullocks from the most valuable item in the list of Madagascar exports; but as as the only markets are Mauritius and Réunion, and occasionally Natal, the utmost limits of the trade have apparently been reached; yet there is no country in the world where live stock is so cheap as in Madagascar, and other markets ought to be found. Fine fat bullocks can be purchased in many districts for two or three dollars each, and bullocks, too, of the best breeds. All of them carry those humps whose dainty flesh is prized so much by the epicures of other countries; and when it is known that such cattle can be delivered on board ship at about forty-four shillings a head, it surely becomes a question whether the grazing grounds of Madagascar may not be rendered available for the supply of Great Britain. Mutton is now shipped to England from Australia, and Australia is distant from England some six weeks steaming against four weeks from Madagascar: so that the length of the voyage ought to prove no obstacle. Madagascar cattle weigh on an average about seven hundred and fifty pounds, yielding five hundred pounds of meat. That is to say, beef can be delivered free on board in the roads of Tamatave at a shade more than a penny per pound. These are actual figures, not estimates, and I submit them for the study of those interested in the new refrigerating processes for preserving meat during voyages by sea. It is startling to think that from Madagascar, perhaps, good fresh beef might be laid down in England under four pence per pound. Indeed, there is no good reason why the cattle themselves might not be profitably transported. A conveniently-built steamer, properly fitted out and able to steam the distance in thirty days, ought to succeed. On her outward voyage she would take cargo for Zanzibar and Mauritius, as well as for Madagascar; and for her trip home, while carrying cargo in her lower hold, she would depend upon bullocks. Cattle are cheap in Madagascar because there are no droughts, and because the grazing grounds are practically inexhaustible. In the interior, over vast tracks herds roam wild, and a market is alone required to induce the people to drive the herds to the coast. The trade in indiarubber has only recently sprung up; but it is rapidly increasing, and from this port alone already amounts in value to over fifty thousand pounds. Of course, the sources of supply have as yet been barely tapped. The existing method of Government, which resembles far too closely in some respects that of China, especially as regards the reprehensible practice of "squeezing" men supposed to possess means, affords no inducement to the accumulation of riches. But, doubtless, at no very distant date a larger proportion of the population than are at present engaged in the industry will set themselves to drawing more freely from the rich stores which the mountain slopes afford. Coffee, too, could be grown in Madagascar to any extent. The vast and elevated plateaux of the interior are peculiarly suited to the growth of this plant; and already considerable quantities of wild coffee are shipped to Mauritius. The quality is good, and, although grown wild, many parcels which I have seen would, in richness of colour and in size and shape of bean, compare not unfavourably with the better sorts of Ceylon produce.

But it is upon sugar that those who believe in a great commercial future for Madagascar pin their faith. In Réunion people talk constantly of the rich mines which are supposed to lie hidden in the interior of the great African island, and they anathematise copiously and in vigorous French, as they bang their dominoes on the *café* tables and drink their absinthe, the Conservative Hova Methodists, who have ordained that to dig or search for gold is a crime punishable by death. But two English and two Creole firms of Mauritius have, meanwhile, discovered in sugar a source of wealth which, if properly tapped, will draw from the soil of Madagascar a stream of gold that in value may rival the richest mines of the earth. Bullocks and coffee are articles the export of which to Europe may be calculated upon to grow in due time. With them, however, a beginning has as yet to be made, and pioneers willing to undertake the risk of experiment have to be found. But as regards the profitable production of sugar, the experimental stage has already been passed. That there is "money in it," and lots of money, has been conclusively proved, and only a few obsolete and impracticable Hova laws have to be removed, and Madagascar may be expected to develope rapidly into the chief sugar-producing country of the world. Four years ago the first real attempt at establishing a sugar plantation in the neighbourhood of Tamatave was made; and already dividends of fifteen to twenty per cent on the capital invested are being realised. Next year one estate, which is becoming the property of a joint-stock company, promises to pay thirty per cent, and the limit of remuneration has by no means been reached. Last year these four pioneer estates, aggregating one thousand acres, exported five hundred tons of sugar. The season just closing will yield a total of one thousand tons, and next season is expected to produce double that quantity. These figures and these results merit the attention of British capitalists, who in Madagascar may find a new, a safe, and a profitable field for their enterprise. A few notes made during a visit paid yesterday to one of these estates may prove interesting. Starting from Tamatave in the early morning, we were rapidly carried on the shoulders of our porters over eight miles of the beautiful green sward which all along the eastern coast of Madagascar reaches close down to the sea. Here we reached the mouth of one of the numerous rivers that, emerging from the uplands, meander placidly through the belt of lowlying coast country, and emarked on board a canoe. The estate lay ten miles up the river, and over that distance we were paddled and poled in an hour and a half. Soon after leaving the vicinity of the sea we found ourselves in that rich country of which I had heard so much in Mauritius. The banks on either hand were edged by long lines of the most gorgeous vegetation. To detail the different trees and plants would be to run over half the list of the tropical vegetable world. Palms of all the different species, magnificent groves of mango trees, wild cardamoms, and the coffee, indigo, and breadfruit plants were to be seen, while the long slender and graceful bamboo toned down with its shade of delicate green the more flaunting colours of the robuster growths.

On approaching the factory this wild and profuse jungle gave place to fields of tall sugar cane, towering high above the river banks, their tops rustling in the breeze as if in one long continuous sigh. We were met at the landing-stage by the estate manager, one of those energetic, pure-blooded Creoles who have done so much for the development of Mauritius, and who now looks to Madagascar for a new and larger field in which to put their special knowledge to account. A crowd of canoes were also at the landing-place discharging cargoes of freshly-cut cane brought from fields further up the river, and the mill close by was in full work. The making of sugar in such a factory is an interesting process to watch. Standing in the centre of the mill, every stage of the manufacture is visible. At one end, the canes—long, thick, and jointed—are carried in a confused mass, a yard and a half broad, on an endless revolving plankway, to the ponderous rollers, where, crushed into pulp, they yield a little brook of frothy juice, which, boiled and cooled, and thrashed into thick molasses, is eventually dried and manipulated into white crystallised sugar fit for the table. And throughout the whole place that heavy saccharine odour pervades which in Mauritius is encountered faintly at every turning in the streets and at every station on the railway. Close to the factory is the little town where dwell the three hundred Malagasy labourers on the estate, with their lady adherents. The social customs of the coast Malagasies do not include marriage. A merry, laughing crowd they are, who, if they do not work as well as Indian coolies, are infinitely superior to the Zulus and Kaffirs of Natal. They are paid about nine shillings per month, and get their food in addition. Altogether they cost about sixteen shillings per month each. A coolie in Mauritius costs the planter about thirty-three shillings, so that, even putting down two coolies as equal to three Malagasies, labour in Madagascar is fifteen per cent cheaper than in Mauritius. And there is not the preliminary outlay required to bring the coolies from India, and to send them back when their term has expired. Another immense advantage for Madagascar is that the virgin soil is so rich and deep—on an average from six to eight feet of the special loam required for cane—that no manure is necessary. But the great and crowning advantage of all is that there are no cyclones. The majority of the joint-stock sugar-planting concerns of Mauritius pay dividends in ordinary years of from ten to twenty-five per cent. But every third or fourth year comes a tornado, which lays everything level with the ground; and for that season, and sometimes for two or three following ones, there is little or no dividend paid. From this risk and from this grinding anxiety the planter in Madagascar is free.

Following our guide, the manager, we made our way to the topmost eminence on the estate, and as we went passed through fields of gigantic canes, towering from twenty to thirty feet high overhead. Nowhere in Mauritius, and at no period, we were assured by the enthusiastic manager, did canes grow in such perfection, a statement which certainly our own observation confirmed. And the view which unfolded itself as we reached our destination cannot be matched, I make bold to say, for the wealth of tropical growth displayed, all the world over. I have seen nothing like it in the richest portions of India, even where irrigation aids the efforts of Nature and of man. But here was no other irrigation than the rain of Heaven afforded. The country is studded with little knolls, and it is in the tiny valleys between, and on the slopes reaching down to the river banks, that the cane is cultivated. The latter are preferred, as the waterway affords easy carriage for the canes to the factory. What with the tall green canes, the palms, and for temperate climes, the rare and beautiful plants which form the undergrowth on the knolls, the ground itself was everywhere shrouded from view. When it is stated that a strip of country equal to, and sometimes surpassing, this in richness, from twenty to forty miles broad and several hundred miles in length, with wide navigable rivers at intervals of from ten to twenty miles, awaits cultivation on the east coast of Madagascar, it will be understood how great a future there is in store for the country. And not only sugar, but on the knolls which dot his estate the planter can grow tobacco, cloves, pepper, cinnamon, and all the spices in profusion. "No wonder," as a Creole in Mauritius said to me, "our eyes are directed towards Madagascar."

At first and for many years to come, before the river frontage is exhausted, the sugar mills and the estates will be placed along the river banks. There is ground enough of that description available to grow many times the three millions' worth of produce turned out annually by Mauritius. But, of course, as with all industries, there are obstacles to be overcome. Under the original Treaties between the Hovas and England, France, and America, it was agreed that the subjects of those nations shall be permitted in any lawful manner to "purchase, rent, lease" land in Madagascar. But this clause in the Treaty has almost remained a dead letter. Any native landowner knows that if he parts with his property to a foreigner he is likely to suffer dire retribution at the instance of the native authorities. Short leases the Hovas do not object to; but then, of course, it is impossible on such short security for capitalists to invest the large sums required for sugar enterprise. The fact is, the French subjects in Madagascar talked so much about what France would eventually do that the Hovas got frightened. They argue that if foreigners were allowed to acquire land indiscriminately, such hordes of them would come that the country no longer would be their own, and a pretext for its annexation would be afforded. Then they are able to refer to Mauritius, where none but British subjects are allowed to own land, and so they say "We are not so uncivilised in our determination to maintain a similiar rule there." As the English Consular authorities at least have refrained from pressing the matter, the question has gone on increasing, until at last the French have seized hold of it as a base upon which to found their quarrel. But the Hovas are firm, and if hostilities are to be avoided, the matter must be settled by a compromise. Probably for sugar estates ninety-nine years' lease will be authorised for the ground on which the factories are built, with ample provision for a valuation at the end of that period should the Government wish to take over the land. Then, in the vicinity of the factories, the land will be thrown upon to planting leases of from twenty to thirty years. The cane in that case would mostly be grown by natives, by Indians, perhaps, and Creoles from Mauritius, and sold to the mills. Two of the existing factories are already working on that principle, which is found to answer well. On this subject I will, however, be able to write more definitely after my arrival at the capital, for which I start to-morrow. I will only say at present that, in the opinion of all British subjects here, difficulties might have been avoided and an arrangement long ago come to if England had maintained a Representative at the Malagasy capital. France has her chief Consul at the seat of Government, and a Vice-Consul on the coast. We, with a far greater trade, and with double the number of subjects in the country, are content with a Consul resident at this port only. The Government are most anxious to have English official advice, but, of course, when the nearest officer is seven days' journey distant, they have been obliged to do without it, and British interests in Madagascar have suffered accordingly. French traders, by means of the pressure which their Consuls are always prepared to exert none too scrupulously, obtain advantages over the English. In a word, British interests in Madagascar, which in the next few years are likely to increase indefinitely, demand that a Diplomatic representative capable of watching closely and skilfully whatever concerns them shall be stationed at Antananarivo. I find a universal complaint here on the part of Englishmen, Indians, and Creoles, against the English Consular Office. It is declared to be inefficient, procrastinating to the last degree, and careless of their interests. How far that complaint may be well founded I cannot, of course, say. I can only testify to its unanimous existence. At all events, it is a fact that from Mauritius alone considerable sums are awaiting investment in Madagascar, and it will be a pity if so desirable an extension of British trade should be lost through lack of a little encouragement and support from our own Government. So soon as the legal obstacles have been removed, we may expect to see large tracts of land on this coast brought under cultivation on the system which is answering so well in Mauritius—that is, in small joint-stock concerns of from twenty to forty thousand pounds each. And where returns of from twenty-five to thirty per cent are to be obtained, British capitalists are not likely to remain long behind those of the Colony—provided that French aggression does not close Madagascar to British enterprise altogether.—*Standard.*

As a rule, a tree that is growing vigorously will no fruit much. To make a tree bear fruit there must be some check to its growth. After a certain age there is a natural cessation of the growth, and trees then bear. But we do not always care to wait until that time comes. We want fruit sooner. This may be had by checking the growth in some way. The check must not be too violent, or the tree will be injured. It may be said briefly that all summer pruning, cutting back, root pruning, or any other practice that strikes at the life of the tree, or retards the growth in summer, tends to the formation of fruit buds. Among these are bending down, or gently breaking in branches, hanging weights on them, tying them down to stakes, slightly barking the tree or branches in June, etc. But it must be borne in mind that all such checking or pruning should be done carefully and judiciously, to balance or check the force of the tree and retard its wood growth, if the tree is large enough to to bear and fruit is desired.—*Southern Planter.*

MR. HOWARD'S PAPER ON CINCHONAS.

We now give the notice of Mr. Howard's paper by the London correspondent of the "Ceylon Times," as our own correspondent has failed us in a matter which he ought to have known was of great interest to our readers. It is clear that even now we must wait for the appearance of the paper itself. In the "Times" account Mr. Howard is represented as impeaching the nomenclature of Mr. Moens (who has had unrivalled opportunities of observing the yellow barks from the most inferior of calisayas up to the richest of Ledgerianas) but there is not a word about the charge that Dr. Trimen had figured *C. micrantha* as *C. Ledgeriana*, and nothing about the injurious effects of the alkaloids of the grey bark. Until we see the charge explicitly made in Mr. Howard's paper, we must refuse to believe that the great quinologist accused the eminent botanist of having figured and described an inferior grey bark as representing the very king of the yellow barks, *C. Ledgeriana*. And then about *C. robusta*, as Mr. Howard regularly receives our paper he must be aware that Dr. Trimen's special recommendation of this name was that it left the question of hybridity an open one.* What Dr Trimen proved, by getting reference made to the specimens at Kew, was that *C. robusta*, whatever else it was, was not *Pátá de Gallinazo*, as Mr. Cross represented. As to hybridization, all we can say is that we resisted belief in the process as long as we could, and that our change of opinion was largely influenced by the fact that so orthodox a naturalist as Mr. Howard himself admitted that hybrids had actually occurred in India. Mr. Howard has also in his works recognized important influences, short of hybridization, which the various species of cinchonas growing side by side exercise on each other. As to Ceylon and Indian planters growing the inferior kinds, the planters grew what they could procure and what survived as the fittest. As red bark from Ceylon sold the other day at 4s per lb., it seems clear that inferior species can be enormously improved. Many Ceylon and Indian planters have attempted to grow Ledgers and have failed. If this plant would grow anywhere it would be everywhere grown. We do not understand about *C. verde and C. morada* trees yielding each 7 lb. of bark. At what age, and, is it by uprooting and taking all the bark away, by coppicing, or what? But we must wait for Mr. Howard's paper. Meantime, it seems that Mr Howard has recognized the great value of *C. verde* and *C. morada*, introduced by Mr. Christy, but not by him alone. Mr. Howard, too, seems to have characterized Ledgeriana bark from Ceylon as superior even to that from Java.

* In a letter dated March 3rd, 1882, Mr. Howard remarked to us that "the name *C. robusta* seems well applied to the *pubescens* of which I have a flourishing specimen 8 to 10 feet high."—Ed.

MR. HOWARD ON LEDGERIANA.

The correspondent who lately sent us a brief and evidently imperfect notice of Mr. Howard's paper read before the Linnean Society now sends us a fuller report. Of course we must reserve final conclusions until we have seen the actual terms of Mr. Howard's paper, but it certainly seems to admit of little doubt that the great quinologist has impeached the botanical discrimination of Mr. Moens and Dr. Trimen. The latter, trusting to the judgment of the former on a subject where his experience had been larger than that of any living man, described and figured as a true type of *Ledgeriana* a plant growing in Ceylon. Mr. Howard is represented, in the first place, as adhering to the view that Ledgeriana is not a distinct species, in which light Dr. Trimen regarded it; and in the next as denying that the plant figured and described by Dr. Trimen as Ledgeriana was "the real Simon Pure": it is, "Mr. Howard seemed inclined to believe," the male form of *Cinchona micrantha*, var. *Calisayoides*, the female plant of which is figured in *Curtis's Botanical Magazine* as *C. Calisaya*, var. *Josephiana*, by Sir J. D. Hooker. It is a grave charge to bring against two of the leading botanical authorities of the day, that they should give information so erroneous and misleading, and we do not doubt that both Hooker and Trimen will be speedily heard in reply. We do not know the age of the plant which Dr. Trimen figured, but even young trees of true Ledgeriana give results in quinine enormously in excess of that ever yielded by the best forms of micrantha or grey bark. We suppose the plant is in existence and that Dr. Trimen will not lose a day in having some of its bark analyzed. It may be possible to trace the genealogy of the plant, and, if it is from seed sent by Mr. McIvor from the Nilgiris, there are the cases of the splendid Ledgerianas on Yarrow and on Mr. T. N. Christie's estate to prove that, however stunted trees from Ledger's seed grew on the Nilgiris at very high elevations, seed from them sent to Ceylon resulted in Ledgerianas with bark as rich as any the undoubted plants in Java yielded. If bark yields 7 to 13 per cent of quinine, it is of little moment to the planter what its exact scientific place may be; but to a scientific man like Dr. Trimen it is a question of first importance whether he did or did not, in an elaborate paper with a carefully coloured drawing, describe and figure as true Ledgeriana what was really a calisaya-like micrantha: confound the very lowest form of the cinchonas (economical value considered) with the very highest. As for Dr. Kuntze and his hybrid craze, Mr. Gammie's testimony puts him out of court, and we cannot suppose that a man like Mr. Howard attached much importance to the eccentric German's opinions. One thing is certain: if, as is stated, Mr. Howard recognized as true Ledgerianas Mr. Christy's *Calisaya verde* plants, then the external features of Ledgerianas vary from satiny green to velvety scarlet leaves; and while pure white blossoms generally distinguish the genuine Ledgers yet one of the best trees in the Java plantations was a pink-blossomed one. It will be curious if, after the prevalent belief that Mr. Ledger had rescued the best form of calisaya from extinction *Calisaya verde* and *Calisaya morada* should turn out to be mere varieties of the same tree, with the advantage of a more robust habit. Are not some of the plants in the possession of Mr. Owen and others old enough for the bark to be analyzed? Even twigs of the true Ledgerianas give good results at $2\frac{1}{2}$ years of age. We may as well point out, that, whether Dr. Trimen is or is not mistaken in regard to the plant he described as Ledgeriana, he had nothing to do with sending a hybrid plant to Jamaica as calisaya.

CINCHONA LEDGERIANA.

At a recent meeting of the Linnean Society in London, Mr. J. C. Howard, F. R. S., read a paper which cannot fail to have considerable interest for those who cultivate this valuable plant. For some months past a discussion has taken place amongst various botanical authorities on cinchona culture, as to whether "*Cinchona Ledgeriana* deserves the rank of a species. Mr. Howard believes it to be a form of *C. Calisaya*. Dr. Otto Kunze considers it to be a hybrid of *C. micrantha* and *C. Calisaya*, and Dr. Trimen has raised it to the rank of a distinct species.

In the paper read at the Linnean Society Mr. Howard reiterated his opinion that the Ledgeriana is only a variety of *C. Calisaya*, and criticized the figure and description of the plant given by Dr. Trimen in the "Journal of Botany" (Nov. 1881 p. 321) remarking that there appeared to be no proof that the plant therein figured was descended from seed sent by Mr. Ledger, and that its identification rested chiefly on Mr. Moens' accuracy of botanical discrimination. Mr. Howard seemed inclined to believe that the plant figured and described by Dr. Trimen is the male form of *Cinchona micrantha* var. *Calisayoides*, the female plant of which is figured in Curtis's Botanical Magazine as *C: Calisaya* var. *Josephiana* by Sir J. D. Hooker. It also bears some resemblance to the plant described by Howard as *C. Forbesiana*. Mr. Howard exhibited some living specimens of the plant which he considers the true *C. Ledgeriana*, the bark of which yields on an average from 7 to 12 per cent of Quinine. The leaves of this plant were easily distinguished from other varieties of Calisaya placed upon the table at the meeting by their beautiful satiny gloss which gave them a lustrous appearance like green velvet, also by the hairy margin of the leaves like those of the Calisaya of—[blank in the MS.] A tree covered with leaves of this character must indeed be a glorious sight, such as the best calisaya is described to be by travellers in Bolivia.

At the same meeting Mr. T. Christy, F. L. S., exhibited young plants grown from the seed recently obtained by him from Bolivia. Several of these were evidently absolutely identical with Mr. Howard's Ledgeriana both in the glossy appearance and in the shape of the leaves. Others were evidently judging from the large size and different shape of the leaves and more vigorous growth, the calisaya "verde" of Weddell and Markham. Mr. Howard acknowledged that Mr. Christy's plants (apparently obtained from his "morada" seeds) were true Ledgeriana* and that the "verde" also appeared to be the true plant. He added that no seed of such extreme importance to cinchona cultivators had been obtained by any one since Ledger sent home his valuable supply and that great credit was due to Mr. Christy for his success in procuring it.

The difficulty of procuring the seed of Ledgeriana from Bolivia was illustrated by the fact that Schuchkraft, who was 35 years in that country and married a wife having estates in the Yungas and most of whose servants were bark cutters, was unable to procure the seed, while Markham, Weddell and others equally failed.

It would appear from Mr. Howard's remarks that there are several cinchonas in cultivation both in Java and Ceylon, and possibly elsewhere under the name of "Ledgeriana," which are not that plant.

It was in ignorance of this fact that a hybrid plant was sent to Jamaica as calisaya. An analysis of the bark of a small tree of the *C. micrantha* var. *Calisayoides* gave only, quinine 0·50, quinidine 0·25, cinchonine 0·85.

Mr. Howard's opinion is also supported by that of Dr. Otto Kuntze, who states in the Journal of Botany (January, 1883) that the Mungpo Ledgeriana has very divaricate panicles of inflorescence with slender ramification like those of *C. micrantha*, while the Bolivian Ledgerianas, as seen in Java and Southern India, have a more dense panicle with thicker or shorter branches. The Mungpo plant is shrubby in stature, while the Bolivian plant is a veritable tree. Various other points have been discussed, such as the sterility of *C. Ledgeriana*, the small size of the flowers, etc. The point of greatest interest to planters is however that Mr. Howard has now again described the plant which he calls *Ledgeriana* and has pointed out the characters which distinguish it, stating at the same time that the plant described by him yields 7·12 p. c. of quinine. Those who have this plant in cultivation should therefore look out for the form having leaves with a velvety lustre and hairy margin. If analysis confirms Mr. Howard's statements, and the flowers are found to produce hybrid seed, grafting must be resorted to, in order to propagate the best varieties, as this process was stated by Col. Beddome to have given the best results in the yield of quinine. It must also be satisfactory to those who have, through your recommendation, purchased seed of Mr. Christy to know that some of the plants obtained from this seed have been recognized by Mr. Howard as the true *C. Ledgeriana* and others as the real "Verde Calisaya."

* What Mr. Howard seems to have state was not that *Calisaya verde and morada* were Ledgerianas, but that Mr. Christy had successed in obtaining seeds of the Ledgeriana.

THE WARS OF THE QUINOLOGISTS.

"*De Cinnamomo Disputatio*"—the question whether cinnamon is indigenous to Ceylon which once troubled the souls and exercised the pens of the German *savants*—is likely to be eclipsed in energy and interest by the Cinchona controversy, in which Howard, Trimen and Moens fight a triangular duel. As is usual in such cases, there are some elements of human nature mixed up with the purely scientific questions round which the contest rages. This will be obvious on a perusal of the letter which Mr. Howard addressed to the correspondent of a contemporary in reply to a request for the real purport and object of his paper. This we quote:—

"My review of the whole subject is briefly as follows:—Dr. Trimen and Mr. Moens—wishing to describe (as a new species) the very same *Ledgeriana* trees of which I had given decriptions and analyses of the bark, with plates drawn and colored by our most able artist, and which I had thus published as a variety of cinchona calisaya,—took for typical specimen of the same a tree found in Ceylon, derived apparently from seed given by Mr. McIvor, of uncertain origin. I think it will be evident to any botanist comparing the plates and descriptions that they differ very widely, and on Mr. Moens' own authority I claim that mine alone are authentic. I believe the tree figured as *C. Ledgeriana*, Moens, proved to be no calisaya at all but either a true species standing intermediate between calisaya and micrantha, or a mere variety of micrantha. Comparison of plants manifest this still more closely, and also shews the very close resemblance between the *ledgeriana* and the *morada* and *verde* varieties of calisaya, all perhaps standing under the var. *microcarpa* of Weddell. The real *ledgeriana* is not the *verde* nor the *morada*, but that which is known in its native habitat as the *rojo*, or red, from the leaves turning a bright red (under circumstances), as noticed by Mr. Ledger, in Bolivia, and by Mr. Christy and myself in our authentic plants. The leaves of these seem to me more sensitive, both to the influence of light and temperature, than the others named. The *rojo* seems to be a more delicate tree than the *verde*, and is (perhaps consequently) not found in patches, but isolated: neither has it as yet been cultivated. I have noticed various points of difference from the *pseudo-Ledgeriana* of Trimen, which would no doubt, in part disappear, through the rough influence of climate and weather, but the glorious calisaya of the Bolivian forest cannot permanently be confounded with the *micranthoid* variety with which it has been supposed identical. The bark alone, as noticed by Mr. Van Gorkom, is a sufficient distinction."

It is quite true that Mr. Howard in his magnificen work, "The Quinology of the East Indian Plantations, figured and described *Calisaya Ledgeriana*, var HOWARD, from specimens received from Mr. Moens Mr. Howard, with his life-long experience of and investigations into the multitudinous species and varieties of the cinchonas, regarded *C. Ledgeriana* as a very rich and valuable variety, but still only one of the many varieties into which the species *Calisaya* subdivided itself. If, therefore, without overwhelming evidence of true structural and botanical differences, to justify their procedure, Mr. Moens and Dr. Trimen conspired to erect a new species with which their names should be associated, then no one will deny the fittingness of the Nemesis which has overtaken them. "The old man eloquent," who is quinine personified, figuratively points the finger of scorn at them and says: "You *may* have the honour and glory of discovering and describing a species, certainly, but the species is not *C. Ledgeriana.* Moens and Trimen, but a wretched grey-bark *micrantha.* But, more probably, you have mistaken for *Ledgeriana* the male form of a Calisaya-like *micrantha*!' If Mr. Howard's position is established, then Mr. Moens and Dr. Trimen will have to cry "Peccavi!" and walk softly and speak humbly, clothed in sackcloth and ashes for a protracted season! One thing is quite certain: that, as we remarked when we saw the plate, Dr. Trimen was unfortunate in his specimen. It *was* poor and stunted. Nevertheless it may have been true Ledgeriana, for nothing could be more stunted and bushy, with a dozen small stems instead of one good stout trunk, than the undoubted progeny of Ledger's seed which we saw on the Nilgiris. But the bark of those very bushes sold for 12s 8d per lb. Our inclination is strongly to believe that Dr. Trimen's tree had the same origin (seed from the Nilgiris) as the magnificent trees on Yarrow estate, which Mr, Howard distinctly recognizes as true Ledgerianas.

* * * * * *

Mr. McIvor's initial mistake, which we and others repeated in Ceylon, was to try and grow the Ledgerianas in the highest and most exposed portions of plantations. In such situations many grew, but did not flourish as they have done between 2.000 and 4,000 feet. With good soil and shelter, however, we have no doubt Ledgerianas will grow fairly well between 4,000 and 6,000 feet altitude. That Mr. Moens should have blundered as he is represented to have done, seems to us incredible, when we remember all his discriminating reports, and recall our own personal experience of the readiness with which, on the ground of peculiarities not obvious to our unpractised eye, he at once distinguished the true Ledgerianas from the inferior species and varieties. "That," he said, as we went over the plantations together, "is *C. Schuhkraft*, that *C. Hasskarliana*, that *C. Josephiana*, and that *C. Javanica*, all inferior kinds which (except a few specimens preserved for experiment) are to be rooted out. But here is the true Ledgeriana with its long petioled leaf and its blossoms looking down at you." If Mr. Moens does not know Ledgeriana when he sees it, we shall next doubt Mr. Proctor's knowledge of the worlds of space, formed and in course of formation. It was from Mr. Moens that Mr. Howard received the undoubted specimens which he figured and described. Did Mr. Moens lose his senses when he deceived Dr. Trimen into the belief that a micrantha was true Ledgeriana, and did Dr. Trimen become oblivious to all his carefull botanical training and indifferent to his scientific fame and moral responsibility, when the decision was arrived at to erect Ledgeriana into a distinct species, and to give as its type a male micrantha?! That "*some one* has blundered" is evident, but "who?" is the question.*

* * * * * *

Meantime, it may be well to advert to the "rojo" or red-leaf peculiarity. *All* the Calisayas at certain stages influenced by drought or other reasons show brilliant coats of foliage, varying from dark red to the brightest scarlet. We have made beautiful collections of such leaves which have been much admired, and we can imagine the magnificence of a Ledgeriana tree "500 years old" so (temporarily) clothed. But, besides this tendency, a large number of the Calisayas, when young, have leaves richly purple or red on the under side. We have already mentioned that Mr. Moens, in order to test the (doubtful) value of such trees, grew them in a separate portion of a plantation. Our own impression is that although green leaves and white blossoms are, *generally*, the best indications of true Ledgerianas, yet the red-leaved and pink-blossomed trees are not to be despised until their bark is tested. As a matter of fact adult Ledgeriana trees have all green foliage: at least we remember no exception. For beauty, the old trees with their small green leaves are not to be compared to the young plants with their rich, red velvety foliage. Dr. Trimen's plant, if Mr. Howard is right, is a *pseudo-Ledgeriana* and a *micranthoid*, which is very dreadful; but there is some consolation in the hope that *all* varieties of Calisayas may find refuge in the bosom of Weddell's *microcarpa*. There is still, therefore, a *locus pœnitentiæ* for the Dutch and British sinners, if they will but confess their error.

* * * * * *

There is an abstract of Mr. Howard's paper, but we prefer to wait for the full report. Mr. Howard will be the more lenient to erring brother botanists seeing that he confesses to having sent seeds of micrantha to Jamaica as those of Ledgeriana. He was deceived and then he was an agent of deception. With his warning against the cultivation of the impostor micranthas which simulate Calisaya, we quite concur; but for reasons repeatedly given, of vigorous growth where Ledgerianas refuse to live, and of gradually improved bark under cultivation and renewal. we stand up for our old red-bark friend succirubra. He is not an aristocrat, like Ledgeriana or *calisaya verde*, but he is a useful member of his family nevertheless. Apart from improvement from mere age, the renewed bark seems to come nearer to that of Ledgeriana at every shaving and renewal. How long this process may go on, we cannot say as yet, but clearly, while following Mr. Howard's advice as to growing the best kinds, and especially Ledgeriana, where and when we *can*, let us make a distinction (as the Cardinal said with reference to the Pope's soup and its affinity to hot water), and let the distinction be in favour of growing what will best succeed in our exposures, soils and climates. Mr. Christy's zeal in the cause of *Calisaya verde* and *morada* is as noticeable in its way as Howard's jealousy for the reputation of the true "rojo" Calisaya, and we trust and hope that *all* the best cinchonas yet will be grown successfully in Ceylon.

* All this must now be read in the light of Mr. T. N. Christie's letter subsequently received, shewing that the plant described and figured by Dr. Trimen was an undoubted Ledgeriana, the bark of which gave on analysis, over 11 per cent sulphate of quinine.—Ed.

COFFEE PROSPECTS IN COORG.

Mercara, May 20th.—As one interested, I have the greatest pleasure in communicating to the South Indian world the cheery and prosperous outlook there is before us, planters, during the ensuing season. My former letters were doubtless gloomy enough, and with reason, for the crop of 1882-83 was one of the most terrible failures in the annals of the coffee industry in the country. The causes and its results I have already described. The planters who sent their coffee to be cured at Messrs. Morgan and Sons, Mangalore, speak in the highest praise of the manner it has been attended to. In some instances the turn-out was at the rate of 83 parchment bushels to the ton. New machinery has been added to their works, by means of which, the silver-skin, all-to-be desired in coffee curing is kept on, and not broken off as in former years. This silver-skin, I may add, is a specialty of the highest class of Mocha coffee, and until this year has never been arrived at by our coffee, whilst the prices realised in the London market have fully satisfied the highest expectations. Second class or B. coffee selling at 97s; of first class there was very little, it bringing fancy prices ranging from 107s up to 114s per cwt. But to resume—our blossom showers have been very favorable, commencing early in March; they freely watered the majority of the coffee estates in South Coorg, bringing out the flowers in first class condition. A fourth of the blossom came out at this time in North Coorg, which set well. In April, however, there was a second general blossoming, surpassing anything of former years with its promise of great plenty. At the time when all was in flower, every one was asking the same question, "where has all this blossom come from?" It may have been the shortness of last year's crop, the condition of the trees and the great decrease of leaf-disease, and perhaps the irritation of the little showers, not enough to do harm, which prepared in a way the coffee trees to respond at once on the first good downfall of rain. Upon the hopeful assurance of Government, in connection with the "Bane Land Rules" that the heavy fee of R20 per acre will not be enforced, planters are plucking up courage and much land that had been bought two or three years ago, is being now rapidly cleared to be ready for the July planting season. Labor is not over plentiful. The few Tamil coolies who venture up here from Salem and that neighbourhood find ready employment. They were first attracted here in 1881, and migrate in yearly increasing numbers. Several have returned from the Ceylon estates.—*Madras Standard.*

THE TROPICAL LABOUR PROBLEM.

The Government of South Australia have great faith in the future of their Northern Territory, and, knowing the success which has attended tropical agriculture at Mackay, they have lately sent one of their members to see for himself how this has been accomplished. Mr. Langdon Parsons visited the Northern Territory last year. This year he has visited Mackay to see how tropical agriculture by coloured labour is carried out there; and now he has reported pretty fully upon what he has seen. Such a report is valuable to us so far as it goes, inasmuch as it is made by a perfectly impartial man, though one who went there committed to the principles of tropical agriculture so far as it is connected with the employment of coloured labour. At Port Darwin they have certainly not solved the labour question. They have had, and they have, Chinese, Malays, Indian coolies, but up to date none of these have turned out as well as they could have wished that they should. It may be that there are reasons for this attributable to the primitive and comparatively isolated condition of the settlement. These may be overcome, and Mr. Parsons has made it his business to ascertain how best they may be overcome. At any rate, he visited Mackay to ascertain what has been done there. And he gives a very flourishing account of the place. He tells us certainly, nothing which we do not know ourselves, but his narrative is conveniently summarised in pamphlet form, and it is a fair and impartial statement of the case.

There are those, of course, who object to coloured labour in any form, but even these people will not gainsay, and indeed they cannot gainsay, the actual results of tropical agriculture. The figures are sufficient. Exports and imports tell their own tale. Everyone who visits the district is amazed at the wonderful results produced by the combination of capital and labour. It has all been done by island labour, combined with European labour of the intelligent kind aided by machinery. The profits have been large, and the interests now involved are so extensive that it has become no longer a question of whether it is an enterprise which, as a matter of choice, we should encourage. There it is, successful, prosperous, and extending. Mr. Parsons tells his story simply enough. He speaks in high terms of the island labour, but he seems to regard it as having reached its maximum of supply. The demand for it is large, and, though the supply has been larger this year than it has ever been before, still the demand is no doubt so great that no supply from the islands is likely to be adequate. He admits the failure of the Cingalese importations; the want of judgment shown in the selection of these incompetent people; and he hints that it was not wise of the planters to anticipate the decision of Parliament on the whole subject by this attempt to supply themselves in an illicit sort of way. No doubt they had the legal right to do so, but it was a critical experiment, and it was not conducted with prudence or with ordinary foresight. Mr. Parsons expresses an opinion, however, in favour of the Tamil coolie under agreement, with the sanction of the Indian Government, and he states the exact position of the question politically, so far as we are concerned.

The Government and Legislature of South Australia recognise the fact that the Northern Territory needs a different class of labour to that required in the southern parts of the colony, and have passed an Act authorising the introduction of coolies which does not apply to the old province, and no one at present dreams of making it applicable. With us it is somewhat different. The island labour which has now for so many years been domesticated among us has proved of great service in tropical Queensland. It is a matter of dispute whether it is absolutely necessary in southern extra-tropical Queensland. The prevailing impression is that, though it may be useful, it is not essential, and that we could survive the effects of its discontinuance altogether.

In tropical Queensland it is quite another thing. It would be hopeless, for instance, to think of attempting to supply the demand at Mackay or the Burdekin, the Herbert or at Cairns, either by islanders or by European emigrants. It is a question of latitude and climate. We make distinctions by limiting the employment of islanders to sugar plantations. Might we not make somewhat similar limitations as to the employment of Indian coolies? Is the absolute prohibition of the Indian coolie to be made a matter of severe political definition? Are we to understand that the position of parties is to be rigid—No coolies either North or South? The Indian authorities, in their correspondence with our Government, seemed to recognise a distinction between tropical and extra-tropical Queensland—a distinct opinion was at any rate expressed by them that the natives of India would be more at home, and would probably thrive better, in a tropical climate than in one which was only semi-tropical. Can we recognise this distinction? or is the Indian coolie to be regarded politically as such an unclean thing that neither North or South, and not even experimentally, can he be tolerated? We tolerate Chinese. We do not permit them to increase so as to render it at all probable that they can have an injurious effect upon us. We restrict them, and our restriction has been effectual and completely successful. Why not restrict Indian coolies? All the testimony available from experience goes to prove that, in almost every respect, they are preferable to Chinamen. We are masters of the situation. We can do exactly as we like. We can restrict or we can prohibit. It is pertinent to the question, therefore, to inquire from the politicians whether the party opposed to Indian coolies are opposed to them altogether. We presume it is so. It seems to be a pity for the party. Coloured labour will certainly come to tropical Australia as surely as water finds its level, and it is a pity for any party to place itself in antagonism to an inevitable destiny. The duty of those who are desirous to maintain and to extend the character of our "institutions" as perpetuated in this portion of Australia is frankly to recognize the facts with which they have to deal. It is in their power to regulate as they please, to restrict coloured labour to certain industies, and if they think fit to certain latitudes; but the current of industry and commerce is too strong for total prohibition. The influence of the planters, the success of the sugar industry, is so great that it will be carried on either by Asiatic or by island labour. It must be controlled therefore, for it cannot be prohibited. Already it is indigenous, and if there are those who think that it is an evil it is manifestly their duty to master it and to keep it in order.—*Queenslander.*

THE SUGAR INDUSTRY.

Certain remarks in the monthly circular of the Queensland Mercantile and Agency Company, Limited, anent the sugar industry, are worthy of reproduction:—

"The Government of South Australia, recognizing the great advantages to be derived from such an important industry as sugar-production, if only it could be established in their Northern Territory, lately requested the Hon. J.L. Parsons, Minister of Education—and who has the Northern Territory particularly under his care— to travel to this colony, and, by personal inspection of the various plantations, get so acquainted with the occupation as to judge whether it would be possible to establish it. Mr. Parsons, having returned to South Australia, has published, through the press, his views on the subject, and they are so favourable that he does not hesitate to advise the capitalists of our neighbouring colony to embark their money in the occupation.

"It is worthy of notice that so determined are the South Australians to—at any rate attempt to—wrest from us our supremacy as sugar producers that they (observing that the weak point of the Queensland planters is the uncertainty of labour) have already passed through their legislature a bill arranging for the introduction of coolie labourers from India. It is to be hoped that no party of our political rulers will be so shortsighted as to drive away to the Northern Territory the immense amount of capital which can be invested profitably in Queensland, if only the reliability of abundant manual labour is guaranteed."—*Queenslander*.

RESULTS OF THE ANALYSIS OF SAMPLES OF CINCHONA BARK GROWN IN JAMAICA.

(*From the Pharmaceutical Journal for May.*)

BY DR. B. H. PAUL.

It having been considered desirable that analyses should be made of the samples of Jamaica cinchona bark, presented to the Museum of the Pharmaceutical Society by the Colonial Office, portions of these samples were placed in my hands for that purpose, and the following table gives the results arrived at.

It will be seen that there is some considerable difference between these results and those referred to by Mr. D. Morris in his notes*, as having been obtained by Mr. John Eliot Howard, and to some extent this is to be accounted for by the fact that the samples analysed by Mr. Howard two years ago were specially selected samples of the richest part of the lower trunk, while those recently presented to the Museum are a fairer average representation of the bark product for sale in Jamaica. This is especially the case as regards the sample of "officinalis," as I have had opportunity of ascertaining by a comparison of my results with those obtained by the analyses of a parcel lately sent over from Jamaica.

Variety of Plant.	Kind of Bark.	Quinine.	Quinidine	Cinchonidine	Cinchonine.	Amorphous.	Total.
1 *Cinchona officinalis* -	Trunk -	3·74	0·04	1·77	0·23	0·30	6·08
	Twig -	1·08	trace	·37	·60	·20	2·25
	Root -	2·90	1·01	·67	4·60	·58	9·76
2 *Cinchona succirubra* -	Trunk -	2·01	·13	2·58	2·45	·50	7·70
	Twig -	·78	—	·47	·23	·29	1·77
	Root -	1·76	·34	1·39	4·40	·90	8·79
3 Hybrid ! - - - -	Trunk -	2·47	—	2·24	·90	·52	6·13
	Twig -	1·00	—	·87	·40	·36	2·63
	Root -	2·45	·57	2·02	3·54	·56	9·14
4 *Cinchona Calisaya* -	Trunk -	·34	·23	·82	·82	1·80	4·01
	Twig -	—	—	—	—	—	1·30
	Root -	trace	4·07	·45	1·80	·65	6·97
6 *Cinchona micrantha* -	Trunk -	1·13	·30	·67	3·24	·68	6·02
	Twig -	·43	—	·28	·60	·50	1·81

The data in the foregoing table are also interesting in some other respects: thus, for instance, the large proportion of quinidine in the root bark of the "calisaya" sample is quite exceptional, and taken together with the small amount of quinine may perhaps be evidence of unhealthy growth or of the influence of unfavourable conditions of soil or climate. This small amount of quinine may, however, be due to the circumstance, referred to by Mr. John Eliot Howard at the Linnean Society last Thursday evening, that the plants sent to Jamaica as "calisaya" were really plants of *C. micrantha*, var. *Calisayoides*, instead of the true *Ledgeriana*, characterized by the large amount of quinine contained in the bark. Again, the amount of quinine in the "succirubra" sample shows that there is a very good type of this cinchona being cultivated in Jamaica.

While referring to these analyses it may perhaps be useful to publish some analyses made by me in 1878 of some of the first samples brought from Jamaica by Mr. R. Thomson. These samples were all very thin and green, probably having been taken from very young trees. The results furnished by the dried bark are as follow.

A comparison of these results with those furnished by the samples of bark presented to the Society's Museum shows such differences as may be taken to justify the inference that with further growth there has been in most instances an improvement in the quality of the bark. In the "succirubra" samples there is on the average more than twice the amount of quinine, and in the "officinalis" samples there is a considerable increase. In the case of the samples represented as "calisaya," however, the reverse is the case and this may be due to the bark having been derived from different varieties of that species.

	Quinine alkaloid. Per cent.	Cinchonine alkaloid. Per cent.	Cichonidine, alkaloid. Per cent.	Moisture Per cent. in bark as received.

O. TENGA AND ODAL TREES.

(*Indian Tea Gazette.*)

SIR,—I have to thank your correspondent with the long name for his courteous remarks in No. 10. The O. Tenga (*Dillenia Indika*) I had not put in the list of "post timbers," as it is so seldom felled for this, or any other purpose. It is a fruit tree, and O. tenga jelly is not at all bad; it has also a reputation for allaying thirst better than water, in the jungles. I could not guarantee it as a bridge post, but if put *wholly* under water, its naturally white (heartless) wood turns jet black, and lasts many years. It is hardly safe to infer that a wood must be good for bridge posts, "as it grows in swampy ground," or Pani Kodom, and Pani Mudi, should be good. I did not know that "Udal" (*Sterculia villosa*) was good for fences; I have grown it for fibre, and the wood is; like cork or pith. Perhaps your correspondent means "Ural," (*Bauhinia*). It is good as a fence, as the branches, like "Pani Kodom," often grow as well up, end down, as the natural way. I shall be glad to get botanical names of trees, many are not known. We must all remember that names common in Assam are only a mystery to planters in Cachar, Darjeeling, &c.* The botanical name should, if possible, always accompany the local one. Above all things, 1st accuracy, 2nd brevity.—Yours, &c., S. E. P.

THE NORTH TRAVANCORE PLANTING COMPANY.

[TO THE EDITOR OF THE "MADRAS TIMES."]

Madras, May 30th.

SIR,—I have seen an extract from the *Madras Times* reprinted in the Ceylon *Tropical Agriculturist* which, I think, is calculated to convey an unfair impression of the operations of the North Travancore Planting Society. In the extract it is stated that the Talliar valley is a "sinecure"; that what as been planted there has proved an entire failure, and it is recommended that the cultivation of tea, coffee and cinchona should be given up, and planting of ceararubber and cocoa commenced. I have just returned from a visit to this valley, and can therefore state with some authority what has actually taken place. The oldest clearing is about 23 acres in extent, and is planted with coffee. These trees are about three years old, and have, for a virgin crop, a remarkably fine show of berries. A crop of at least 5 cwt. per acre is expected, and this for a first crop can scarcely be called a failure. Forty acres of cinchona were planted out last year, and it would be difficult to find better or healthier looking trees of the

*To which should be added Ceylon.—ED.

same age. A large number are four feet high, still more are 3 feet, and the remainder are about 2½ feet high. Of course, there are vacancies in parts, but this can scarcely be called a failure. The young coffee, planted last year has certainly suffered a great deal from insects; but 1882 was an exceptional year for this plague, and the plants which have escaped, all look strong and healthy, whilst those attacked are again springing up. Nothing could be finer than the plants in the nurseries, and, with the advantage of the great experience of the present manager, Mr. Payne, I have no hesitation in saying that if any body will visit the Tulliar next year, he will find the plantation contrast favourably with any other in South India. When I add that there are about 440 acres cleared, and that about 300 of these have been felled during the last 12 months, I think you will agree with me that to say the place is a "sinecure" is ALL WALKER.

NOTES AND STATISTICS OF CINCHONA BARK.

BY JOHN HAMILTON.

London: J. W. Collings.

This little pamphlet of seventeen pages professes to give rough statistics of the importation of cinchona bark into some of the leading European countries and into the United States. The compilation of tables of statistics might appear, at first sight, to be an easy matter; but there are so many possible sources of error, and so many difficulties in the way of obtaining information, that the author may be congratulated upon being able to obtain even rough statistics on so complicated a subject as the commerce of cinchona bark. Mr. Hamilton has evidently taken much pains to collect reliable information, yet he has been unable to obtain any account from Spain and Austria; from the latter country because all importations of drugs are classed under one heading. There must naturally be much difficulty in making divergent accounts from different sources agree, and hence it can hardly be wondered at, that the statements on page 6, of the amount of cinchona bark exported in 1881 from England to France and the United States does not agree with that of the quantity imported from England in the same year by those countries, on page 10 and 11. This is more especially the case when one is at the mercy of printers. Thus in a foot-note on page 6, Mr. Hamilton remarks that he received the following reply anent the Table A, when making inquiries as to the difference between statements obtained from the Board of Trade and others published in the *Ceylon Observer*:—

"The Board of Trade monthly accounts only give approximate quantities and value; the great difference in the values of 1878 arises from a printer's error in the monthly accounts."

Nevertheless tabular statements are always of considerable value, if even only approximately correct, and must of necessity afford abundant food for reflection. Thus the conclusion is arrived at that England is the chief market of the world for cinchona bark, and the value of its importations is shown to have increased from £218,565 in 1870 to £1,816,501 in 1881. Although more than half of the imports are again sent out of the country, the value of the exports is less than that of the portion retained, indicating that the best cinchona barks remain in Great Britain. It is also an instructive fact that the value of the imports of East Indian Barks has increased from £22,682 in 1876 to £248,894 in 1881.

Comparatively little is said concerning the West Indian barks, these having only entered into commerce within the last few years. There could, however, be no difficulty in obtaining information from Jamaica under the present active administration of the Botanical Department. So far as can be gathered from the tables, it would appear that most of these barks find a market in the United States.

Another singular fact revealed by these statistics is the speculation which takes place in the cinchona market. The variation in the price of quinine, of which 6*s.* 6*d.* in 1875 and 13*s.* in 1878 may be taken as examples, has led to frequent interchanges of bark where least expected. Thus England has imported cinchona bark from France and Germany, although it has sent back in the same year more than it received. America also has imported cinchona bark from twenty-eight different countries, instead of only rom those which produce it.

It is interesting to note also that while the Java bark received in Amsterdam in 1881 amounted to only 268,540 lb., in the same year 1,864,912 lb. of East Indian bark was imported into the United Kingdom. The care taken in the cultivation indirectly comes out in the fact that the Java *Ledgeriana* bark has steadily increased in percentage of quinine from the maximum percentage of 5·48 in 1872 to 9·00 in 1881. There are many other important facts and much useful information afforded by this little *brochure*, which should be in the hands of every one connected with the cinchona trade.

It may be hoped that in a second edition the author will be able to add some tables of the respective values of the different varieties of cinchona barks, such as would give to planters some idea as to the species which would pay best in cultivation, and as to the country which would afford the best market for special varieties.—*Pharmaceutical Journal.*

THE EKMAN-FRY-ESPEUT SUGAR PROCESS.

The two chief difficulties that have been raised against the process. These are (1) That it will be impossible to treat in cylinders the immense weight of canes cut upon an ordinary sugar plantation, at any rate during the time now usually occupied in reaping and crushing. The answer to this in a general way is that if plant can be provided to evaporate the juice immediately after it is crushed out, then it should be comparatively easy to provide "converters" (that is the right term, not cylinders as we gave it) to treat the canes. We understand that these "converters" will be constructed to contain from twenty to thirty tons of canes each, or perhaps more, and that it will be easy to work six "boilings" per day with each "converter," or, in other words, to treat from 800 to 1,000 tons of canes per week with one converter, and it would only be necessary to multiply their number according to the requirements of the plantation. Under the old crushing process, it is usual to cut the canes before they are quite ripe, because, otherwise, the outer surface becomes too hard to crush properly, and the consequence is a proportion of inverted sugar; but under this chemical process it will be better to let the canes get quite ripe, when a larger quantity of saccharine matter can be obtained from them, and the hardness of the outer surface will offer no resistance to the chemicals introduced into the converter.

The second difficulty raised by those who have addressed us is that the chemicals put into the "converter" must necessarily amalgamate with the saccharine juice, and so affect its taste or quality, as to render it unfit for crystalization into pure and wholesome sugar. Now this is so obvious an objection, that it must necessarily have occurred to the eminent chemists who have been working out this process at the first moment of its inception, and as we have their explicit assurance for it, that this has not been overlooked, and that the supposed difficulty does not arise in practice, we must just be content to accept their assurance of the fact, until we are in a position to state fully what is the chemical employed and how it is to be got rid of. We may add that when the juice has been expressed from the pulpy mass of canes ejected from the "converter," we believe that lime is thrown in, and that this precipitates the chemical to the bottom of the vat "like a fall of snow," to use the words employed to us to describe what takes place. We are quite prepared to hear that our description is still provokingly vague, and we do not deny it; but it is all that we are at liberty to say at present. We may add, however, for the comfort of sugar growers who admit that this process would immensely improve their position if it were practicable, but who are sceptical as to its success, that one of the largest proprietors in Demerara, and one too who is universally recognised as the most scientific and successful of his class, has thoroughly examined into it so far as has been possible in this country and is very confident that it will answer.—*Planters' Gazette.*

TWELVE TONS WEIGHT.—A log was recently hauled to a mill in Wabash county, Ind., that was 51 in. in diameter at the big end, and weighed over 12 tons.—*Forestry.*

BRAZILAN SLAVERY.—*Estudos sobre a Libertação dos Escravos no Brazil*; by J. I. Arnizaut Furtado. Pelotas, Livraria Americaua. The publication of these "studies" on the question of slavery began in 1869 two years before the adoption of the present emancipation law. They are therefore an interesting exposition of the views of and old abolitionist who had the courage to assail this great evil before the law of 1871 was adopted, and who is still dissatisfied with the slow progress of emancipation. At that time Sr. Furtado pointed out the necessity of acquiring colonists for the development of Brazil, a result, however, which could not easily be realized because of the obstacles interposed by the church and by slavery. Now, after thirteen years of emancipation have expired, Sr. Furtado again takes up the pen to urge an earlier emancipation than is contemplated en the law of 1871. His estimate of the present slave population of Brazil is 1,000,000 individuals, a figure certainly much below the actual number. The total in 1880 was stated to be 1,419,000, and as the annual decrease is only about 2 per cent. the present slave population cannot be far from 1,350 000. His plan of accelerated emancipation comprises only three stages: 1st, the immediate emancipation of all slaves over 50 years of age; 2nd, the emancipation of all slaves now between 32 and 49 years after a period of 4 years; 3rd, the emancipation of the rest, now between 13 and 31 years, after a period of 8 years. The labor question, the author believes, can easily be met by immigration, providing the proper inducements are offered.—*Rio News.*

TEA.—The Report on the administration of Assam for the year 1881-82, only just issued, and which we may notice more in detail hereafter, shows fully the value that the tea interest is to the province and the benefits it confers on the coolies employed on the gardens, Mr. Elliott says:—

Tea, the chief and peculiar industry of the province, had for once a prosperous season. The crop was a good one, and prices ranged from three or four annas ℔ lb. above the low rates of the preceding year. The area under mature crop is returned (partly on accurate data and partly on estimate) at 133,293 acres, in the previous year it had been 120,512. The outturn of tea was about 38 million lb. (it was 34 millions in 1880), or an average of 282 lb. ℔ acre of mature plants. The Kachar district stands first with an outturn of $10\frac{1}{2}$ millions; Sibsagar, however, was almost equal to it. The other districts came in the following order:—Lakhimpur, Darrang, Sylhet, Nowgong, Kamrup, Goalpara, Khasi Hills. There are 1,058 gardens, of which 781 lie in the Brahmaputra and the rest in the Surma Valley. The average cost of cultivating an acre of tea may be roughly put at R50, the average cost of manufacture at about 5 annas ℔ lb. or, if an acre produces 250 lb. nearly R80 ℔ acre. Thus, the total cost of a lb. of tea is a little over 8 annas, and the average selling price may be roughly put at 12 annas, or $28\frac{1}{2}$ millions of rupees for 38 million lb. From this, however, must be deducted the cost of freight and agency charges. The amount actually spent in the province is about 19 millions of rupees. Of this, it is estimated that about 60 ℔ cent. is expended in wages of labourers, the rest going to the pay of the higher establishment and to machinery. The tea-coolies, therefore, earn about $11\frac{1}{2}$ million of rupees in actual wages. This sum divided among a population of 200,000 tea-coolies (men, women, children, and infants all told) gives an average of $57\frac{1}{2}$ rupees ℔ head, or for a family of four R230 ℔ annum and R19 ℔ mensem. Such wages are far beyond the wildest dreams of any of these people in their native districts.—Calcutta *Englishman*, May 8th, 1883.

DIVI-DIVI.—I shall shortly have some divi-divi plants for sale from Indian seed. I am booking orders at R5 per 100. *They are said to make a capital and light shade tree.* The produce of each full-grown tree has given R9. News this in Ceylon, surely, as to their being suitable as a shade tree? How about sapan, of the same family, and very nearly allied? Have the pods of the latter been tested for *tannin*?—*Cor.*

WOOD GROWTHS IN WASHINGTON TERRITORY.—Reports state that Fir, Pine, Oak and Cedar of unsurpassed quality, and practically unlimited in quantity clothe the mountains, overhang the rivers, and shadow the plains of the Puget Sound district in Washington territory. On a moderate estimate it is claculated that this region will yield the almost inconceivable quantity of 160,000,000,000 ft. of valuable timber. The trees attain a remarkable development, both in height and beauty. The yellow Fir is frequently found growing to the enormous height of 250 ft., the White Cedar to 100 ft., with a girth of over 60 ft.; the White Oak is 70 ft. in height; while ordinary-sized specimens of the Sugar Pine yield from 6,000 ft. to 8,000 ft. of cut timber.—*Forestry.*

A LEEDS gardener, writing to *The Garden*, says:—"Paraffin as an insecticide is one of the very best that can be used, and also one of the cheapest, but such directions as the following are misleading: 'In syringing with this mixture, the syringe should be drawn full and again discharged into the vessel, then quickly refilled and discharged on the plant.' This a very unsafe way to use paraffin, as I and many others have proved. Some years ago I carefully followed the same instructions, using one wine-glassful of paraffin to three gallons of water applied to some crotons. The result was, some of my plants died, and the others lost every leaf. I therefore discontinued paraffin for some time, but meeting with a friend who said he used nothing else, and that he mixed it with soft soap, I ventured again to try it, and this time was more successful. I find it now to be the best of all insecticides for general use. I mix it thus: to half-a-pound of soft-soap, I add one pint of hot water, stir until the soap is thoroughly dissolved, then add half-a-pint of paraffin and stir well; to this I add two quarts more of hot water and put the whole into a stone bottle and shake it well before using. This I always have in readiness, and for syringing or sponging we dilute it as may be necessary. It mixes readily with cold water, and thus mixed may be safely applied to any plant." By paraffin our readers are to understand kerosene, and when it can be rendered soluble in water, as stated above, there is no doubt that it will prove invaluable as an insecticide, even for the coccus and acl e which infest orange and lemon trees.—*Queenslander.*

NEW PRODUCTS.—"J." writes:—"I was glad to see your notice of the walnut tree. It was mostly for its very valuable wood, so much sought after that I wrote you that it flourished in the tropics, doubtless it would grow well in Ceylon. *In re* the recent information anent arrowroot I have made some cwts. of it myself for the good folks at home and my own use. I would say that East Indian arrowroot is prized in London on account of its astringent properties, and if of best quality it is sure to bring far more than St. Vincents or other West India islands produce. Then there is a kind called Tous-le-mois—used by doctors in diarrhœa. Ask Mr. John Maitland to give us full information on thr subject and say what the best kind is worth pe cwt.; it should be clear, *lumpy* and *crisp*. The Tous-le-mois bears a pink not a white flower. Of course all stuff made from cassava and called arrow root is *ungenu ne*, as the Yankee would say, and is not the ticket for soup. There are two or more kinds of cassava: one called the sweet and the other the poisonous kind; from the latter the celebrated cassaripe is made, the juice being simply expressed and slowly boiled down to a proper consistency. Those who have tasted meat cooked in cassaripe as I have do not forget its delicate flavour: it can be used in stews. The poisonous cassava has I think purple veins under the leaf."

Correspondence.

To the Editor of the "Ceylon Observer."

MR. STORCK ON VEGETABLE PHYSIOLOGY.

Belmont, Rewa River, Fiji, April 10th, 1883.

DEAR SIR,—I have always with much interest followed any publications in your paper which could serve to give me an insight into the present physical condition of the coffee-fields of Ceylon, which is more or less intimately connected with the cure of the fungus as practised and recommended by me; and nothing has ventilated that question so well as the writings of your correspondent "W." and the answers and controversial remarks thereupon elicited from others of your readers, especially as to the importance of foliage to plant life.

The functions of plant-life are twofold: firstly structural, and secondly progenitive, or reproductive. Both these functions have by the cultivator been taken advantage of for commercial purposes, and the importance of the foliage remains the same, whether the marketable portion of a plant is gained from its structural parts, roots, stem, or leaves, as roots, fibre or the monstrosity called a cabbage, as when a coffee berry, a peach, or even a favourite flower, is aimed at by him. Keep persistently pulling off the leaves of the commonest weed, it will die; off a growing carrot plant, it will make no root; off a cabbage plant, it will not make a "head"; off a coffee bush or a peach tree, it will not bear. And whilst in all or any of these cases an always feeble and often premature blossom or effort at seeds, that means at reproduction of species, may take place, you will as often find it die before making this impotent attempt.

Through having been violently, continuously and unseasonably deprived of those most important structural organs, the leaves, the conductors and elaborators of food their breathing organs, and, in the instance of coffee and fruit trees, the natural shelter of young wood and young crop, your coffee-fields have arrived at the stage you now see them in. It is through the leaves that plants draw their chief supply of carbon (an element without which the formation of a plant is simply impossible, as the analysis of any vegetable matter shows) and in turn exhale the superfluous nitrogen generated within its tissues—surely ample reasons for their unimpaired preservation. *Hemileia vastatrix* and its effects upon the foliage are quite sufficient to account for all that "ails your coffee trees." What Dr. Hooker said in his professional opinion on *Hemileia vastatrix* is certainly very abstruse. *Hemileia vastatrix* is *not* a disease, but the cause of one, a most emphatically legitimate object for the action of Government, as shown by precedents in other countries with other epidemics. The features of the matter dictate an examination of its life history in a scientific sense, with a view to curative measures based upon the knowledge so gained and subsidized by Government. The disease in your gum trees is just as much the effect of a fungus and a leaf-disease a in your coffee trees: loss of foliage and dying back of extremities are the same, but the gumtree very likely succumbs sooner because strictly speaking it is not a tropical forest tree but with you an exotic. [Dr. Trimen could find no sign of fungus on the gums.—ED.]

I was rather surprized at "W." trying to prop up his argument by putting the loss of foliage by pruning on a par with that lost by the wholesale ravages of leaf-disease. Pruning is a species of amputation by which you remove after proper selection any structural irregularities of shape, and secondly superfluous growth which presently or prospectively interfere with the conditions of the highest reproductiveness for commercial purposes, *i. e.* "crop." Other trees besides the coffee—the apricot, the peach, the grape—are heavily handled in full flush and for the same reasons. The juices of the amputated limb or cavity are diverted from waste to productiveness. But just pull off only the leaves of a tree, leaving the bare wood to draw upon the physical powers of it for a new coat of foliage, without which, as shown above, the tree cannot live, you will, if you repeat the process often enough, constitute a parallel to leaf-disease. Loss of foliage through insects, wind, or cropping, as with tea, is a different matter again. They seldom occur often and regularly enough to do lasting harm, and, when they do, there is generally enough of foliage, leaf stalks, ribs and shreds of leaves—with tea, old leaves—left to keep up a circulation until by renewal of foliage the balance of supply and demand, the organic functions of the foliage, is restored.

With *Hemileia vastatrix* and its ravages it is a different thing: they occur so repeatedly and persistently, as to undermine, independently of crops of berries produced in previous seasons, the physical stamina of your coffee trees and their by this time indirectly debilitated progeny that the plant becomes impotent to more than in a restricted manner perform its reproductive functions, and is compelled from very poverty to confine itself to its structural duties, the ever and ever reimposed labor of replacing its indispensable foliage, to enable it to live, exist, vegetate. I have elsewhere compared leaf-disease and its effects to a sort of arithmetical progression, which continues until the sum of its duplications and reduplications is equal to the original physical power of the coffee tree. This means, in other words, that the debilitating effects of one season will be doubled the next, at first but slowly, but, as powers of resistance decrease, ever more fatally and rapidly as season follows season. This is only meant to apply to the coffee tree as a commercial plant, without taking into account the counteracting influence of more or less intelligent and liberal treatment in working and manuring, about which so much has been ably said and written, that I would find it difficult to say anything new or suggest anything better than has as yet appeared. A plant in its wild state is of course equally subject to the laws of nature, but less an object of solicitude to man.

Although I have not heard much lately about the carbolic acid treatment against the fungus, I was glad to notice that it is not abandoned and that a party of planters admit that they have had results, whether by my own system or another, and boldly declare that carbolic acid *does kill* the fungus. I had told you so and eminent chemists confirmed me in their opinion, giving preference to the fluid indirect treatment to that by the powder; and time will prove them correct: but I do not only profess to kill 90 per cent of the spores, but all and utterly. I have done it and will do so again. Considering the vast importance to you and all in the East, I would have expected greater interest and hoped for better faith in my scheme. In my own small plantation—I had to make an entirely new start after having the old field and a large nursery destroyed by Government 3 years ago and am besides cultivating a considerable area of cane, is perfectly free of leaf-disease, Liberian and all. A year ago I offered to arrange with other proprietors for trials on terms, but the only response I had was the magnificent offer of traveling a hundred miles, bear all expenses, and treat *one acre*! What was the gentleman afraid of in making this restriction? He had probably never given the subject a thought and suspected something heroic. Others seem to think: "We have got it (*Hemileia vastatrix*) and we must keep it. Allah is great!" I must confess to a lurking leaning towards fatalism in some remote corner of my own psychical make-up, but not in the abject sense of the proverbial Turk.

If there is anything I blame myself for, it is for speaking perhaps too early of my discovery, but I was satisfied from the results I had that I was on the right track, and, when I did speak, I distinctly warned planters not to rush into experiments until they had heard more from me (*Gardeners' Chronicle*, February 8th, 1882) because I then saw room for improvement. The very various, and often very great tenacity of life of the spores of *Hemileia vastatrix* compelled me to gradually change my system from the employment of *restricted* to that of *assisted* evaporation of the acid, all else remaining the same. The floating wicks of rolls of bagging once recommended I have now altered into upright collars of the same material, and anyone may adopt these without any alteration in his arrangements. Presuming that the vessels are of the required diameter and charged with good acid, take fairly round bagging, cut it into strips of about 2½ inches in width, of sufficient length (about 1 foot) to go once round the inner circumference of the vessel, put it down edgeways to the bottom of the vessel, have it stand straight up if possible against its side, but take care that, if the vessels are shallow, it must not bend outwards and overhang the rim, as it then would act as a syphon and cause loss and possibly damage. In a few minutes the collar to its very top edge will be moist with acid and give off volumes of vapor which no fungus can resist. Old acid, which had been lying for months in the vessels and which I had thought effete, began to act again and continued for several weeks afterwards. I do not think it necessary as yet to depart from my original estimate of 30 vessels per acre and their cost with four three-monthly supplies. This latest improvement of mine so much increases the evaporating surface and accelerates the evolution of the vapor, that I would not recommend any closer arrangement of the vessels, until the density of the gas was still insufficient to kill *all* the spores under *all* conditions. Besides, without some artificial way of promoting evaporation, the acid would lie comparatively idle in the vessels, nor would according to my experience the three-monthly charge evaporate in that time.

From what I can gather, the effects of the disease and the fungus itself are far more pronounced with you and obstinate than with our comparatively recently infected trees, insomuch as, according to the statement of one of your correspondents, even after a decided abatement of the fungus on a field under treatment, a fall of leaves took place, showing very few traces of fungus; whilst with me the first effect of the treatment was that the whole foliage, even though copiously marked with wornout spore-patches and dead pin-spots, *remained* on the trees. This difference in behaviour under identical conditions can only be charged to a state of greater exhaustion. Under continued treatment you will find that, as the fungus becomes thinner and weaker (I say so advisedly, because it does sicken by degrees), your trees will, although perhaps still bearing the marks of the fungus, retain their foliage and resume their crop-bearing. What it took ten years or more to effect is not to be recovered by magic.

A good deal has been said about more or less disease-proof trees among Liberian and Arabian coffee, and from my observation I have come to the conclusion that the readiness or otherwise of certain types, varieties and individuals of either species to receive infection much depends at first upon the *texture* of the foliage, until even such plants become, by repeated attacks, however slight, by degrees debilitated, lose their individual peculiarity of texture epidermis, and become at last as subject or nearly so to the inroads of disease as their neighbours. Mr. Ward, with whom I entirely agree in everything, except the wellknown point, speaks of an experiment he made of sowing spores upon the top of leaves, only succeeded after removing the epidermis, under all other conditions, through its denser texture and greater thickness than that of the lower side of the leaf, impervious to the germ tubes of the spores. It takes no great stretch of fancy to expect that the longer a tree suffers and the oftener it has had to make a new flush of foliage, which foliage, formed out of season, would of necessity be of less substance and lighter texture than others formed under normal conditions, the more readily the germs will enter. It may be for this reason that more spores (germs) survive as yet than ought to be expected, because they enter before the enemy has had time to destroy them, although, according to *my* experience, they are not even then beyond reach. I think a destruction of 90 % for the first season a very favorable result under the conditions given, with badly diseased fields all round the area under treatment and the atmosphere charged with myriads of floating spores. Reduce the remaining balance at the same rate and what will be left? A practically clean field! Let the treatment become general and abandoned plantations destroyed, the clouds of floating spores rarefied, and mark the difference in the results. But I still uncompromisingly maintain that, if my system is carried out strictly, as what *I* conceive it to be, and as what I have been at great pains to describe it to you and others, *not a spore can survive.* Intelligent management of your estates will do the rest, and you will find your trees recover faster than they declined. All the physical powers of resistance shown by them in their long struggle will be doubly in their favour on the way to recovery, when once they reach the turning-point.

I have not by any means given up my intention of a personal visit to you, which I hope soon now to be able to carry out.—I remain, dear sir, yours very faithfully,

JACOB P. STORCK.

P. S.—On referring to the paper containing Sir W. Hooker's professional report upon the expediency of offering a reward for a *de facto* cure of *Hemileia vastatrix*, it strikes me very forcibly that he meant firstly to punish a certain want of conciseness in the use of terms on the part of the petitioners, and that secondly, he did not show sufficient appreciation of the different conditions under which the prospect of an award has proved "worse than useless" for a cure against phylloxera in France, and what we find to be the case with *Hemileia* and the few men who have with more or less claim to practical success endeavoured to find a remedy for it. If I am rightly informed the Government of Java had offered and subsequently withdrawn an award for the suppression of leaf-disease (or its cause) which was open for competition for some time *without a single claimant appearing.* In the English colonies no award had ever been officially offered: but, although anyone lucky enough to solve the question would with good reason eventually expect some acknowledgment for his services, and there have, with the exception of one or two rather wild schemes which were plucked at once by the public press, been only four competitors for the honor in the field—Messrs. Morris, Schrottky, Ward and the writer, all of whom have been equally honest and earnest in their several proposals—a very different aspect of things to the disgraceful scramble said to have taken place in France, if you consider that these men came forward without any definite prospect of award in the event of success.

In the event of an award being offered I would suggest, by way of safeguard against abuse, that each competitor for it should submit, as first condition, his method in writing for the publication by the press of Ceylon, and will be bound that few would attain to the dignity of examination by an official committee. J. P. S.

[It would be well for Mr. Storck's own credit that he visited Ceylon, for the general impression now is that the carbolic gas cure has been far more a failure than that by lime and sulphur. The feeling is strong that, if Mr. Storck's remedy had been successful even in his own case, the Fiji planters would not neglect it as they have done.—ED.]

AN INSECT ATTACKING TEA PLANTS.

May 25ht, 1883.

SIR,—A considerable number of tea plants about here have gone out this year, and I have been puzzled to account for the cause. The tea plants in question, from one year old up to four, had lost a portion, from ⅜ to 1 inch, of their stem bark just about the level of the ground. A cooly has today brought me a poochie which he says he caught biting a tea plant in the part mentioned. I enclose you the poochie for your inspection, and shall feel obliged by your informing me whether it has anything to do with the matter.—Yours truly, PLANTER.

[The insect, a small green beetle, unfortunately escaped before we could get it identified ; but the damage may have been caused by the black or brown grub, which by ringing young coffee plants, just at the junction with the soil, often necessitates repeated replantings. This grub has usually done little harm to tea beyond nipping the top of nursery plants which have grown again. Crickets are great tea pests in India and in the low-country in Ceylon.—ED.]

THE FUTURE OF COFFEE.

Kandy, 25th May 1883.

SIR,—Is coffee doomed to extinction inevitable and irretrievable ? For my part, I have no desire to write dogmatically on a subject of such importance, for only a very wide experience of its history, condition, and prospects, in every district in the island, can justify the expression of a decided opinion. After a long absence from the country, and the continual receipt of bad news from Ceylon—of leaf-disease growing worse and worse, and crops growing shorter and shorter—I was surprized, on first visiting the coffee districts, to find the trees apparently in such good heart and vigor. I thought I never saw them looking better. Leaf-disease seemed to me to be conspicuous by its absence, and I asked : "Why do these trees not bear ?" The answers usually were a simple reiteration of the fact, that pruning and manuring produced new wood, and new leaves, but very little crops. Even where good blossoms came out and set, the berries could not be depended upon to ripen. Failing to *see* the affected leaf disfiguring every tree and every branch, as was the case ten years ago, I jumped to the conclusion that not leaf disease but some abnormal and mysterious atmospheric condition was the true cause of our calamity. This might change suddenly, and restore to the coffee its old fertility, and to the country its old prosperity. But further observation has compelled me to modify this opinion. While I took that view, I persuaded myself that everything pointed to the fact that we were on the eve of a change. I am now, however, of a different opinion. Nothing, it seems to me, but the immediate disappearance of leaf-disease will save from destruction the remnant of the coffee which has not already been virtually killed by it, and by it alone ; the end being accelerated of course by neglected, because, apparently, profitless cultivation. What I failed to see in the apparently luxurious coffee, until it was pointed out to me, was that the effect was produced by entirely new leaves, and that the inside old wood upon which ought to hang an almost impenetrable mass of old foliage, was quite bare and leafless. Professor Attfield, in a recent paper on the *sap of plants*, calls the "leaf system" of a tree its "great digesting, or rather, developing and transpiring apparatus" ; and, although there is nothing new in this, it is as well sometimes to be reminded of it. He further says that "the substance of a tree" (which of course includes crop, or its seed) is formed from the sap, which is caused to circulate by "chemical force" ; and that this chemical force is derived "from the heat force poured on to its leaves by the sun." Now there must be a very great difference between old matured leaves and the new leaves hanging only to new "wood." The function of these latter must be restricted to the service of the new wood, and can have little to do with the economy of the tree, or the circulation of the sap. Leaf-disease has deprived the tree of this essential part of its system. What wonder, therefore, that the tendency—in order to restore this equilibrium—is to run into leaf instead of into crop (where the trees are still vigorous) or that little or no effect is made at all where the tree has already been for a season deprived of its entire leaf system, except a few at the ends of the branches, which at last disappear also, leaving the bare and ruined trees now seen on thousands of acres, to which each year will add thousands more ? Judicious pruning and manuring and favourable aspects and lay and soil will preserve coffee so treated and situated the longest. The question is : how long will it be (if leaf-disease continues its ravages) until the best and last of the coffee, shares the fate of that which has already succumbed ? Perhaps, not one only, but many, of your correspondents will give their views on this question.

Would you also be good enough to republish a short and concise account of the life-history of the leaf-disease ? The ignorance that prevails on this subject is astounding. Notwithstanding its importance I have not found one who could tell me anything of the earliest, intermediate and last stages of its life and action. OLD PLANTER.

[We shall look up the subject and try to give a succinct summary.—ED.]

CALISAYA VERDE LEAVES.

DEAR SIR,—I send you various leaves of Calisaya verde plants. You will note they have nearly all the characteristics of the typical Ledgerianas, but, as a whole, perhaps show a heightened red in the underleaf and midrib. I do not think all Ledgeriana trees lose the red foliage. I have trees of 2½ years which still shew the deep red on the underleaf. This, of course, is quite distinct from the red colour leaves assume at certain periods, or previous to decay. There are, I believe, several sorts of Calisayas distinguished in Bolivia by the red or yellow in the leaves and midrib or by the green of the leaf, such as Morada, Zamba Morada, Roja, Narangada, and Calisaya verde.

I am sending samples of verde bark to Mr. Howard, which perhaps may be of interest on analysis. The trees, however, are now only 4′ 6″ or so—at a year old—and are the result of small 4-leaved seedlings put out to save the season.—Yours faithfully,

J. V. H. OWEN.

P.S.—The leaves may be of interest to any who may wish to examine them.

[We did not fail in our latest article on Mr. Howard's *Ledgeriana-micrantha* paper to point out the difference between the natural red colour of the leaves of some Ledgerianas and the brilliant red to scarlet colours assumed by the leaves of all the calisayas when in a state of decay. The collection of leaves now sent by Mr. Owen are all luxuriant and some show very beautiful purple colouring and pink veining. Excepting, perhaps the very large pure green leaves, all the other types are familiar to us as occurring in the foliage of trees grown from Ledgeriana seed received from Java. In some cases, those of large leaves, with purple colouring on the undersides, we should have suspected micrantha, but that Mr. Howard spoke so strongly in favour of Mr. Christy's specimens. We sincerely trust that Mr. Howard's report of the bark will show strong affinity, if not identity, with the best Ledgerianas. The growth of the plants, as recorded by Mr Owen, and the luxuriance of the leaves are all that could be desired, and we are very sanguine that even Mr. Howard may yet be satisfied with the extent to which the best quinine-yielding cinchonas are grown in Ceylon. The leaves lie at our office for inspection.—Ed.]

SEASONAL INFLUENCE AND SHORT COFFEE CROPS—MORE ESPECIALLY IN HIGH DISTRICTS IN CEYLON.

June 2nd, 1883.

Dear Sir,—In the *Observer* of 30th May, your general planting correspondent says that we cannot complain that the past blossoming season has been an abnormal one and yet the crop is short.

In taking up the seasonal side of the question, I am aware that I am advocating an unpopular cause; but I am still rash enough to maintain the opinion that the season is mainly responsible for the difference between paying and non-paying crops. In the first place, the calculation was that, after such a season of wet and low temperature as we had experienced from the time that the last S. W. monsoon set in till the end of the year, we should have an unusually dry blossoming season. A wet blossoming season in fact following upon a wet S. W. monsoon was an unknown experience in the memory of the oldest planter. Now the blossoming season just ended was not an abnormal one if it had followed a season of moderate rainfall, but was nevertheless a far less favorable season than we had reason to expect after such months of continuous rainfall as we had been favored with from the setting in of the previous S. W. monsoon. Up to the middle of February, there was no blossoming weather whatever and at that date the hopes of most planters were at zero. From that time till the real burst of the present S. W. monsoon, the season was of a fairly favorable character in the middle and lower lying districts, while in the higher districts rain fell every ten days. I maintain that an unusually dry blossoming season, such as we had reason to look for, was alone capable of doing away with the ill-effects of the previous immoderate rainfall, and that in all the years since leaf-disease set in never was blossom formed and crop set therefrom under greater difficulties. The March blossom, from which most estates expect to get such crop as they have, was only converted from leaf into blossom by the sun which shone upon us for a short three weeks after the February rains ceased. In the middle of February the coffee was running to leaf as fast as it was possible to do so, and this leaf was pulled up short and converted into blossom, contrary to its previous intention and much against its will. It is not to be wondered at, therefore, that a large proportion of it failed to set, seeing that the weather had once more become undecided at the time of its opening. From that time forward the weather never held up fine for more than a fortnight continuously, and the history of the April blossom is only too sadly present to the minds of all to need recounting.

Such is a pretty true record, generally speaking, of the blossoming season of 1883, not an abnormally bad one doubtless, but still far from being a favourable one, taking into consideration what had preceded it.

The reason why the '*seasonal*' view is looked upon with such disfavour is that the old planters, who are naturally referred to as the local oracles, cannot get out of their minds the pre-leaf-disease era, when coffee was capable of putting on a crop in unfavourable seasons even. No one, as far as I know, denies the ill-effects of leaf-disease, but still we have had paying crops during the period of its reign whenever the seasons were favourable. I hold, therefore, that coffee, though leaf-disease has made it more sensitive to the effects of unfavourable weather than it used to be in former days, will still give us remunerative crops in the future when the good seasons return, and that it is the combination of adverse influences which is responsible for its present low condition. Remove one of them for a few years and it will again gather up its strength to stand as the leading cultivation of the country.—Yours faithfully, W. D. B.

[We do not know that the seasonal theory is so unpopular as our correspondent supposes; although, in respect of the older districts at a medium and low elevation, we certainly have heard it said that the blossoming season was simply "perfection. We suppose a large number hold the view that the higher districts suffer from abnormal seasons added to the effects of leaf-disease, but that had leaf-disease never appeared our coffee trees would have continued to give fair returns even in the face of unfavourable seasons. We trust our correspondent's sanguine views may be speedily justified, but the good time coming has been "lang o' comin', lang o' comin'."—Ed.]

LEDGERIANA FLOURISHING IN POOR SOIL.

Kaloogala, 3rd June 1883.

Dear Sir,—The following details are interesting as showing the comparative growth of cinchona ledgeriana and succirubra.

In 1879 I planted a poor piece of patana coffee with purchased plants of cinchona succirubra. Last year only I discovered that one of the trees amongst those planted at that time was a true Ledgeriana. It was rising three years old before I found it out, and had received no special care, neither is it growing in the spoil of a road or drain, and has always in fact had exactly the same chance as the succirubra surrounding it.

The measurements of the Ledger tree and the succirubras on each side show that the former, at this elevation and in this climate at least, will grow as fast as succirubra, to say nothing of the bark being nearly twice as thick. The measurements of the succirubra show a very slow growth for the age, the soil being exceedingly poor, but it is satisfactory to know that Ledger will do well in a poor soil. No holes were cut for any of the plants put out in this patch. The measurements were taken in March last and the trees were planted in November 1879. [3 years and 7 months.—Ed.]

The elevation at which they are growing is about 2,800 feet.

Ledgeriana Tree.

Height	12 feet
Girth at foot	12¼ inches
,, at 1 foot from ground ...	9½ ,,

Succirubra Tree.

Height	9½ feet
Girth at foot	9½ inches
,, at 1 foot from ground ...	7½ ,,

Succirubra Tree.

Height	... 10¼ feet
Girth at foot	.. 10¾ inches
,, at 1 foot from ground ...	9 ,,

This goes to prove that the Ledger is the fastest growing tree and the most profitable one to cultivate.—I remain, yours faithfully, HENRY MANNERS.

[This result is interesting and encouraging. The soil, though poor, is no doubt free, and the subsoil may possibly be better in quality than the surface.—ED.]

DR. TRIMEN'S LEDGERIANA: MR. T. N. CHRISTIE TO THE RESCUE.

St. Andrew's, Maskeliya, 7th June 1883.

DEAR SIR,—Were the question raised by Mr. J. E. Howard purely technical it would be presumption on my part to say anything in support of Dr. Trimen's description and figuring of *C. Ledgeriana* but it is not so, and a statement of some facts—which are always stubborn—may help to clear away any confusion resulting from Mr. Howard's latest paper. The plant which Dr. Trimen figured was one of those raised from McIvor's seed by me, and planted on Mahanilu by Mr. Agar, and its descent from Ledger's original seed is undoubted. Other plants, exactly similar in blossom, raised from the same pinch of seed, have given over 12, 13 and 14 per cent sulphate of quinine; and the very trees which Mr. Howard called in to help him, the Yarrow Ledgers, have the same blossom, and came out of the same nursery bed as the Ledger figured by Dr. Trimen! Before the least doubt had been thrown upon his figured type, Dr. Trimen selected a tree here for specimens, as being botanically a typical Ledger, and his selection was well borne out, when on the following day, the analysis of that very tree arrived from England and showed 11·29 S. Q. The statement that the "satiny gloss and hairy margin of the leaves" was put forward as a characteristic of true Ledgerianas is almost incredible. The veriest tyro in cinchona cultivation could have told Mr. Howard that these "characteristics" are common to Ledgeriana and all the Calisayas when young, and that there is not a sign of either in the mature foliage. When Mr. Howard goes on to identify by these characteristics Mr. T. Christy's Bolivian calisaya seedlings as true Ledgerianas, his bases are as reliable as those by which a gipsy foretells your fortune. I have some of Mr. T. Christy's Bolivian plants, 18 months old, and I most certainly say they are *not* Ledgers. They seem to be Calisayas of some kind, but are as protean in appearance as they have been in name. That there are several cinchonas in cultivation in Ceylon (and I suspect in Jamaica also) underthe name of Ledgeriana, which are not that plant, is to a great extent due to Mr. Howard himself. We all remember the misunderstanding which arose about the Annfield and Emelina Calisayas, some two years ago, due chiefly to the fact that most of these Calisayas seemed exactly similar to Mr. Howard's figured "Ledgeriana"; and here I may quote what I wrote 9 months ago, in the Dikoya essay, long before I had any idea of this controversy arising :—"Dr. Trimen's illustration of the blossom (but not of the tree itself) is particularly good, a contrast to that given in Howard's great work, where the figured plant is far from being a typical Ledgeriana, if indeed it is one at all." If you will refer to Kew Gardens Report for 1880, p. 12, you will find :—

"*Ceylon.*—In 1876, some seed was received at Kew from Java, and part of this was communicated to Mr. J. E. Howard, F. R. S., who raised seedlings. He carefully selected the most promising of these, and very kindly supplied Kew with cuttings both of the figured and of another selected plant in the course of last year. Three of the rooted cuttings were given to Mr. J. A. Campbell of Lindula Ceylon, who was anxious to have a perfectly authentic strain.

"*Jamaica.*—Three other plants propagated at Kew from the same authentic strain were sent to Jamaica."

Now, if, after having lived for years beside mature Ledgerianas, which have given the highest analyses we have yet heard of, I may presume to think that I know a Ledgeriana when I see it, I say that those "authentic" cuttings, which I have seen in the Waltrim clearing, are not Ledgerianas at all. Mr. Campbell himself writes to me on 5th instant :—"No one who knows a Ledgeriana tree of a pure type according to Mr. Moens' idea of one, would think of calling the trees I have (raised from cuttings received from Mr. Howard) Ledgerianas. Two of them are very shrubby in their growth, and with hard shiny leaves. The other is a Calisaya of the broad-leaved variety, very much like what I believe is called in Java *Calisaya Anglica.* I have also another plant that Mr. Howard kindly gave me which I understood him to say had been raised from Ledgeriana seed received from Java. This is the best, so far as appearance goes, but I should not call it a Ledgeriana."

Mr. Howard seems to have absolutely nothing to base his assertions upon. He clings to "Mr. Moens' own authority" only so far as he himself wishes to believe, viz., that the first seed received at Kew was genuine; he repudiates Moens' identification of Dr. Trimen's plant, and he asserts that other seed forwarded to him by Mr. Moens as true Ledgeriana turned out to be nothing of the kind. Now, why should the infalibility of Moens be relied on in the one case a bit more than in the other?

Those who know *C. Ledgeriana*, and who have read its literature, can only arrive at one conclusion, and that is that Dr. Trimen, who has seen the Ceylon and Indian plantations, and many mature analyzed trees, knows and has figured *C. Ledgeriana*, and that Mr. Howard, with the knowledge of hot-house plants and dried specimens, does *not* know and has *not* figured *C. Ledgeriana.*—Yours faithfully,

THOS. NORTH CHRISTIE.

CEYLON GAMBOGE: WHY SHOULD IT NOT BE COLLECTED?—THEFTS OF CINCHONA BARK.

DEAR SIR,—A short time ago an article appeared in your paper on gamboge which set at rest some doubts I had as to the value of Ceylon gamboge. Several years ago my attention was drawn to this article as a dye, when seeing the pillars and walls of the inner temple of the Maligawa (chief temple) in Kandy being repainted with fanciful flowers and animals, &c. On referring to some works there on the subject there appeared to be a difference of opinion as to the value of Ceylon gamboge, both as a pigment and as a medicine. Dr. Pereira speaks of two kinds discovered in Ceylon by Hermann in 1670. He (Pereira) describes the color of Ceylon gamboge as excellent and its medicinal effect precisely the same as that of Siam. A Dr. Royle about the year 1837 used it and described it as in every way inferior! It seems now beyond doubt that it is not so, and Dr. Royle must have had some badly collected article to experiment with. Dr. Pereira says the two kinds are the goraka and the *kana* (Sinh. "eating") goraka, and further on that "there seems to be no difficulty in obtaining the gamboge in a pure state, and if so it might become an article of commerce from Ceylon." This was stated in 1832, and, though fifty years ago have elapsed, it has not yet become an article of commerce and never will be unless the Government initiate a practical scheme, spending a fair and liberal sum in doing so—a sum which will be insignificant compared to the ultimate gain in direct and indirect revenue the trade in this article will yield. The price in Europe varies from £5 to £13 per cwt. according to quality. As to there being two kinds of goraka, it is a mistake. There are as many varieties as regards shape of leaf, color of flower and fruit, and shape, size and flavor of fruit, as there are of mangoes, plantains and all other fruit. The varieties hardly deserve botanical distinctions. The coarse gamboge sold in the bazaars is not what is collected in Ceylon but is imported from Southern India. What is collected in the island is never sold. It is used sometimes by the Buddhist priests to dye their robes, a mixture with sapan dye, giving thus brownish-yellow or yellowy brown which distinguishes the robes of the Amarapura sect of priests. It is used also to color mats, for painting walking sticks, spears and bones, doors and walls of temples, &c. The mangosteen (*Mangostana cambogia*) belongs to the same or similar family, and from the rind of the green fruit particularly the gamboge flows abundantly on mere pressure. There are some of the Ceylon gorakas yielding fruit quite as delicious for eating as the mangosteen.* The half-ripe rind of some of the Ceylon varieties is dried and sold in the bazaars for pickling fish with. It has a peculiar sharp acid flavor. There is a variety grown in fruit gardens known as the *rata* (foreign) goraka. The fruit is quite yellow when ripe and like the mangosteen round with a smooth surface, but the rind is soft, not leathery or rough. The seeds of this kind are like the mangosteen and goraka covered with a pulp not white but yellow in color, and, though sweet, quite different in flavour from that of the mangosteen or goraka. The tree resembles the mangosteen but is smaller in size. The leaves are as large but of a darker green and with a greater droop. Can this be the *Garcinia Hanburii* of Siam? It is not a favourite fruit. When ripening it is picked and pickled in vinegar, the seeds being removed and the fruit stuffed with other pickled fruit, &c., finely chopped. It seems that the goraka was considered of such little value that immense numbers have been felled from private and crown lands and supplied to the railway as fuel. Measures should be taken to stop this wasteful destruction. As regards the mode of collection, it is very doubtful if the stick gamboge is collected by bamboos being placed below incisions in the tree for the liquid to flow into. The liquid exudes very slowly and dries too soon to flow. The peculiar marks in the stick gamboge is attributed to the inner formation of the bamboo in which it is collected, but I am inclined to think it is the result of the daily additions of the semi-dried liquid put in as soon as it is *scraped* off from the tree. The few natives who gather it do exactly as was described by Colonel and Mrs. Walker in 1839. A piece of bark from the trunk, about the size of the palm of the hand, is cut off and the resin scraped off it next morning. By boiling the leaves, the rind of the green fruit, &c., a gamboge, inferior only as a coloring matter, is obtained, but with care and using the scraped and clean bark only, gamboge as a dye-pigment ought to be obtained in this way too. The goraka tree is now scarce in the Central Province owing to their destruction when the forests were felled for coffee. But countless numbers yet remain in the island along the western coast from north to south. It would be difficult for Europeans to set about collecting the gamboge, as the trees are so scattered over the country. A group of 5 to 10 trees together in a plot is rarely found.

Cinchona thefts are no doubt mostly perpetrated by the thieves of other classes and instigated by a large number of the lowcountry Sinhalese and Moors who are squatters in the villages bordering estates. These men prospered when coffee was king and traded in coffee, were owners and lessors of coffee gardens or general boutique-keepers. If the trade in gamboge is opened up a large number of these men would prefer returning to their homes and earning a less profitable but a less precarious and more honest livelihood. The Government should initiate the collection and open a market. If the Government Agents fancy that by merely imparting information to headmen they will open up a new trade they are very much mistaken. They may even go further and induce headmen to bring in samples which will find their way to museums and shows, but there the matter will end. In the first place a sum should be specially voted; intelligent and responsible persons of the country employed to visit one of 4 or 5 villages as "centres" with the aid of headmen and a small gang of village coolies set to work collecting gamboge, giving practical instructions &c. The headmen should be warned to co-operate, making them understand that their promotion depends on their efforts and trouble in such matters, and to those whose village collects unusually large quantities, special promotion and bonuses should be given as incentives to others. The whole body of collectors of each village should be requested to appear with whatever they gathered by certain dates at the Kachcheri or other appointed places. The produce of each individual collector should be weighed and the value paid to him and into his hands. Half the European market rate will enable Government to recoup themselves for the outlay in carrying out the scheme. If the villagers were paid as suggested, they would return to their homes and act like leaven, stimulated with the few rupees so earned, and the whole lowcountry would be up and doing. Supposing the scheme fail, the loss would not be such as to ruin the country. Have not a few thousands been spent on useless commissions, *e. g.* cattle murrain commission, &c. and abortive irrigation schemes? There is no reason to doubt of success. No precarious cultivation is needed or loss of time. It is a mere matter of harvesting. The first twelve months' produce can be publicly sold from time to time in Colombo as the Government cinchona used to be, or exported for sale to Europe to enable European and native merchants here to ascertain its value outside and induce them to go into the trade. Ultimately the trees in the forests can be farmed by the Government and a direct revenue obtained. A small export tax can be, if needed, added. I can imagine some high officials in the revenue line wishing at once to *begin* with licenses. They will by doing so stamp out every chance of its becoming a merchantable commodity. After a year or so, if proper measures are taken to ensure success, the Government can leave the mattter to public enterprize. Agricultural shows all round the year, for the next fifty years, will do as much good as a drop of water in the ocean. Something of course, but "mighty little." What is wanted are practical schemes with a liberal outlay "an ounce of example is worth more than a pound of precept." The money acquired by natives in produce will find a healthy circulation in the island and not out of it.—Yours faithfully,

W. PROWETT FERDINANDS.

[We differ from our correspondent about the effect of District Shows, which however, ought to be combined with model gardens—already established at

* Some of the goraka fruits *are* exceedingly nice, but there is always some acid, while the mangosteen is deliciously sweet.—Ed.

several points—so as to afford the needful example. Agri-Horticultural Shows have done a great deal for the British farmer and there is no reason why they should not do much for Sinhalese and Tamil farmers. We do not mean "Headmen's" Exhibitions such as those held spasmodically in Colombo; but much less pretentious gatherings which, if held near to every Kachcheri in the island where the farmers might really see for themselves, could not fail to do good.—ED.]

AN ABNORMAL BLOSSOMING SEASON AGAIN THE CAUSE OF SHORT COFFEE CROPS IN THE HIGH DISTRICTS OF CEYLON.

Del Rey, Bogawantalawa, June 8th, 1883.

SIR,—I can fully confirm "W. D. B."'s remarks, in your issue of the 16th instant, so far at least as this district is concerned. I have never noticed during the so-called "fine weather" in any previous year so great an absence of direct, hot sunshine and so much prevalence of partially clouded or gray skies.

The mean shade temperature this year is again a little below that of last year, and this is especially marked in the means of the *maximum* temperature for each month. While we have not had much more rainfall than usual, the rain has been more evenly distributed, that is we have had fewer "breaks" of quite rainless weather than usual, and (as I said above) these were "breaks" of *fair* rather than *fine* weather. I have felt no really hot weather here until that which we have just had between the 10th and 25th May: the fine weather at the end of February was not hot enough to dry up more than the mere surface of the soil.

Under these circumstances, with the soil sodden with the excessive wet and cold of last year, it is little wonder that the trees have not been able to blossom better than they have done.

In addition to this, on most estates here rain fell heavily on the only really good blossom we had with the result that but little of it has set. On two or three estates where the blossom escaped the rain it has set well.

In fact I cannot recall a more unfavourable season here for coffee than that of the past twelve months. I agree with "W. D. B." in believing that on all good estates coffee will again prove remunerative when the present cycle of cold and wet seasons has come to an end.

I subjoin an abstract of rainfall and thermometer results for the past 5 months, a comparison of which with the results sent you previously will confirm what I have said.—I remain, sir, yours, etc.,

GILES F. WALKER.

THE FIRST TEA IN DOLOSBAGE, YAKDESSA AND DIMBULA

[The following letter has been found amongst our papers, and, as we believe it was never published, we now give it as a contribution to the history of tea in Ceylon. The writer, who is about to leave Ceylon, has recently published another letter on the same subect. —ED.]

Beaconsfield Estate, Maskeliya, 11th July 1879.

DEAR SIR,—I see your luck is up about the Dolosbage tea, and no wonder, and I shall send you a few facts that may console you, as I happen to know the oldest tea in Dimbula and Yakdessa, next door to Windsor Forest. The oldest tea in Yakdessa is on old Nagastenne, and the oldest tea in Dimbula is on old Radella, Lindula. In both cases the bushes must be over 30 years old, and any one interested in the future of tea in Dimbula and Dolosbage would do well to visit the districts first before jumping at conclusions. They will then have an idea what like Dimbula and Dolosbage may be 30 years hence. The Nagastenne tea is only about 10 minutes' walk from Stow Easton bungalow, and the Radella tea on the roadside going up to upper Radella; in both cases growing on old abandoned lands I must say that the Radella bush is the finest, largest, oldest and best that I have ever seen, and the last time I went to show a gentleman interested in tea the old abandoned tea in Nagastenne in 1874 it was still in life, and what took my fancy to it, when I first saw it in 1870, was that it was flourishing, and, though it had been at one time surrounded by coffee, the coffee was nowhere to be seen, but the tea had a sprinkling of seed on it, which I got gathered and secured, and put into a nursery on Horagalla, and which came up splendidly. When opening up Seaforth in 1872. I experimented on 2 acres near my hut, lines and cattle shed, with the tea plant, and in each pit or hole I planted a tea plant and a coffee plant. The result was that the tea plants took possession, and eventually killed out the coffee plants; at the same time the plants throve most luxuriantly. In 1873 I secured as many plants from seed from old Nagastenne, and planted up over 5 acres on Seaforth, and, although planted on the worst piece of soil the only piece of patna on the estate, people were astonished at their growth, and a young gentleman, who had just returned from Darjiling, who was sent there to learn the art and science of tea planting, on being brought down by my visiting agent or Periya Durai in 1874, to give his opinion, at the first sight pronounced my tea clearing plants hybrids of the first water. I told him that he might change his mind after seeing the mother-plants in old Nagastenne, and that, if he was game for a walk, I offered to take him and show the old tea, and we went; but when he saw the old bushes, he was rather disappointed, and at once put them down as a very low caste of China tea. I asked the same young gentleman how they cultivated in Darjiling. "Oh," he said, "when they can't clear the tea properly from weeds, they knock them down, now and again." This will let you see how people may be taken in, coming from a tea district, where shuck cultivation might be carried on, although their tea bushes might be of a very high caste of hybrid or indigenous.*

Dolosbage is a forcing climate and no mistake, and I shall give you an instance of the forcing growth it can produce. I put in a nursery of over 3 acres of tea seed from Darjiling, 64 maunds, hybrids and indigenous. I finished putting in the seed on the 29th December 1874, and on the 15th May 1875 I had over 9 acres planted with plants from the same nursery. The nursery was put in on St. Rumbolds on the riverside, elevation about 2,300. It was a great success, although put in in a most trying time, the hottest part of the year.

Another advantage planters have on that side is this: In 1875, when I was burning off a large clearing on Seaforth, the fire got into old Palampittia and burnt off a portion of the old place below the road, going towards Kandal Oya. About 3 acres of the same I planted for an experiment, and when I returned from home in 1877 I went and had a look at the same. I was delighted with the appearance of the plants: they are A 1. The only thing that spoiled the look of the strip: it had not been supplied.

* Not very clear.—ED.

This will prove to you that I was the first to plant tea in Yakdessa, and Dolosbage, with success, and prove that tea would succeed and thrive, when coffee was nowhere. I never heard the *Observer* run down Seaforth, or Windsor Forest tea, quite the reverse; but from observations I have made, I would recommend tea planters in Dimbula to plant their [illegible] wider apart than those in Yakdessa or Dolosbage. J. D. W.

PROFITABLE CULTIVATION.—According to Mr. D. Morris's last Jamaica report, the harvest of 21,000 lb of cinchona bark which realized £2,539 was chiefly taken from New Haven Garden 6 acres, Monkey Hill Garden 15 acres, both 11 years old in 1880. A gross return of over £100 an acre cannot be considered bad.

SILK CULTURE.—The action of the Chinese Government in interfering with the class of industrious silkworm cultivators, taxing cocoons, stamping out local manufactures under foreigners, &c., is not unlikely to afford further reason for encouraging the silk industry in other places, and why not in Ceylon?

CINCHONA.—In the *Journal de Pharmacie* for the present month there is an interesting note by Messrs. Regnauld and Villejean on an analysis of some bark from a plant of *Cinchona succirubra*, which had been grown in the open air in the botanical garden of the Faculté de Médecine, Paris. Notwithstanding the unfavourable conditions, climatic and otherwise, under which the plant was reared, the bark is said to have yielded 1·47 per cent of quinine and 1·05 per cent of cinchonine.—*Pharmaceutical Journal.*

PRICES OF TEA.—We ought certainly always to remember that, in comparing prices of teas, the *average* only should be considered. Thus, though Imbulpitiya tea reported at last sale fetched a penny more in *one* quality, the Sembawattie sale was really better one. There were only 8 chests which fetched 2 3½d out of an invoice of 68, while 12 chests Sembawattie fetched 2s 2½d out of an invoice of 41. Then again, the prices of all the other 3 grades were better for Sembawattie than for Imbulpitiya. It is evident therefore that the average per lb. over the whole invoice compares in favour of Sembawattie very considerably. Probably some such advantage might be claimed for Dunedin and some others if looked into. At any rate, it must be remembered that the average, not the maximum, is the proper test.

EUCALYPTUS AND MALARIA.—A project has been prepared for sanifying the malaria regions in Italy, which is of the greatest importance for the Neapolitan provinces. For this purpose a map of malaria has been prepared, which shows only too plainly the desolation of the above-named provinces. The malaria regions are divided into three classes, namely, weak, serious, and most serious. Among the 13 provinces classified as having weak malaria only one belongs to the Neapolitan provinces—that is, Aquila. Among the 29 classified as serious, there are three belonging to the Neapolitan provinces, namely, Avellino, Chieti, and Naples itself and among the 21 classified as most dangerous, we find Bari, Catanzaro, Caserta, Cosenza, Foggia, Lecce, Potenza, Reggio, Calabria, and Salerno. In fact, on the Tirenian coast from Cape Vaticano to the Gulf of Gaeta, excepting the region watered by the Volturno, the malaria is weak; but on the Ionian coast, from Cape Spartivento to Santa Maria Leuca, that once Paradise of Magna Grecia, there is a country desolated by malaria, full of stagnant, putrid swamps, with not a sign remaining of the ancient cultivation and florid commercial life. Misery and want of well-paid and constant work obliges the population to emigrate, and death reigns over a vast region where agriculture can find but little space for its operations. The new project will give to the Government the right of expropriating territories lying in the region of most serious malaria contiguous to the lines of railway for a distance of 200 metres on each side, unless the proprietors have themselves undertaken the work of sanification. For ten years from the passing of the law prizes and indemnifications will be granted to any one in the circle of malaria who makes a plantation of Eucalyptus trees. The Government provinces and communes are also authorized to grant subsidies. All proposals relative to sanitary works will be examined by an executive committee.—*Daily News.*

FRUITS.—The fruit of one variety of the *Diospyros kaki*, variously known as the Chinese date plum and the Japanese persimmon, is being grown to great perfection by Mr. A. Williams, of Eight-mile Plains, and a sample of it was kindly left with us a few days ago. This variety is large, single specimens weighing over 10 oz., and measuring fully 3 in. in diameter. But size is not its only or even principal recommendation, for in flavour it is very rich and luscious, and when fully ripe nearly of honeyed sweetness. This variety is stoneless, and as a desert fruit can scarcely be excelled. Orchardists and cottagers with small fruit gardens cannot afford to be without it, for it is a prolific bearer, and with good cultivation the tree quickly attains a great size. The fruit at present is a scarce commodity, as the tree is not readily propagated; but, as the demand for it is sure to be brisk when once its excellent qualities are known, measures will be taken to meet the demand. Mr. Williams has about 100 young trees ready to send out this winter, and those who secure a specimen will do well. It is one of the fruits adapted to a very wide range of climate, and might with safety be planted largely almost anywhere in Queensland.—*Queenslander.* [We should think the Persimmon might succeed in Ceylon. If so it would be a great addition to our list of fruits. Bushes we saw in Melbourne were literally loaded with fruits.—ED.]

THE REMEDY FOR WHITE ANTS is thus further explained:—Referring to the official correspondence recently published in our (*S. M. Herald*) columns between the Commissioner for Railways and the late Secretary for Public Works respecting the efficacy of the specific recommended by Mr. Lackey for destroying the white ant in wooden bridges, we find that the subject has attracted general attention, and the result has been that numerous letters have been received by the Commissioner for railways from persons seeking to know the component parts of the specific and proper mode of applying it. Upon making inquiries, we have been favoured with the following information by the Commissioner:—In all instances the sapwood must first be removed. Then the parts infested by the white ants should be syringed with boiling water by means of a syringe holding about two gallons. When this has been done a mixture should be applied, consisting of 1lb. of arsenic to either three gallons of kerosine oil or 12lb. of tallow. It should be mentioned that in cases of underground work it is necessary to dig down about 2ft., and when the sapwood is removed, char, and then apply the mixture.—*Queenslander.*

JOHORE, May 23rd.—I send you the rainfall on Drumduna estate, Gunong Pulai, Johore, from the time it was first taken, and hope it may be of some use. The Batu Pahat range of hills get far less rain than this: in 1882 we had about 3 months drought. Things are beginning to look up, and labour is better.

Temperature under shade Fahr. max. 91 deg. min. 68 deg. at an elevation of about 700 ft. This is not the average, but the highest and lowest it has ever been.

HARVESTING INFERIOR CINCHONA BARK IN CEYLON.

It is no wonder that a cry of "halt" has arisen in reference to the harvesting of branch bark (including twigs and suckers) from our cinchona trees. The prices offered for this description have fallen so low as to barely cover the cost of harvesting. In many cases the transactions have already resulted in a loss and, therefore, shippers as well as planters must agree that it is best for all concerned to stop harvesting under present circumstances. The more of the inferior bark that is sent into the market the more are stocks increased, statistics overburdened, and a glut apparently created, and, although the planter gets little or no benefit from the sales, there can be no doubt that these affect the value of the better kinds of bark by the full extent of the quinine obtained from the branch and twigs description sold. It is reckoned that, for every 25,000 lb. of twig bark withheld at this time, the supply of quinine will be reduced by a thousand ounces, and to make good this deficiency, 6,000 lb. weight of "one per cent" bark would be required. In other words, supposing 6,000lb. of one per cent bark to be worth nett R2,000, growers would receive this sum additional profit on their other bark for every 25,000 lb. of unprofitable twigs held back. The duty as well as policy of cinchona planters is, therefore, very clear. No inferior branch bark should be cut for market until such time as a revival of the demand with paying prices again sets in, and all prunings should be buried rather than stripped at a cost which cannot be covered in the present state of the cinchona bark market. No doubt this state of affairs is a sad disappointment to many hardworking planters who may have been looking this year for help from the product which did so much for them—even in prunings, branches and twigs—in the time of their necessity during the past two years; but the stoppage of demand must be faced, and the hope entertained that it will only prove temporary, and that the majority of the South American bark-cutters must shortly find "their vocation gone" owing to the continuance of prices that cannot cover the cost of their labour.

MADAGASCAR PLANTS.

The Rev. R. Baron contributed to the *Antananarivo Annual for* 1878 "a few jottings on some of the plants of Imerina," the district in which the capital of Madagascar is situated and which (the district) is not included in the curious ring of forest which goes round Madagascar. We find it stated of one of the COMPOSITÆ, having yellow flowers or rather capitulæ, that the natives use the leaves for annealing their water pitchers. The pitchers are made hot in the fire and then rubbed with the leaves. Are any leaves used for a similar purpose in Ceylon? Of the LEGUMINOSÆ, the pigeon pea (*Cystisus cajan*) is grown *to supply food for the silkworms*; of a particular species, we suppose. The beans are eaten by the natives. The Malagasies convert tobacco leaves into snuff, but instead of putting the powder in their nostrils they suck it in their mouths! Is Mr. Baron correct in saying that the berries of *Solanum nigrum*, which are so poisonous in cold latitudes, lose their deleterious power in tropical countries? We do not seem to have in Ceylon the scarlet bracted euphorbia thus described:—

Songo-songo (Euphorbia splendens), with its brilliant scarlet and yellow bracts, which may easily be mistaken for petals or sepals, is perhaps the most attractive plant in all Imerina. Its beauty has gained for it a place in many conservatories in England. Its prickly stem gives it a resemblance to the *Cactaceæ*, but its flower and fruit shew that it is a true *Euphorbia*. There are two varieties, one having bright scarlet bracts with leaves all along the stem, the other having yellow bracts and leaves which are terminal and larger than those of the scarlet variety. The plants are monœcious and not, as the Malagasy suppose, unisexual. The milky juice with which the plant abounds is sometimes used by the natives as bird-lime. Another use the plant affords is this:—the bark of the root is pounded, put in water, and given to calves to help them at their birth. The *songo-songo* is commonly employed for hedgerows and fences.

The next plant noticed seems to be that which we know in Ceylon as the "Persian lilac," although some of the properties mentioned are those of the true *neem* or *margosa* tree:—

Under Aurantiaceæ may be named the *vóandèlaka*, which I believe to be the *Melia Azederach*, and not a lilac. Its strong scent is similar to that of the lilacs and hence, probably, it has been supposed to be one of them. If it is the *Melia Azederach* it belongs originally to Persia and Syria. It is a tree that has been naturalized in various parts of the world, and was introduced from the Cape of Good Hope by missionaries in the time of Radama I. All its parts contain bitter and purgative properties. The tree has become exceedingly common in many parts of Madagascar.

An Indian fig eighteen feet in circumference is noticed. The leaves of the pomegranate, the native name of which signifies "the great drum of heaven," are used in dyeing black. We quote as follows:—

Kafé, or coffee, cultivated to some extent by the natives. It has probably been introduced by the French as the name would lead us to suppose.

Tsikirity, a species of *cinchona*, is a shrub with very pretty yellow flowers having a bright red-bearded throat. It is a very common plant in Ikongo,* but rare in Imerina.

The fruit of the common prickly-pear is eaten and also used as a substitute for blacking by rubbing it in the soot of a rice pan and applying to their boots, which, it is said, gives them a bright polish. Then, what is again new to us, the natives of Madagascar make ink from mango stones by scraping them into water and allowing them to remain ten days. Under ZINGIBERACEÆ, we hear of a great belt of Madagascar cardamoms (*Amomum angustifolium*), the fruit of which is pleasantly acid in flavour. Added to the other uses of the tomato, too, its leaves, mixed with water and soot, make a not very endurable ink, while the fruits are used for blacking, the same as the prickly-pear.

THE LEDGERIANA CONTROVERSY.

Mr. Thomas North Christie of St. Andrew's Estate, Maskeliya (who must not be confounded with Mr. Christy, the London plant and seed dealer), comes forward with a statement of FACTS by which the tables seem to be turned with a vengeance on Mr. Howard (see page 37). It is *he* who has figured Ledgeriana wrongly! In any case the vindication of Dr. Trimen, and the genuineness of the specimen of Ledgeriana which the eminent botanist figured, seem perfectly conclusive. There are the facts that the typical tree chosen by Dr. Trimen was raised from the same seed as the Yarrow

* The word Ikongo refers here to the country often called by that name. Strictly speaking, however, it applies only to the large hill to which the people resort in time of war. The plant is found in Isandrabe, one of the divisions of Ratsiandraofana's country.—ED.

plants, acknowledged by Mr. Howard himself to be high class Ledgerianas, and (most conclusive of all) that the analysis of the bark of that particular tree, shewed 11·29 sulphate of quinine! We erred, therefore, in saying that Dr. Trimen was unfortunate in his specimen. The picture, certainly was poor, compared with our recollection of the splendid plates in Howard's book-but then Dr. Trimen's picture was a true present, ment of a true Ledgeriana, while Mr. Christie throws doubt on Mr. Howard's drawings. We have not these latter to refer to, as our copy of the Quinology of the East Indian Plantations is upcountry. But we can corroborate what Mr. Christie mentions respecting the Annfield Calisayas. Mr. Anderson was, naturally, anxious to ascertain if his trees were true Ledgerianas and we took the book to Annfield for purposes of comparison. Leaves from Mr. Anderson's trees, placed side by side with the coloured foliage of Ledgeriana in Mr. Howard's book, were declared not only by us, but by several planters present to be counterparts of Howard's types, in every respect. The late Dr. Thwaites, C. M. G., made the same comparison and came to the same conclusion. But Mr. Moens, who sent Mr. Howard his specimens, pronounced the Annfield calisayas not to be true Ledgerianas! The mystery, therefore, thickens, and it is not Dr. Trimen but Mr. Howard who now seems placed on the defensive.

The great comfort for us in Ceylon is that this controversy does but confirm the fact, that we have Ledgerianas of the best possible types, growing in our island—on St. Andrew's, on Yarrow (Mr. Howard himself being witness); on Mattakelly and on many other plantations. Independently, therefore, of seed from Java or anywhere else, the king of all the cinchonas is here established and supplies of pure seed and good plants are available and will be increasingly so.

WHAT IS GOOD TEA?

MR. KONG MENG,

the Chinese merchant, holds that all tea if pure and unadulterated is wholesome, the only difference between the choice descriptions and the commoner sorts being that the former is composed of carefully selected leaves, which give an infusion of better and more delicate flavour, although not necessarily of greater purity. There is, he thinks but little tea of bad quality, or which is adulterated, made in China, the law there being very stringent and providing for the infliction of heavy penalties on offenders. There are no means by which the ordinary consumer can distinguish good from inferior tea, that requiring a special training; and it is only the expert who can determine the quality of samples placed before him. The general idea that good tea gives a strong black liquid is a mistake; the best tea gives a liquid of a pale sherry color.

BY J. O. MOODY.

A good tea has always a small to moderate sized leaf, improved by having golden Pekoe tips; it is usually black, grey, or red, or modifications of these colors; is regular, wiry, or well twisted: is never, irregular, open in the leaf, flaky, stalky, seedy, dusty or dirty, or contains any impurities. The infused leaf is always bright, never dull colored or mixed with black or dark leaves.

The liquor is strong, full, brisk, and flavory, never dull, insipid, soft, thin, or burnt. The aroma is strong, and rich scented, never the sickly scent of artificially made teas, or dull, burnt, or mousey.

Genuine tea is prepared by two methods, the fermented and underfermented. Both kinds can be made from the same bush, it is simply the process of manufacture that determines each; they are easily distinguished by infusing in hot water, when the fermented shows a bright reddish brown, and the underfermented a bright green leaf.

A third and fraudulent process of manufacture adopted by the Chinese is to make a strong decoction, and exhausted, decayed and rotten leaves and other rubbish is steeped in it and then dried, rolled and made up into tea. This has deceived many people, but is easy of detection.

Fermented teas are all black teas, with in the dry state grey, red, or black leaves or variations of these colors, and usually have bright red liquor. The underfermented vary in color from black to bright vivid green, but these two extremes are always artifically colored, the natural dry leaf being a dull olive color, the liquor is pale, almost colorless.

In India the fermented teas are known as Pekoes, Pekoe Souchongs, Souchongs, and Congous, and the underfermented as greens or Namoonas.

In China, the black teas are all Congous and Souchongs, and the underfermented teas Oolongs, Pekoes, Capers, Gunpowders, Imperial Hysons, Twankays, etc.

Underfermented teas are invariably the strongest, but the infusion is almost colorless, showing the popular fallacy of color as a guide for strength. Our American cousins are the largest consumers of this class of tea, which in the writer's opinion is the worst to drink, owing to the heavy percentage of tannin it contains.

The process of fermentation no doubt acts on the juices of the tea leaf in a similar manner to the change that takes place in barley when converted into malt, and a well fermented young leaf, with its silky, tender gossamer texture, semi-transparency, and succulence, indicative of quick growth (size no guide), its rich reddish brown leaf, bright, ruddy infusion and delicate aroma, at once points out a first class tea, and one that any invalid, however delicate, can drink with safety.

Nothing is easier than to tell if a tea is good. Follow this plan:—After a meal drain the tea-pot, then empty the leaves on a white cloth and pick them over.

1.—Take out the leaves described above; this will indicate the first quality.

2.—Then leaves hardly so bright or young, this will indicate the second quality.

3.—Dull looking leaves of dark brownish color will indicate age or indifferent fermentation.

4.—Black color will indicate decayed, rotten or charred leaves; they should not be in and condemn a tea.

5.—Tough or hard leaves indicate a perished condition and condemn a tea.

6.—Hard stalks or tea seed if in quantity indicate addition for the purpose of adulteration.

7.—Green leaves may be added for flavouring, but are often used to hide the faults of a portion of the bulk.

Dust and fannings are valued for their strong dark infusion; they are in demand in the London market, but are best avoided.

The good teas of this season have been Darjeelings, Assams, Cachars, Dooars, and Rangoons from India; Ningchows, Keemuns, Kutons, and Tong Ma Quams, from Hankow: Paklums, and a few Panyongs, and Ching Woos, from Foo Chow.

Probably as fine teas have come to Melbourne this season as to any part of the world but unfortunately the bulk has been very common, while in spite of our boasted Act some teas have been admitted unfit for human consumption.—*Melbourne Herald.*

WEIGHT OF TEA BOXES.

(*From the Indigo Planters' Gazette.*)

Camareah, Mirzapur, 19th May, 1883.

SIR,—Mr. Tweedie is right with regard to the mangoe chests absorbing moisture. I had a striking proof of this in December. Owing to some cause a cart-load of packed chests which had come from an out division, was weighed about 8 P. M., after coming about 16 miles by road, there was found to be a discrepancy of from 0-1-14 to 0 0-10 chittacks in each chest—although they were carried with a sheet. The following day they were again weighed in the afternoon and had returned to their original weights or very closely so. If chests can thus absorb damp and part with it, no wonder the tares are sometimes erratic. I have no doubt that thoroughly dried and seasoned chests reweighed in the damp climate of England would shew over a pound average difference. EDGAR HILL.

TEA MOSQUITO-BLIGHT.*

So far no remedy has been found for this formidable pest, and it still continues with impunity to commit its ravages and upset the calculations of the most experienced of our planters. A couple of years ago Government at the request of some of the leading tea agencies sent up Mr. Wood-Mason to report upon the insect and suggest some remedy to reduce its ravages, but alas! after being up for some time in the tea districts nothing new was found out, although a sensational telegram to the Chief Commissioner was sent round to the different planters in all the districts as a circular. The circular recommended a severe plucking or a series of pluckings as soon as the mark appeared on the bushes where the mosquito lays its egg or eggs. This remedy had been tried for many years, and was found in many instances, when the bushes were weak, to be worse than the disease, as the bushes became so debilitated that they in consequence were longer of being able to combat the insect, and force a clean flush through. Mr. Wood-Mason threw no light upon how the insect had come to prey upon the tea shrub, more than other jungle plants. Some of our oldest planters no doubt remember the time when the pest was almost unknown, so are we to come to the conclusion that the introduction of the tea plant also introduced the insect? This theory would hardly hold, as in many parts of Assam the plant is indigenous to the soil, and strange to say enjoys comparative immunity from blight. Some ten or twelve years ago when it first began to assume a serious form, covering over the bushes with blankets, and smoking the bushes in something like the manner bees are smoked in England was tried as an experiment, but no brilliant results attended it. Then again, some planters resorted to catching the insect, and in many instances thousands upon thousands were caught and killed, but without any seeming benefit, for all the slaughter. Many and various dodges have been tried, but as yet unfortunately with no brilliant result. Perhaps one of the most successful, and yet we cannot call it success either, has been the wholesale destruction of forest jungle lying contiguous to the plantations. One established fact about this insect is that it avoids exposure to the sun as much as possible, and consequently if jungle lies near the plantation it retreats there at sunrise and lies in wait to repeat its depredations after sunset. That every insect does not retreat into the jungle we are aware, for at any time almost if the tea bush is shaken, where insects have been at work, one or more will be found to rise out of the bush, but what we believe is, that when the greater proportion of jungle is close at hand, they will retire there during the day, and consequently if jungle, be it forest, be it grass, or any other kind, is removed, it must necessarily tend to keep away the insect, more especially if during the cold season, it is cut down and burnt, as during the cold season not an insect will be found amongst the tea bushes, all having migrated into the jungle. Some planters, we believe, advocate manure to keep it off, whilst again others will inform you that it aggravates it. Our own opinion is, that there may be truth in both. That manure will strengthen the bushes we do not suppose any one will doubt, nor that the insect always selects the young and succulent flushes just as they come out, and will not touch an old leaf, hence our opinion supports the latter theory, that the bush being more vigorous throws out more flushes, and hence seems to suffer more. But then this extra vigor given by the manure causes it to push through the blight and recover more quickly than its more sickly neighbour without the manure, thus supporting the first theory. The mosquito may be found at any time between March and November, but its ravages do not seem to become serious before June or July, and continue most severe during July, August, September, and the early part of October; during the latter part of October it begins to lift, and generally disappears for good in November. Like everything else, the weather seems to have a good deal to do with it, and dull cloudy weather seems to propagate it faster than bright sunny days. Last season, 1882, it appeared very late, but came on very suddenly, and with great severity when it did come. This was naturally put down to the season, which was bright and sunny throughout, with a short rainfall. In many gardens this accounted for the large increase in quantity over former years, and it may be that in 1883 those gardens will again return to their former normal yield. It is, however, quite impossible to foretell or forecast in any way, the possibilities of blight and although this pest has been increasing for many years, we are still in comparative ignorance regarding it. As we have mentioned before, the only thing that has been found of any avail up to date is a wholesale destruction of jungle in and around the cultivation. We are much afraid that many of our planting friends will say, when they read this "*Ah, we knew that before; tell us something new,*" and our only answer is, we wish we could. If we could discover some natural enemy to the insect, and introduce it into the tea districts, we would feel we had acted the part of a benefactor, but up to date our search has been in vain.—*Indigo Planters' Gazette.*

* *Helopeltis Antonii,* which in Java attacks cinchona eaves as well as tea flushes.—ED. *T. A.*

SILK IN THE MACCLESFIELD CHAMBER OF COMMERCE.

The quarterly meeting of the members of the Chamber of Commerce was held on April 9th.

Refuse Silk from South India.—The directors have had submitted to them for examination a sample of refuse silk from Southern India, for the purpose of ascertaining whether a market could be found for the article in this country. After careful consideration, the directors were of opinion that the waste is too worthless to be of any commercial value.

The Silk Trade of Lyons.—Lyons purchases on the average £17,708,333 of the raw silks of France, Italy, the Levant, India, China, and Japan; and exports £20,833,333 os goods manufactured therefrom, or mixed with wool and cotton, being about three-fourths of her entire production. Great Britain and the United States are the principal markets for these exports. The trade in cotton and woollen stuffs exceeds £833,333. The number of houses large and small, engaged in silk manufactures, reaches nearly 600. Besides these, there are some eighty houses engaged in the raw silk trade, and about 60 commission firms, whose business extends to all the countries of the globe. The manufacture of silk tulles, owing to a newly-perfected loom, has regained its old favour, and is largely extended. Silk handkerchiefs (foulards) are exquisitely manufactured, and command orders from every country. Trimmings (tissues of silk, with gold and silver in particular) are here produced superior in artistic beauty to any market in the world. Eight hundred looms are constantly engaged in this production. Church regalia, altar cloths in silk and velvet, wrought with gold and silver and the most precious jewels, military and masonic banners, flags, emblems, and trimmings are unrivalled in their beauty and production. A silk exchange has been established in New York. It furnishes silkworms, eggs, cuttings of the trees upon which the worms feed, and purchases the cocoon. It also gives full directions for the beginning of silk culture.—*British Mail.*

INDIAN GOLD MINING AND ITS PROSPECTS.*

QUARTZ OUTCROPS OF TRAVANCORE.

First, then, in point of time, we have the report of the committee appointed by the Indian Government on December 14th, 1832, to examine the gold mines in the Zillah of Malabar. They allude as follows to the geological features of the country:—"Nearly the whole of the province of Malabar except that part immediately along the coast consists of lofty mountains covered with dense forest or thick jungle. The principal chain more immediately connected with the present subject is formed of the Koondah and Moor Koorty Hills to the south-east of Calicut, the Neilgiris to the east, and the Wynaad mountains to the north-east. These send off numerous lateral ranges, between which are deep valleys, in most places closely covered with forest. The most extensive of these is that of Nellamboor, including nearly the whole of the Ernaad Taluk, bounded on the east by the Neilgiris, on the north by Wynaad, on the north-west by a lateral range running south from the Ghauts called the Wawoot hills, and on the south by the Koondah and Moor Koorty mountains. From these on all sides innumerable mountain streams descend, and meeting near Nellamboor form the Beypore river of considerable magnitude, which falls into the sea about eight miles to the southward of Calicut. In the mountainous districts of Wynaad, streams in the same manner descend through every valley, and unite into larger rivers which fall into the Cauvery in the Mysore and Coimbatore countries. The whole of the mountains above mentioned seem to be of primitive formation. In the Nellamboor valley, so far as the observations of the committee went, the prevailing rock is gneiss, a kind of stratified granite. Above this in most places is a species of clay-ironstone, which from its softness enabling it to be cut into the form of brick for building purposes, received from Dr. Buchanan the name of laterite. It is what geologists call the over-lying rock of the whole country, between the Ghauts and the sea to the westward, and many of the smaller hills are formed of it. When first dug it is perfectly sextile, but on exposure to the heat of the sun and to the weather it becomes of considerable hardness. So far as the gold mines are concerned it may be considered to be a deposit formed in the lapse of ages, from the gradual disintegrations of the immense mountain masses in the neighbourhood, in which process part of the precious ore may be supposed to have been worked over along with the earthy particles. However this may be it is certain that gold exists more or less abundantly in the whole of the country on the western side of the Ghauts in every stream which takes its rise from the Koondah, Neilgiri, and Wynaad mountains, and in the sands of the sea-shore along the whole of south Malabar it is throughout in the form of minute grains."

Further on in the same report the committee in alluding to the geological formation of the country in the neighbourhood of the Beypore river, near Mamboot, say—"the superstratum consist of sand and gravel, below which are large nodules of quartz and gneiss."

Mr. Brough Smyth, in his report on Wynaad gold fields, alludes to the lithology of the gold district as follows:—"The granatoid schists or the gneissoid rocks of the south-east Wynaad are, it is probable as will be shown hereafter, only comepletely metamorphosed sedimentary strata. The minerals observable are felspar, quartz, hornblende, mica, talc, chlorite, pholerite, and magnetic iron. The ordinary foliated rock usually massive or composed of thin impact layers of quartz and felspar or of quartz and hornblende. Magnetic iron takes the place of one or other of these constituents or accompanies them in some places; and at, and in the neighbourhood of Marpanmadi, North peak, magnetic iron is largely present in the rock, the decomposed surface stone exhibiting layers and reniform, and nodular masses of sesquioxide of iron. Some specimens are composed almost entirely of quartz and magnetic iron, and in others the iron occurs with quartz and felspar, and again there is a variety composed of translucent quartz, magnetic iron, and an asbestiform mineral resembling iron amphibole."

Again, Mr. Oliver Pegler, in his report on the Wynaad gold fields, alludes to the geologic characteristics of the district as follows:—"The range of mountains, on which is situated the Wynaad district, is of very ancient date, belonging to the Palæozoic period, more especially to the Silurian formation. The highest peaks of the range, as in the neighbourhood of Otakamunde, are formed of hard dense dark crystalline rocks of the metamorphic series of granites and syenites, the more fissile varieties of which are also here present, and are softer, and, having thus yielded to the disintegration and denudation of time, have formed the valleys and dells adjacent to the peaks. These softer rocks are of a much higher colour than the harder granitic crystalline formations, and give a reddish brown appearance to many portions of the surface of the country. Before leaving this portion of the Nilgiris for the more auriferous districts of the Wynaad, I may observe that the whole of the formations are impregnated with black magnetic oxide of iron, which after a shower appears as black sand on surfaces where the rain runs over in streams of water, and this is very noticeable along the roadsides."

I have now, I think, quoted sufficient from the reports of these several authorities to show what are the geological and lithological features of that gold zone of which in view of recent discoveries, the Wynaad may be considered as forming the centre. The commission of 1832 and Mr. Brough Smith agree that the leading rocks of tho Wynaad and Neilgiri districts are composed of granatoid, schists, and gneiss rocks, and as a consequence there can be no divergence of opinion as to the mineralogical constituents and industrial products of these rock outcrops, but Mr. Pegler says the range of mountains upon which the Wynaad is situated belong to the Silurian formation of the Palæozoic period, though he admits that the highest peaks of the range are formed of hard, dense, dark crystalline rocks of the metamorphic series of granites and syenites. This is somewhat conflicting, but the weight of evidence as regards the lithological characters of the Wynaad places it in the metamorphic system, and hypozoic period. We shall now see how far the characteristics of the Wynaad district agree with those of Travancore. The Ghauts as they pass southwards through the latter country send out, as in the Wynaad, numerous lateral spurs or side branches between which there are deep valleys or gorges covered with dense jungle, and in a region with such an abnormally high rainfall there are consequently numerous streams which have cut through the country rock in some places to considerable depths, laying bare its structure for the eye of the geologist, and, gathering strength from their innumerable tributaries, every yard traversed, they form rivers of no mean dimensions ere they lose themselves in the bosom of the Indian Ocean. The height of these Ghauts varies from 1,500 to 5,000 ft., occasionally forming comparatively gentle declivities, but as a rule they stand out in bold escarpments perpendicular to the horizon. The escarpments usually face the west and south-west, the points from whence come the annual monsoon rain-storms. The most prominent are the Ibex Hills which are passed on the left of the district road proceeding southwards from Augustier estate to where the river is crossed at the foot of Auldbar estate, and also on the opposite side of the same river to the left front of the superintendent's bungalow. A still bolder and more prominent escarpment, however, is to be seen in the southern portion of Assamboo district below Retreat bungalow. It is almost perpendicular and several hundreds of feet in height, and the river which now washes its base has doubtless been an important factor in giving rise, at any rate, to a portion of its present contour, for, here a deep gully has been formed, and the rocks on the opposite side of the stream, which are of the same series, show evidences of having once been part of this precipitous mountain mass.

As the geology of Travancore has up to the present, 1881, been very little studied, and, so far as I am aware, its palæontology less so, few, if any, fossils have been found, especially in those strata which flank the upper portions of tho Ghauts, consequently considerable diffe-

* By J. Macdonald Cameron, Fel. Inst. Chem., F.C.S., etc. (late assistant in the Chemical Laboratories of the Royal School of Mines).

ulty presents itself in deciding whether many of its schists belong to the Palæozoic or Hypozoic periods. All that the geologist has at present to guide him is the lithological characteristics, and these, so far as I have been able to decide, place the various strata of which some of the lower ridges and spurs are composed, and many of those that constitute the higher peaks in the metamorphic system, and within the Hypozoic period.

The Government committee of 1832 found the prevailing rocks of the Wynaad and surrounding districts to be gneiss and a species of clay-ironstone called laterite. Now anyone who for such a short period of time has sojourned in Travancore could not fail to be struck with the presence of this latter rock. Nearly all the houses and offices of the common people, and the bungalows of even the well-to-do natives and Europeans are built of it. It will also be seen from what I have quoted of Mr. Brough Smyth's report that he says the rocks of the Wynaad district are "granatoid schists or gneissoid rocks;" and Mr. Oliver Pegler also admits that "the more fissile varieties" of the metamorphic series are present, "and are softer, and having thus yielded to the disintegration and denudation of time have formed valleys and dells adjacent to the peaks. These softer rocks are of a much higher colour than the harder granite crystalline formations and give a reddish brown appearance to many portions of the surface of the country."

Who that has seen those parts of Travancore which have been converted into coffee gardens has failed to notice the soft gneissic rock studded with small nodules of quartz, varying in size from that of a pea to that of a walnut, and which, when exposed to atmospheric influences, have had their felspathic constituents decomposed, leaving the quartz scattered over the ground? This soft gneissic rock is essentially the rock to whose decomposition, through the lapse of ages, the coffee soils of Travancore are due, just as surely as it is the source of those of the Wynaad and Nilgiri districts. Where the rock is impregnated with a large amount of ferruginous compounds the resulting soil has a yellowish or reddish-yellow colour, and where these iron compounds are absent in the under-lying rock the colour passes to that of kaolin or potter's clay.

Chemical and Metallurgical Laboratory, Lime-street, E. C.—Mining Journal.—Madras Mail.

BARK EXTRACT.—It is said there are produced annually in North America 100,000 barrels of hemlock bark extract, of which a single Boston firm produces 72,000 barrels.—*Forestry.*

ANTS of many varieties are a troublesome pest in different ways in these colonies. House-wives find them a great affliction, and would gladly welcome any effective means of getting rid of them. In gardens also they bother the operator in many ways. Some varieties take every possible care of scale insects, guarding them from harm, and tending them as assiduously as the stockowner his flocks, and are therefore fairly chargeable with a portion of the mischief and ruin they occasion. The reason of this is that ants "milk" these insects, and thus live by them. The gardener is also very much disturbed with their nest-making pertinacity, in hard dry walks, and sometimes about the roots of valuable plants and trees, so that no one desires more thoroughly their extermination than the careful gardener. Kerosene, carbolic acid, and coal tar have all been tried at different times with very partial results. Coal tar poured hot into their holes, and mixed with the material of the ant-hill, is more effectual and lasting than either kerosene or carbolic acid and is less costly. But to destroy them some method of poisoning must be resorted to. M. C. Read, of Hudson, Ohio, says that ants may be effectually destroyed by the following application:—"Mix thoroughly one part of Paris green in four parts of flour, and stir the whole into such a quantity of molasses as will run into the small holes in the ground in the ant-hills. Most of them will be poisoned by the first application, and one or two more in a few days will finish the work." Paris green and London purple are rival powders for destroying the Colorado beetle, so fatal to the potato, and either of these powders would be likely to do good work if they could be had. Australian ants would greedily devour the materials mentioned.—*Queenslander.*

QUININE.—The *Gazeta*, of Campinas, São Paulo, of the 14th inst., states that a counterfeit sulphate of quinine has recently made its appearance in that market. The counterfeit, according to our colleague, is put up in bottles labeled "*Sulfate de quinine de la société anonyme.*"—*Rio News.*

ROOT-PRUNING fruit trees to make them bear is often necessary. Its object is to diminish the vigor of the tree, which induces fruitfulness, probably by the instinctive endeavour of any plant when threatened with destruction to hasten the seed-forming process by which its kind is perpetuated.—*Southern Planter.*

TEA SEED: AS TO DEPTH OF SOWING.—I have planted seeds, as an experiment, from 1 inch to 6 inches. The seed at 1 inch came to nothing: it germinated, was a weak plant, and dried up. The seed from 2½ to 3 inch depth came up well, and turned out healthy plants; 4 inch depth rather weakly, and seed at 5 and 6 inches never came up at all.—*Indian Tea Gazette.*

BUYING A HORSE.—The *Turf, Field and Farm*, than which there is no better authority on the subject, says that "in buying a horse first look at his head and eyes for signs of intelligence, temper, courage, and honesty. Unless a horse has brains you cannot teach him to do anything well. If bad qualities predominate in a horse, education only serves to enlarge and intensify them. The head is the indicator of disposition. A square muzzle, with large nostrils, evidences an ample breathing apparatus and lung power. Next, see that he is well under the jowl, with jawbones broad and wide apart under the throttle. Breadth and fullness between the ears and eyes are always desirable. The eyes should be full and hazel in color, ears small and thin and thrown well forward. The horse that turns his ears back every now and then is not to be trusted. He is either a biter or a kicker, and is sure to be vicious in other respects, and, being naturally viscious, can never be trained to anything well, so a horse with a rounding nose, tapering forehead and a broad, full face below the eyes is always treacherous and not to be depended on. Avoid the long-legged stilted animal—always choosing one with a short, straight back and rump, withers high and shoulders sloping, well set back and, with good depth of chest, fore legs short, hind legs straight, with low down hock, short pastern joints, and a round, mulish-shaped foot. By observing the above directions a horse may be selected that is graceful in his movements, good-natured and serviceable—one that will be a prize to the owner.—*Prince George Enquirer.*

SALE OF GOVERNMENT CINCHONA BARK AT MADRAS.—The following "office note" from the district forest officer to the acting Collector of the Nilgiris, gives an account of the sale of the Government cinchona barks at Madras:—Schoenbrunk, Engel and Co. and Dr. Currie. Two hundred and forty bales with a total of 26,236 pounds were offered for sale. Twenty bales containing 2,723 pounds had however to be withdrawn, as no bids were made, so that only 220 were sold containing 23,513 pounds of bark. The total sum realized amounted to R36,095 and including some surplus, which sold for R124—altogether R36,219. The results are on the whole not quite so favorable as those of the last sale. The price for Crown bark being less, while that for red barks is as high as before; but, considering that the price of bark at Home is just now very low and very much less than it was in September last, we can congratulate ourselves on having disposed of our bark at very fair and remunerative rates. I had to withdraw 20 bales of Mossed Crown as no one seemed disposed to buy

The Government consider the results of the sale to be on the whole satisfactory.

COFFEE IN JAVA AND BRAZIL.

(*Translated from Java newspapers for the "Straits Times.)"*)

The immense yield of coffee of late years in Brazil has resulted in quotations for that article falling below the cost of producing the sorts usually grown in Java, and undergoing very great and frequent fluctuations from conflicting reports on last year's and the present year's crops in South America. Hence the Batavia Chamber of Commerce recently memorialised the Governor General of Netherlands India in favour of appointing a commission of experts to inquire on the spot into the state and prospects of coffee cultivation in Brazil and report on the same, thus supplying capitalists and coffee growers in Java with trustworthy information likely to result in steadying and improving the prices brought by that product. The chief secretary to Government, in reply, assured the Chamber that the Government, for the same reasons, had already suggested to the Home authorities to instruct the Netherlands Consul General at Rio de Janeiro to gain every possible information regarding coffee cultivation in Brazil, and that the result of his inquiries will in due time be communicated to the Chamber of Commerce, the appointment of a commission of experts for the purpose being hence considered needless.

Mr. Moens on Cinchona Prospects.

On behalf of the Society for the advancement of medical science in Netherlands India, the firm of Ernst & Co., at Batavia, has just published a work in the Dutch language entitled *The Cinchona Culture in Asia from* 1854 *to* 1882, by Mr. J. C. B. Moens, which is thus noticed in the *Surabaya Courant*:—

"Mr. J. C. Bernelot Moens, ex-Director of Government Cinchona cultivation in the Preanger Regencies (Java), shortly before his departure for Europe, saw to the publication of his book on cinchona, upon the preparation of which he has worked for years with unflagging energy. Having taken measures to secure his copyright, the author, who certainly before long, and with his permission, will be read and consulted everywhere in all languages, has brought out a splendid scientific work, which by its get up and typograph alone, is fully worth attention. Messrs. Ernst & Co. of Batavia have hereby shown that, in this department, Java stands only a little below Europe, if at all. It is also provided that several choice photographs by C. Lang of Buitenzorg, which besides depicting the plantations and operations thereon at different periods, comprise distinct photograms of the Director himself and his personel, so distinct that different persons are easily recognizable. We quote from the work only two observations of direct interest to all cinchona planters, namely Mr. Moens' opinion on possible substitutes, and on the future of the culture. As to substitutes, he states that, though so often announced to be found (one authority enumerates 136 of them) not one of them could hold its ground beyond a few months. He foresees that the now rapidly extending cinchona culture will not, within the next four years, be productive enough to affect prices materially. A fall in value after the lapse of four years will so depress the trade in that article in South America that those sources of supply which can no longer bear the cost of carriage will cease to flow, thereby preventing prices falling too rapidly. The same is to be foreseen, 12 to 15 years hence, when production in Java will have increased so considerably as to meet the demand of the whole world. In case of over production, he who grows the varieties yielding the most quinine will be the best off."

USE AND ABUSE OF MANURES.

The best methods of manuring the land will be found on examination to be among the most critical of all questions connected with farm management. All soils may be made productive if a sufficient outlay be incurred, the amount of the expenditure differing with the character of the occupation and the system of farming. Among several noted plans for the farming of arable land, which have been brought before the public within the past twenty or thirty years, there is the Sawbridgeworth method, and there was the Tiptree system—sustaining the fertility of arable occupations by purchases of artificial manures in one case, and by the use of cattle feeding stuffs mainly in the other case. It may be said at once, without fear of contradiction, that only a consummate master of the art of stock feeding could have made the Tiptree system pay good interest on the capital employed; and, on the other hand, an expenditure of £2 per acre per annum on light manures, would hardly prove expedient in the general practice of the agriculture of the country.

The propriety of each of these varieties of high farming has been challenged; in fact there are critics of all the systems.

In regard to the Tiptree dogma—which inculcated high farming as a sort of moral duty—the most disastrous losses reported by the sub-commissioners of the recent Agricultural Commission occurred on highly farmed land, and this is a fact worth pondering in connection with the teaching both of practical and scientific men. It happens that several excellent authorities have contributed to the literature of farming recent essays on the all-important subject of manuring, and among them Sir John B. Lawes, on "The Action of Manures," at the Newcastle Farmers' Club; Mr. W. Stratton, on "The Management and Application of Manures," at the London Farmers' Club; Mr. Alfred Smetham, on "Natural and Artificial Manuring," to a Lancashire Agricultural Society; Mr J. Coleman, on the same subject of Manures and Manuring, at the Tunbridge Wells Farmers' Club; Professor Jamieson, on "Compensation for Manures," Mr. Jamieson having superintended a series of experiments on the effect of manures on various crops in Sussex; and Dr. Voelcker on the same subject, during the discussion on the recommendations of the Agricultural Commission at the London Farmers' Club, the learned doctor having superintended the experiments at Woburn.

In considering these latest teachings on manure, it may be well to recall the knowledge we have gained as well as the difficulties we must still encounter. Dr. Daubeny, Professor of Chemistry at the University of Oxford, and an able exponent of the science of farming, forty years ago published a paper on the dormant and active ingredients of the soil, in which he stated that a ton of phosphate of lime would supply the necessary phosphorus for a hundred and twenty-five crops of wheat, or forty-five crops of turnips; and, those figures being fairly accurate, Sir Harry T. Thompson's maxim, "phosphorus for turnips, nitrogen for corn," seem at first sight somewhat puzzling. Sir John Lawes has again given the explanation of this apparent paradox. He has also treated at length the behaviour of nitrogen in the soil and its pre-eminent value as a fertiliser. It is remarkable that Dr. Daubeny does not once mention that all-important substance, nitric acid, in his paper. He gives an admirable explanation of the effects of fallowing and tillage in admitting air, and thus dissolving inorganic substances and rendering dormant principles active; but the science of forty years ago did not enable him to notice what is in fact the most active of all the "ingredients of the soil." We have since learned that nitrogen is the prime element in the production of wheat, and that no other constituent of plant food presents to the practical farmer anything like the same difficulties; it is a substance which he cannot dispense with; which he may readily loose by misapplication; and which costs 10d. or 1l. per lb. The phrase "nitrogen for corn" embodied the experience that soils which are rich in minerals only require the addition of the single constituent they are deficient in. The fortieth year's crop of wheat will be grown this year at Rothamsted, and the unmanured plots will no doubt yield, as usual, twelve or thirteen bushels per acre. As the soil contains already sufficient minerals, the crop will not be increased on those plots where phosphates, potash, or any other manures containing no nitrogen are supplied; but, according to the saying, "nitrogen for corn," the plots treated with that manure will yield an additional 100lb. of wheat and wheat straw for each pound of nitrogen taken up by the crop. The future of our farming therefore hinges mainly on nitrogen; and we can now understand the lesson of exhaustion written on the face of every corn district in Europe, or any other old corn-producing region where nitrogen is not easily obtained, and only scantily applied to the land in the ordinary practice of husbandry. We can now understand Sir Harry Thompson's remarks that

"Land has a natural store of the materials required for the production of grain, which confers upon it a certain moderate standard of fertility."

And also his assertion that

"Nothing short of the most wilful and long-continued cropping, without any return whatever, can materially injure the staple of the soil. It is scarcely possible to destroy the natural productiveness of the soil, since its condition can be quickly restored by manure of the right kind."

It is hardly correct that land can be "quickly restored" when the loss of "condition" includes the usual consequences of neglect, such as filling the farm with weeds; but, so far as "condition" is dependent on manure, the assertion is strictly true.

Enough has now been said to establish the importance of nitrogen. The careful study which this substance required beyond all other constituents of plant food, is further explained in the extent of its loss by drainage, especially when injudiciously applied. It is most soluble and most easily lost in the form of nitrate of soda, when sown in the rainy season, and therefore nitrate should be employed as a spring dressing; and, as the yellow colour of corn in spring is one of the signs of impoverishment too often observed after unusual rains, a dressing of nitrate at that season is advisable, as the right remedy for the malady of innutrition. Light nitrogenous dressings should be applied in spring when the drains have ceased running, as they should do with the advent of March winds; but farmyard dung may be applied at any period without the occurrence of any loss by the washing-out of nitrogen. Another group of facts surrounds this part of the inquiry into the conduct of nitrogen, and they should be mastered by every practical farmer.

According to the old-school farmer, "There is nothing like farmyard dung;" but the adept in light manures who has grown capital crops of all the cereals, with only 1 cwt. or 2 cwt. of nitrate of soda per acre sown in April, might prefer another saying quite as true, "There is nothing like nitrate of soda." Unnumbered contradictions in farming are due to varieties in weather, soil, and climate, but many of them must be attributed to ignorance of the nature and use of manures.

As Dr. Voelcker told the Farmers' Club, the unexhausted value of manures depends upon their permanence, and he seemed to have in mind those political theorists who have sometimes claimed heavy payments for the advantage of that great favourite of theirs, the outgoing tenant, on account of manures for which experienced agriculturists would certainly refuse to pay anything under the circumstances of their application. We have seen how rapidly nitrate of soda may be washed out of the land, and how valueless phosphates and other minerals may prove to be unless they are applied with skill. Light manures are valueless even in the first year, except when applied in proper quantities at the right time. They are rarely worth anything in the second year. Enormous sums of money are annually thrown away through the improper application of artificial manures, because, says Dr. Voelcker, "the man who applies artificial manures should have a good deal of experience—which is not so general amongst farmers as it ought to be." The essays we have enumerated supply this much needed knowledge, and, it should be added, they confirm to some extent the time-honoured prejudice in favour of farmyard manure. Dung, at any rate, has the merit of reliability. It is a safe manure, on account of the comparatively permanent form in which its nitrogen is combined with carbon, so that nitrification takes place slowly, and only in those portions of the substance which are near the surface, and exposed to the immediate action of the oxygen of the atmospheric air. Grass land, too, is safe from a scientific point of view. The moment the surface of the soil is covered with vegetation, permanent or otherwise, the preservation of nitrogen commences. A clover layer a year old will have had time to collect a useful amount of nitrogen, while a top spit of old turf—prairie land or common pasture—forms a rich storehouse of the same precious substance.

In these various essays and lectures sound advice is offered on the use of weeding stuffs and their value in manure, and the whole subject of dung and purchased manures will be found to have been exhaustively treated. But agriculture does not rely alone on the instruction conveyed in its literature, and those who are seeking knowledge can always turn from lecturing to farming; from the discussion of details to the details as carried out in the field. It will be found on examination that in this respect the practice of farming is taking the direction which theory indicates. In these bad times, the safe method offered in the increase of permanent pastures has been resorted to, and in the "use of artificials" the necessary caution has been exercised, and there are many signs that the necessary knowledge is being sought wherever it may be deficient. The law of "survival," hard as it may be for those who suffer, applies to agriculture, and our best systems in every generation are "survivals of the fittest." As nothing can survive in practical farming which is not founded on scientific teaching, these various essays deserve, and will no doubt receive, general attention.—H. E.—*Field.*

THE CULTIVATION OF THE POPPY IN EUROPEAN TURKEY.

The following is a translation of instructions as to the cultivation of the poppy and the method of extracting and preparing opium, which have been drawn up under the authority of the Turkish Government, and distributed throughout the agricultural districts of Macedonia, with a view to promote development of the opium industry in that province:—

"If we take into consideration the fact that poppy seed is capable of yielding 6 okes [22½ lb.]* of opium and 10 kilos of seed to every dunum [100 sq. metres] of land sown; that an oke of opium realizes 400 pias [£3 12*s.*], and a kilogram of poppy seed 40 pias, and therefore that altogether a dunum of land sown with poppy seed may be worth as much as 2,640 pias [£23 15*s.*]; if at the same time we bear in mind that a dunum of land sown with wheat seed yields at most 10 kilos of wheat and 2,000 okes of straw, and that with wheat realizing 25 pias the kilogram, and with straw being only worth 30 pias per 200 okes, the total possible value of a dunum of land sown with wheat is 280 pias [£2 10*s.*], we see at once that in comparison with wheat and other similar products the cultivation or the opium poppy is a most lucrative industry.

"Seeing then how productive of wealth the cultivation of the opium poppy has been to the agricultural population of the sandjak of Broussa, the following is a short treatise supplying information on this point.

"*The Various Species of Poppy Seed and the Proper Season for Sowing.*—Poppy seed is also sometimes styled 'Khashkash' seed. It is very small and it is of two kinds. One is white and the other is of a darker hue, both being contained within shells or pods, which are sometimes termed cocoons. These cocoons are globular in shape, and of the size of a Jerusalem artichoke, having on the upper side a roundish mark which is termed the 'comb.'

"The darker-hued seed is of two species. The outer shells or cocoons of the first species are small, and may be distinguished by a row of small holes, through which if great attention be not paid, as soon as the outer shells are fully matured and ready to receive the produce of the seed the latter drops and is lost. The flowers of this first species are generally of a red or purple hue. So also are the flowers of the second species, but the outer shells of the latter are larger and of an oval shape, and they have no holes in their combs.

"The white poppy seed is also of two kinds, of which though one is white the other is yellow. In other re-

* The figures between brackets are inserted as approximately correct.—ED. PH. J.

spects there is very little difference between these two kinds, both having large oval-shaped, outer shells with no holes under their combs, the flower, like the seed, being white. The opium extracted from this species of poppy is more abundant and of a superior quality to that which is the produce of the first-named species.

"Although in some localities the 'Khashkash' or poppy seed is sown, as a rule it is only utilized by yielding an oil which is extracted from it. From 100 okes (275 lb.) of seed may be obtained a yield of 30 or 40 okes (82½ or 110 lb.) of oil, which is of two kinds, of which one is obtained by first pounding the seed, then heating it and extracting the juice, while the seed is still hot. This oil is used in Europe in the composition of water-colour paint and oil paint, and is also burnt in lamps. It is also used in the manufacture of glass shades.

"The other kind of oil is obtained without heating the crushed seed, and having a pleasant taste is used in the preparation of food.

"Arkara-Hissar Sahib ('Afion Kara Hissara').—The seed is first heated before the oil is extracted, which is then universally used by the inhabitants in the preparation of food.

"The oil extracted from the yellow poppy seed, like the opium so extracted, is of a superior quality to the others. In localities where there is no hoar frost in spring and autumn, poppy seed is sown from the month of September up to March; but in places where there is hoar frost the seed must without fail be sown in the month of September and in the spring after the chilly weather is passed. However, seeing that in most places there is hoar frost both in spring and autumn, and that in spring, even in the month of April, there is usually some hoar frost, and that after the month of April seed time is already passed, in this country the seed should be sown in September, or at latest in the beginning of October; if the seed be sown at the season mentioned the yield both of opium and of poppy seed is more plentiful than if that operation be performed when the weather is chilly.

"*Description of the Kind of Soil most suitable to the Poppy.*—The poppy seed must be sown in light, rich, and yielding soils. If it be sown in cold clayey soil or in damp localities the yield will be small and the opium of an inferior quality.

"Ground which is to be sown with poppy seed, of whatever kind it be (*i.e.*, the seed), should be well manured, sheep's dung being of course preferable. Experience has proved that if a field which has just yielded a crop of opium be immediately sown with wheat, the crop resulting from this last sowing will be remarkably good.

"*The Method to be adopted in Sowing and the necessary subsequent Treatment.*—The soil of a field which is to be sown with poppy seed should be ploughed two or three times and well turned up. The seed should then be scattered about with the hand, just as flax seed is. After this the soil must be thoroughly stirred up and mixed by a rake or a row of bushes bound on to the back of a harrow.

"If 100 drachms (*i.e.*, Turkish drachms) of poppy seed be sown on every dunum of land, or on such an extent of land as will take a kilogram of wheat seed, it is sufficient. As soon as ever the young poppy plants begin to appear above the surface of the soil and to bear three or four leaves, in those places where they are too close together they must be taken up and planted again in such a manner as to leave a space of a span between each plant. In order to remove any weeds that may make their appearance in the [illegible] ground must be hoed once or twice. This use of the hoe must never be omitted, for if there be many weeds in the field they stunt the proper and healthy growth of the plants, and cause a considerable [illegible] of the crop. [illegible] the seeds of such weeds remain in the soil it becomes subsequently impossible to [illegible] other [illegible].

"*The Cutting [illegible].*—Opium being [illegible] pods or [illegible] become green [illegible] the green hue changes to [illegible]. [illegible] change of colour takes place there forms over the pods a very thin watery film of a light green hue, though somewhat indistinct in appearance. This film is called 'cougak.' If it be wiped away with the finger its place remains quite visible. If at about this time the pod be squeezed between the thumb and forefinger, it becomes so far strengthened that it cannot be easily crushed. It is then that the juice which forms the opium must be gathered.

"In order to gather the juice or paste, the first step is to take a knife made especially for this purpose, being small and as sharp-pointed as the end of a penknife, and with it to cut a semi-circular line in the pod beginning from the middle and going round the edges, at the same time leaving a space of about a finger's breadth. Immediately this is done there appears a white milk-like fluid of a bitter taste, and there forms. This fluid little by little increases in consistency, and its colour becomes darker and darker, until in twenty-four hours it becomes coffee-coloured, and as thick as paste. This is opium. This must be scraped off with the edge of a somewhat large and blunt knife and put into a poppy leaf, and so on until as much as 20 or 30 drachms of opium have been collected on one leaf, the edges of which must be turned in so as to prevent it being spilled. If, while the opium is being collected, the film above described be mixed with it, it has a beneficial effect.

"At Karahissar the work of cutting lines in the pods of the poppies is generally begun early in the afternoon and continued until nightfall. As the opium must be collected twenty-four hours after the above operation has been concluded, the following day also, soon after twelve o'clock, they begin on the one hand to collect the opium from the pods which were cut the day before, and also to cut lines in other pods, which work occupies them until the evening. But should they come across pods which are not quite ripe, they leave them alone, and five or six days afterwards they again visit them, and after cutting lines in them collect their juice.

"In order that the exact season for collecting the juice may not be missed, the whole work must be gone through and finished in five or ten days. Moreover, the proper time for marking the pods must be accurately ascertained, for if the pods be cut say ten days before or after they are quite ripe, there is no yield of opium. As an instance of this it may be mentioned that in the plain of Broussa the experiment was made. Although the plants had reached their full growth, the pods were marked or cut both before and after the exact time when the operation should have been performed, and consequently there was no yield of opium. Sometimes it happen that a dry wind begins to blow at the very time when the poppy pods should be cut, and the atmosphere becomes chilly in consequence. During such weather the yield of opium is very small. The pods also should not be cut when it is raining, for the rain washes away and destroys the juice as fast as it exudes from the seams that have been cut for it.

"After the opium crop has been gathered in, the pods change their previous hue of either green or yellow to rose colour; when this change takes place the poppy plants should be taken up by the roots one by one and collected into small bundles. Each bundle should then be bound by a young green withe, and then so placed upright in the ground that the roots of the plants be covered, in which position they should remain for a few days until the seed contained within the pods shall have become thoroughly matured and dry. Then the pods should be threshed with a stick until they break open, when the seed may be collected.

"Another method is to sever the stem of the plant at the knot which is to be found close up to the pod, with the finger and thumb, and after collecting the ends so severed to spread them out to dry in some open place, and then to break them open by threshing, or else to pull them to pieces, and, after sifting the seed until is quite free from extraneous matter, to collect it.

"At Karahissar they purposely burn most of the pods and reduce them to ashes, a fluid extracted from which they use to [illegible] the ground that it is more effective than [illegible] from ordinary ashes.

"After [illegible] from the poppy seed, there remains a sediment technically called '[illegible]' on which buffalo, cows, and black kine generally are fed, on the ground that such diet increases the amount of milk and so of 'caimak' (cream)."—*Pharmaceutical Journal.*

ESSENTIAL OILS AND DISTILLED WATERS.

BY PERCY WELLS.

Now that the season is approaching for the distillation of essential oils and perfumed and other waters, I desire to call attention to a very simple and inexpensive plan for improving the odour and quality of oils, and preventing the decomposition of distilled waters. I have given the process a fair trial, and can, therefore, speak confidently of its efficacy. The article I use is permanganate of potash, and it should be added to water before it is put into the still only in quantity enough to make it a *faint* pink. If any chemist has rose, elder flower or orange flower waters, which are partly spoiled, let him add to them just enough of the salt to give the permanganate tinge, and then distil them, and he will find the products to have recovered their odour and not again change. I have some waters which I treated in this way nearly two years ago, and they are perfect. I have also redistilled oils, adding to the water permanganate in the proportion of ½ to 1 grain per ounce of oil, and the result has been most satisfactory.—*Pharmaceutical Journal.*

COMMERCE, INDUSTRIES, AND RESOURCES OF OMAN, EASTERN ARABIA.

DATE PALMS—SALT FISH.

The United States Consul at Muscat has lately issued a report upon the commerce, industries, and resources of Oman, which the Department of State has published, and called particular attention to, as "being rendered doubly interesting by reason of its dealing with a district and people very imperfectly known to commercial communities." Oman is a country situated in the south-east of Arabia, between the Persian Gulf and the Arabian Sea, or Sea of Oman, and forms the central part of the Muscat Dominion. Its agricultural products are considerable, but limited in quantity, owing to the unfavourable nature of the country for vegetation. The labour attending production is very great, as, on account of the small annual rainfall, which seldom reaches six inches, the inhabitants have to supply artificial irrigation by means of wells and "felegs." In the former case the water is drawn up from a considerable depth by means of a bullock, and a leather bucket or bag, which, when emptied into a small reservoir at the surface, runs along the channels prepared for it, to the section to be watered. This system prevails principally on the Batinah coast, whilst in other parts of Oman the "feleg," or conduit system common to Persia, is to be met with, though it is generally a monopoly of the wealthy. The cultivated patches are usually some distance apart, and where wells can be sunk, in the plains of the vicinity of Jebbel Akhdur and in El-Dha-hiveh, the crops are more abundant, but extensively cultivated tracts of land are unknown. The soil is exceedingly poor, and hard and caked in appearance. The cereals, fruits, and vegetables grown in Oman, in their respective seasons, are as follows:—White and red wheat, gowaree, maize, barley, small quantities of sugar-cane—from which a very inferior description of sugar is made—dates (of which there are at least forty varieties), mangoes, figs, vegetable marrow, bananas, sweet limes, lentils, grapes, apricots, peaches, tamarinds, mulberries, quinces, potatoes, guavas, citrons, onions, limes, oranges, radishes, cucumbers, almonds, plums, spinach, pomegranates, pumpkins, apples, &c. Of these, the date is the most valuable, and trees are cultivated in every available spot suitable to their growth. Groves of these date trees extend along the Batinah for a distance of 200 miles, but owing, it is supposed, to the saline air nature of the soil, they do not retain their colour. This is not the case with those grown in the Ishmailee and Sharkeyah districts; these are largely grown for exportation, in fact it has been proved that no other description will stand a long sea voyage. These are pressed into mat bags, on the spot where they are grown, and brought into market on camels, when each bag is carefully cut, examined, weighed, and the dates again placed in bags, before shipment. The same dates, but not pressed, called "nuther," are brought loosely in baskets from the interior, and after selection, are packed in ten and fifty pound boxes, and shipped. The Batinah or donkey dates are the cheapest kind, and form the staple food of the poorer classes of the inhabitants. A prolific date tree, under the most favourable circumstances, will produce from two to three hundredweight of dates in a season. Date stones, when boiled down with fish heads, old date baskets, and other refuse, is largely used as food for cattle. Pomegranates and limes are largely exported to India. Rice is not grown and cereals are only cultivated in a small degree. The rotation of crops is very imperfectly understood. The farm implements in use are ploughs, harrows, hoes, sickles, and threshing machines, all of very primitive and rude form. The threshing is performed sometimes with a light kind of flail, but generally a heavy log is drawn over the corn and cattle are driven over it. Manuring is carried out to a small extent only, fish, and cattle litter being the only manure known. The manufactures and industries of Oman are insignificant, and with the exception of textile fabrics, "kharak," or dried dates and salt fish are only for home consumption. The most important industry is the preparation of dried dates, called by the Arabs, "bisir," which are largely exported to India, where, under the name of "kharak," they are a necessary ingredient at certain Hindoo festivities. The variety from which they are chiefly prepared is the "mubsoli;" but the "khuneyzi" is also sometimes employed. The process observed is as follows:—The dates are picked before they are quite ripe, and put into copper cauldrons, filled with boiling water, when they are allowed to simmer for half-an-hour, until a certain quantity of the juice is extracted; on being taken out, they are put in the sun for two or three days, and continually turned they are found to be quite dry and hard, when they are packed for export in mat bags. The house in which the boiling takes place generally contains five or six boilers, capable of holding about five gallons each, and has a chimney about fifteen feet high, to increase the draught. As the water in the boilers extract the juice, fresh water is added until it is too thick to be longer used, and it is then put aside to be fermented into liquor. The earthenware used in Oman is almost exclusively made in the country. There are several potteries at Nakhl, Funja, Rostak, Saham, and Multrah. The potter's wheel is much the same as in other countries, a low horizontal wheel being generally used, on the centre or axle of which a lump of wet clay is fashioned by the hand as the wheel spins. The pots are coloured with Indian red, and burnt in a kiln. Toys are also made of clay. Next to agriculture and the date cultivation, the fisheries form one of the most important industries in Oman. The Oman and adjacent waters abound with fish, comprising, among other varieties, the seer, bonita, shark, sword and saw fish, and sardines. Immense quantities are exported, and nearly the whole of the coast population live entirely upon fish. At Muscat, and some places in the Batinah, the fishermen are generally Belooch and Persians, in other parts they are Arabs. During the pilgrim months, the fishermen go to Jeddah to fish, attracted by the high prices prevailing there at the time. The nets used are the cast and the seine, besides lines and trap baskets. Large quantities of salt fish are sent to Bombay and the Malabar coast for consumption and re-export to China. The method of salting practised now in Oman is of the most primitive kind, and entails a large amount of waste. It is estimated that about 2,500 boats and 20,000 persons are employed in the Oman fisheries. As regards the trade of Oman, it is impossible to obtain reliable information respecting the imports, owing to the manner in which the returns are kept at the Custom-house—the customs being farmed annually to the highest bidder, in whose interests it is to show the smallest returns. It is well known, however, that of late years the trade and population of Muscat has been declining, owing to the insecurity of the country from the raids made by the Bedouin tribes. The exports from the interior of the country are principally brought by caravans to Muttrah, a town distant about two miles, and are carried from there by water to Muscat, and in the same way the imports are conveyed back, native craft being used for the purpose. All supplies from the interior are sold to local merchants at Muscat and Muttrah.—*Journal of the Society of Arts.*

AGRICULTURE IN LOWER BENGAL.

BY W. S. SETON-KARR.

THE DIFFERENT RICE CROPS—SUGARCANE—DATES—MUSTARD—VEGETABLE GARDENS—INPLEMENTS.

I must request my hearers to bear in mind that the subject of my paper is not agriculture in India, or even the Bengal Presidency, but in Lower Bengal, and more particularly in those large, fertile, and populous districts in the neighbourhood of Calcutta, which may be termed metropolitan. I may, occasionally, just refer to the features of western Bengal, where the alluvial plain ceases, and the land undulates; but my remarks will have mainly reference to such well-known and level plains as are comprised in the districts of Nuddea, Jessore, Pabna, Hooghly, and the twenty-four Pergunnahs. None of my remarks must be taken to apply to the Doab of Hindostan, or even the Provinces of Behar and Orissa. I will assume that most of my hearers are aware of the fact that these districts of Lower Bengal are entirely made up of alluvial deposit. No such thing as a natural or indigenous stone is to be picked up in any one of them. The ordinary roads, made by magistrates and engineers, are composed of burnt brick, and the very streets of Calcutta are paved with grey stone brought as ballast from the Mauritius. The soil of the Gangetic Delta has been created by sil throught down, in the course of centuries, from a network of rivers; and it may be doubted whether, in the wholeof our Indian Empire, there exists land more productiveor more fitted for the labour of the agriculturist than in Bengal Proper.

Now, this land may roughly be divided into three different sorts, for it is scarcely necessary to remind you that, before entering on a description of the staple produce of the country, the varying nature of the land ought to be considered. The ryot himself is accustomed to designate the soil as, first, *mattial*, from *mati*, the earth, which practically is thick, viscous, tenacious clay. This earth, in the rainy season, becomes a quagmire, in which carts stick and beasts are impounded. In the dry season, from November to May inclusive, it presents a surface almost as hard as rock, on which neither plough nor mattock can make the smallest impression. The second kind is known as *doas*; a rich loam with an admixture of sand. The third is *balu*, or pure sand, which absorbs moisture, rapidly pulverises, and can be most easily traversed by cart and bullock, by palanquin or passenger, after heavy rain. Or, again, the lands may be classed analogously in another wider and three-fold division. The first comprises the vast plains which periodically suffer from the inundation of large rivers, such as the Poddha, or Ganges Proper, the Gorai, the Kumar, the Damudaha, Rup Narayan, and others. The second division of this category comprises these low levels or depressions which are beyond the reach of the Ganges or its tributaries, but, from their clayey soil, hold water like a cask, and never dry up till the crops have been reaped and carried, and the cold season has given way to the heats of March and April. The third sort is the high, dry, and sandy tract which is never affected by stream or river, and which rapidly absorbs or throws off any amount of rain. The ordinary ryot makes two divisions only, and is familiar with the expressions *denga mulk*, a dry country; or, *jola mulk*, a low and wet country.

Bearing in mind this triple division of the earth itself, or of the plains with relation to the innumerable rivers and streams of the Delta, and also recollecting that the rainfall over a large portion of Bengal may be taken at 65 to 75 inches a year, we now come to the produce which is raised in the districts already enumerated. I should add, that the rainfall is heaviest towards the eastern, and lightest in the western districts of Bengal; and that, whereas in Tipperah and Chittagong, it may nearly average 100 inches, in Bancorah and Beerbhum it may fall to 50 or 60 in the year. But, for practical purposes, in an ordinary year it could be safe, in Jessore and Nuddea, to put it as 65 or 70. All of you are aware that rice is the staple production of Bengal. Indeed, so prevalent is this notion, that erroneous deductions have been made as to the necessity of this article of food for all Hindoos anywhere. The inhabitants of Upper India live on wheat, *joar*, or *bajra*; and though in Behar some castes are said to make one meal in the day of rice, it is in Bengal Proper that this staple is most widely cultivated and universally consumed. The late Mr. Buckle fell into the mistake of basing an estimate of the qualities of natives of all India on the assumption that they all were brought up on rice.

Of the cultivation there are three main varieties well and widely known over the whole of Bengal. They are called respectively the *aoos*, the *aumon*, and the *boru*, crops which late famines have made familiar to a wide circle. Philologists have busied themselves, not improperly in deriving these terms from the Sanskrit, as follows:—*Aoos* is a contraction from *Ashuvrihi*, the quick growing; *Aumon* means *Himanta*, the season of cold; and *Boru* is thought to be a corruption of Varuna, the Indian Neptune, or Regent of waters.

I shall take the Aoos crop first. In the month of March, or April at latest, the ryot, as well as the Mahajan and the indigo planter, look anxiously for a sowing shower; for rain, in short, which, without flooding the land, will drench and resolve it sufficiently to allow of agricultural operations, and will bear the next few days that sufficient amount of moisture which the Ryot is accustomed to designate by a term not found in the dictionaries, or *Jo*. The Aoos is grown on high and sandy localities. If it is sown in March or April, it is usually cut in August or September. Once or twice in my experience I saw a crop of this kind cut as early as the very last day of July; and now and then I have noted a field of Aoos uncut in the first days of October. But, roundly speaking, the Aoos is sown, grown, and reaped in about 100 or 110, or 120 days. It does not need to have its roots in water, like other varieties; it requires a succession of showers to keep it moist; but from its mere position, it is never ruined by disastrous inundations; and though its returns are smaller, its stalks less than, its grain inferior to, the Aumon crop, it is a universally serviceable product, and in ordinary seasons a reliable crop. Less rent is invariably demanded for lands sown with Aoos. It comes in early in the season, to enable the cultivator to pay his landlord, or to discharge the debt due to the Mahajan, or what in Ireland would be called the gombeen, and, as I shall show presently, it leaves a considerable portion of land at the close of the rainy season free for the cultivation of what in Bengal is known as the cold weather crop.

The Aumon, or winter crop, is the next great division. I must guard myself and others against the mistake of supposing that two crops of rice are grown anywhere on the same piece of land in the same year. In all my experience and inquiries, I never knew this to occur but once, and this local exception, of course, proves the universal rule to be the other way. I find that I saw a man cut the Aoos on the last day of July, and plant the same piece with Aumon three days afterwards. Aumon is grown in depressions, in vast plains which extend for miles, which separate populous villages, which for six months in the year are often impassable for pedestrians unless they can pick their way along the slender embankments which divide the fields, and which, from July to October, are deep in water, and are constantly traversed, rice crop and all, by light *doongas*, or *Saltis*. In a general way, it may be said that the Aumon requires from five or six months to ripen for the sickle. The harvest will vary according to the level of the ground, and not according to the climate. In stiff clay, but not in the lowest depressions, this crop may be sown in June, and cut towards the middle or end of November. It is, perhaps, most correct to say that the Aumon harvest occupies the months of December, January, and February. I have seen the reapers at work as late as March—I have even known them begin by the 10th of November. In very low-lying lands—known everywhere as bheels or jheels, *Anglice*, marshes—the ryot has no sooner cut his winter crop, than he begins to think about preparing his soil for next year. As the Aumon is much heavier, richer, more paying than the Aoos, so it is more exposed to the fluctuations, caprices, and irregularities of the seasons. It is really the most important crop of the year. If too much rain falls in April or May, the ground cannot be got ready for the plough until heavier showers come down in a ceaseless deluge, flood the low soil in June, and prevent work. If little or no rain falls in these spring months, a stoppage of work equally ensues. Perhaps the best years are those in which the land can be ploughed by timely rains in May; the seed sown broadcast in that month, to be fed by continuous but not too heavy showers in June or July. In very deep levels, ploughing operations can be got through on the strength of the moisture left by last year; that is to say, I have seen the winter crop cut by the villagers, in their boats shaped out of hollow trees, in February, and the same villagers ploughing the same land in March and April, when the surface water of last year had just dried off, and left the soil in a condition for the plough. A great deal of the Aumon is sown broadcast, and once it gets a fair start above ground, it will run a race against inundation, and beat it. Abul Fuzl, Akbar's celebrated minister, has declared, in the "Ayin Akbari," that this rice could sprout six inches in a night. I hardly like to endorse this dictum, but I think it very likely that it grows a couple of inches in that short space. Inundation of long continuance ruins it, but I have known it to be twelve hours under water, and then emerge without injury; and it is quite certain that if the water, whether rain alone or inundating river, will only rise gradually and not with a sudden rush, the rice plants will hold their own, and result in a magnificent crop. The length to which the stalks grow is surprising. I have pulled them fourteen feet in length, and am assured that they reach to eighteen. As the water recedes or falls this rice lies slanting on its surface; and a crop of Aumon rice in one big sheet, towards the end of November, presents the appearance of having been beaten down flat by some violent storm of wind and rain. A spectator, fresh from England, would imagine it ruined, a little experience teaches him that the crop, flat, tangled, white for the harvest, with a foot or two of water yet below it, and the blue sky, warm sun and pure air of December above, is in that condition described in the Virgilian hexameter, "Votis demum respondet avari Agricolæ." But the whole of the Aumon crop is not sown broadcast. A large portion is called *roa* (from *ropan*, planting), and is planted out with the hand. A nursery is first selected near the cultivator's house, and sometimes in his kitchen garden, where the rice is sown as thickly as the ground can hold it, or the stalks can stand together: when this nursery has attained to at least the height of ten or twelve inches, it is taken out to be planted in rows in the ryot's field. To this end the field has been well ploughed, scraped, and cleaned. I have watched the same process in Ceylon. It is essential that it should hold from a foot to two or three inches of water, or at least of that mixture of mud and water which is popularly denominated slush. I have seen this work performed in water two feet deep, the ryot doing it from his boat; but usually the cultivator wades and sticks the plants in, with the utmost rapidity, in long even lines. In the first few days the transplanted rice wears a pale, sickly, weak appearance; but in a short time, with the water at its roots, and the sun striking its blade and incipient ear, the plants raise themselves upright, and become green and lively. At an agricultural lecture, I may be pardoned for again quoting from the greatest poet of agriculture. The great Roman poet would have said that they were amazed at their own strength and magnificence.

"Nullo tantum se Mysia cultu
Jactat, et ipsa suos mirantur Gargara messes."

So much, first, for the Aoos, with its simple and uniform culture; and next, for the Aumon, divided into the crop sown broadcast, and the crop planted out with the hand. There remains the Boru, and my remarks on this head will be brief, as this variety is only grown to a limited extent, on the edge of those huge swamps of which mention has been once or twice made. Where the swamps never dry up, and there is no other way of utilising the soil, the Boru rice is planted in January, or as late as March, just when all other harvest occupations are at an end, and being fed regularly with water, which can be dammed up or easily conducted by simple machinery, from one plot to another, the rice is ripe before May. The fiercest heat never injures rice, provided there is water to keep the roots wet.

I should explain further, that though the cultivation of rice is limited to three kinds, the varieties of the grain are much more numerous. Mr. Hunter, in one of his recent statistical works, states that there are some fifty kinds of rice. I can easily extend that list, and so could many other public servants. From a manuscript of my own, taken many years ago, I find that in one district alone, Jessore, there were thirty-eight varieties of the Aoos, sixty-two of the Aumon, and six of the Boru. A little practice enables us to distinguish the most prominent varieties as they grow. Some of them have elegant and expressive names. There is the pearl of the sun, the golden rice, the foam of the ocean, the Ganges and the ocean, the repast of the king, the supreme repast, the Balam well-known to Eastern epicures, and many others.

But it will be remembered that though the largest portion of the soil is occupied with the Aumon; that though no second crop is possible from land so cultivated, and that, when the crop is once harvested, the only use to which the soil is put is that of pasturage for the numerous herds of cattle, we have yet to account for the remainder of the year in regard to the Aoos. I have never seen regular pasture set apart for cattle, except in the scrub of Baucoorah and the West. I have allotted a period of about 110 or 120 days for its seed-time, growth, and harvest. What, then, does the ryot do with this land for the other eight or nine months in the year? When his rice crop has been cut and carried, say, in August and September, the last showers of the rainy season may be looked for any time in October. This rainfall is often the turning point of the year. In 1844, and again in 1848, and again in 1851 and in 1862, the population of Bengal was saved from scarcity, possibly from famine, by a timely fall of several inches, which occurred between the first week and the last week of October. Rain is then anxiously looked for, to give the Aumon crop its fullest development. It is also desired to fill the tanks, to prepare the land for what, in Upper India, would be called the Rubbi, or spring crop, and in Bengal, as I have said, the cold weather crop. The ryot sets to, ploughs up the land from which he has just cut and carried his Aoos, and sows it with the crop to which it is most suited. Amongst the favourite products are mustard, linseed, some oats, barley, the species of pulse which the natives call *sola* and Anglo-Indians gram, millet, *dhal*, and two or three smaller kinds of vetches. Once the seed is got in while the ground is still moist, there is little more to be done. For the next two months, which, in the Hindu calendar, are the *shishira*, or dewy season, the dews are heavy and scarcely a drop of rain will fall; though sometimes in the cold weather, generally at the end of January, a fall of rain, not tropical but rather English in its character and duration —for it may last for a couple of days—has the happy effect of laying the dust, of prolonging the moribund cold season of Bengal, and of revivifying and ripening the cold weather crops. The Bengali have a saying that in the month of Magh—end of January and first half of February —they experience heat, rain, and cold—all the varieties of the year. The plains of Bengal, for ten months of the year, present features which redeem them from ugliness, and which are a pleasant contrast to the arid, brown, adust, or yellow look of Behar and Hindustan. There, the eye is offended as soon as the crops are off the ground. From June to October, nearly every plain in Bengal is one unbroken sheet of rich, green, rice cultivation; the small embankments, or divisions of heritages and fields, are hidden from the eye by the crops, and from the edge of one village shrouded in fruit trees and bamboos, to the other on the opposite side plain which forms the horizon, half-a-mile, one mile, or perhaps three, four, or even five miles off, nothing meets the eye but the even, unbroken sheet of rice. In the winter, one half of a plain may be white with the late rice crop; the other, higher and drier, is diversified with oats and barley, gram and vetch; and a sweet and delicious perfume from the golden flower of the mustard plant is wafted on the breeze to the traveller or sportsman. I hardly ever recollect seeing wheat grown in Lower Bengal.

It must not be imagined that this brief description of Bengali agriculture exhausts the list. I have said nothing about garden land or the higher kinds of produce. Jute, or hemp is a crop largely grown by substantial ryots or tenant proprietors. It is sown in spring, and cut in the rains; and then put to soak in tanks, exhaling a powerful and unpleasant odour; and there are two or more kinds of vetches which flourish in the same moist atmosphere, and anticipate the cold weather crop. In some parts of particular districts much attention is given to *pan* gardens. These plants, of which the leaf is chewed together with the arecanut, are grown in rows, just like our raspberries: but the peculiar feature of this cultivation is that the gardens are not only enclosed by mats at the side, but are roofed over by the same material, so as to concentrate heat, and yet exclude the direct action of the sun. Tobacco is also grown in small plots by the same substantial class; and a good deal of time and money is expended on sugar-cane. The crop, while it demands skill, perseverance, and expenditure for its development, returns large profits, and I have known instances in which an outlay of 20 rupees a beegah has been followed by a return of 40 rupees, or just cent per cent. But the supply of coarse brown sugar of molasses, in Bengal, is mainly derived not from the cane but from the date tree, and the date plantations have, during the last fifty or sixty years, enormously increased over several well-known districts—Jessore, Burdwan, Baraset, and Nuddea. To explain all the operations by which the juice is collected and treacle boiled, would extend this paper to too great a length. It may be sufficient to say that the trees are planted in rows or clumps, and are not grown for fruit, as in Arabia or Biluchistan; that the tree becomes profitable after seven years' growth, and may continue to yield a return for thirty or forty. In the month of October the ryots are seen ascending their date trees, and making incisions on alternate sides, in alternate years, on the lowest branch of the feathery tuft at the top. An earthen pit is placed under each incision, and when the cold nights begin, the liquid flows slowly into the pot beneath, whence it is removed in the morning. The colder and stiller the weather the greater the flow of juice. Rainy weather, such as now and then interrupts the enjoyable climate of the cold season, stops the flow of juice for a time, but the process goes on, with few intervals, between November and March. The juice is boiled down and clarified by means of a coarse weed that grows in almost every tank, and the whole cultivation is highly remunerative. The spaces between the trees in a date plantation are turned to account otherwise, for early rice and for the second crop of mustard. Many substantial ryots own 400 and 500 and even 1,000 of these trees, and the traffic in *goor* or treacle, adds life and animation to the interior of Bengal. Towards February, the sight of fifty or a hundred country carts, groaning and creaking over the fair-weather roads under quantities of molasses on their way to such celebrated marts as Kissubpur or Kotchandpore, in Jessore, is one which—to borrow an expression of Sydney Smith when he imitated humorously the grave style of Macintosh—explains the objects of commerce, approximates the different regions of the earth, and justifies the industry of man.

But ryots who have neither the industry nor the capital to construct *pan* gardens, or to plant the date or the sugar-cane, yet generally contrive to have something of a garden. A village in Bengal is usually hidden from the eye by its dense mass of foliage. It was a characteristic and just observation of an eminent North-west civilian (now Member for the Kirkaldy Burghs), when he first came down to Bengal, that there were few or no large towns to be seen. There are, on the banks of rivers, some very large *gunges*, or wholesale marts, or centres of trade; but a rural village which contains 300 houses often appears to the eye as a mere jungle, the wild cane and brushwood, the feathery grass, the plantain, and scrub of all kinds growing with clumps of bamboos, while waving above them are seen the cocoa palm, the date, the toddy palm, the graceful stems of the arecanut, and, here and there, the pipal and the banyan, those grand trees which Macaulay said were perhaps older than the Mogul empire itself. No one can have resided a week in the interior or visited a few villages, without being struck with their perplexing similarity, with the recurrence of the same landmarks, with the same features of narrow winding paths, of tanks of every degree of size, cleanliness, or pollution, of gardens surrounded by deep ditches and slender fences, of sluttish, careless, rotting abundance, of spaces where weeds and undergrowth seem to struggle for mastery with the egg plant, the red-pepper, the tobacco, and dhal and pulse. It has been truly remarked that a traveller taken half an hour's journey or ten miles out of Calcutta, and suddenly put down in the centre of an umbrageous village, would be puzzled to discern the slightest difference between it and a hundred similar villages, situated north or east, three or four days' journey off. It seems impossible to get villagers to understand that air, light, and ventilation are essential to health, that fruit trees can be planted too thickly, and that everything ought not be sacrificed to the mere object of excluding the rays of the sun, and shielding the woman-kind from the intrusive glance of strangers.

I turn now to the actual processes and the very implements of Bengali culture. Fortunately, I have by me exact models of the implements in use by thousands of cultivators, made twenty-five years ago by a village carpenter, and I have no reason to think that, even in this age of progress, their form or substance have in the least altered from what they were then, and possibly also were in the days of Manu. The plough is in shape very like an anchor. It is generally made of the wood of the mango or the baubul, and it is a common occurrence for the ryot to find the wood and even the iron for the shares, then go to the village carpenter, who will put the two together for four annas, or 6d. I mean that this is more common than buying a plough ready made. It must never be supposed that furrows are turned by this implement to the depth and regularity seen on any English farm. The ryot begins by a series of intemperate and intermittent scratches; ploughs down the field and across the field, and down the field again, but in the end often produces a complete pulverisation of the glebe. It was remarked to me by a friend, at the time when a late Lieutenant-Governor 20 years ago was holding agricultural shows all over Bengal, and trying practical experiments with steam ploughs and deep furrows, that no ryot would ever be satisfied with any conceivable plough except one which he could put over his shoulder and carry home after the day's work. I think the outline of the native plough might be amended, for I have actually guided the plough myself, and found that it is difficult to get the share to bite, but even on this I hesitate to have a decided opinion, being convinced that, in many points, the ryot has more to teach us than we have to teach him. Then comes the sowing broadcast, and afterwards what we should call the process of harrowing. The Bengali harrow is, however, as unlike our harrow as any one instrument can be. It is a simple ladder of bamboo, on which one man takes his stand, while his fellow draws the bullocks to which the ladder is attached, by two cords, over the sown field. At a distance the ladder is imperceptible, and the ryot seems to be moving over the surface without using his legs, as if by some magic power. The effect of this process, when carefully carried out, is to make the rice ground almost as level as a bowling green. The Bengalis have a third process, in which an instrument with teeth, a large sort of rake called the *bida* in some districts, is brought into play. It is used when the rice is about six inches high, and is drawn over the open spaces, avoiding the roots of the rice, to prevent the surface caking too much, and to admit of the exhalation of moisture and the sun's rays. The next operation is that of weeding, and this is often well done, is often half done, and is sometimes not done at all. The best agricultural classes weed the Aumon crop sedulously in August and September. They use, for this, a small hand-spud, and squat on the ground, covering their heads with an umbrella without a handle, made of leaves and split bamboo, in which position they resemble gigantic toadstools. It is a pleasing feature of this operation that each man takes it in turn to help his neighbour. In village language this is termed the *ganth*, or knot. It is the *ganth* of Ram Gopal one day, and Tin Kaori, Panch Kaori, Nou Kaori Mandal, and all the rest, turn out to weed Ram Gopal's plot at his call, being sure of a like co-operation the next day, each man in his call or turn. The whole stock-in-trade of an ordinary agricultural ryot will then consist of a pair of bullocks, or, it may be, two pairs; a plough, which may cost one-and-a-half or two rupees, and may last for twelve months or two or three years; the bamboo ladder, which costs much less; the *bida*, or scuffler; the weeding spud; a fishbasket, to be set in the rush of water from one field to another to catch the fish which leave the tanks, and frequent the rice fields in the rains; a *kodali*, or mattock, for breaking up new land, excavating ditches, and repairing embankments; and a *dao*, or bill-hook, for cutting wood, splitting coconuts, and shaping bamboos. I am sorry to say that this latter weapon is a sore temptation, and plays a prominent part in domestic or social quarrels; and many a wife, or cousin, or nephew, or neighbour, has had his head cut open and his limbs slashed, by an impatient husband or jealous relative, when heat exasperates the temper, when words run high, and provoke retaliation by deed.

Of cultivation by hired servants, there is not much. Substantial men, respectable Brahmins, owners of rent-free lands, and small talukdars occasionally get their crops sown and reaped in this way. But the best agriculture is to be seen on the lands of the Hindu agricultural castes, the

Kopali, the Teor, the Sudgope, the Kaivert, who correspond practically to the Jats and Kurmis of Upper India. There is, however, a third mode of cultivation, besides ploughing your own land with your own bullocks, or sending your own hired servants to do the work. It is known in Bengal as the Barga system. One man may have land but neither plough or bullock; another man may have bullocks, but not too much land, and can devote spare time to the lands of others, when he has sown his own. So the two agree in this fashion. The ryot who has a pair of oxen, brings them to the plot of another, and expends on it his labour and time. Sometimes seed is advanced by the tenant proprietor who has no bullocks; but when all the agricultural operations have been gone through, the simple contract is determined by the division of the crop, grain and straw, as sown and reaped. The man who does the work is, of course, under no liability for the rent of the land. Threshing, I should mention, is generally done out on the plain, and not near the ryot's house. A spot on the edge of the field is smoothed, cleared of weeds or stalks, and hardened till it becomes like a pavement, and the threshing is accomplished by the simple process of allowing the bullocks to tread out the seed. The Scriptural precept of not muzzling the animal is invariably observed. The rice, when threshed, is carted or carried away to the ryot's house, and sometimes half-boiled, and stored in pits, or oftener stacked on round frames, called *golas*, till it is wanted for consumption or sale. The process of separating the husk from the rice, and making the latter fit for cooking, is carried on by an instrument, called a *dhenki*, or wooden pestle and mortar. This duty is usually performed by women. My description of agriculture takes no account of the years when the failure of the usual rainfall inflicts misery on thousands, and chills the hearts of administrators and financiers. To enter on the subject of famines would require larger space and time than be afforded; and the Report of the Famine Commission, I believe, deals effectively with this subject. I keep strictly, therefore, within the limits originally proposed. A few words on the general effect and outturn may not be amiss. Nothing is more striking to a patient observer than the variety, not of the processes, but of the results. I was once in a position to observe narrowly and constantly the difference between tilth in the hands of capable and incapable workmen. Within a couple of miles of each other were two villages, enjoying the same advantages of soil, rainfall, and climate. One belonged to the agricultural caste of Hindus known as Sadgope. Men of this class have no handicraft, desire no appointment as peon, watchman, or policeman, do not even care to drive a cart, but devote themselves exclusively to agriculture. The result was that bullocks and milch kine abounded: large families occupied each homestead; every plot of ground was thoroughly ploughed, harrowed, and weeded; the returns were solid and each family or household was, if not rich, certainly independent, and far removed from indigence or suffering. The other, a much larger village, was occupied by the class of Mohammedans known as Jolha Karigars, or weavers. In the lands of this village were comprised early and late rice, orchards of mango trees or plantains, and date trees. Several of the ryots had small local employments, which brought them regularly in a few rupees a month. Several carried on the trade of weaving, and turned out light suits of clothes, which, I am sorry to say, twenty-five years ago were being gradually improved off by the market by Manchester or American piece goods. There could be no doubt that more money circulated in the Mohammedan than in the Hindu village, but the difference in agriculture was apparent to the casual glance. The ploughing was superficial, the harrowing careless, and the weeding was neglected. I lay stress on this point, because I have seen it stated that the returns from Indian agriculture might be indefinitely increased by what is termed the outlay of capital, scientific processes, the use of manures, and other grand and ambitious schemes. As regards manure, I am glad to observe that Mr. Hunter, in his recent statistical volumes, puts this matter on its proper footing. Most ryots know the value of manure for high lands, and it is constantly applied to date and sugar cultivation, and to gardens. For the deep and late rice no manure is needed. The best restorative to the lands in such cases, I hold to be continuous tropical rain, or the silt brought down by the Ganges and its affluents or distributaries. In any case, the absence of manure is due to poverty and not to ignorance, and it would require an exhaustive description of the rights, privileges, and duties of superior ownership to explain why large Zemindars do not direct cultivation, and cannot be expected to expend capital on manure. Cowdung, which abounds, and has certain fertilising properties, is too valuable as an article of fuel to be stored up for manure. It has always appeared to me, from close attention given to this subject, that (as I have already remarked) those who talk glibly about instructing the Bengal ryot will have to admit, when they have watched him at work, that they may derive a good many lessons from his operations. No doubt there are many instances which appeal to the eye of imperfect tilth and second-rate crops. But the average ryot is thoroughly well acquainted with the set and lay of his fields, his neighbour's, and their watersheds. He knows when to sow, and plant out, and weed. He rarely puts the Aoos where the Aumon should be planted, though I have noted one or two instances of perverseness or obstinacy in this respect. He knows how to dam up water, and store it or let it off as required; he is quite aware of the fact that tobacco, sugar-cane, red pepper, or the pulse called dhal, require constant and close supervision. He will frequently sell the very stubble off his field for fuel to the sugar manufacturer, after the regular straw has been carted away; he knows how to build, repair, and thatch his house; how to store his straw; and the neatness and cleanliness of his actual residence, including courtyard, verandah, and cooking house, is in striking contrast to the accumulation of dirt and decaying vegetation outside his residence, which taints the air, defiles the water, and engenders divers forms of deadly disease.

No doubt the labour of a Bengal ryot is not equal to that of the thews and sinews of a Northumbrian or Yorkshireman. A strong Hindu agriculturist may plough one beegah of land in a day; and the Bengal beegah, in contradistinction to that of Tirhoot, is about one-third of our English acre. He would drive the harrow or ladder over eight or ten beegahs. To weed only a quarter of a beegah would be an extremely good day's work; and to plant out a beegah of land with rice plants would require the undivided labour of three men a day. I have timed men at this operation, and noted that one good worker put in sixty-five to seventy-five plants to the minute. His rapidity and dexterity were perfectly surprising. A less vigorous worker only put in fifty to the minute, and three Mohammedans admitted to me that this part of the work broke their backs. A few other minute statistics may here not be out of place. They were collected when I had no thought of presenting them to an English audience.

A stalk of late rice, 4 ft. long, taken out of a fair average crop on the 1st November, about three weeks before the harvest, contained 174 grains; another, in the same plot, 3 ft. 10 in., had 134 grains. On the 7th November, 206 grains were counted on a single one of six or eight stems growing from one and the same root; another stem had 133. Later, in the same year, on November 30th, a rice stalk from a thick clump, about which in ordinary years there would have been a foot of water, gave 233 grains. On the 30th December following, three stalks of rice, in the same plot, gave respectively, 200, 115, and 168. Here again is an account of the return of rather more than one beegah of early or Aoos rice. Two varieties were sown (Mahesh Dhali and Baro Janmiya), the former gave fifty-five baskets of ten seers each; the latter, thirty-six baskets. The best ears of the Mahesh Dhali gave 290 and 270 grains each. The Baro Janmiya gave less, but of a finer kind, being 117 and 113. This was cut the first week in September, and it was roughly calculated by my informants, the owners, that about two maunds had been shaken out by the wind and lost.

Here is the produce of a piece of sugar-cane on four cottas of garden land; or, length, 35 ft.; breadth, 25 ft. There were nine rows —

1st row	51
2nd ..	77
3rd ..	72
4th ..	73
5th ..	91
6th ..	87
7th ..	89
8th ..	83
9th ..	74
	697

The proceeds, at one pice a cane, was nearly eleven rupees. The height of the tallest cane was 15 feet 8 inches. The expenses of the slips for planting was seven annas; labour, three rupees; propping the canes by bamboos and ropes, about eight annas—in all, some four rupees; so that the clear profit was nearly seven rupees.

A few words towards the conclusion of this paper may not be out of place, in connection with the possibilities of improving agriculture, and getting more out of the land, an object of importance, both with regard to the contingency of famine and the enormous increase of the rural population. This matter assumes a gigantic proportion when we remember that, in some districts, the population averages 500 or 600 to the square mile. I will reiterate that glowing estimates as to power of the soil of Lower Bengal, if skilfully cultivated, to give a return of 50 and even 75 per cent over its present outcome, appear to me to rest on neither probability nor proof. In the first place, on a large portion of the deep land of Bengal, the cultivation has been stereotyped by Nature herself. It will bear the late crop of rice, and it will bear nothing else. It is idle to talk of manuring, or ploughing deeply, land that needs nothing but plentiful, continuous, and seasonable rains to produce rice of the largest stalk and the heaviest ear. With a good season, there is nothing to prevent this sort of land bearing a fine harvest year after year.

It may happen that an excessive rainfall every now and then ruins these deep lands, but loss from inundation in India is partial and even trivial compared to that inflicted by drought. I except, of course, such visitations as the tidal wave of the Megna. Some miles of country may be submerged by the overflow of a river, and the harvest spoiled, but such damage is local and temporary, and is partly compensated by the filling of tanks, the flushing of ditches, and the deposit of rich silt left by inundation. But as a physical fact, the land of the Delta is rising, and has been rising for years. Bheels and swamps are gradually silting up by the action of rain-water, or water charged with deposit, and every now and then a distributary of the Ganges pours a fertilising flood over a large span of country on each of its banks. Within the memory of man, many a Bheel or swamp, the haunt of waterfowl and fish, of coot and heron, has so risen as to be fitted for the plough; and while swamps have been converted into rice-fields, rice-fields in their turn have become villages and gardens. Something has been done by the Government of India by the creation of a Special Department of Agriculture, to record statistics and to establish model farms; but this Department has, if I mistake not, been recently abolished or doubled up with another, and I doubt very much whether there exists in Bengal any machinery for ascertaining accurately the gross or the net return of any one given area. Statistics of population, of cultivable, cultivated, and waste lands have, no doubt, been ascertained by the survey. The Pergunnah rates of rent are also well known. But though it is quite possible to judge of the difference between careful and slovenly tilth, between the best of Hindu and the worst of Mohammedan cultivators, I reiterate that it would be rash to predict from the most careful husbandry an increase of more than 10 or 15 per cent in the produce. It is impossible to show, in the limits of this paper, how large Zemindars cannot be expected to vary or improve the general cultivation of the country. Bengal Zemindars exercise no influence over the course of cultivation. They may cut a canal, dig a tank, lay out a road, or establish a weekly market. But the whole custom of the country, whether based on traditional precedent or confirmed by judicious legislation, is against their spending capital, as an English landlord does, in scientific agriculture and high cultivation. The introduction of the higher and more lucrative products has been entirely the work of substantial Gantidars, jotedars, or tenant proprietors, call them by any revenue or local term that you choose. These men may own a village, or half a village, or fifty beegahs. Something, of course, may be done to manure the land by those who can afford it; to cultivate garden produce, with some attention to the pruning and grafting of fruit trees; to introduce fresh seed from other Provinces; to improve the breed of cattle, and, possibly, on the high lands, to give the soil rest by rotation of cold weather crops. But, in a very large aera, rotation is a simple impossibility, from the very nature of the crop. A good deal has been done by the Government to assist the agriculturist, by opening up new communications, and improving those in existence. Railways have connected distant provinces, and have been supplemented by metalled and by fair-weather roads; law and order have become paramount; the great waterways have been made secure against dacoits, and crimes of violence have been put down; and all these reforms tends to the security of the producer, and enable the surplus of one division to supply the deficiency of another. To all this no one, in this day, has contributed more than the eminent public servant who fills the chair tonight. You will remember, also, that manufactures in Bengal are only just in their infancy; and hitherto—except by emigration to Assam and a few other places—there have been found no ready means of easing any part of Lower Bengal of its surplus population. But I do not attempt, at the close of this paper, to do more than show the inherent serious difficulties of the agricultural problem, and to warn you against putting faith in the jaunty predictions of confident prophets, who maintain the feasibility of indefinitely increasing the outturn of the harvest, and in making everywhere, two or three blades of rice grow instead of one.

I now think it not out of place to state that very little, if anything, is taken at second hand, or from books and reports. It is, be its value what it may, the fruit of past, direct, constant, personal inquiry into the means and status of the ryot, and of notes and statistics gathered unofficially in walks and rides round the plains and homestands, the garden and the tank, and immediately commited to manuscript or to print. In this I lay claim to no special merit, and only pretend to have followed the example, as far as was possible under a different system of revenue and official agency, of those eminent administrators who, in the North-West Oudh, and the Punjab, have laid the foundation of order and contentment on an intimate knowledge of the habits and requirements of the masses. And I may express a hope that the present generation of able and rising civilians in Bengal may neither be so drenched with statistics, nor overwhelmed with calls for returns, nor so cabined and confined to the desk, as to be unable to mix freely with the agricultural population, and so obtain that familiarity with village life which examination papers or Blue-books can never equally afford. As I write, the old familiar scenes seem to rise before me; the vast plains with unbroken sheets of rice, and the dense artificial jungle of the village; the reservoirs of deep water and high banks which the munificence and piety of one generation had called into existence, and the negligence of a succeeding one had allowed to fall into decay; the network of rivers, teeming with fish and covered with craft of every description, from the lightest canoe to vessels of the most unwieldy bulk and ample stowage; the myriad population with their carts and ploughs engaged in taxing the soil for existence, or carrying their produce to the nearest mart; the spire of the missionary's church unexpectedly rising out of the exuberant foliage of some hamlet, the lonely bungalow of the civil engineer or the planter; and the white kutcherry, where a young man, not thirty, with an alpaca coat and a felt hat, is the representative of British authority, and the guarantee not only that the harvests shall be gathered unmolested by Mahratta raid or Mohammedan invasion, but also that, however protracted or fierce may be the passing controversy as to tenant rights, executive changes, and legislative progress, yet whenever a wise and judicious course of action has been determined on, the States shall be served with that heartfelt loyalty and that disinterested obedience which neither shows any trace of party conflict, admits any invidious distinction of race or creed.—*Journal of the Society of Arts.*

THE INDIAN MAUND.—The following is an answer to a query in the *Indian Forester*:—In reply to K. H. in the "Indian Forester" for March 1883. In the Punjab and in the North-West Provinces the Government maund equals 82 2-7th lbs. Avoirdupois, or 82·2857 lbs. Avoirdupois (Molesworth's Pocket Book, 21st edition, page 598.) The maund at Changa Manga plantation cannot be other than the authorised Government maund of North India.

ON THE CULTIVATION OF LIBERIAN COFFEE, COCONUTS, AND OTHER PRODUCTS IN CEYLON.

Report by Major R. J. Wimberley, Officiating Deputy Superintendent of Port Blair.

[For the following Report we are indebted to the Indian Government.]

LIBERIAN COFFEE.

This is almost a new product in Ceylon, planters having only introduced it on a large scale since their plantations commenced to suffer so severely from the "Hemileia Vastatrix," or leaf disease; it is therefore at present almost in its infancy, but, after seeing a considerable extent of land under this crop, and hearing the opinions of men interested in its cultivation, I think that the following information may be considered reliable.

The Liberian coffee appears to grow equally well in the immediate neighbourhood of the sea and at considerable distances from it; it grows as well on level grounds as on slopes, care being taken that on slopes the rich surface soil is not washed away, and on level ground that there is no accumulation of stagnant water. As regards elevation it will grow from the sea level up to 1,700 feet, but being essentially a low-country plant, it has shown a decided preference for the warm, moist and stimulating climate of the plains; virgin forest soil is considered best for it, simply because it contains sufficient plant food and saves the expense of manuring for several years; ordinary soil, however, will answer as well, provided it be of loose texture, for the tree will not thrive in stiff clay soils. The size of the holes is a matter of taste, the larger of course the better, but a good practical size is two feet cubic which, filled with surface soil, gives the plant a large quantity of the richest material the land affords to forage in. Experience has not yet shown the proper distance at which it should be planted, as it is not known whether the plant produces best when topped, or when allowed to carry out its natural vertical development. The general concensus of opinion I find is that the tree will require to be topped for the convenience of picking the fruit, as it is found that where the trees are allowed to grow up tall, they are frequently injured by climbing with ladders and pulling down the limbs, and much of the blossom and young fruit is robbed off the tree, whereas topped trees can be picked by coolies standing on the ground. It is therefore considered that the most convenient size to top at is 5' 6", and the best distance to plant 12×12.

Although it actually possess no immunity from the deadly coffee-leaf disease, being of a much stronger growth than coffee Arabica, it has hitherto suffered very little from it, and those trees which have been attacked have borne the effects much more successfully than Coffee Arabica.

With regard to its commercial value, Mr. Morris, a great authority, thinks it will probably be lower than the best varieties of Arabian, but he states that it is the opinion of experienced coffee dealers that the Liberian bean would ultimately find its level alongside Java and Native descriptions selling at about 90s. a cwt., and he thinks that from its more robust and prolific character, and from the generally more economic treatment to which it is amenable, it is quite possible that its cultivation will prove even more remunerative than the high-priced varieties of Arabian coffee. It is considered that a market is already assured in America where a trial shipment in January last realized 93s. per cwt. The trees begin to bear at three years, and it appears to have no very marked blossoming season. The cherries ripening throughout the year, and the crop is estimated when in full bearing at 4 to 7 cwt. per acre, which, judging from the promising appearance of exisisting Liberian coffee estates, is a very safe estimate.

The following rules have been kindly furnished me by a gentleman interested in this product:—

(1.) Obtain good fresh seed.

(2.) Build a shed that will admit light and air but exclude sun and rain.

(3.) Prepare a compost of equal proportions of loam sand and well rotted cow-shed manure, and lay it in beds four inches deep in the shed; smooth the surface and lay the seed down 2 2 to 3 inches apart and cover with coir dust or fine sand, in no case putting more of the covering matter than is necessary to exclude light from the seed.

(4.) Put into a tub, holding from 20 to 25 gallons watter, one quart of quick lime and a wine glass of kerosine oil; stir the mixture well and give the beds through a watering pot with a fine rose just as much as will settle them, and repeat the operation as often as may be necessary to keep the surface moist.

With this treatment of fresh and sound seed, plants will begin to appear about the 25th day.

(5.) As soon as all the plants in a bed have thrown off the parchment husk and fairly expanded the seed leaves, they should be transplanted into bamboo-baskets nine inches high and six inches wide at the top.

The baskets should be filled with the same compost as the beds, with a little more loam and a little less manure: they should be kept in the shed and regularly watered for ten days, after which they may be exposed to the morning sun and taken in as soon as the leaves show any symptoms of drooping, but may be left outside entirely as soon as they can stand the sun without drooping.

(6.) The plants may be put out in the field when they have three pairs of leaves, but of course at the proper season during the early part of the south-west monsoon.

On some of the Liberian coffee estates I found that attempts had been made to propagate the plant by cuttings and by suckers; both attempts had been successful but the trees raised from cuttings appeared dwarced and unsightly plants. Those raised from suckers, however, were strong, healthy and well-shaped trees, and could not be distinguished from seedlings.

On the whole, I feel confident that Liberian coffee, if introduced at the Andamans, will be a decided success the rainfall and temperature seem to be identical with that of much of the low country of Ceylon, where Liberian coffee is now being successfully grown. Much of the soil in the low parts of Ceylon is similar to that around Port Blair harbour; in both places the soil is decidedly poor, and if any difference exists, the Port Blair soil, in my opinion, is the better. As leaf disease is now attracting much attention and seems to appear spontaneously wherever the coffee plant is grown, I have thought it advisable to extract the following information regarding the progress of the disease from a paper by M. Scheffer, Director, Agriculture and Botanical Gardens in Java.

Ordinarily the disease is not noticed except when the parasitic plant is in fructification. The lower surface of the leaves is then covered with a yellow orange dust, which can be easily removed with the hand. The dust is formed by the spores which afterwards germinate and produce a large quantity of filaments, "mycelium," which penetrate the stomata and develope speedly in the intercellular dusts.

Some of these filaments again leave the interior of the leaf and produce new fruit.

The "mycelium" soon extends not only over the entire surface of the leaf but over the stem.

The spores produce innumerable new filaments which by their rapid growth require abundant nourishment, which they draw from the shrub. The consequence is that the leaves, the young berries and the extremities of the stems wither and finally die. The tree usually produces fresh shoots, but the disease immediately renews its attacks. The young leaves again die. The second attack is very dangerous, and few plants, without a long enough respite, survive.

The general public do not believe in the attack except when the spores are visible, but the presence of the fungus can be recognised at other times also and with the naked eye. It may then be noticed on the leaves in almost transparent spots which are caused by the destruction of the cellular tissues of the leaves on which the filaments of the "mycelium" feed: no remedy has yet been discovered. The preventives will be to uproot and burn the infected trees, and to prohibit the introduction from places where the disease exists. But after all high cultivation is the best preventive.

I brought with me 4,000 Liberian coffee cherries from the the Botanical Gardens, Kandy, and 1,000 cherries from Galle, and if we have any luck, we should, I think, get 10,000 plants from this seed. I opened the boxes containing the seed the day after I landed here, and had the seed prepared and planted out at once: a very small proportion appears to have lost its vitality.

COCONUT CULTIVATION.

During my sojourn in Ceylon I have paid careful attention to coconut cultivation, and have seen many millions of trees, the greater part of which of course belongs to natives.

The trees naturally thrives best in sandy soil close to the sea, but I find that it is grown successfully up to 2,000 feet, and at a distance of 40 miles from the sea as the crow flies.

The natives as a rule plant from 100 to 150 trees per acre, while on English estates the uniform rule is 90 trees to the acre, equal to about 25'×25'.

The general appearance of the trees in Ceylon is markedly inferior to those grown at the Nicobars and to the young plantations of Nicobar seedlings; at the Andamans the nuts too are of a smaller description. I consider that we are doing wisely at the Andamans in planting 40×40, and several gentlemen interested in coconut cultivation, with whom I conversed, agreed with me that on the Ceylon plantations the trees are too close. The only point I learned in connection with cultivation was that the trees are much improved by toddy being occasionally drawn from them, say for one year in every eight or ten. If the toddy is drawn from a tree year after year, it is highly injurious. I mention this, as I believe on Ross Island the same trees are handed over to the commissariat for this purpose year after year.

The principal coconut estate which I visited was at "Horekelly," and belongs to a company of which Mr. C. E. H. Symons is the Managing Director. The company manufacture "kopara" and fibre. The estate is 800 acres in size and in full bearing, and contains about 70,000 trees. Mr. Symons kindly accompanied me over the estate, and gave me much valuable information regarding the preparation of the fibre for the market. A main line of tramway runs through the estate, and cross lines run at convenient distances. The nuts are picked every two months or six times in the year. They are collected in carts, and drawn by bullocks to the nearest tramway line, then trucked to the manufacturing works, piled in heaps, and left for about six weeks to dry. They are then split open in the usual way, and the nut divided into two pieces, removed from the shell. It is then dried in the sun on "barbecues," provided the weather is fine. In cloudy and wet weather it has to be dried artificially on heated plates of sheet iron. The sun drying is much preferred, as by this mode the nut retains a better colour which considerably affects its market value. The present price of the "kopara," which is very low, is R7 per cwt., but there is an unlimited demand for it at this price. The husks are soaked for 24 hours in large vats containing fresh* water; they are then passed through a coir fibre-breaking machine, a revolving drum with long steel spikes, driven by machinery which cards out the fibre called in the trade "no mark," and leaves the bristle fibre behind.

The bristle is then passed a second time through a combing machine, and a fibre called "one leaf" is removed. The man who handles the bristle during this process picks out any dirt or woody matter which the machine has not removed. The bristle is then made into small bundles, about four inches in thickness, tied with a piece of the fibre and hung up in the shade to dry. The "no mark" is passed through another roller of a similar description, but of a larger size, which separates it much in the same way as a hay-making machine shakes out hay. It is then washed, dried in the sun, all dirt and refuse picked out by hand, and sifted through large cane seives made in the form of a charpoy. The "one leaf" is merely dried in the sun and picked by hand. All three qualities are then removed to a building, where they are subjected for 12 hours to the fumes of sulphur which is introduced by means of pipes. The process whitens and improves the colour. Half a cwt. of sulphur is required for 80 cwt. of fibre. The bristle is then packed in large bundles weighing about 30lb.

* Mr. Stalkart, of Harton and Company, Calcutta, informs me that for the Calcutta market the nut must be soaked in salt water.

The other two qualities are pressed into bales or ballots, measuring 1' 8"×12"×6" tied with coconut twist and are ready for the market. The present rates in Ceylon are for—

No. 1, or bristle, £25 per ton.
No. 2, or "one leaf", R6 per cwt.
No. 3, or "no mark", R4-8 per cwt.

The one leaf is so called because a piece of palmyra leaf is placed in each bale to distinguish it from No. 3 or the "no mark." Mr. Symons, however, informed me that if Nos. 2 and 3 were converted into fine two-strand twist of 120 feet in length, there would be a ready sale for it at R17 per cwt., and I learn from the Inspector-General of Prisons that this is one of the principal industries in the Ceylon jails.

The nuts if sold in bulk are sold at R25 per thousand. With the large number of coconut trees that will in a few years hence come into bearing at the Andamans, it appears to me highly desirable that we should introduce the necessary machinery, and make the manufacture of twist one of our principal industries. To obtain an even fibre which is necessary to ensure a good market price, the twist must be hand-manufactured, and this labour would be highly suitable for old and sickly men and for women. In Ceylon it is considered a more paying business to prepare the kopara than to manufacture oil; but as our labour costs us nothing, and a better price can be obtained for coconut oil than for the "kopara", it would appear desirable that we should manufacture and export the oil. The leaves of the coconut are used on a very large scale for roofing buildings and houses in the Island. The leaves are plaited and called cadjans: they are laid on in pairs at intervals of 8 inches, the leaf having been first split down the mid rib. The mid rib is tied on to the baton in three or four places, according to length, by a piece of twist.

The roofs last well for one year, and considering the rapidity with which they can be made and put on the roof, I think we should certainly adopt them at Port Blair instead of jungle leaves. The leaves used for this purpose should be those which have fallen from the tree, as they last better than green leaves which are cut. I was unable to obtain any accurate information as to the cost of coir fibre machinery, as the Company to which Mr. Symons belonged had purchased the estate with its plant; but Mr. Symons believed that suitable plant for this purpose, without engine, to work up 6,000 to 7,000 nuts a day could be obtained for R1,500 to R2,000, but Messrs. T. E. Thomson, Calcutta, promised to obtain this information for me from England. The old steam engine on Chatham could be repaired and fitted up sufficiently to work this machinery. A hydraulic press for packing the coir fibre into bales costs about R4,000, but at Horekelly a press has been made on the spot out of a heavy log of timber, and a crab winch; and as it is found to answer the purpose, we could use similar presses here.

CINCHONA.

As the question of introducing cinchona cultivation at the Andamans had been mooted, I thought it advisable to make enquiries about it and to visit several of the nurseries and plantations. The cultivation I find is simple enough, and can be carried on by any person who understands planting at all. Dr. Trimen, the Director of the "Botanical Gardens" assures me that cinchona plantation in this latitude at any elevation under 2,500 feet would be prefectly useless. *C. succirubra* would no doubt grow at a very low elevation, but would contain no alkaloids, and I found his opinion was fully corroborated by other persons experienced in cinchona cultivation. If Saddle Peak Mount at Port Cornwallis is really 3,000 feet, the height which is supposed to be, it might be a question for consideration whether it would be worth while opening a small settlement there for the cultivation of cinchona. My own opinion, however, is that this cultivation is now being so enormously extended, that in the course of a few years the bark will literally be a drug in the market, and instead of paying the enormous returns which it is now doing, it will barely pay the expenses of cultivation. I have met many gentlemen interested in this product who holds these views; anyhow it appears perfectly useless attempting to grow it at Port Blair.

COCOA.

Dr. Trimen appeared to think that cocoa would grow well at the Andamans, and strongly recommended us to try it,

In Ceylon it is being most successfully grown at from 1,000 to 1,500 feet; in the low country it has not done so well. In Trinidad, which lies three degrees farther north than Ceylon, it grows down to the sea level, the temperature rarely exceeding 85 degrees and falling to 78—conditions which appear very similar to those of Port Blair.

It requires a warm steamy climate, with a moderately good soil; shade is essential, and either the jack or the Ficus Indica is considered the best shade tree.

The young plants are raised in the usual way in nurseries and planted out 10'×10'; for some days after transplanting they require to be protected from the sun by fern leaves of small leafy branches of trees.

The shade trees are planted 60'×60'. In some places the plantain is used for shade, planted at 30'×30'. Great care must be taken in planting the young tree, to place the tap root quite straight, and it is essential in the choice of the land to provide against there being a substratum of cold clay, as the tap root upon reaching this would be unable to penetrate, and would turn up and die. It commences to bear the third year, and should give a good crop the fifth year. The crop is gathered as follows:—

Coolies are given long bamboo rods with a small sharp curved knife attached; they also carry a small cutlass. The lower pods are removed by the cutlass, and the upper once by the curved knife; great care is used in severing the stem of the pod from the body of the tree, as the future crop depends upon careful manipulation. A clean cut is required, about half way between the stem of the pod and the tree. The pods are gathered from the trees and heaped at stated intervals. The pod is then opened with a cutlass at the large end by a neat circular cut.

The beans lie exposed at the top, but remain clinging inside to the bottom by means of the fibrous stuff which holds them together. The pods are then taken by women who scoop out the beans with a flat wooden spoon on to plantain leaves. The bean is then squeezed through the hands to clear it of the fibrous substance; they are then removed to the sweating house and placed in a large heap on the flooring. Plantain leaves and bits of old sacking are thrown on the top, the doors of the house are closed, and they are left for four or five days. At the end of that time the doors are opened, when the heap will be found quite hot and of a deep brown colour; they are then spread in the sun on a barbecue, and a very fine kind of red clay is shaken over them. When quite dry the cocoa is carefully picked and cleaned of all dust; the beans are sorted into three sizes and packed for the home market. It appears that the whole of the future excellency of the bean depends upon the sweating process, and it is most essential that the building in which the fermentation proceeds should be air-tight. Mr. Tytler, a gentleman who was the pioneer of cocoa cultivation in Ceylon, and who has about 1,000 acres under this crop, sweats his beans in large pits, the bottom and sides of which are carefully plastered with clay, and apparently finds this system efficacious, as his cocoa realized in London 100 shillings 6 pence per cwt., which was a higher price than cocoa sent from Trinidad. Mr. Tytler has himself been to Trinidad to learn all about cocoa. This gentleman kindly accompanied me all over his estate, and gave me every information in his power. As I thought this would be a crop well worth trying, I obtained from Dr. Trimen 1,000 cocoa seeds. On opening the case containing this seed I found it had all germinated. I have had it planted out, and I hope it will be a success. I also obtained from Botanical Gardens, Calcutta, a case containing a few young plants.

INDIARUBBER TREES.

The cultivation of these trees is now attracting very great attention in Ceylon, and Dr. Trimen thinks that the "Ceara" and the "Hevea" would be likely to succeed at Port Blair, though he has some doubts whether the wet season would not be too much for the "Ceara," and stated that I should be able to obtain a large quantity of "Hevea" from Dr. King, of the Botanical Gardens,

Calcutta. On applying to Dr. King he said that all his Hevea plants had failed, and that inasmuch as the Indian Government had paid the whole cost of the plants which Ceylon now possess, he thought Dr. Trimen was bound to furnish them. I subjoin the following extracts from notes on these rubbers furnished me by Dr. Trimen. There can be no doubt of the hardiness of the "Ceara," its readiness of culture, and adaptability to circumstances. It grows equally readily from seed or from cuttings, and, though a native of a tropical sea level, thrives well in Ceylon up to at least 3,000 feet, and on most barren soil. *Germination of seed.*—The seed-coat is of remarkable thickness and in the natural process of germination occupies a long period—it is said more than a year. All that is necessary to hasten this is to assist the seed-coat in splitting; this is effected by holding the seed firmly and rasping off with a file both edges at the radicular end; it is best not to file off the actual end, as it may thus easily happen that the radicle of the embryo may be injured. After this treatment the young plants should appear above ground in two or three week. The seedlings require no particular attention, they grow rapidly, and may be planted out at 20'×20'. Cuttings will take root as easily as a willow; they should be taken from the points of strong shoots, and may be foot in length. In planting, each cutting may be put into the soil to a depth of six inches. If scarce the entire shoot may be cut into pieces, each possessing a bud, all of which will grow if covered with half an inch or so of soil; loose sandy soils and hard dry gravelly wastes are also suitable sites. Holes might be made in strong land with an iron jumper, and a stout cutting put into each, and filled with pebbles. On bare or thinly covered portions of rock the cuttings might be laid down flat, and a little heap of stones or any kind of "débris" about the size of a mole hill, piled over each, care being taken that the extreme point of each cutting with a bud is left uncovered.

System of collecting the rubber.—On commencing to work the collector takes with him a stout knife and a handful of twigs to serve as a broom. Arriving at a tree, any loose stones or dust are swept from the ground around the base, and some large leaves are laid down to receive the droppings of milk which trickle down. Some do not go to the trouble of sweeping the ground, or laying down leaves, for which reason the milk adheres to sand, dust, decayed leaves and other impurities. The outer surface of the bark of the trunk is pared or sliced off to a height of four or five feet. The milk then exudes and runs down in many tortuous courses, some of it ultimately falling on the ground. After several days the juice becomes dry and solid, and is then pulled off in strings and rolled up in balls. Collecting is carried on during the dry season only when rain seldom falls. It appears that "Ceara rubber" may be tapped on obtaining a diameter of four to five inches or about two years' growth. I saw a large number of these trees at the Henaratgoda Botanical Gardens, where they appeared to be thriving remarkably well; and as the climate seems very similar to the Andamans, I think it probable that it would succeed with us. I shall, I hope, be able to make the experiment with the 100 seeds obtained from Ceylon.

The "Hevea," or "Para rubber," is found abundantly in the enormous forests of Central and Northern Brazil The climate there is remarkable for its uniformity of temperature, usually not exceeding 87° F. at midday, or below 74° at night. The rainfall occurs principally from January to June, the maximum being in April, when it reaches 15 inches; for the remaining six months of the year very little falls. The whole country is covered with dense moist forests, and the soil near the numerous rivers is deep, heavy and very fertile. During the wet season much of the low-lying country is flooded. In the "Gopos," near "Para," visited by Mr. Cross, be found a flat district only three or four feet above the highest tides and completely intersected with water-courses, at low tide, filled with a soft rich mud. The forest here, in which caoutchouc-collecting was vigorously carried on, was 80 or 100 feet high, and very damp and unhealthy, the soil full of moisture and very rich and fertile; the young plants, however, were not often observed to grow actually within the reach of the tides, but it is evident that they must frequently be subject to be partially covered with water.

Propagation and Planting.—In Ceylon this valuable species has been as yet propagated from cuttings only. At Henaratgoda the largest trees, three years old, are 30 feet in height with a slender stem scarcely branched, and about 12 inches in circumference near the base. The tree when fully grown does not exceed 60 feet in height and 6 feet 10 inches in circumference at 3 feet from the ground; from its upright habits, it will not be necessary to plant at any great distance apart, and the Superintendent of the Henaratgoda Gardens informed me 15'×15' would be sufficient. Cuttings may be taken from the green lateral twigs as soon as they begin to harden; they strike readily in rich firm land. For planting on inundated lands the period of high floods should be preferred. Cuttings of greater length would be required in this case, the lower ends of which should be sliced off in the form of a wedge. The workmen could take a bundle of these, and wading into the water, would plant at proper distances but perfectly upright, taking care to push each cutting down deep enough in the soft muddy bottom, so that no more than three or four inches is above the surface of the water; the same rule would be applicable when planting in sludge or soft marsh mud. The crowns of the cuttings must not, if possible, be put under water, as the young growths springing therefrom might rot.

Collection of the Rubber.—The trees are tapped if they have a circumference of 18 or 24 inches, and the process is carried on for many years until the constant and extensive injury to the young wood cause their death. At about daylight a collector arriving at a tree strikes it with a small axe in an upward direction as high as he can reach, making a deep upward sloping cut across the trunk which goes through the bark an inch or more into the wood. The cut is an inch in breadth; with a small ball of well-wrought clay he attaches to the tree a small cup of burnt clay holding about the 15th part of a pint, in such a manner that the milk, which is of a dazzling whiteness, trickles into the cup. At a distance of four or five inches, but the same height, another cup is luted on, and so the process is continued until a row of cups encircle the tree at a height of about six feet from the ground. This work should be concluded by 9 or 10 o'clock in the morning. If the tree is large, the majority of the cups will be more than half full, and a few may be filled to the brim; but if the tree is much gnarled from tapping, many of the cups will contain only about a table-spoonful of milk. On the following morning the operation is repeated in the same way, only that the cuts or gashes beneath which the cups are placed are made from 6 to 8 inches lower down the trunk than those of the previous day. Thus each day brings the cup gradually lower until the ground is reached. The dry season is most suitable for caoutchouc-collecting, but tapping can always be carried on when the weather is fine. At about 10 o'clock daily the collector empties the contents of the cups into a large calabash which he carries in his hand. As he pours the milk out of each cup, he draws his thumb or forefinger over the bottom to clean out some which otherwise would adhere. The cups on being emptied are laid in a little heap at the base of each tree to be ready for use the following morning.

For the preparation of this rubber for the market it is desirable to reduce it to solid mass as quickly as possible. For this purpose the cautious application of dry heat is the best. The best Para rubber is prepared by being poured over a flat paddle-shaped mould which is held in the thick hot smoke from burning wood and palm nuts till it solidifies, then slit down one side, the mould taken out, and the "biscuit" hung up to dry. Probably carefully conducted evaporation in shallow pans by artificially regulated heat would be found an effective method. The purity of the prepared rubber is a matter of first importance, and all pieces of bark and earth should be removed by passing the milk through sieves. In the market small pieces of thin sheets of caoutchouc are preferred to large masses, from the facility of estimating the purity of the article. Absolute dryness of the rubber is also a point requiring the greatest attention, and may require, for its thorough attainment, hydraulic pressure. In 1874 as much as 129,163 cwt. of caoutchouc were imported to England, of which 70,866 cwt. were American. The value of the latter was £1,007,413, or upwards of £14 per cwt. The demand for the best sorts is constantly increasing. It would seem pretty nearly certain that this tree would succeed at the Andamans, and I would recommend that the Ceylon Government be addressed through the Government of India and asked to furnish us with 100 cuttings of this tree.

CARDAMOMS.

This is another crop which is being successfully cultivated in Ceylon, and which, Dr. Trimen thinks, would succeed well at the Andamans. They can be raised either from seed or from the bulbs, the latter being preferable, as the stools raised from bulbs give a crop the second year, while from seed a crop can only be obtained the third year. They require to be grown in very shady places, the best situation being under large forest trees from which the undergrowth has been removed. The cultivation and curing are very simple: the bulbs or seedlings are planted out at 6'×6', and the soil should be of a light sandy description and rather moist. The scapes, or flower and fruit-bearing stalks, three to four in number and from one to two feet long and resting on the ground, make their appearance from the base of the stems. When the fruit is ripe they are dried in the sun, the ends clipped by women; they are then sorted in sizes by means of sieves, and are then fit for commerce. The Malabar cardamom is the best, and commands the highest price in the London market. The present price is from 4*s.* to 9*s.* per pound. The average crop is from 170 to 200 lb. per acre, but in very favourable localities, I am informed, that it has frequently yielded 1,000 lb. to the acre. This at the low rate of 4*s.* a lb. would make the crop worth £250 an acre. Dr. Trimen furnished me with a dozen plants for experimental cultivation, but I regret to say that on opening the Wardian case contaning them I found them all dead. I would recommend thae the Government of India be asked to obtain for us from the Malabar Coast 300 or 400 bulbs for experimental cultivation. During the first year the ground requires to be clear of weeds, after which little weeding will be required. The plants continue productive for six or seven years.

NUTMEGS.

Nutmegs is another crop which would appear to be suited to the Andamans, the only disadvantage being that they take seven years to come into bearing, but, on the other hand, they are said to improve up to 100 years. The tree will grow on almost any soil. They are raised in nurseries, and should be planted out at 20'×20'. The trees are estimated to yield from 1,000 to 2,000 nuts per annum, which, at R1 per hundred, gives a gross return, of R10 to 20 per tree. The average yield in the Straits is, I am informed, R400 per acre. I obtained from Dr. Trimen 200 seeds which appear to have reached this in good order.

CINNAMON.

Dr. Trimen thinks that cinnamon would succeed at the Andamans. This, however, is not a crop which gives anything like the handsome returns of those previously mentioned. The seed is raised in the usual way in a nursery and planted at 6'×6'. Half a dozen plants are put in each hole, and, beyond keeping clean for the first two years, it requires no other cultivation. The third year a crop is obtained, and, with occasional manuring, it will continue to crop for many years. The yield is estimated at 150 lb. per acre, and the present price ranges from 9*d.* to 1*s.* 11*d.* per pound. When the sticks turn brown they are cut, the bark pulled off and the outer skin is scraped off. The bark is then cut into suitable lengths, rolled, dried, and is ready for market. Dr. Trimen has supplied me with a few plants which have reached this apparently in a healthy condition; but if the Chief Commissioner thinks it advisable to try this crop, it would be necessary to obtain a large quantity of seed from Ceylon.

CITRONELLA.

This is another crop which I looked at in Ceylon, and which I have no doubt would thrive remarkably well at Port Blair. It is raised from seed and planted like guinea grass, and will give two or three crops a year. When fit to cut the grass is carried to a large boiler and the oil is distilled. It is estimated to give about three dozen bottles of oil to the acre, but the demand is limited, and price therefore fluctuates from 2*s.* 6*d.* to 4*s.* 6*d.* a bottle; at the latter price it pays handsomely, while at the former it little more than covers expenditure. A still capable of turning out a dozen bottles a day costs £300. I hardly think it would be advisable to attempt this cultivation at Port Blair.

SUGARCANE.

I have had an opportunity here of visiting two native estates where raw sugar is made by native process without machinery, and it is of so simple a description that there is no reason why we should not manufacture similar sugar at Port Blair. On one estate a cane-crusher, driven by a six-horse power engine, is used, the manufacturer of which is G. Fletcher, London. It is a horizontal mill with 3' roller; on the other estate a similar crusher, but with 3' 6" rollers, manufactured by J. Gordon and Company, London, is working. This, however, is worked by four bullocks, and would appear to be better suited to our requirements. The latter machine is worked for six hours daily, and is said to turn out 700 gallons of juice. The juice is then boiled in vacuum pans 6' 6" diameter, and when of the proper consistency, is turned out into wooden coolers. When quite cold it is poured into wooden casks, the bottoms of which are perforated with holes to allow the treacle to escape. In a few weeks this process is completed, when the sugar is spread in the sun to dry, sorted into different qualities, and is ready for use.

TAPIOCA AND BREADFRUIT.

I brought with me a few cuttings of the true [true?] tapioca plant and three or four plants of the bread fruit tree, as I thought both these would be very valuable for vegetables for convicts. They have arrived in good order.

R. J. WIMBERLEY, Major,
Officiating Deputy Superintendent.

WOOD STAINS.

Herr Leo, a pharmacist of Benshein, Germany, recommends the following stains for oak, pine, beech, poplar, etc.

1. *Yellow Stain.*—Wash over with a hot concentrated solution of picric acid, and, when dry, polish the wood.

2. *Ebony Black.*—Wash with a concentrated aqueous solution of extract of logwood several times; then with a solution of acetate of iron, of 14 deg. Baumé, which is repeated until a deep black is produced.

3. *Gray.*—One part of nitrate of silver dissolved in fifty parts of distilled water; wash over twice; then with hydrochloric acid, and afterwards with water of ammonia. The wood is allowed to dry in the dark, and then finished in oil and polished.

4. *Light Walnut.*—Dissolve one part of permanganate of potassium in thirty parts of pure water, and apply twice in succession, and after an interval of five minutes, wash with clean water, and when dry, oil and polish.

5. *Dark Walnut.*—Same as for light walnut; but after washing with water the darker veins are made more prominent with a solution of acetate of iron.

6. *Dark Mahogany.*—Introduce into a bottle 15 grains alkanet root, 30 grains aloes, 30 grains powdered dragon's blood, and 500 grains 95 per cent alcohol, closing the mouth of the bottle with a piece of bladder, keeping it in a warm place for three or four days, with occasional shaking, then filtering the liquid. The wood is first mordanted with nitric acid, and when dry washed with the stain once or oftener according to the desired shade; then the wood, being dried, is oiled and polished.

7. *Light Mahogany.*—Same as dark mahogany, but the stain should only be applied once. The veins of true mahogany may be imitated by the use of acetate of iron skillfully applied.—*Rural Californian.*

THE EUCALYPTUS OR BLUE GUM.

On suitable soil it will produce a greater number of cords of good hard wood and in less time, than any other tree they will bear crowding, and still grow well. They can; be planted 8×8 feet apart—making 680 trees per acre. So far as we have noted they do best on a moist sandy loam, that is free from alkali, with a subsoil that can be penetrated by its strong fibrous roots. The ground should be in a good state of cultivation, and the young tree taken from thr box in which it was sprouted with its roots enveloped in the ball of dirt in which they have grown, and planted in the place in which it is to grow. If the ground is sufficiently moist, and the weeds are kept down, by cultivation for two years, they will take care of themselves in future, and in ten years will average ten inches in diameter, and sixty feet high. How many cords of wood the trees would make, we do not know, but it would be a large quantity; the wood makes the best fuel, but it must be cut and split to the size it is wanted for use, whilst it is green, as when dry it be comes as hard as iron, and cannot be worked.

A forest of blue gums has this advantage—it is a permanent investment. When a tree is cut, suckers immediately spring up from the stump, and if those on each are confined to two, in five years the stump will have produced two trees of equal size with the first, and thus the forest will perpetually reproduce itself. Any one who has money for which he has no immediate use, cannot make a better use of it than to invest it in a piece of suitable land and plant it in blue gums.—*Rural Californian.*

CAFFEIC ACID FROM CUPREA BARK.—The bark employed differs from ordinary cinchona bark in that its aqueous solution becomes reddish violet on the addition of potash, and moreover, it yields caffeic acid when employed for the manufacture of sulphate of quinine; the caffeic acid is found in the mother liquors as quinine caffeate. The presence of this acid furnishes an additional proof of the relationship existing between the coffee and cinchona plants.—*Pharm. J. Trans.* [Only that the trees from which cuprea bark is obtained are not cinchonas.—ED.]

RATION OF HAY FOR HORSE.—Will you please state, to decide a question of payment, how much hay a horse will eat per diem in addition to eight quarts of grain? He is a medium-sized horse, weighing less than 950 pounds, twelve years old, used in the country to a buggy only, and not driven every day.—W. W., New York. [The experiments of Wolff and others, at German experiment stations, show that a horse weighing 1,100 to 1,200 pounds would eat from twenty-two to twenty-seven and a half pounds of hay, if no other food was given. With grain, twenty to twenty-five pounds was usually eaten by working horses of that weight. Lighter horses would not need quite so much, but we can find no data of experiments with horses weighing less than 1,000 pounds.]—*Rural Californian.*

PRUNING FRUIT TREES.—Much butchery is committed by unskillful persons under the delusive idea that they are judiciously pruning. A skillful pruner, by taking a glance at a young tree, can easily tell what buds to take off and what to leave, and can prune it with his thumb nail, so the tree will need little more through the season. Trees managed in this way will have few limbs required to be cut away. Sometimes a limb is cut off, leaving a stump two or three inches long on the tree. Aside from unsightly appearance, such a wound can certainly never heal over. If it is necessary to remove a limb, it should be sawed off as closely as possible to the stem, and then smoothly trimmed off with a sharp knife.—*Rural Californian.*

ACCLIMATISATION OF PLANTS.—With reference to the theory that, as coffee got acclimatized in Ceylon, it succeeded at higher and higher altitudes, we quote as follows from the *Indian Forester*:—Mr. A. Smythies, from Messrs. James Backhouse & Son, the great nurserymen of York, writes:—"In reply to your enquiry, we believe that, in point of fact, there never was such a thing as what is usually called 'acclimatisation' anywhere. What *has* been done has been merely *finding out* what the constitution of each species, or variety, *will bear* in the way of climate. We think you will find, as a rule, that where natural hardiness is the result of *high latitude*, there is nothing to fear, but that when supposed hardiness results from *high altitude* of native locality, the risk in all our low-lying ground is very considerable." Our readers will of course understand that the last sentence refers only to the British Isles.

FIJI AS A SCENE OF PLANTING ENTERPRIZE.

We do not think any of our readers interested in planting will justify the apprehension of our correspondent A. J. S., that his letter (page 62) is too long. From it we gather that sugar, tea and the products of the coconut palm are likely to be the staples of the Fijian group. Cacao does not seem to have been, as yet, tried. For coffee, curiously enough, the climate of Taviuni, at least, seems to be too wet, even at 1,000 feet above sea-level. At that altitude the rainfall is equivalent to that of Upper Dimbula at 5,000 to 6,000 feet, viz., 110 inches. Not only is the absolute rainfall thus heavy, but it is spread more uniformly over the months. The result is that coffee suffers severely from "black rot." *Hemileia vastatrix* seems to have temporarily abated its virulence, although Mr. Storck's carbolic acid cure does not get the credit of this result. Our correspondent at one time tried a series of experiments on behalf of Government, and he retains his preference for hyposulphite of soda, a substance which, we think, has found some favour in combating the insect plague, phylloxera. In Fiji (south latitude 15° 30′ to 20 30′), the best coffee and the best coffee crops are to be found *below* 1,000 feet altitude, which is not true of Ceylon nor of Jamaica. At all altitudes, however, crops of all kinds are liable to suffer in Fiji from hurricanes, which are practically unknown in Ceylon, although cultivation here suffers much from steady, strong, monsoon winds. Tea grows readily in Fiji, and, unless it should turn out to be true that here as in Java, volcanic soil should not be favourable to fine flavour, the Fijian group may yet be the great tea as well as sugar gardens of the Australian colonies. What our correspondent says about the quality of Fijian coffee and its standing in the Australian markets, is a curious commentary on the savage attacks made by the *Fiji Times* and its correspondents on the Ceylon Commissioner to Melbourne, for venturing to question the picked beans, packed in blue-green bottles, exhibited in the Fiji Court, as at all representative of average Fiji coffee. Now a curing establishment has been set up, and Fiji coffee may improve even more rapidly than was the case with the Ceylon product, after science and skill had been applied to its preparation. Of cinchona, it will be observed, our correspondent does not speak very hopefully. Sugar is the great and growing industry, but even in the sugarcane field disease has claimed its prey. The sugar planter, however, has the great advantages of being able to eradicate canes attacked by fungus or insect, and to replace them by any one found most suitable out of scores of varieties. *The* great difficulty, in regard to sugar as to everything else, is that connected with an adequate labour supply. Although there may not necessarily be neglect on the planter's part in regard to lodging, food and sanitary precautions, the mere change of conditions of living and diet affect the Polynesians, including the Fijians, most unfavourably, and the mortality amongst these people is occasionally so appalling, that we cannot wonder at the threats held out to stop the labour traffic, and the tendency of Fiji legislation to keep the people in their birth localities. The evil in Fiji seems to be the pressure of labour to pay the Government tax in kind. The Government, however, claim that their measures have stopped a decrease—led, indeed, to a small increase—in the native population. Island labour being thus so difficult to procure, our correspondent does not give a bright picture of the coolies introduced. Our correspondent himself was the subject of complaint by one of those litigious people for calling him "a bloody fool." Perhaps our good friend will not be so blunt next time, but use the periphrasis, "You sanguinary individual of indifferent intellectual capacity." Or he might imitate the Ceylon planter who spouted passages from the *Ingoldsby Legends* at recusant coolies, thus :—

> "O ! turpissime !
> Vir nequissime !
> Sceleratissime ! tissime ! issime !
> What ! cut off the head of a holy prior,
> And say it was *only* a bare-footed friar."

The relations of the planters in Fiji to each other, to the Government, and to their coolies, seem capable of improvement. Coolies who brought false charges of manslaughter and other crimes ought certainly to have met with severe punishment; but we confess to having no sympathy to throw away on the planter who got imprisonment with hard labour for putting *four* mustard poultices on a cooly's chest and then tying the tortured wretch in a sack. Malingering may be very annoying, but human beings are, at least, as much entitled to protection from cruelty as the brutes. As is the case in all large bodies of planters, the good amongst them in Fiji no doubt suffer from the misdeeds of a few *mauvais sujets*. That the policy of the Fijian Government is approved of at home, is shown by the recent honours bestowed on Governor des Voeux.

It may be well, too, to note the other side of the shield displayed by a correspondent of the *Colonies and India* who seems to be far more sanguine than "A. J. S."—probably because he has less experience. We quote as follows :—

A correspondent, writing from Levuka date March 17th, says :—"The Message of His Excellency the Governor is in many respects a most encouraging document, and will make those friends at home who ever give a thought to us here in the South Pacific more sanguine than ever of the great future that belongs to the group. The estimate of receipts for 1883 is 90,675*l*. In 1881 the sum actually received was only 73,678*l*.; while in 1882 it amountet to over 82,000*l*. The principal items in which this increase is expected are import duties and other dues levied by the Customs. The Governor thinks that the returns of sugar export in the past year will exeeed 1,800 ton, and anticipates that this total—a large one for a young sugar colony like Fiji—will be doubled in 1883, and more than quadrupled in 1884. If such is the case the exports, which up to 1880 had never exceeded 177,000*l*., will in 1884 approach very closely to half a million sterling.

"The high price at which copra still stands in the English market has made a wonderful deal of difference to us. The rise of the past six months has put 20,000*l* into our pockets. Of course the export returns for 1882 are not yet to hand, but I should say that the copra exportsof last year will exceed those of preceding years by at least 1,000 tons. Cinchona is doing remarkably well, and tea and coffee are 'gradually forging ahead.' The pineapple and banana trade to Australia—though not with New Zealand—is as brisk as ever. I append a short summary of the manifest of the s. s. 'Rockton' on her last trip to Sydney. She had 7,000 bunches of bananas, about 800 bags of copra, 200 bales of fibre, &c., a large number of pineapples in boxes, cotton in bales, and other produce. Some attention is being given to the pearl-shell deposits lying to the east of this group, notably in the Marquesas, which were till lately thought to be fished out. At least, this is the gossip here; and advices from Sydney say that a pearl-shell expedition will be ready to start from that city before June or July."

Our readers will see that in one important respect, that of a good labour supply, Ceylon has great advantages over Fiji and most other sites of tropical culture. Let us keep up courage, therefore, and persevere in efforts to retrieve our position by the cultivation of "new products."

LOWCOUNTRY PLANTING REPORT, CEYLON.

LIBERIAN COFFEE—COCOA—RUBBER—TEA, &c.

(Report for April and May for a Lowcountry Estate.)

It has been rather a curious season, this 1883 in this (Siyane Korale) section of Ceylon : from the beginning of the year, till past the middle of April, it was much drier than than the average of past years since 1873, which was even drier than this year ! Before the little monsoon came the Liberian coffee had begun to droop, but when the heavy thunder showers came on about the 25th of April everything began to pick up and grow rapidly. The little monsoon culminated in that terrible rainstorm of the 8th and 9th ult., after which, for 18 days, there was not enough rain at any one time, to lay the dust. On the 27th we had another wet day, and ever since we have had a rapid succession of heavy rain and bright sunshine ; proper planting weather there has been none.

On some of the Liberian coffee, the wave of *Hemileia*, that swept the place between October and January, has left a permanent mark, but the greater part of the trees have entirely thrown it off, and since the rains came are growing at a rate that requires much handling. This species is not so amenable to discipline as its Arabian brother : half the secondaries grow back toward the stem, and there is a fierce tendency to the production of *gormandizers* on the primaries, that have borne crop. All the trees of good *jât*, two and a-half years out, have a heavy crop from 1,000 to 2,000 cherries—*i. e.* one to two pounds clean coffee. I want a time of daily rains and little sun for the planting I have to do, but I dread continued wet weather, for the sake of the Liberian coffee. *Hemileia* comes to a dead pause in dry weather. No fresh spores grow, but there still exists spores enough to sow a world, and thirty hours of wet leaves will bring the attack on as bad as ever. I live henceforth in terror of two consecutive wet days, with too little sun to dry the leaves. If providence would give us one hour of sunshine in every twenty-four, this mighty foe would pass away out of our list of enemies. Liberian coffee in the first year of bearing puts its best foot forward. I have trees that do not cover a circle of six feet, with more than 2,000 cherry, say two pounds of clean coffee, but the larger trees, that bore a like crop this season, and that look immense creatures, bear very little, and when we strip the irregular growth and dispose our bearing wood to our mind, we must come to the conclusion, that though there is crop on the trees all the year, it is only once in eighteen months that we will get a crop of any consequence Whatever may be the case elsewhere, the Liberian coffee does not produce crop and young wood at the same time here. It takes twelve months to perfect the fruit, and six months to produce wood for the next crop. It is true that some little blossom comes out on the bare wood that has already crop. borne crop, but this is many months after the first

It is our misfortune that this place is a rugged and exposed piece of land, exposed to every wind that blows, and therefore over the greater part unfit for cacaos. I have fought a hard battle on their behalf, and have only won a few positions, while driven from most of the ground I originally took up. Driven from the older fields, I have taken in fresh land, and sown some fifteen acres at stake, reserving my nurseries for the inevitable vacancies. My former failures in this method of planting were due to two causes, namely, silt before the plants got above ground, or dry weather coming on them before they were sufficiently advanced to stand it. On the present occasion I have fully provided against silt, but if a long spell of dry weather should set in my work will be all in vain. Come or go what will else, the white ants will have their share, and I know no effectual way of circumventing them. I am now planting under partial shade, though I do not believe in it as a permanent arrangement. In all exposed situations failure is a foregone conclusion, but in moderately sheltered spots the much finer tree is produced, in the open ground, than either under shade, or particularly well guarded from wind. The varieties with light-coloured fruit pods are much the handsomest trees: the stem opens into five equal branches, whereas the red branches irregularly, and as a rule the tree is more or less one-sided.

The advice now tendered to planters, on all sides, is to forswear all more doubtful products, and addict themselves to tea. I put down my nursery in the first days of February, and there was no rain to mention for two and a-half months. I had put out 2[illegible],000 just before the great rainstorm of 8th and 9th ult. which was followed by 18 days without any, and though we have had heavy showers occasionally up to date, there has been no planting weather ; on the morning of the 5th things looked promising, up to 8 a. m. There was a succession of showers, and I managed to get down a thousand before the sun broke out and I had to stand by. The 6th was a bright rather windy day, with thunder and rain at night, and this morning the sun rose bright as ever. I am sorry to say that the dry weather that succeeded the great burst has set hard on the plants previously set out. I fear the loss will not be covered by twenty per cent.

I placed the seeds of the African rubber (*Tabarnæmontana crassa*) in a box in the verandah of the bungalow, and attended them myself, but not one seed germinated. The seeds are evidently not of a kind that retain vitality during the double voyage from Africa to England, and again from England to Ceylon. If Mr. Christy is anxious for the establishment of this plant in Ceylon, he should send plants instead of seeds.

I was desirous to try whether the grinding of Ceara rubber seeds could be done away with, and I sowed 1,000 seeds in a box in my verandah. Twelve per cent of them germinated and became plants within a week ; a month has passed and there is no more. The seeds that fall and are left under the trees grow in sufficient numbers for the cause of propagation, and grinding off the shell is as likely to destroy as facilitate germination. Those who have trees eighteen months old may trust the droppings to give any amount of plants they require.

9th June.*—Yesterday the true monsoon weather opened. I set to work at the planting, but was fairly beaten out of the field before 10 o'clock, after having to take shelter several times from the mighty rain-squalls. We had a promising morning today, and went to work vigorously, but at 7 we had to lie by because no creature could stand out ; past 8 the rain toned down into something endurable, and and at half after 10, it ceased and the sun came out, and shone its brightest till between 3 and 4, when the rain again began.

FROST AND COFFEE CROPS.—Of course, the clear, radiating, rainless weather which has occasionally frosted coffee on flats and swamps in Dikoya must be favourable to the ripening of fruit, but it is new to us that there never has been a good coffee crop in Dikoya without frost, during which the thermometer marks down to 42°. In Mr. Heelis's ten years observations in Dimbula, the cold recorded never went below 41°. There has been no frost in Dikoya since 1878, and hence failure of crops? This is a new theory on which we should like to have the opinions of planters. We never heard a good word for frost in connection with coffee before ; but it is not the first, but the clear sky and hot days, it indicates, that benefit the planter.

Correspondence.

To the Editor of the "Ceylon Observer."

NEWS FROM FAR FIJI.

Fiji, 14th March 1883.

DEAR SIRS,—I have not written to you now for several mails past: so some news from this outlandish spot may be acceptable. First and foremost I will start off with

The Weather.—We are, as you are doubtless aware, now in the hurricane months which, are supposed to commence about the beginning of January and end with the present month. On the 11th, 12th and 13th January we had very high winds, more severe in their character than the gale we had about the same time last year: taken altogether the damage done was but slight. Corn and bananas were the chief things to suffer. Coffee, tea and buildings all stood the blow well, and but little hurt was done to the former. The crop on the trees was not advanced sufficiently to receive much hurt. Taviuni is supposed to have felt the blow worst: if so, but very little harm must have been done to the other islands, as I can see no damage done to speak of in Taviuni. About the end of February we had a stiff blow one night. This affected Levuka, the old capital, more than elsewhere. Some houses got their roofs blown off, and one house was blown completely over. Luckily it lasted but a very short time, or the results would have been disastrous. Other portions of the group escaped pretty well. We have had more rain during the last two months than I have known for the same period before. In January I gauged 28·17 in. and in February 28·75; 14 inches fell during 3 days in both the months. This month I have already gauged 11·50 in. In January 1882 the rainfall was 21·06 and in February 13·34. The total for the year, viz., from 1st January 1882 to 31st December 1882, was 110·55 in. This was at an elevation of 1,000 ft. above sea-level. The rainfall on the coast, I should say, would be considerably lighter. There is a talk of a very severe hurricane having been prognosticated about 20th inst. For my part I am quite satisfied with what we have had, and hope the prognostication will prove as false as that one about the world ending in 1881—Mother Shipton's prophecy, if I remember rightly.

Hemileia Vastatrix.—Strange to say, we have not had a regular attack now for upwards of a year. Traces of the disease have always been and are with us, but not in a severe form. I was expecting it to appear during the rains we have lately experienced, but as yet we have escaped. We are suffering though in some parts of the estate on the flats and coffee close to the jungle, principally from a disease known out here as "black leaf," which you have not in Ceylon.* It generally comes on after several days of continuous rain and lasts as long as the weather is at all rainy or moist, and does a deal of damage to the foliage and crop while it lasts. The disease goes up the stem of the coffee seemingly and along every branch in the form of a thin cobwebby string, which as soon as it reaches the leaves covers *all* the *under surface* with stuff resembling tissue paper, or say a cobweb with the meshes so close as to look like extremely fine muslin. This layer chokes the leaves and kills them effectually. The disease, when in a bad form, after killing the oldest leaves, goes right in to the top part of the young leaves and even kills them, leaving the boughs entirely denuded of all foliage. Should it come across the berries, it surrounds them with the cobweb and dries them up, making the bean light and worthless. Should the bean happen to be ripe, there is a difficulty in pulping it and the pulper generally takes off pulp and parchment together. After the fine weather sets in, the disease apparently disappears and returns again with continuous wet. Fortunately coffee planted on slopes does not suffer so much as that on flats and close to the jungle. Coffee also at lower elevations than 1,000 ft. escapes to a great extent.

* The "black rot" of Southern India probably.—ED.

Re Mr. Storck's cure for *Hemileia vastatrix* I have not heard further than what I have read in the papers. The solutions I see are recommended to be made stronger. I have not seen the coffee treated by Mr. S. for a long time; so cannot speak authoritatively on the subject. From what I have seen, I do not think the proposed remedy will be a success.

The best agent I have used in all my experiments for the eradication of *Hemileia vastatrix* was hyposulphite of soda. This certainly, when not applied too strong to the leaves, seems to kill the fungus right out. What a fearful change leaf-disease has made in old Ceylon! When is the tide going to turn?

Cinchona.—The succirubras I planted out last August are growing apace and look healthy. The blow did some damage to a few, knocking them over and bringing them close to ground. I am not satisfied though with the growth of succirubra, the only kind I have tried. Taken altogether, the growth seems to me to be less than trees of the same age with you, and are, I fancy, not so vigorous.

Coffee Crops.—The strong winds we had in August last and which destroyed a splendid spike we had then on the trees took away all chances we had of getting a good crop. Ours in consequence, I am sorry to say, will turn out a poor one: very disheartening when the trees were in good heart and capable of giving a bumper, towards which we should have gone if the August blossoms had set. Estates at a lower elevation, and which blossomed earlier than we do, are doing much better. My neighbours, whose coffee I should say is fully 500 to 600 feet lower than mine, expect 6 cwt. an acre. We experience a great difficulty in getting rid of our coffee in the colonies. A few tons seem to swamp the market, and the brokers have the coffee sometimes for months on their hands without being able to effect a sale. The prices at present realized are wretched. In fact, one wants a big crop to make the 'totam' pay at all decently.

Curing Mill.—We have had a difficulty always to cure our coffee. Some pound the parchment out, damaging the beans considerably, and, in consequence, getting but a poor figure when sold. Others have put their coffee through a cylinder which takes off the parchment, a pulper similar to those you sometimes see fixed on to the water-wheels to run the tails, &c., of a crop through when finished. This also damages the beans. The crop then was bagged and shipped to the colonies without being sized, or properly picked over. All this of course told against the coffee in the markets and was likely to give Fiji a bad name. This will all be remedied for the future, as a Mr. Wilson has erected a very nice curing mill not very far, 12 miles, from here, and commences to cure all coffee sent to him from 1st proximo. I went over the mill the other day and was pleased with it. It was made by Gordon, and is exactly like those in Colombo; only it is smaller. Mr. Wilson is prepared to cure for 5s a cwt., packing the coffee in double bags. I hope for his and our sakes the mill will be a success.

Liberian Coffee.—A neighbour has succeeded in raising several thousands of plants and has just put some of them out. Judging from the old plants from which the seeds were gathered, the newly planted field ought to do well. Most of the old plants were bearing heavily and were pretty free of disease. I am sorry to see though, by your papers, that the Liberian coffee in some parts has been so badly attacked by *Hemileia vastatrix* that people seem to be doubtful whether it will do to plant up more.

Tea.—Our oldest tea planted clearing, about 18 months old, is looking very well; so are all the younger clearings. Some tea was made by a planter a short time ago, who had never had any experience in tea-making before, and was forwarded to Mr. Moody in Melbourne for his report. His report was most favourable and was very encouraging. For fear you may not have seen a copy of it, although copies were sent to several papers, I enclose one cut out of the *Fiji Times*, and I think you will agree with me that, when you take into consideration the tea was made by a novice and with bad appliances, the report is all that could be desired.* I shall commence manufacturing soon and I trust we shall get prices equal to Mr. Moody's valuation.† Our climate here is all that a tea planter could wish for, I should say, backed up by good soil, and the return per acre ought to be large. Our rainfall, as the annexed return for last year will show, is well distributed and the temperature equable.

Rainfall for 1882. Elevation 1,000 feet.		Average temperature 1882.	6 a.m.	noon.
January	... 21·26	June	...69	... 78½
February	... 13·34	July	...69	... 76½
March	... 12·81	August	...69	... 79
April	... 5·16	September	...71	... 79
May	... 8·99	October	.. 70	... 80
June	... 3·09	November	...73½	... 83
July	... 4·82	December	...73	... 83
August	... 11·12	1883.		
September	... 4·21	January	...73	... 81½
October	... 11·92	February	...73	... 79
November	... 4·05			
December	... 9·78			
	110·55			

The above refers to an estate 1,000 ft. above sea level, in Taviuni.

Rainfall 1883, Jan...28·17
February...28·75

Heavier than I have known before here.

I shall be able to send you correct meteorological returns, as I am keeping a daily register of rainfall and temperature. Correct returns are very difficult, I may say impossible, to get from different parts in Fiji, as only very few planters go to the trouble of keeping them and have not rain-gauges, &c Government ought to issue instruments, free of charge, to planters residing on the different islands, if they would agree to forward monthly returns. I feel sure a lot of planters would only be too glad to do this, provided they received the instruments, but as yet I have not heard of any being given, except perhaps in one or two solitary instances. The consequence is, as I said before, correct returns are not to be got, and, if one plants anything, such as coffee, tea, cinchona, &c., he does so with a certain amount of risk as regards rainfall, &c. This is not as it should be in such a colony as Fiji where the climate varies so very much.‡ Government ought to do all in its power to collect correct meteorological returns from every part and have them regularly published, for the benefit, not only of residents, but also of outsiders who might be probable investors. I like this climate better for tea than coffee, and, should I extend, I should plant the former, except in two or three favorable localities for the latter.

*We lately inserted a copy of Mr. Moody's very favourable report.—ED.

† Prices of large breaks are almost always far below the valuation of specimens.—ED.

‡ One side of an island being rainy and the opposite side dry.—ED.

Sugar Cultivation is gradually making way, and one hears of visits being made to parts of Fiji where there are no mills, by capitalists, with the object of ascertaining if there is a good prospect of success should they erect mills. The Colonial Sugar Company seem to be gradually acquiring the monopoly of the Rewa river. They have bought a lot of land belonging to private parties and are still buying. At present they have an enormous mill at work which they are going to double. The extra machinery I hear is already ordered. When all is up, I suppose this mill will be one of the, if not the, largest in any of the colonies. Mr. Hedges, formerly of Ceylon, has successfully started his mill, and is now manufacturing sugar. The firm have about 700 acres planted and still intend planting more. Others close by are also growing cane for the mill. Some of the canes I have seen lately in Taviuni seem to be suffering from disease. The canes are stunted in growth and the leaves all split. This disease affects the red canes principally, and planters therefore are planting the yellow kinds. Not being close to the principal part where sugar cultivation at present is carried on the most extensively, and not having heard, I cannot give you correct information regarding yield per acre, outturn of sugar, &c. There must be a large margin for profit or I do not think the Col. Sugar R. Co. would go in so largely as they are doing. Of course, the Company being their own refiners, brokers, &c., must make a great deal more profit than anyone else. Nevertheless if any body who understood the business erected a good mill and cultivated properly, he would make money and a good deal of it too. [Provided he could obtain labour.—ED.]

Labour.—This question has lately attracted more attention than usual in consequence of a native ordinance which was brought forward and passed by the Governor. There used to be a difficulty before in procuring Fijian labour, attended generally with a great deal of trouble, but I fancy they will be much harder to engage now that the new ordinance is passed. Plantations situated in districts where there is plenty of labour will doubtless benefit by the ordinance, but others, and by far the majority, will suffer seriously, as the aim of the ordinance seems to be to confine the Fijians to their own province as much as possible. If the ordinance had been passed as originally drafted, a death-blow would have been dealt, in my opinion, to Fijian labour altogether; but all the unofficial members, wonderful to say, rallied up and fought the Ordinance out clause by clause. Important concessions and alterations were made. Meetings were held by the planters in different places and petitions, &c., forwarded. All these shewed what a serious thing the planters thought the ordinance was and strengthened the unofficial members in their fight against it. Unanimity is a thing not to be found amongst the Fijian planters and the consequence is their complaints are but little attended to, Government knowing their weakness and treating them in a way which would open your eyes: it's perfectly astonishing. Two or three meetings have lately been called in Taviuni and have always ended unsatisfactorily and that on subjects where one would think the planters could have no two opinions about. There is none of that cordial feeling amongst planters here that you have in Ceylon, where men will stick shoulder to shoulder and fight against what they consider any slur on their character as gentlemen and planters or against any injustice. Here there is too much jealousy, and it's every man for himself. One is afraid to do anything for fear of getting marked down by the Government, and, if some are ready to move on any question that affects their interests, others will make some excuse and back out. Its a wretched state of affairs, and as long as it lasts the planters may make up their minds to be sat upon. Just to give you examples Since the short time I have been in the colony no less than six planters have been had up for *manslaughter*, two have been imprisoned, leaving aside others who have been fined heavily for trivial assaults, and nothing has ever been done, although every planter who was tried for manslaughter was found to be *guiltless*. Even as I write, I hear there are two more manslaughter cases pending against two planters, and another is in jail undergoing *three months' imprisonment with hard-labour* for what do you fancy? He got one month for giving a Fijian labourer six lashes with a rope, and two mouths for puttings four mustard plasters on another labourer! What aggravated the last offence was the fact of the planter putting the man into a sack, and tying the mouth round the waist. The labourer asserts he was also tied round the ankles and knees, but this the planter says is false. Even granted the man was tied, the punishment inflicted is disproportionate to the offence altogether. There were about 120 labourers on the plantation, and twenty-five said they were ill on that day. The man who got the plasters complained of a cold and pain in the chest. I wonder what the planters with you would think if they got well fined or imprisoned every time they were had up for striking Ramasamy with the chance of all your men being removed from the estate if you were convicted three times of assaulting your labourers! I assure you I consider it a dangerous thing to work labour in Fiji now, if one is determined to get a fair day's work out of one's men. They are almost sure to complain of getting too much work to do, and then there is an enquiry and the Government keep an eye on you. Assaults, even of a most trival nature, are dangerous to indulge in, amongst coolies more especially, as they are, out here, the most litigious fellows out. A cooly went and complained to the magistrate the other day that I had called him a "bloody fool." This is a fact and will prove how fond they are of cases. What I complain of most of all is that, when coolies take cases against you, and you are fortunately able to disprove them and to shew the man has been perjuring himself, nothing whatever is done to him. Coolies here have only to take a dislike to you and combine and take cases and they are sure sooner or later to get you into serious trouble, and, believe me, they are quite capable of doing it. Now, if a man, when bowled out in a lying case, were punished, say by a severe imprisonment, or better still a few lashes administered before his fellow-labourers, it would act as a deterrent, and cases of the character I have mentioned would cease to be. A cooly complained that his master had outraged a girl, a perfect child. An enquiry was instituted and the man was found to have told a deliberate falsehood; yet nothing whatever was done to him as far as I can ascertain! All these sorts of things combined make it, as I said before, dangerous in Fiji to work men, as one stands a chance of losing one's character.

In my last letter I mentioned that the Government had only succeeded in getting one vessel to recruit Polynesians last season and that the estimated cost was £16 per head. The vessel was unsuccessful and the men have been given out at £30 per head to those planters who care about giving that figure. When I first came out, going on for 5 years now, men used to be £9, including depôt expenses. Compare that with £30 now!! Men not only cost more, but are not nearly so easy to procure. Some vessels find difficulty in getting a full complement and a good many last season only made 2 instead of 3 trips and even then returned without a full load. The men also are not of such a good stamp as they used to be: mere boys and old men are allowed to come. Owing to Queensland and other places competing with us, there is no doubt that Polynesian labour will get scarcer and that wages will still go on increasing. In a late minute of the Governor, he complains and writes very strongly about the mortality amongst Polynesian labourers in Fiji, and hints that the immigration will, in all probability, be put a stop to, if the mortality still goes on at the same rate. He also says that animal food must be given to the men and that a clause will be inserted in the ordinance to that effect. This will of course increase the yearly cost of men and it is to be hoped will help to lessen the mortality. In Taviuni for 1881 the death-rate was, I think, 39 per 1,000 and in other parts 60 and even over. On some estates on the Rewa the deaths were so numerous amongst the Polynesians that the allotment was stopped for a time. Strange to say, the coolies escaped and were healthy enough. The labour question is, I can assure you, a most serious one in Fiji, and I should not be at all surprized to hear that the Polynesian immigration was put a stop to within two or three years' time. What arrangements have been made to introduce coolies this season I do not know, nor the number applied for. Planters must fall back on Indians whether they like it or not. If labour goes on increasing in cost as it has done the last two years, I do not know what cultivation, except sugar, where a lot of hands are required, will pay. Coconut planters who want but few men will be able to carry on. Taken altogether it is a blue lookout, and the more one considers the subject the greater pity it seems that we cannot freely make use of the large native population in Fiji, the Fijians themselves. This we cannot do for reasons too numerous to mention. One will suffice. Fiji was taken over to try and preserve the native race, and Government thinks that, if they were allowed to do as they liked, they would die out. Therefore, they are induced to stay at home as much as possible and keep themselves to themselves, to cultivate Government gardens to enable them to pay taxes. How the policy will answer, and whether the native race *will* be preserved, remains to be seen. For my part I fancy they are certain to die out gradually, as natives have done in other places, and, if another epidemic, like measles did before, happens to break-out, off they will go rapidly. In the meantime, Sir Arthur Gordon was right when he said "it was not a country for the white man." Fiji has great capabilities and only wants a liberal policy to be carried out to develop her resources. Land wants to be thrown open and cheap labour got; she would then soon go ahead and shew a good export list. At present we are gradually going ahead, but very, very slowly to what we ought. We are almost in a half stagnant state, so to speak. With the almost unlimited extent of land we have—and a great deal of it very good land—and the large native population, the progress made since the British took over the colony has been but slow. Not a single public Government land sale has taken place since my first arrival in the colony, and only one, of *one* small block, ever since the annexation in 1874!

Several Ceylon men have arrived lately and all are on sugar plantations. There is a greater demand now for overseers, as they are termed here, and salaries are increasing. Formerly they used to get £100 to £150 and find themselves. The latter sum was considered a good screw generally, though the overseers would get, say £5, £6, or £7 a month, and be found. The find would consist in flour, tea, salt beef, &c.; no liquor. The fare was not luxurious by any means, nor did it tend to make one an epicure. A good overseer, or sub-manager would get from £150 to £250 now, managers from £300 to £400, or perhaps, more, but billets like these are scarce, very, and have only occurred of late, since sugar cultivation, properly speaking, commenced.

My letter has reached a length much greater than I intended and I fear will weary your readers long before they ever get to the end of it, *i. e.*, if they ever try to get so far. My only excuse must be that you seldom get news from this out-of-the-world place and therefore what we are doing, how cultivations are progressing, &c., may possibly interest some of your numerous readers.

If you have any copies of "Tea Cultivation in South India and Ceylon by a Neilgherry Tea Planter" *with diagrams* please forward me one. I have one of th original issue *without* diagrams.*—I am, dear sirs, e yours truly, A. J. S.

CEYLON, CHILE AND CALIFORNIA.

Edinburgh, 30th May, 1883.

DEAR SIR,—In order to show you that Ceylon is not the only country suffering from decay of its chief product and exhaustion of soil, I enclose an extract from a private letter from my brother in S. America, which may be of interest to you.—Yours truly, P. D. MILLIE.

"Coquimbo, Chile, 14th April 1883.

"No doubt, frequent crops wear out plants and soil, and heavy manuring can only put off the evil day, as *disease* then takes the place of exhaustion.

"Here, hundreds of thousands of acres of heavily cropped land (wheat and lucerne) are now nearly useless, and in California it is much the same, the only remedy is a return to a state of nature and to original condition for an unlimited period.

"We read in the Bible of fat lands being turned to barrenness: a state of things which the children of Israel probably attributed to divine agency of a *direct kind*, but which was due to the most simple and natural cause, namely, over-cultivation, drought, caused or increased by forest clearing, wars, etc.

"The races of Peru were as industrious cultivators of every available spot of ground as are the Chinese, but since their subjugation by the gold-hunting Spaniards, everything seemed to grow barren.

"Later on, the Spaniards for their own sakes, were compelled to turn agriculturists, but have never achieved what the original race did in the way of high cultivation and irrigation.

"Guano was used by the former, centuries before it was known to be of any use by Europeans: indeed, whatever vague ideas ab ut its virtues the Spaniards may have had, it only dawned upon European agriculturists that it was valuable about 1830.

"Planters are quite right in looking upon the decline of coffee growing as inevit ble, and happy will those be whose 'new products' come in as coffee goes out. T. J. W. MILLIE."

PLANTING NOTES AND QUERIES.

North Mysore, 6th June 1883.

SIR,—Permit a few of the above from a novice:—

Clearing Land.—What is the best way to get rid of bamboos in quantity? Apparently there are two—(1) clean burning, which also destroys suitable shade trees; (2) lopping, piling and burning, which is expensive. Evidence as to treatment in the Bamboo (Coorg) district is conflicting. Possibly, as a rule, bamboos and good shade trees are not found together. [This is a query for Indian planters to answer. In Ceylon we have not much bamboo land and we do not leave shade trees.—ED.]

The Weed Question.—Much food for thought has been presented in your valuable pages but it seems to be stil an open question whether it is better (1) to take them away altogether, (2) to dig them into the soil, or (3) to pull up or cut and leave on surface. Here the second mode of treatment finds favor, and I have never heard of anyone adopting the first. [When ageratum or other bad weeds have been allowed to seed, they certainly ought to be burnt. In all other cases, surely the best plan is to bury in the soil, adding some lime.—ED.]

Ceará Rubber.—I should be thankful for advice as to treatment here. Should the seed be filed, soaked, pricked out into nursery at beginning of June, and planted out in field two or three weeks later? Treated so, would it not get far too much rain, and be likely to rot? Perhaps it would be better not to put it in nursery till August, or would it do to put unfiled seed straight out into the field at the beginning of June? What is now considered the right number to an acre, and what are the latest experiences as to probable yield per tree, and ideas as to soil? The bare rock theory is, I fancy, exploded. Digging after planting is presumably not necessary. [Those only who have had experience can reply. The question is *elastic.*—ED.]

Twin Crops.—Where conditions for both are favorable, will it pay better in the long run to grow two products on same ground rather than one? I should say not, except, perhaps, in the case of cinchona amongst coffee, if former is as good shade as the best class of jungle trees. [Two strings better than one.—ED. C. O.]

The Future of Coffee.—Brokers at home say that coffee goes in cycles of 15 years, and that we were lately at the bottom of one; prices, however, doubtless depend chiefly on Brazil and Brazil, on the labor question, and if planters there succeed in establishing free foreign labor, they may become permanently lower than they have ever been. [Coffee prophets only can reply.—ED.]

This District.—European planters are slowly increasing in numbers. Why don't more come, and bring their wives and daughters? Ladies are very scarce; also railways, but otherwise the conditions of life are favorable, and planters generally are hopeful as to prospects of coffee. Cannon's "Mysore" is well known, and there are other guns of less calibre. [The writer can surely answer his own query in this case and tell us about the Mysore railway.]—Yours truly, R. T. D.

P. S.—I see that Dr. Trimen says, that cinchona Ledgeriana does not prosper at high elevations. Would 3,000 feet be high enough? [We have seen Ledgeriana flourishing at 4,500 feet. With free soil and good shelter we should think they would do well at 5,000 feet. But probably 3,000 feet constitute a good elevation.—ED.]

JAMAICA CINCHONA BARKS: A CORRECTION:

Botanic Garden, Hakgala, Nuwara Eliya, 12th June 1883.

DEAR SIR,—I beg to inform you that the *Cinchona Calisaya* mentioned in Dr. Paul's old analysis of Jamaica cinchona barks (sent to him by Mr Thomson in 1878) which is published on page 30 was not *calisaya* at all, but that which is now known as the hybrid, *cinchona robusta glabra.*—I am, dear sir, your obedient servant, W. NOCK.

[Dr. Paul as editor of the *Pharmaceutical Journal*, which is sent us in exchange, will no doubt take a note of the above. For the proper nomenclature of the cinchonas as well as for a good deal else, it is evident that our friends in the West must look to Ceylon.—ED.]

THE *CINCHONA LEDGERIANA* CONTROVERSY: A CORRECTION.

13th June 1883.

DEAR SIR,—There is a slight inaccuracy in your article on the cinchona controversy (page 41) which it would be well to correct. The tree selected by Dr. Trimen here for specimens was not the figured one, but one of similar type, and it analyzed 11·29 sulphate of quinine.—Your faithfully, THOS. NORTH CHRISTIE.

---

* The diagrams were never engraved, unfortunately; but a new edition of Mr. Brace's Essay, with special information regarding tea planting in Ceylon, may yet be issued.—ED.

HOW TO COLLECT RUBBER: OLD PLANS REVIVED; WHO WILL TRY AND REPORT?

16th June 1883.

DEAR SIR,—Many an old-fashioned idea has proved to be the best after all, when modified or improved to suit our more extended notions, and, perhaps, I have now stumbled across one that may be of service in one branch of of our planting industry. Referring to that valuable product of ancient days known as balm or balsam of Gilead, Josephus in his *Antiquities* says :—"At Jericho, where the palm tree grows and that balsam which is an ointment of all the most precious, which, upon any incision made in the wood with a sharp stone, distils out thence like a juice." Tacitus, the great Roman historian, contemporaneous with Josephus, also refers to it thus:—"They [the Jews] have also, besides ours, two trees peculiar to themselves, the balsam tree and the palm tree. Their groves of palms are tall and beautiful. The balsam tree is not very large. As soon as any branch is swelled, the veins quake as for fear, if you bring an iron knife to cut them. They are to be opened with the broken piece of a stone, or with the shell of a fish." Now, divesting the latter of its romance, these paragraphs simply point out that by making use of a sharp stone or a shell to make the incision in the bark, a greater quantity of gum exuded than when a knife was the instrument employed. The only objection (theoretical) that I see why this primitive system should not be equally applicable to extract the milk from rubber trees is that gum is contained in cells or vessels ; its motion is by an edosmotic action, and it is one of the forms through which vegetable matter passes in being applied to the purposes of plant life ; whilst the milk of the rubber plant is contained in intercellular canals lined by a special membrane, forming by their union a network like the veins of animals, and its movement is analogous to the capillary circulation in those veins. However, it is a matter that can easily be determined by experiment, and it seems at first glance reasonable to expect that a lacerated wound, such as would be caused by a sharp stone, should bleed for a longer time than a clean cut from a knife.—Yours faithfully,

CAOUTCHOUC.

ENEMIES OF COCOA: HOW TO COMBAT THEM?

18th June 1883.

DEAR SIR,—You would confer a great boon on cocoa planters generally, if, by ventilating the matter in your paper and *Tropical Agriculturist* you could collect information as to the most effectual way to set to work for the wholesale destruction of the different animals that feed upon the ripening pods.

I refer more particularly to bats, flying-foxes, squirrels and crows. The mischief they cause is very serious, and shooting is not a sufficient remedy, although it is the only one tried as yet.

Bats and flying-foxes only work at night, so they must be poisoned I should say, only what would they eat that poison could be mixed with. Do gardeners at home or on the continent do anything for them?

Squirrels, I am told, will eat vermin paste spread upon slices of bread. Has anyone tried this?—Yours faithfully.

MATALE.

COFFEE DROPPING FROM THE TREES.

Colombo, 20th June 1883.

DEAR SIR,—I herewith extract from a letter dated 9th) instant just received from Rangala :—"A good deal of the coffee which seemed to be set is dropping off the trees ; in parts where the coffee is good the crop seems to be filling out very well. I send you by the post a sample of what is dropping. The sample is from under one tree"—accompanied by the sample referred to, and I think when you examine the various stages of the cherry succumbing you will agree with me we must look much further than these abnormal seasons for the cause of our misfortunes in coffee.—Yours faithfully. J. W.

[Certainly the green coffee cherries sent to us, of all sizes from peas up to three-fourths full size, are a most melancholy sight : a case of "insidious defunction."—ED.]

TEA AND PLANTING PROSPECTS IN MASKELIYA.

Maskeliya, 21st June 1883.

DEAR SIR,—I send a few leaves off a tea tree on the Mahanillu estate, Dunedin seed, planted at stake in May 1880, at an elevation of 4,350 feet on a small clearing that was considered too exposed to grow either coffee or cinchona. It is now a very nice even field of tea, and this leaf speaks well for the jât. How will these compare with the dimensions of large tea leaves from warmer and lower districts. I would be glad to hear there being an idea afloat that the China and hardier jâts suit the high elevations better than this large-leaf hybrid.

We are having a very mild monsoon : not more rain than is required by those planting. All at tea. Cinchona has a few friends still who are putting out numbers of plants. They are selling cheap. The May and early June coffee blossoms have set fairly, and will make up crops a little. In the upper end of the valley they have been good. Maskeliya will do fairly well.—Yours truly, C. S. A.

[The leaves sent are from 9 to 9½ inches in length by 3 to 3½ in breadth and indicate a splendid jât—good for low or high altitudes.—ED.]

DR. TRIMEN'S TYPICAL LEDGERIANA TREE.

[We publish below a letter from Mr. Agar, which places beyond question the fact that the tree figured by Dr. Trimen was an undoubted Ledgeriana, Mr. Howard himself having given testimony to that effect after having analyzed the bark.—ED.]

Lawrence, June 22nd, 1883.

DEAR SIR,—I have little to add to what Mr. Christie has written on the subject of Ledgerianas, but that little is, I think, important.

The tree, which was sketched for Dr. Trimen's work, is dead.

It was one of several Mr. Moens saw in flower at Mahanilu estate. Dr. Trimen was with Mr. Moens, and both agreed the trees were true Ledgerianas. The bark of some of these trees was sent home by Mr. Campbell for analysis to Mr Howard, who pronounced it to be Ledgeriana bark, giving 7 per cent of pure quinine (equal I believe to 9 of sulphate) and only a *trace* of other alkaloids. The trees were only about 4½ years old from the time the plants were put out, and were growing in a bad situation and not robust.

I have many plants from the seed of the specimen tree as well as the others that Mr. Moens declared to be true Ledgerianas, so that it will be easy in the future to determine the question.

I have also in my possession the bark from the tree itself, but taken when it was dying.—Yours truly,

WALTER AGAR.

ABNORMAL SEASONS AND SHORT COFFEE CROPS IN HIGH DISTRICTS.

Del Rey, Bogawantalawa, 23rd June 1883.

SIR,—A correspondent in your issue of the 19th instant, under the signature of "M.," impugns the conclusions to which I, as well as others, have arrived as to the bad seasons of late years and their effect upon the coffee crops. He accuses us of having our 'firm convictions,' meaning, no doubt, our unsupported convictions, alone to bring forward in support of our views, while he totally misunderstands the point of view from which we consider the 'seasons.' I for one have never laid much stress upon excess of rainfall, whether as regards the actual fall itself, or its distribution: although at the same time we have undoubtedly suffered from this cause also during the last year or two. That from which we have suffered chiefly has been the gradually increasing want of direct sun-heat and a corresponding decrease of temperature; and if, as is now generally admitted, it is the direct rays of the sun in an unclouded sky that alone are efficacious to produce crops, we have here a cause, and a very potent one, to account largely for the short crops of the few years. For we have undoubtedly in this district at any rate, experienced lately an increasingly large number of days on which the sun has been more or less veiled by a misty or cloudy sky, and the maximum, *i.e.* the day heat here, as shewn by the thermometer, has been lower correspondingly. My observations with the thermometer extend back only to 1872, but I have at all times been a careful observer of the weather, and am absolutely certain that in no previous period since 1868, when I first came to Dikoya, have we experienced such *fair weather only* instead of the *fine hot weather* of other years This may be nothing more than a 'conviction' perhaps, but against this what has your correspondent and those who agree with him to set except their own 'convictions,'—convictions which, as far as appears as yet from their letters are more unsupported than mine? Let it however be clearly understood that I do not complain here so much of too much rain, as of absence of sun heat when there is no rain. Neither do I lose sight of the ill-effects of leaf-disease, because I contend that there are other factors to be considered when we enquire why our coffee bears so badly now.—I am, sir, etc., GILES F. WALKER.

COFFEE AND THE SEASONS.

SIR,—In discussing the influence of seasons on our coffee crops, we ought to have something more definite than the "firm conviction," even of such reliable men as Messrs. Bosanquet and Walker, in proof of the asserted abnormal weather during the blossoming season. No one probably will deny that the blossoming months for some years back have been more unfavourable for developing crop than the corresponding months of some years early in the seventies. Instead of consecutive weeks of scorching heat, causing the leaves to droop and roads and barbecues to crack and gape, we have of late years had a succession of showers, not heavy or continuous, but sufficient to keep leaf growing to the exclusion of blossom. It is therefore assumed that these recent seasons have been abnormal, and to this abnormity the failure of crop is attributed. Has it been conclusively proved that continuous hot dry weather during the months of February, March, and April, *is* normal in Dimbula and Dikoya? Is it not possible that these seasons of scorching heat were really the exceptions? These are questions to be answered by the card. There is probably no authenticated record of rainfall for any very remote period, but there are at least estate monthly reports for the last 25 years. Broken reeds they may be. Too often the weather is "remembered" at the end of the month, and filled in according to the taste and fancy of the reporter. Still they might throw light on the subject. Has the weather in Dimbula during the early months of 1880-81-82-83 been more rainy than in 1860-63? Who will give us a table, the fuller the better, of the rainy days in February, March and April in one of the higher districts for the last 25 years? We shall then be able to judge whether we are really in a cycle of abnormal seasons, which will eventually run its course, or merely having the weather to which we are entitled.—Yours faithfully, M.

[Not authenticated. Surely not the redoubtable "W. McK."?—ED.]

COFFEE CROPS: SEASONS, MANURING, AND WEEDS.

DEAR SIR,—Can you tell me what sort of weather we would have if everyone had a rope of his own to pull the weather to his liking? I am inclined to think, we would have perpetual rain. As someone would be sure to want a shower and another would think a little more would do good so that it would be one continual pour. We were told in the early part of the year by Dr. Trimen, that this was a great year for flower, and so it was for coffee blossom, and more, the blossom set, but when dry weather came on the growth of the tree was not only checked but thrown back to a certain extent, and with that dying back most of the tiny berries died off and disappeared. Will those who are so fond of blaming the weather, explain how it is that one estate in Dimbula has 8 cwt. an acre on it, and the surrounding ones not? And, again, a fine vigorous tree has a good crop on and those round it not. Were there not estates that used to give crop all the year round so that those estates must have blossomed in all sorts of weather? If one considers that coffee grows in as it were a pot, that is, that its feeding extent is limited to 5′ × 6′ and about 2′ deep, can any other result be expected? A plant in a pot has in proportion to its size more soil to feed on than a coffee tree, and how often has the soil in a pot got to be removed, and yet it is expected that coffee is going to give crops without [the cultivator] in some way renovating the soil I dare say some have been able to manure, and if they have not got results they are to blame and not the weather.

Coffee, by extending its roots and getting into some food, may give a crop, but, if not manured, it may be the last flicker of the candle. There are several ways of killing the goose that lays the golden eggs, and one of them is by starvation. What is coffee-planting, horticulture or agriculture? If horticulture, we must manure at least every year; if agriculture, we must give up aping horticulture and resort to the old style of a few periodical weedings in the year, and put the weeds where they will feed the coffee. Coffee must have a constant supply of food somehow to keep it in a state of vigorous growth.—Yours truly, G. F. HALLILEY.

THE "TROPICAL AGRICULTURIST."—Mr. Henry Prestoe, Superintendent of the Government Botanic Gardens at St. Ann's, Trinidad, writes:—"I beg now to return you sincere thanks for the kind assistance afforded me in this excellent publication and to which I decided to become a subscriber from the first. I will be most happy to forward you all reports I have of a sufficiently important nature for the publication, and will do all in my power to promote its circulation; indeed I can already claim the credit of being the means of increasing your readers, for I never fail to direct attention to the *Tropical Agriculturist* in my correspondence with West Indian agriculturalists." Mr. Jenman, the Government Botanist of British Guiana, writes:—"I am much obliged to you for sending me your excellent journal the *Tropical Agriculturist*, which I have read with much interest from its first issue. I am sorry that I have not a complete set of my reports, but those I have to spare I send herewith. They deal chiefly with the very rough elementary works of the gardens I am forming here."

COFFEE AND ITS ALLEGED ENEMIES: AGENTS—CLEAN WEEDING—AND ABNORMAL SEASONS.

We call attention to letters (page 66-7) in our correspondence columns, discussing the troubles of poor "king coffee" from different standpoints.

Has Mr. Halliley ever heard of monomania of weeds on the brain? Of the preacher who, give him what text you liked, was sure to go off into questions of cosmogony? When by way of a text a blank slip of paper was handed to him, he seized the occasion to show that the world was created out of nothing. So, if our correspondent were presented with some of the finest tobacco that ever grew, and told to put that in his pipe and smoke it, instead of lauding dirtiness on coffee estates, he would regard the circumstance as a providential call to pass from the praise of the particular weed to that of weeds in general. We fondly hoped to hear of some mode of manuring which would produce coffee without encouraging the leaf fungus, and here is the old story: weeds! weeds! weeds! We feel now that the best wish we can wish our good neighbour is a plentiful crop of weeds to manure the soil, and result in 10 cwt. an acre of coffee all round. Only we must beg him to *bury his weeds before they run to seed.* That would be scientific culture.

Mr. Walker, it will be seen, does not under-rate (neither he nor anyone else can *over-rate*) the malign influence of leaf-disease, and we doubt not he gives due weight to the ravages of grub, though more partial in effect. But he holds that, notwithstanding the continued existence of the virulent leaf-destroyer, we should get much better crops than have rewarded the enterprize and industry of our planters for some years back but for the absence of normal sun heat, conveyed direct to the bushes by the rays of the great vitalizing orb. Coffee has been literally as well as metaphorically under a cloud. That is Mr. Walker's theory, and he has a right to maintain it, because it is founded on very careful observation by the ordinary use of his senses and by the aid of scientific instruments. There is a large element of encouragement in the theory, seeing that in the common course of nature we may speedily expect what our poor friend Tytler used to call "the swing of the pendulum": a reaction to a cycle of sunniness. Such a reaction might not only result in giving us good crops in spite of *hemileia,* but might by its genial influences gradually rid us of the fungus, or reduce it to harmless proportions. May all good omens be fulfilled! Let us cherish hope of the good time coming.

THE LABOUR QUESTION IN FIJI.

According to the *Fiji Times* of April 25th the Governor has addressed a minute full of denunciations and invective to the Planters' Association in reply to a letter from them denying that they were responsible for all the high mortality amongst labours, a good deal being attributable to the Government establishments. The planters had also denounced night visits to estates and examination of labourers in the absence of their employers. The following seems a hard case:—

The Chief Medical Officer reports upon the diet of the laborers and indicates the advisability of diversifying a purely vegetable regimen with an occasional ration of beef, flour, rice, &c. This His Excellency so thoroughly approves that he forwards that portion of the report to the Association for the guidance of its members. During a time of such scarcity with respect to yams that not even the Government could obtain them for the men in depót and in gaol, but had to substitute rice and biscuit, a planter adopted the suggestion of the Civil Medical Officer, which His Excellency had approved, and fed his men on beef and flour. For doing this an inspector charges him with a breach of the regulation, prescribing the daily issue of yams, and as he has failed to comply with the letter of the law, although he has improved upon its spirit, he is convicted and punished. Was, or was not this prosecution frivolous and vexatious? Does it, or does it not, indicate the very state of things to which the letter of the Association has reference?

The payment of Polynesians in Fiji is effected after a fashiot which is stated to be anything but satifactory to the labourers. They get goods to the value of their savings from a store supplied be contract with Government and under guidance of a Government officer:—

The labor vessels sail on the 1st of April, and some short time prior to this date the men are marched down to the contractors' store in gangs, to receive their trade in the presence of a Government inspector. Now it can easily be understood that this is a novel experience for the Polynesian who for the first time in his life, perhaps, finds himself in the position of a man of capital. He has nine pounds to credit, and he is required to spend it all at once. He finds himself in a store full of miscellaneous articles, and, as would be the case with any one white or black under the circumstances, he wants a little leisure to look round and make his selection This would, however, entail a loss of time which the other parties to the transaction cannot afford. The vessels must sail on a fixed date, and in the interim so many men have to be paid off. Expedition is therefore the order of the day, so the storeman and inspector relieve the capitalist of all bother by virtually taking the matter of selection into their own hands. The one has contracted to supply certain goods at a fixed rate. The other holds the list in his hand or knows where to turn his eye to it. The man is called up and the business of selection begins, while he stands by utterly dazed by the bustle and activity, so foreign to his nature, which is in progress around him. He may from time to time express assent, but it is not his practice strongly to dissent from the proposition of white men, and he is not likely to do it when he knows one of them to be in authority. The business accordingly proceeds "Want a box, musket, powder, ball, shot, caps?" "Oh, yes, they want those things." "Knives, axes, tomahawks, fish-hooks, eh?" "Yes, put them in." "Prints, braid, beads, etc.?" "All right, go on, how much is that?" "Seven pounds. What will you have for the other two?" Articles are suggested to that amount, the man makes no objection, the box is locked up, the key given to him, and in less time than it would have taken him to select perhaps a single article he finds himself "paid off."

Following his purchase of the goods comes his actual inspection of them, and his loudly expressed dissatisfaction amongst his comrades. They are not the things he would have selected, if left to himself. Possibly the articles he particularly desired were not on the contract list or in the store, and though if he were loudly to assert his wish for them they might, perhaps, be obtained for him, in the absence of this demand he must do without them.

The second matter of complaint respecting the quality of the goods supplied has its origin in the erroneous official idea that the Polynesian is more favorably impressed with quantity than the quality of the goods he receives. This is only true within certain limits, but it is a great mistake to suppose that he does not know the difference between a good axe and a bad one, a knife with a steel blade and its iron counterfeit, or print of decent fabric and texture, and that which is mainly composed of "dressing." He does know the difference right well, and under no circumstance can he be induced to place a value on any quantity that may be offered him of the inferior goods. To ensure greater satisfaction amongst these people, and to prevent disappointment and mortification, it is necessary that the system of paying them off shall be more closely assimilated to the Queensland practice. There the men have the money given them, and make their purchases wherever they please, buying whatever they like. These transactions are subjected to the supervision of a Government officer whose duty it is to see that the men are not imposed on, and under these conditions the laborers return perfectly satisfied with their payment. Subject to certain restrictions the same practice could be adopted here, and if the business could not be disposed of so expeditiously, the loss in time would be more than compensated by the benefits accruing from the laborer's contentment. The money need not be given him, but a credit note issued by the department would enable him to purchase anywhere to the extent of the sum it represented, and the furnishing of accounts to the immigration office would sufficiently protect him against unfair treatment.

Coffee and Cinchona.—The Java news given on page 46 is of more than usual interest because it shows that the Netherlands authorities are to cause a thorough enquiry to be made into the condition and prospects of coffee-planting in Brazil; and we get also an idea of Mr. Moens opinion of cinchona prospects as given in his new book. He does not anticipate any great fall in price for four years; after that the South American bark to a great extent will be shut out; and in 12 to 15 years Java will supply the world! We shall see if Ceylon and India do not hold their own for a share of the business.

The *T. A.*: Planting in Travancore.—A correspondent writes :—"The *T. A.* is indeed a great treasure of useful matter. You refer to 'crops.' Alas! that is now a melancholy note. They are very short again, generally, this year: I mean, of course, in coffee. I have some under shade of the old jungle trees at an elevation of 1,500 and upwards which has a fair crop now, and has borne pretty regularly year by year. This is sheltered from wind; higher places on the same estate are exposed to wind and though they bore for some years are now abandoned. They are now nearly 20 years old. I was deputed by our T. P. A., together with our Secretary, to represent the failure of our crops to the Sircar; and to ask for a remission of land tax which is assessed at R$\frac{3}{4}$ per acre per annum, and now the Sircar has replied that the tax will be held in '*abeyance*' this year. We cannot accept this, if it implies that he tax is to be paid up next year in arrears. The thing looks absurd, and a mere mockery. I am going in for cocoa, or cacao, pepper, dividivi and Ceará. These on low elevations. We have lots of rain and mist now."

Mr. J. E. Howard will shortly receive from Mr. E. G. Harding, Manager of the Lanka Company a series of plates drawn and coloured from nature by Mr. G. de Alwis, showing the various types of cinchona growing on the Company's properties in Dikoya. These will enable the veteran Quinologist to form a good idea of the character of the different varieties of cinchona growing in our higher, districts. The Lanka Company has been especially fortunate in its cinchona investments: Gonagalla and Fordyce (in some parts a perfect forest of cinchona) giving large returns last year, and again this season. On the lower portions of these properties, there is also a very good coffee crop; but Mr. Harding bears testimony to the correctness of Mr. G. F. Walker's observations as to the adverse seasons lately experienced. Coffee on "slab rock," usually burnt up, is doing splendidly in the present over, wet year. Again Yattawatte in lower Matale is giving a very good coffee crop, while cocoa already flourishing over 400 acres here is being argely extended and all "waste land" planted up with Ceará rubber. The men who are doing hard work have no time to croak.

Blossom and Crop.—A lengthened experience of monsoons and crops enables me to lay before your readers one reason for this failure of crops, which appears to have escaped the observation of the querists. The fault has generally been laid on the weather at thetime of blossoming, the want of a spell of fine weather in January and February, or heavy rain at the time of the blossom. In regard to the latter it may be observed that now-a-days, the blossom hangs on the tree, unopened, until the rain comes and destroys its fertility; it seems to require moisture, to cause it to unfold, instead of its being opened by the strength of the tree's own sap and moisture, as it used to do, and then being so strong and healthy as to set in spite of rainfall or drought. But, I cannot help coming to the conclusion that the infertility of our trees is in great measure caused by the extraordinary length of the south-west monsoon, accompanied, as it has been for several years past, with more than ordinarily cold rain and wind. From the middle of May to the end of August, was the usual term of this monsoon. We then expected fair weather for a month. Clearings which unluckily had not been burnt in due season, had a chance then, and a marked interval was observable between the monsoons. The roots of the trees were warmed up, the soil dried, and the tree prepared for the flush of leaf and young wood which came as soon as the heavy afternoon rains set in, in the the middle or end of October. The mornings being blazing hot and the thunderstorms in the afternoon lasting only a limited time, and running off the surface of the ground with but little sinking into the soil, the whole atmosphere was steamy and extremely forcing for vegetation. The foliage that covered the tree softened the older wood, and freshened it up ready for blossom, which came in the following January, sooner or later, according to elevation of the estate. In any case the trees prepared in the 3 months, October, November, and December, for doing their duty in the next ensuing three months. Even trees that had been bearing heavily, and were comparatively weakened and had lost their leaves, began to come round immediately the crop was gathered. It was then the preparation our trees underwent for coming crop. What has it been since 1878? Almost without exception, commencing in May, the monsoon has gone on till October and November, without any interval of rest between the two monsoons. The ground has been saturated with cold moisture for 5 or 6, nay 7 months in succession. There has been no drying of the soil, no warmth to the roots, no forcing out of foliage on the older wood, which has for years past shown white and bare over nearly the whole of the estates. There has been no handling to be done in the autumn months except on manured trees, consequently, the flush of wood and leaf which is absolutely necessary to enable the trees to produce crop, comes on only when the warmth of January and February forces it out, too late by a quarter of the year to influence the following crop. In some years this necessary stimulance has never come at all,—varying of course with the condition of the estate, its age, and elevation. Warm weather so late in the season is of no avail unless the trees are ready to make use of it. Blossoms which should have come in January and February and March, are kept back till March, April and May, and consequently exposed to the usual April rains. Years ago, I came to the conclusion that in the higher districts, unless your crop was on the trees in March, you needn't look for any till the following season. If you have a good crop by the end of March, a continuance of fine weather would make an addition to it, and the result be a very good crop.—D. E. in Local "Times."

PEAR-TREE "BLIGHT."

BY CHAS. D. ZIMMERMAN, BUFFALO, N. Y.

* * * *

In 1880, Professor Burrill announced that "blight" in the pear, apple, and quince was caused by bacteria, the smallest living organism known. He found that they destroy the stored starch grains, causing the same to ferment, leaving the cell structure apparently unharmed.

With the poisoned sap he inoculated healthy trees, of which over sixty per cent showed signs of "blight," clearly proving that bacteria is the cause and not the effect of the disease. No counter evidence has been brought against these experiments of two years ago.

About twenty years ago, Derlaine stated that bacteria belonged to the vegetable instead of the animal kingdom, as was the belief up to that time, and only a few years since it has been proven that they attack and destroy living matter. They increase by "fission," dividing in the middle, under favorable circumstances, once every hour, and sometimes even oftener. Once an hour would be at the rate of sixteen and a half million in twenty-four hours. A few species are also perpetuated by spores, like fungi. The most favorable temperature for their rapid development appears to be about 95° Fahrenheit, together with plenty of moisture.

Remedies: Eternal vigilance and a sharp knife. Carbolic acid is extensively used to destroy bacteria; it may be diluted with 1,000 parts of water to one of the acid. Quinine is also used. Cold does not kill them, but activity ceases at or nearly the freezing point. Frische claims that 123° Fahrenheit below zero will not kill them. In the adult state most bacteria are destroyed in water heated to 150° Fahrenheit; spores have been known to survive a short immersion in boiling water.

I have often prevented the increase of poisoned parts by carefully cutting off the outer bark with a sharp knife, and applying linseed oil. This must be done very soon after the appearance of "blight."

In the case of contagious diseases among animals caused by bacteria, it has been found that the bacteria may be cultivated, whereby it loses most of its poisonous qualities, and animals inoculated with it take the disease in a mild form and are ever after free from that disease.

Now let us hope that some genius will contrive a way to cultivate the species of bacteria under consideration, so that by inoculating pear trees with it they would be "blight" proof. This would open a field for a new profession—a tree doctor.—*The Gardeners' Monthly Horticulturist.* [Query? Can bacteria have anything to do with "canker" in cinchonas?—ED. *T. A.*]

THE NEW SILK CROP IN CHINA.

It is always extremely difficult to estimate the outturn of the silk crop in North China. We have to reply upon the reports furnished to us by the Chinese who are engaged in the trade of selling silk to foreigners, and the information which they give us varies considerably. At this time last year the estimate of the crop of the season which is just closing ranged from 65,000 to 80,000 or more bales. We ourselves had reasons for estimating 65,000 bales, and even those low figures have proved somewhat in excess of the actual receipts. Had prices, however, advanced here we might have had some 10,000 bales more offered; but in any case the quantity would have been much under the expectations of the most sanguine. The cocoons turned out to be light, and thus the anticipations as to the crop proved erroneous. It now seems improbable that the silk crop for 1883-84 will give more than from 42,000 to 45,000 bales for export. Had the weather been favourable during the last month there was every probability that the amount of silk available to foreigners would have been close on 100,000 bales, as the quantity of seed that had been laid down for this season was very large. But in order to produce such a large crop the most fortunate circumstances were necessary; clear, settled weather, with a great deal of bright sunshine, and no thunderstorms or damp, heavy, days. Now, during the critical time in silk culture this season we have had weather the reverse of what was desirable, the sky having been overcast, with many wet and cold days. It makes the most serious difference in the crop when the mulberry leaves are not thoroughly dried in the sun, as too much moisture in them makes the young worms sick. The news from all the producing districts, except Kahing, is bad as regards the quantity of silk produced, and although a considerable advance in prices might bring more silk on our market than the amount we have estimated, there is little to make us anticipate such an improvement in the home trade as would lead to this. Of the silk produced in China about one half is usually offered to foreigners, though this quantity is increased whenever the prices are high. But the last telegrams received from London report very favourably of the prospects of the European silk crop, while there is a large stock of China silk in London—the requirements of the trade now-a-days being taken into account—with reserves at Lyons, Marseilles, Milan and other places. Here, too, the policy of the Chinese speculator who has disturbed our market during the last two seasons, has established a reserve of 15,000 to 16,000 bales of old silk; and the knowledge that sooner or later these accumulations must be sold will prevent any considerable speculative advance in prices, such as would otherwise have occurred. The home trade now requires much less China silk than formerly. Many excellent fabrics which suit the fashion of the times are now made out of waste silk. Surahs, made up from waste, have vastly reduced the cost of clothing women and children, while there are endless varieties of mixed fabrics, composed of a little silk with waste and cotton, which have ousted from their position the handsome and genuine silk dresses of former times. The laces, velvets and brocades which are now so much worn can be supplied from the carding room instead of the filature; and one effect of all the changes and improvements in the silk piece goods trade at home is that the export of waste silk from all China and Japan has advanced to 60,000 piculs per annum, from the 20 to 25,000 piculs which were sent a very few years ago.

The English and French markets for China silks were very disappointing last season, chiefly owing to the fashions in Europe and America requiring silks of clean, even, sizes, such as are made in the filatures here. France, Italy, and Japan give large supplies of that kind of silk; and consequently the prices obtained for Chinas were low. China silk is likely to be less used at home every year until it is properly reeled, and as soon as this desirable condition has been brought about it will regain its old high position in the European markets. China cocoons make the firmest reeled silk and the best quality, and our silk has been brought to its present degraded position in the estimation of foreign manufacturers, by the stupid inattention to the requirements of trade which the native silk men have all along displayed. There are many persons who are throughly acquainted with the silk trade, who see little or no hope for the future of China silks, except in the establishment here of filatures on a large scale. They say that the Chinese will not improve the reeling of the silk, and that either their own ignorance, or the action of their rulers, prevents their acquiring that information which would enable them to rectify the carelessness or mistakes which are ruining the trade. Cheaply reeled and coarse silk are no longer suitable to the goods that are produced in Franc. All this time, while the deterioration that has taken place in the quality of China silks is being carefully maintained by the natives and protected by the mandarins, other countries are bestowing increased care and capital on seri-culture. Great attention is being given to it in India, America and New Zealand, while Italy is extending every year the cultivation of the mulberry tree. In Persia, also, efforts are being made to revive the silk industry. The discoveries of M. Pasteur, by which he enables silk farmers to separate the good from the bad or inferior seed, have already had an important effect on the industry in France. Anything which lessens risk, and makes more certain a business with which chance has hitherto seemed to have so much to do, must improve it and draw to it more attention and capital. All these things pass unheeded by the China silk dealers, its cultivators, and the rulers of the land.

(Communicated.)

It is too early yet to speak with certainty as to the extent of the North China silk crop, as so much depends on the quality and out-turn of the cocoons produced; it is, however, well known that the year's crop has been reared under rather disadvantageous circumstances as regards weather. The hatching of the eggs of the silkworm takes place about the 20th April, and according to Chinese accounts the rearing should be accomplished, if the weather is warm, say 69° to 74°, in 23 to 24 days. The books read thus:

"If the meals of mulberry leaves be given frequently the warms will advance rapidly to maturity; and if seldom they will be long in arriving at the mature age. If this stage be arrived at in 25 days it is calculated that each hurdle of worms will produce 25 ounces; of silk; if in 28 days then each hurdle will produce only 20 ounces; but if the worms are a month or 40 days in coming to maturity then each hurdle will only give ten or a dozen ounces; when the silkworms fall into and awake from their torpor at irregular intervals the silk will be deficient in quantity. After the great (fourth) torpor, silkworms only require fifteen or sixteen meals before they arrive at maturity." And these meals must be very large ones, as may be judged from the following remark: "When the worms are aroused from their third torpor, put a pound of them in one basket, from which you will afterwards obtain eight pounds' weight of cocoons."

The silkworm as a rule objects to damp moist weather, changes of temperature, and clouds charged with electricity; when these occur in the fifth age, or aft r the fourth sleep or torpor, the mortality becomes very great, the worms are attacked with a *flacherie*, or wasting away, they refuse to eat and die. It is only necessary to refer to the meteorological tables published from the Siccawei Observatory to discover what would most probably be the weather in the silk-districts at the critical ages of the silkworm; and as they live 23 days before arriving at the fifth age, it follows that on the 13th May, the worms hatched on the 20th April would be in their critical period and the vicissitudes of the weather would have their worst effects. On a reference to the weather tables of the 12th to 15th May, we find that the weather was exceedingly wet and boisterous, and that thunderstorms and damp mists and muggy weather were the rule. Father Marc Dechevrens explained that it was caused by the débris of a typhoon, and referred to the weather of the past month as deplorable. Father Dechevrens also says that since the vernal equinox no fewer than thirty whirlwind have been observed at Siccawei. That considerable damage has been done can be inferred from the Chinese statements, which have the probability, or rather the certainty, of being correct, and if any further testimony be needed it may be found in the low price of mulberry leaves, which tends to show that in their most voracious age there are not worms enough to consume the supply of leaves.—*North China Herald*.

CORK.*

Cork is yielded by the cork oak, *Quercus liber*, which chiefly flourishes on the shores of the Mediterranean. There are, in Spain and Algeria, large forests of this tree, which is also cultivated in the departments of Lot-et-Garonne, and Var, in the south of France, and in Corsica.

The cork oak arrives at its full growth in about 100 years, when, in hot climates, it attains a height of sixty or seventy feet, with a diameter of six to eight feet. The bark consists of two distinct portions, the inner formed of a fibrous tissue, and the outer, tuberous, and of a porous and elastic consistency, which constitutes the cork proper. The first cork naturally produced by the tree is called the male, and has scarcely any value; but if this be removed, a second layer is formed, finer, more elastic, and less irregular, which is known as the female cork; and this it is which is generally used.

The stripping or the cork takes place in summer, when the circulation of the sap facilitates the separation of the outer from the inner layer of bark. The removal of the first growth is affected when the tree is twenty to twenty-five years old. Several annular incisions, and one vertical incision, are made with a hatchet, care being taken to cut the cork only, without touching the inner bark; the layer of cork is then easily detached. A young oak yields about 10 lb. of cork at the first stripping, while it is capable, ultimately, of yielding, over 300 lb. The first cork has a thick and hard exterior, which diminishes with each successive growth. Formerly, after the first stripping, the tree was left to itself without any protection. Being very tender, it was liable to be killed by exposure to variations of temperature, while numerous insects attacking the tender surface of the tree, reduced the value of the future cork. Besides, a thick and irregular crust formed, which it was necessary to remove, thus causing a loss of 30 per cent of cork.

A better plan is to employ the method of M. Capgrand-Mothes, which consists in covering the tree during several months after stripping, with the cork which has been removed. A few vertical incisions are made in the inner bark, to prevent irregular furrows being formed. The pieces of bark are then restored, being fastened by iron wire; and the joints are made good underneath with strips of cellulose cardboard. After three months, in the autumn, the pieces of bark have become quite dry, and are taken off. The effect of this practice is to induce the formation of a protecting layer, tuberous, homogeneous, and elastic, under which the growth of the cork goes on without danger of injury.

The detached pieces of cork, flattened by being piled up with the outside uppermost, are freed from their external surface by boiling and paring. The boiling of the cork, which lasts about half-an-hour, is effected in large cubical boilers fired with refuse cork, and closed by a cover which presses upon the pieces. The paring is done by hand, or by means of horizontal rollers provided with iron blades; but this last-named operation may be dispensed with when the practice of covering the tree with the detached pieces of bark is adopted.

The principal use of the outer bark is to make bottle corks. They are more frequently cut by hand, though sometimes by a machine, a horizontal knife giving a rotary motion to the piece of cork, and thus cutting it into a cylindrical form. Cork is also used for making life-buoys, swimming-belts, floats, non-conducting linings, &c. It is moreover used advantageously in the form of powder, for packing fragile objects, as a substitute for lycopodium powder, and for the manufacture of linoleum and cork-leather. Cork is, however, on account of its elasticity, reduced to powder with great difficulty. To effect this, mills with grinders in the shape of rasps, mill-stones revolving in a pan, and artificial stones revolving at great speed, are employed.

Linoleum consists of cork-powder consolidated with dried linseed oil. The mixture, in the proportion of about 3 parts of oil to 1 of cork-powder, is passed under heavy rollers, and then stuck on to cloth by means of drying oil. It is allowed to dry for about three months, when the product is ready to receive various designs, and may be readily washed. Linoleum is adulterated by adding sawdust to the cork-powder. Cork-leather, which is waterproof and very elastic, is cork-powder consolidated with indiarubber.

Cork refuse is used for making partitions that do not conduct heat or sound; it also yields a light and porous charcoal. M. Combe d'Alma has proposed to distil them, so as to obtain a very rich gas, free from sulphuretted hydrogen. Old bottle corks are sometimes collected, boiled and washed in acidulated water for again serving to cork boltles.—*Journal of the Society of Arts.*

* Abstracted from a paper by M. Henry Mamy, Ingénieur des Arts et Manufactures, in the columns of the *Moniteur Industriel*.

THE VALUE OF TEA.

[There is much useful information and sound good sense embodied in this paper by our good friend Mr. Moody, the leading tea expert in Australian colonies. The only deficiency is that of a reference to the undoubted nutriment in tea. We would also say emphatically that, while boiled tea is beastly, the best tea will fail to give out its virtues if the water poured on it in the heated teapot is not perfectly boiling; while if the best-and-best made tea is allowed to be much over ten minutes in the pot it is ruined. —ED. *T. A.*

BY J. O. MOODY. (From the *Border Watch.*)

The Australian Colonies consume about 18,000,000 pound weight of tea every year* averaging 6.61 pounds per head of the population.† Great Britain comes next with 4·59 per head. The drink is suited to the climate and character of the people, and the colonies use about 150 million gallons of tea infusion every year. Probably the production of manufactured tea for all countries exceeds 600,000,000, and the known export exceed 350,000,000 pounds, without including the overland trade between China and Russia, which is something considerable.

On the slopes of the Himalayas vast tracts of country are found covered with the indigenous tea plant which there grows to a good sized tree, from 15 to 30 feet high. Probably from this locality the Chinese first obtained the plants which have since been so successfully cultivated and manufactured into tea by them. Marco Polo, who spent some years in Cathay (China), between 1271 to 1295, and wrote a work on the country, makes no mention of tea, and the first account of the product is credited to Giovanni Bolero in 1590.

After the war between Great Britain and China, the British Government and the East India Company did all in their power to encourage the cultivation of the plant in India, and much money was spent with this object, skilled labor was introduced from China, and Mr. Fortune made a large collection of tea seeds and plants from every district in that country, with the result that India now annually exports about 55,000,000 pounds weight of tea.

Ceylon, Java and Japan are steadily increasing their outturn of tea. Natal and Fiji have started growing the product, and no doubt portions of Queensland and the Northern Territory will be found suitable for its cultivation.

The best land in China is devoted to the cultivation of cereals and other produce used for food, whilst the poorest land and steep slopes (with some exceptions) are used for tea planting. This example was followed by the early Indian growers, but the practice carried out, proved its fallacy, and no doubt kept back the industry for some year. Experience has taught "that flat rich lands, with good rainfall, are in every respect the best for tea cultivation." (Col. Money.)‡

Further the European growers now find that the indigenous plant is the best,§ for it does not run so much to wood as the China plant, it produces new tender leaf much more copiously, oftener, and ofter so texture, whilst the manufactured article is finer, stronger, and has more aroma, and commands a higher price in the London market. With the introduction of machinery the old methods employed by the Chinese for making tea are superseded, and the work done far more satisfactorily.

Plants as now cultivated in many parts of China are stunted in growth and twiggy in character, probably from the impoverished nature of the ground, yet shrubs raised from the same seed and grown in rich soil somewhat change their character, vigorous in growth and more like their congener the Assamensis. A good example of this is seen in the healthy vigorous specimens growing in the Botanical Gardens, Melbourne. The Chinese report that they pluck the leaves at intervals and as crops, thus the first crop is always the best, and appears to have the most pains bestowed on it, whilst the so-called second, third, and fourth crops follow, and are usually inferior showing careless plucking or manufacture.

Indian tea planters on the other hand say plucking can only be done as fast as the young leaves or flushes develope that there is no such thing as first, second and third crops though there may be many flushes, sometimes twenty-five in a season; that it is a mere matter of manufacture, the youngest leaves are alway the best; and size of leaf determines the qualities in nearly every case. Probably the careful preparation of the first teas for market has been a custom of the Chinese for a long time, and afterwards quantity and not quality guides them. The notion of crops guiding quality, so long held by tea brokers, must be abandoned as untenable. No machinery is used in the manufacture of tea by the Chinese, each little garden plucks and partially manufactures. The final process of picking over re-firing and sorting is completed by the tea Hongs (usually a company of merchants,) who buy from all the little growers, and make large chops (or lots) of uniform sample. One of these hongs lately sold 30,000 packages of tea, a portion of which reached the colonies and was prounced unit for human food.

All teas are now divided into two classes, the fermented and the underfermented. These can be made from the one plant; it is a mere matter of manufacture, the former in dried over a brisk fire as soon as possible after plucking, whilst the latter, after rolling, is kept for some hours is heaps or rolls, when a change takes place, very like that of barley into malt.* Chinese fermented or black teas are called Congous and Souchongs.

Chinese underfermented teas are called oolongs, Pouchongs, kooloos, flowery pekoes, S. O. pekoes, S. capers, gunpowders, young hysons, imperials, &c. The Chinese as a rule devote the best leaf and the most labor to the manufacture of underfermented teas. Indian fermented or black teas are called flowery pekoes, orange pekoes, pekoes, pekoe souchongs, souchongs, and the broken of each kind, with fannings and dust. Indian underfermented kinds have the same names, but are also called namoonas. The Indian growers as a rule devote the best leaf and the most labor to the manufacture of fermented or black leaves. The underfermented kinds are usually the strongest chemically and in the cup, though almost colorless in liquor, color as denoting strength being a popular fallacy; but because these descriptions give off the largest amount of tannin they are not the best to drink. Fermented teas have a rich brown leaf when infused, with a bright liquor, and of many flavors. They are the best to use. Indian teas now take the lead in quality over all other growths. The Darjilings, with their fine delicate aroma and sweet fruity liquor, will please almost any palate.† Assams and Cachars, with their rich aroma, great strength and body, are at present mostly used to bring up the quality of weak China sorts. Kangras, Dooars, Sylhets, and Chittagongs, are getting well known and liked. The silly cry got up against Indian tea, that it is too strong, is amusing, because the remedy is so simple, viz., use less tea or add more water.

Imports of Indian tea into the colonies for the following years are:—

1879	1880	3,000 pounds weight.	
1880	1881	700,000	,,
1881	1882	1,000,000	,,
1882	1883	2,300,000	,, (9 months only.)

Probably no new article has achieved such rapid success and within such a short space of time. The finest teas from China come from Hankow, in the north, and some of the Ningchows, Kutons, Keemuns, and Toongmowquans imported this season have been of excellent quality. For years past the quality of teas from Foochow has steadily deteriorated, and it seems probable that the colonies will have to fall back on Hankow for their supplies of good teas. Outside a few choice Paklums and Chingwoo's (the Panyongs not up to the mark this season.) The bulk of the

* If New Zealand is included, and if a considerable portion of the tea imported is not again exported to Europe, the figures are surely too low. The imports into Australia and New Zealand were nearly 23,000,000 lb. in 1882.—ED. *T. A.*

† The consumption of sugar per head is in proportion being between 80 and 100 lb.—ED. *T. A.*

‡ Flat lands certainly *not*, unless an expediture is incurred for drainage which would be ruinous. Not only are gently undulating lands good, but some of the finest tea in the world and in remunerative quantity is grown on the steep slopes of the Eastern Himalayas, around Darjiling. No more misleading maxim was ever laid down than that which Colonel Money fathered, to the effect that a climate good for human health cannot be a good tea climate. —ED. *T. A.*

§ As a general rule, the best in every respect is a hybrid closely approaching the indigenous.—ED. *T. A.*

* As far as our experience goes, few black teas in India or Ceylon are fired until four hours after having been rolled. That seems to be the average time needed for the fermenting or malting process. During this process the rolled tea is covered over, and the assumption by the leaf of a salmon colour is one of the tests which sohw that "fermenting" has been carried far enough. But Mr. Moody is writing of China teas.—ED. *T. A.*

†N. B. And those Darjilings are grown on steep slopes. The Tukvar estate near Darjiling, we were told when on it, ran down from over 5,000 feet to 1,700 feet: that is a difference of altitude of at least 3,300 feet on land cultivated as one property.—ED. *T. A.*

import has been made up of low class kinds. Canton seems to have given itself up to the manufacture of spurious teas, tho facing, coloring, and otherwise rejuvenating old samples, so that imports from this quarter must be looked on with the greatest suspicion

Ceylon grows and manufactures after the manner of India, and some very choice samples have reached us, but the bulk goes to London.

Japan teas have not given satisfaction, as most of the samples to hand have been too high fired.* Java teas are prettily made, but rather thin in the liquor. Late shipments show improvement.

Tea as a popular beverage is steadily spreading all over the world. Probably it is the most harmless solace that can be taken, and is credited which promoting thought and sobriety. Indeed, it is "the cup with cheers and not inebriates." The properties of tea are those of a mild stimulant, due in part to the presence of a small percentage of theine, aod for this reason it is advisable to drink it shortly after a meal and never fasting. Essential oil is present to the extent of about one per cent. It pleases the palate and excites the digestive organs. The tannin in tea, if taken iu quantity, is very indigestible, so do not stew tea to get color, for the same process extracts a heavy amount of tannin. See that the water used is good and just brought to the boil, poured on the leaves without delay, and after five to ten minutes' standing use at once. Milk and sugar are highly nutritive, and the practice of adding them to tea a good one. A cup of *good* tea will, generally, thoroughly refresh the tired and depressed and often remove headache. It is one of the greatest blessings to the women of our race, and an important adjunct in the daily life of all sorts and conditions of men.

WATERMELONS—PROTECTION AGAINST BUGS.

TO THE EDITOR "SOUTHERN PLANTER."

As it will soon be time to plant watermelons, it may be not out of place (even to our Hanover friends, who raise them as fine as can be found anywhere) to make some suggestions about protecting them from the ravages of that little enemy and destroyer—the yellow or striped bug. The young vines are frequently destroyed by them in twenty-four hours after they come up. To protect them against this little enemy, until the vines are large and tough enough to be free from much harm from them, is to enclose the top of each hill, when the seed are planted, with four shingles (as broad as you can get them), which is done by imbedding them slightly in the ground, inclining them *inward* to each other, and compacting a handful of earth against them on the outside. You then have, as it were, a box around them. This is a little trouble, but it had better be taken than have them destroyed and the consequent replanting and throwing back the crop a week or so.

It is too obvious to explain how and why this method will shield or protect the vines from the bugs. Suffice it to say, *they don't* get within the enclosure. I discovered this plan after losing my cucumber and cymling vines repeatedly during one year in my garden, and *they* should always be protected, as it is a small job to do so. When the vines are large enough to thin, the shingles should be removed to a shelter, and they will last for years for the same purpose.

To raise a late and fine crop of tomatoes, be sure to stick into each watermelon hill a tomato plant. They do not interfere with the former, and come in after the garden crop gives out. Those coming in late are the best for canning and putting up for winter use.

INCUBATORS *VS.* HENS.

Whether there is more profit in artificial hatching than by the services of setting-hens is an unsettled point, for everything depends on the management in either case. That there are good, reliable incubators is a fact, but that "a child can manage them," as is claimed for some, is not established to the satisfaction of many adults who have engaged in such work. The advantages in favor of incubators are that chicks can be hatched at any season, the danger of vermin is lessened, and cleanliness is facilitated by the method. By early hatching, the chicks come into market to sell at high prices and the pullets that may be kept over will lay in the fall and through the winter. The disadvantages are, the possibility of danger from oil-lamps that are kept continually burning, and the liability of accident, or irregularity of heat, which may destroy all the eggs. A slight accident to an incubator holding several hundred eggs, at a time when eggs are scarce, occasions a heavy loss, and one or two occurrences of such character rather weakens the faith of the operator. It is better, therefore, if large numbers of chicks are to be hatched, to use several small incubators, in preference to a single large one, for then an accident to one incubator will not occasion an entire loss. No matter how well they may be regulated experimenters will have to watch them carefully, as the weather, turning the eggs, and providing moisture call for regular and prompt attendance at certain periods. Some incubators are heated by gas, some by projections of the stove pipe, and others by large quantities of hot water. Nearly all of them will hatch, by *prompt attention and management*, but that they bring forth ninety per cent, as claimed, cannot be depended on. After the chicks are hatched, they are reared in brooders, which are heated in several ways, generally with hot water, the heat being appreciated by the chicks when it is above them, as few survive when the heat comes from below.

In managing the hens, however, the nests should be placed in warm locations in winter and cool places in summer. If the flock is large the hens will commence setting at different periods, and an advantage may be taken of hatching by using the following plan: Suppose, on the first day of April eggs are placed under a dozen hens, as all can be set at one time by keeping those that get broody before the others a few days, and suppose after the lapse of ten days a second dozen are set; and we will further suppose the breeder to continue the practice by placing eggs under all the broody hens on the same day, when a sufficient number is ready. Now, we go back to our point: when the first dozen have finished hatching, give all the chicks to as few hens as can properly carry them, and takes eggs that are under the second lot and place them under the remaining number in the first lot. Then reset the second lot with fresh eggs. We can by that method keep each hen at work four and a half weeks, and two hens will hatch three broods. We give the above as a supposition. It is entirely practicable, and also profitable, and with the same care and management as is required for incubators will give much better results. The hens and incubators may be managed together by placing eggs in the incubator every day or two, and when the chicks are hatched give them to the hen to be cared for. This will save valuable time on the part of the hens, and will enable the brooders to raise a large proportion of chicks. We have no doubt that many of our breeders dread the care of the chicks more than the fear of bad hatches, but the hens will assist the incubator in that respect.—*New Southern Poultry Journal.*

CUTTING POTATOES FOR SEED.

TO THE EDITOR "FARMERS' HOME JOURNAL."

It is too generally the custom when cutting Irish potatoes for seed, to cut at random, heedless of the number of eyes to the piece, and the depth to which the pieces are cut. Farmers are often in too great a hurry at planting time waiting until almost the last moment and then rushing up matters, and frequently losing in the end. Potatoes should be cut before hand, and spread out to dry. Says D. F. Heffron the originator of the famous Early Rose, and, perhaps, the highest authority in America, on the Irish potato: "Cut sometime before planting. It is said that potatoes cut four or five weeks beforehand, if dusted with lime and plaster and spread out or stirred frequently if in heaps, to keep from heating, will ripen ten to fourteen days earlier than if cut and planted green. Potatoes sprouted in a warm room or hot-bed, will likewise give an earlier crop." The miscroscope reveals delicate filaments running from each eye or bud on the tuber, towards the centre of the potato. hence, in cutting for seed always *cut deep*, so that the growing bud may derive all the nourishment nature intends for it. The hair-like rootlets show that the eye, when developing, feeds on the substance of the potato. Says Heffron "The tuber is a short, thick stem, and each eye is a side shoot, that feeds on the neighbouring starch. Then, if an eye is cut to the centre, it takes in the whole branch, and has enough flesh to nourish it. The eyes are arranged

*The "all-fired" Japan Oolongs have so got hold of the taste of Americans that pure Indian and Ceylon teas will have a hard battle to fight in the markets of the States. —ED.

spirally in the potato, and all of them can be used if desirable, by cutting half way between them, and always cutting to the centre." He gives some admirable suggestions about planting, and after-culture. He advises to plant as early as possible either of early or late varieties. "The worse attacks of the bugs are late, and a sacrifice of some qualities is better than a sacrifice of the whole crop. Early planting gives a start to the plant that enables it to resist drouth to a great extent. As regards quality for table use, and as a better keeper through the winter, late varieties are preferred to early. Choose for seed a smooth, medium sized or large potato, cut it into pieces having one or two eyes: a large potato cut to one eye is expensive seed, but is said to be the best possible. Plant in hills or drills to the depth of three and a half or four inches if the ground is light and mellow; if in wet, heavy soil, a depth of two and a half or three inches is sufficient. Rapid growth is best for all vegetables; help the potato crop to it by thorough after-culture. The old idea that frequent stirring of the soil dries it out is an exploded one. About a week before the tops show, harrow thoroughly, it will kill the young weeds just started. As soon as the tops appear, begin to cultivate, and to cultivate, until the blossoms show, but no later. If weeds show after cultivation is over, hoe them out or pull up. In hoeing always draw the earth to the hilled potatoes, it gives them added nutriment." Give the potatoes room, it is folly to have them so close that you cannot see the ground.

SETTING OUT ORANGE TREES—THE FLORIDA PLAN.

(*From T. W. Moore's "Handbook of Orange Culture."*)

"Before the work of transplanting begins, the soil for the grove should be well prepared. It is most generally the case that the great hurry to get the trees into the ground causes much neglect at this point, but this policy is a bad one. The haste should have reference to the early fruiting and rapid growth of the tree; and they are not brought about by careless preparation of the soil. The soil should be deeply and thoroughly broken, and the ground cleared of the roots. To insure the setting of the trees a proper and uniform depth, the ground should be leveled with a harrow or drag. No manure should be used at the time of setting, nor before, unless applied some months before setting and thoroughly incorporated with the soil.

"In taking up the trees great care should be taken to prevent breaking or bruising the roots. As many roots as possible should be taken up. If the distance from the nursery to the site of the grove be short, and the nursery rows have been well manured with muck, and the ground is wet at the time of lifting the trees from the nursery, much of the soil can be taken along with the roots. Immediately on lifting the roots from the ground they should be trimmed with a sharp knife whereever they are found to have been bruised or broken. The lower part of the tap root also should be cut off to prevent its doubling up on being reset. Twelve or eighteen inches is sufficiently long for the tap-root. Put the tree under shade, and cover the roots with wet moss as soon as possible. Do not allow the fibrous roots to dry, as they are very delicate and soon perish. Should they die before setting, cut them off, for if left on after they have died, they will only impede the starting of new rootlets. Keep them protected up to the moment of setting, taking but one tree at a time from its covering of moss. To insure still further against damage to the tender roots, have on hand a half barrel of muck made into a thin paste, and as fast as the trees are lifted and the roots trimmed, plunge the roots into this paste, take them out, and wrap in moss.

"The holes for the trees should be freshly dug. The work of setting is easily and rapidly done by three hands working together—one to dig the holes, one to prune and set the tree, and a third to fill in. The holes should be dug in the shape of an inverted saucer or truncated cone, with about two inches of the top cut off. Proceed thus: Around the stake which marks the place for the tap-root, with a shovel or hoe take away the soil, letting the tool strike the top of the soil at the stake, and continue to dig deeper into the soil until a distance of eighteen inches from the stake it has penetrated six inches below the surface. Proceed thus around the stake until it is completed. This gives the greatest depth of the hole on the outer edge or perimeter of the circle. Now take up the stake, and cut two inches of the top off the cone. Where the stake stood push down the spade by working it back and forth until it has pernetrated the ground about eighteen inches or the full length of the tap-root of the tree to be set. Now insert the tap-root in this hole made by the spade. Be careful not to set the tree deeper than it grew in the nursery. With the hand pack the soil firmly around the tap-root. Next spread the lateral roots over the cone, taking care to distribute them evenly over the cone. Throw on two inches of dirt and press it firmly with the feet. Finish by throwing in soil and leveling the ground, leaving the last layer of soil untrod.

"Before the tree is left it should be trimmed with shears in proportion to the trimming done to the roots.

"If planting is done in summer or hot weather, and the ground is not protected by forest trees, it is better to mulch.

"If trees are older than three years and wild grown, it may be necessary to dig the holes deeper than directed above, but the point of this caution is against deep setting. The writer is satisfied that more trees have been diseased and retarded in their growth, and frequently killed by deep setting than by any other cause."—*Rural Californian.*

THE ORIGIN OF COFFEE.

THE STRIFE WHICH WAS OCCASIONED BY ITS INTRODUCTION AS A BEVERAGE.

It is well known that the coffee plant is not indigenous to Arabia, but was imported from Abyssinia at a date which cannot be accurately given. The taste of coffee itself had a hard struggle at first to find a general welcome among the more select circles. Apart from the oldest legend concerning Shadel's drink, the Medina Sheik Abd-el-Kader is the oldest historical authority on the use of "blood-red Kaweh," as the Tunisian Ibn Waki named to the beverage. In the year 1587, not three hundred years ago, he tells us that in Yemen, people made use of a drink which so lightened the night-watches that the faithful of the place were able to sing the praises of God more fervently and cheerfully than could be done anywhere else. According to him, the Mutti Dhabani was the first to introduce the insignificant little bean on Arabian soil, having brought it with him from Africa.

Certain it is that the districts of Shoa, Euarara and Kaffa (whence the name), in the south of Abyssinian highlands, from the original home of the coffee plant. Dhabani was of a sickly nature, and since he belonged to the order of the Sofi (Ultra-Pantheists), who believed that everything on earth and all being emanated from the Godhead, he regarded a means of excitement of this kind a providential gift. The Medinese and faithful Meccans laid their turbaned heads together in the public places when first they heard the news; a pious sheik in Aden was the first to drink the "black juice" as a sort of public spectacle. In Mecca itself, violent strife arose soon after its introduction as to the propriety of using it. There were great meetings of learned and pious men, who at last, probably after extreme pressure from the Mameluke Governor, Khair-Beg, declared that coffee "disturbed the brain and intoxicated like wine."

But their opponents were of another opinion, and adduced the authority of the celebrated Bagdad physician, Avicenna, in their defence, which, however, did not prevent the transgressor of the edict forbidding the use of coffee from being publicly whipped. At the same time the zealots of the Hedjas proclaimed that all coffee-drinkers would appear before the All-merciful on the resurrection day with black faces. While the great anathema was being pronounced at Mecca, the brothers of the order at Cairo, the very Mamelukes themselves, were reveling in the newly-discovered luxury. A confirmation of the Mecca degree was, therefore, not to be expected from the Sultan, and he, Kanfu Alguris, quashed the order of his Governor, and sent the latter into exile. Then many holy sheiks for example, the elebrated Mohammed Harife, founder of one of the four orthodox schools of Islam, took the side of the coffee-drinkers. Thus was the precious bean fully rehabilitated in western Arabia, at least.—*Southern Planter.*

MAURITIUS: THE SUGAR COLONY:

ITS LABOUR DIFFICULTIES.

Our means of intercourse with the sugar island of the east are so defective that reports of Mr. Napier Broome's farewell speech to the Legislature of that colony and of his assumption of the Government of Western Australia have reached us almost simultaneously. As far as public revenues go and their proportion to expenditure, a greater contrast to the present condition of Ceylon there could not be than that which Mauritius, according to Lieut-Governor Broome, presents. And yet, only half-a-dozen years ago, the contrast was entirely in favour of Ceylon. Such are the vicissitudes of tropical colonies, and, as the pendulum swings to and fro, it may be our turn soon to have an innings of renewed prosperity. Not that all is *couleur de rose* with our neighbours. The labour difficulty had reached such a crisis that one of the highest officers of Government had been deputed to go to India to obtain a force of at least 3,000 labourers. It seems that for three years none had been received, although they had been indented for. Indeed the contention of the *Commercial Gazette* is that no fresh labour is needed, provided laws were passed or enforced which would render available the enormous supply of Indian coolies already in the island. The object to be gained by introducing fresh labour is avowedly that of coercing the coolies already in the island to work for what the planters deem fair wages. But it seems the wages difficulty is not the only one. In is asserted that on estates coolies are so worried by the working of sanitary laws meant for their good, such as compelling them (can it possibly be done?) to use latrines, that they prefer to crowd into their own dirty villages, whither, it is complained, the sanitary officers and the much abominated (more abominated than dirt and disease) sanitary laws do not, so the planters and the press complain, follow them. It is loudly demanded that sanitary and vagrancy laws be stringently enforced, and we have no doubt that there is room for the enforcement of such laws. What the planters really want, however, is a law to compel Indian coolies to renew their engagements to labour on sugar estates or to leave the colony, and this is just the sort of law which the Colonial Office authorities are not likely to sanction, whether demanded by Mauritius or the Governments of Queensland and South Australia. On the other hand it is neither good for Mauritius nor for the Indian coolies themselves that the latter should be allowed to agglomerate in filthy aggregations of abodes and there squat in idleness and vice. What has happened in Mauritius is just what the white Australian settlers object to and never would tolerate; while we do not suppose the Indian Government would sanction the emigration of their labouring classes any where, where they would not be allowed to settle if they chose in order to better themselves after the period of their engagement to labour had expired, as is the case in Mauritius British Guiana, &c. A paper on the labour question drawn up by not a French but a Scotch colonist, Mr. J. W. Shand, has been so lauded by the press and is so generally understood to have guided the decision of the Government to send the Acting Colonial Secretary to India, that we must quote portions of it:—

"I think it is admitted on all sides that the Labour question has reached a stage when it will have to be grappled with immediately and energetically. Otherwise the coming crop will not be got in or at any rate if this is done, the cost will have been so great that expenses will barely be covered. The surplus of profit which ought to be laid up at the end of this favorable season to meet future bad years will not be realized, and the monetary result will be about the same as if the island had suffered from a hurricane, which has not been the case.

"The remedy for this state of affairs is entirely in the hands of Government, and not of the planters as I will show further on, but before going so far it may be worth while examining the causes that have led to the impossibility of procuring a fixed steady supply of labor on estates at a reasonable price.

"The chief reason is that by the action of Government, life upon a sugar estate has been rendered so unbearable to Indians, that they leave them to escape the numerous pains and penalties they are liable to.

"Exeter-Hall people little know the enormous amount of vexation coolies are exposed to by Government whilst engaged on Sugar estates, and they still further know less how callous Government is to the welfare of these same people as soon as they leave an estate. In the Indian villages, the state of filth and agglomeration of men, women, children and animals is simply appalling, and yet Government does nothing to prevent it.

"On estates, the people are bound to keep the ground around their huts clear, to use latrines, to go to hospital, to keep their animals far away from their huts—these huts have to be built of certain dimensions—whilst in Indian villages, none of these regulations exist, or if they do, they are not acted upon. If they are necessary on estates, why should they not be also necessary in these Indian villages? What is the result? The Indian naturally prefers living where there are no restrictions, so he leaves the estates and leases together with half a dozen of his friends ½ acre close by and becomes a day labourer with no one to worry him, and with his animals, etc., under the same roof as himself. He is there perfectly happy in good years. No law can compel him to work. He makes sufficient money in two or three days to keep himself the rest of the week. If he falls ill he goes to some government hospital and is treated gratuitously as a pauper. The men engaged on estates, seeing this, object to reengage, which means submitting themselves to being harassed and worried by Government. Planters do not even expect Government to try and induce men to reengage. All they ask is that their men should not be driven off the estates. It is only when some deadly epidemic will have broken out, which God forbid, and the people in the Indian villages will be dying off by thousands for want of medical care, etc, it is only then that Government will be alive to the fatal mistake they have made in not doing all they could to induce the labouring population to settle down on the Sugar estates, where fine hospitals exist with a medical man and a trained staff of attendants, but it will be too late and the deaths of thousands of poor coolies will be caused by the want of foresight of Government. Let the authorities think over this well.

"Another serious aspect of the labour question is the enormous amount of illegal absence on estates. With a nominal list of 500 to 600 names, there are often only 200 at work. Government is again solely to blame for this. Planters have no *right* to examine the status of laborers applying for work. If one does the Indian goes to some other one who does not, and the consequence is that many men engaged on estates where they have a house, garden, etc. and the use of the hospital, medicines, etc., desert the estate and go and work as day laborers on some neighbouring property. If Government would only enact that all employers of day laborers are bound to register the names and numbers of the men employed, much illegal absence would cease. Punishment for it, is not nearly severe enough. Prison life and labour as it is has no terror for the Indian. He laughs at the notion of a month's imprisonment.

"In Natal every coolie is bound under a penalty of 14 days' imprisonment to carry always about with him a certificate of discharge or a permit signed by his master, which can be examined by almost any one asking to see them. Punishment for illegal absence is much swifter, surer and severer. Employers are liable to heavy fines for taking on a coolie unless they us proper diligence to ascertain whether the coolie is under engagement or not, i. e., examine his papers —Why should not this rule be enacted in Mauritius."

Mr. Shand, having dwelt on the worries to which the coolies were subject, by the well-meant interference of Government, does not forget those of the planter. After showing how much better matters are managed in Natal, he went on to say:—

"The number of small worries a Mauritian Planter is exposed to would astonish a Natal Planter. Some of the vexations were very well shewn up in a series of articles which appeared in the *Cernéen* lately signed 'Trifouillard.' More than half of the time of a 'Comptable' upon an estate is taken up doing clerical work for Government, making out returns, etc.

"Planters have also to do police duty. Whenever an engaged laborer is liberated from prison, for whatsoever offence it may be that he has been condemned, it does not matter, the planter receives an elaborate printed form from Government calling upon him to take delivery of the man, or else he will be sent up to the estate under police escort, the planter paying for the valuable services the police render him, by bringing back some incorrigible deserter. If the planter sends a Sirdar, what authority can he have over a man who will not return to the estate? As soon as the prison doors are opened the man can go where he chooses, and he laughs at the idea of being conducted back to his estate by a Sirdar when it is the duty of the police to do so.

"My object in citing one of the numerous instances when planters are worried is to show that Government does nothing to help planters. On the contrary, it does all it can to harass them and their engaged laborers.

"To come to the question of the supply of labor at present available in Mauritius. I have no hesitation in saying it is not sufficient. The extent of land in cultivation including Indian gardens, for which labor is requisite, is much larger than is popularly supposed. The supply of labor does not meet the demand. A man working two days can make enough money to keep him for a week. Such being the case, we have no right to expect he will work harder.

"This is simply and exemplification of a well known principle of social economy—Government cannot reduce the rate of wages or make men work harder by law. It must assist the planters by doing all it can to facilitate immigration. On several occasions I have advocated this, and when giving evidence before the Purchase Commission with regard to the Terrain Bonnefin, I said that it would be necessary very soon to import a large number of coolies to keep wages down to a proper limit and that the consequence would be that the price of land in the Colony would go on gradually increasing as the men leaving estates would require to be located somewhere. There is plenty of room for many more laberers and there is little danger from a sanitary point of view, provided Government does its duty and enacts stringent Sanitary Regulations for the Indian villages, similar to those in force on sugar estates. Besides, almost every estate camp has a large number of huts empty and many thousand new laborers could be absorbed by the estates without any danger, as hospitals etc., exist for many more than are actually engaged."

This introduction of more Indians where already over a couple of hundreds of thousands of Indians exist, is a very delicate one, and one which, if they had the mental and political status of the white labourers and mechanics of Victoria, the coolies might respond to by saying: "What right have you to introduce more men for the avowed purpose of reducing our rates of wages, while your own mouthpiece, Mr. Shand, states explicitly: 'If the rate of wages is too low, planters must increase it, if they expect to compete with other labour importing colonies'?" The Government officers, however, who in a crown colony are the natural protectors of the labouring classes, had agreed that the introduction of fresh blood was really necessary. Mr. Shand wound up by proposing:—

"1st. That several thousand new labourers are absolutely necessary for Mauritius to bring up the supply of labor to the demand.

"2nd. That owing to some cause or other our Immigration agents seem incapable of procuring coolies.

"3rd. That the punishment for illegal absence is not sufficiently severe.

"4th. That day laborers should be obliged to show that they are not engaged on some estate, before being allowed to work as day laborers.

"5th. That Government should extend the Estate Camp Sanitary Regulations to all Indian villages and to huts in which Indians live.

"6th. That day laborers should pay a small tax to defray the cost and maintenance of village hospitals which should be erected in each district for their use.

"7th. That a latrine service should be insisted upon in each Indian village."

We certainly see no hardship in the imposition of a slight tax on Indians settled in villages for the support of hospitals to which they could resort in illness, nor in a law compelling them to observe the first rules of cleanliness and health. But if, either on estates or in their villages, Indian coolies are really induced to resort regularly to latrines instead of spreading filth over the largest possible area they can reach, then we hope our Mauritius neighbours will reveal to us the secret of their success, so enabling us to enforce a similar law here. The Indian coolies have many good qualities for which let them get due credit; but their best friends would violate truth and outrage conscience, were they to say that the Tamils, at least were models of cleanliness in persons and in habits. We have heard them called, in violation of all parliamentary rule "nasty, dirty beasts," and, like the celebrated Gunpané, we "could make no reply." The acting Governor of Mauritius in giving his assent to the despatch of a special agent to India with reference to requisitions spread over three years for 6,000 or 7,000 coolies of which only 500 had been received, was careful to state that he did so without compromising the future policy of Government based on density of population and other circumstances. The Secretary of State had, in truth, sanctioned the requisitions in question, as also the lowering of the proportion of females to males. Besides the extracts from Mr. Shand's paper on the labour question, we take over a few paragraphs from the *Commercial Gazette*, reserving for next issue a notice of the able and interesting speech with which Mr. Napier Broome closed his connection with Mauritius, the inhabitants of which colony expressed regret at losing him and his clever and amiable wife, Lady Barker.

CARDAMOM CULTIVATION IN INDIA AND CEYLON.

The following notice of Owen's well-known pamphlet on "Cardamom Cultivation" (published at this office) is from "Aberdonensis" a Ceylon planter settled in Mysore where he has the opportunity of watching the cultivation of cardamoms on a scale not yet approached in Ceylon. We believe there is no one clearing of cardamoms in this island exceeding 50 or perhaps 80, acres in extent; whereas in India we have heard of 500 and even 1000 acres on one plantation. It is obvious therefore that the system of working must be rather different in India; but unfortunately "Aberdonensis" does not fully enlighten us as to the difference. He is a little bit sarcastic and very suggestive; but he just stops short at the point of exact practical information. No doubt there are secrets to be learn in India; but the time is past when these can be regarded as a monopoly. For what "Aberdonensis" tells us we are thankful, but like "Oliver Twist" our cry is for "more"!

"OWEN'S PAMPHLET.—This "brochure" is fitted for Ceylon planters who may have small reserves of available forest and who indulge in this cultivation as in a fancy article. But the whole scale is that of a private orchard: great expense in upkeep, or great occupation of capitrl which might be more protibly employed, are two things avoided in cardamom cultivation. You must have good roads; elerthew and barbecues and store; abundance of timber for boxes and firewood; a large temporary labour force while crop and concomitant works are in progress; a large extent of land on easy terms, lease or otherwise; and a proper knowledge of the wants of the plant in the way of light the wants of the labour, in the way of advance and wages—and the wants of the English buyer in the market in the way of the cured article. Ceylon men can't understand why we don't require to clip the fruit, and how it is that though we pull, yet there is no splitting. We can't tell ripe fruit any other way, nor can anyone with surety. You must find that out, and it will pay you to do so. Partially green fruit does terrible damage. Mr. Owen says "the least touch detaches it from the stem and hence the picking is very difficult." Put 'easy" instead of difficult, and you get comparatively nearer the mark; only the stooping down is rough on the pickers compared to coffee. Coffee pickers pick by sight; cardamom pickers by touch. So you must reverse Mr. Owen's note on this point. Ceylon men go to Walker & Co. with their troubles and that firm are kind and responsive. Hence the long-legged scissors, the brass wire-gauze business and the brightly polished and merrily burning stove. The Ceylon drying-room is a fine place for putting missus's dress-boxes and drying master's wet clothes in the monsoon. Mr. Owen is out in the curing. In fact his cardamoms instead of being *cured* are *crude*. Also the trimming and "tittifying" of the stools as the racemes sprout is a Ceylon notion, bearing out my former comparison. The *eye* guides both Ceylon durais and coolies in coffee and everything else. The *touch* is better as regards fruit in the case of cardamoms and rupees in the case of result. Never mind the eye. Pick by the touch: it will profit you much, to listen to such proper hints. As for procuring plants in Ceylon, Mr. Owen says far too much about villagers bringing bulbs for sale. As the natives do *not* cultivate or grow the better variety; and as the villager dearly loves a market for an easily acquired article about which unpleasant questions are *not* asked; and as planters are sorely tempted to secure cheap bulbs and stifle their consciences if possible; and as bulbs are known to be stolen largely; and as no new clearings appear in the neighbourhood of the thefts—it follows—sequitur—that Mr. Owen's notes on "native vendors" ought to be left out or be less prominent. Reverse Mr. Owen's ideas on nurseries. "Mysore" (so called in Ceylon) a dark mystery. There is no variety of the kind here. Root it out frond and bulb. Stick to a good thing and don't have the other to cumber the ground. It is spoiling your market.—ABERDONENSIS."

CHOCOLATE, CACAO, AND COCONUTS.

We quote what Professor Skeat says on these words in his excellent *Etymological Dictionary of the English Language* (1882):—

CACAO, the name of a tree. (Span.,-Mexican.) In Blount's Gloss, ed. 1674, we find: '*Chocolate*, a kind of compound drink, which we have from the Indian; the principle ingredient is a fruit called *cacao*, which is about the bigness of a great black fig. See a Treatise of it, printed by Jo. Okes, 1640.' The word *cacao* is Mexican, and was adopted in Spanish, whence probably we obtained it, and not directly. See Prescott's Conquest of Mexico, cap. v. ¶ The cacao-tree, *Theobroma cacao*, is a totally different tree from the cocoa-nut tree, though the accidental similarity of the names has caused great confusion.

CHOCOLATE, a paste made from cacao. (Span.,-Mexican.) In Pope, Rape of the Lock, ii. 135; Spectator, no. 54. R. also quotes from Dampier's Voyages, an. 1682, about the Spaniards making chocolate from the cacao-nut. Todd says that it was also called *chocolata* at first, and termed 'an Indian drink:' for which he refers to Anthony Wood's Athenæ Oxonienses, ed. 1692, vol. ii. col. 416.—Span. *chocolate*, chocolate.—Mexican *chocolatl*, chocolate, so called because obtained from the *cacao*-tree; Prescott's Conquest of Mexico, cap. v. For the Mexican *chocolatl*, see also Clavigero, Hist. of Mexico, tr. by Cullen, i. 433. Spelt *jocolatt*, Evelyn's Diary, Jan. 24th, 1682. Introduced in England ab. 1650 (Haydn).

COCOA (1), the cocoa-nut palm-tree. (Port.) 'Give me to drain the *cocoa's* milky bowl;' Thomson, Summer, l. 677.—Port. and Span. *coco*, a bugbear; also a cocoa-nut, cocoa-tree. 'Called *coco* by the Portuguese in India on account of the monkey-like face at the base of the nut, from *coco*, a bugbear, an ugly mask to frighten children; see De Barros, Asia, Dec. iii. bk. iii. c. 7;' Wedgwood. Cf. Port. *fazer coco*, play at bo-peep; Span. *ser un coco*, to be an ugly-looking person. The orig. sense of Port. *coco* was head or skull; cf. Span. *cocote*, the back of the head; F. *coque*, a shell. All related to Lat. *concha*, a shell; see Coach, Conch.

COCOA (2), a corrupt form of Cacao, q. v.

We are surprised that Professor Skeat has not pointed out that *coconut* should be spelt without an *a*—(a useful distinction, were it only to distinguish it from the product of the shrub which in the London market is unalterably fixed as "cocoa:" Dr. Trimen suggested as a compromise that the tree should be popularly spoken of in Ceylon as the 'chocolate tree,' so few, at present, speaking of 'cacao,' but of 'cocoa,' planting, which is apt to mislead). Skeat's derivation of *coconut* seems to be the correct one. It is curious to notice how the Dutch gradually dropped the name which they borrowed from the Portuguese, and adopted the Malay name. In the older Dutch books of travels and voyages the coconut is called *kokos*, but after the Dutch had gained supremacy in Java and the adjacent islands the word *klapper* (Malay *kalapa*) took the place of its Portuguese rival. The latter is still however used, especially in Holland, *klapper* being current among the Java colonists. Another source of confusion is the *coca* of Peru. So long ago as 1682, de Vries, in his *Curieuse Aenmerkingen*, impressed upon his readers not to confound this with *cacao*.

QUEENSLAND SUGAR PROSPECTS FOR 1883-84.

It is with some feeling of pleasure that we come before our readers with our annual sugar report, with which we combine a forecast of the coming season's operations; and while the former, though nearly equalling our anticipations, placed on record at this time last year, are by no means highly satisfactory, it is very pleasing to be able to look forward to the coming season as one which, unless any unforeseen accident arises, will go far to make good the losses which some growers at least must have experienced during the past year. It is generally understood that our sugar year ends on March 31st, and it is up to that date each year that the returns are made. The following table will show the difference between the operations of the season 82-83, and the previous one:—

Year	Cane crushed to March 31st	Sugar	Molasses.
	acres	tons	gallons
1882	7,167	10,712	407,020
1883	7,948	7,841	284,090

From this it will be seen that the return for the past season has been a particularly low one, not quite reaching one ton to the acre,—a figure which will go far to reducing the average crop extending over a long series of years. This low return was anticipated by ourselves, although many sanguine people took exception to the low estimate given by us last year, yet, much as we should like to have been a few thousand tons below the mark, our figure of 8,000 tons has proved not far wide of the mark. The return of molasses to the ton of sugar, has, this year, been less than usual, but is still as high as we ever hope to see it. Looking back over the last year we cannot feel that there is any reason for great regrets, because the wretchedly bad season which resulted in the small return was a matter which nobody could have altered; and the fact of the probable small output was, by most people, so long anticipated that its actual coming was the less severely felt. But we will now turn to the more pleasing prospect which is before us, and we find that the area under cane at the beginning of this month was 14 575 acres. Of this it is estimated that 13,152 acres will be brought to the factories during the coming crushing, and the most sanguine anticipations of a fine crop are expressed by the majority of people here, and there is every reason to believe that, assuming that nothing of an extraordinary nature intervenes, we shall have a crop of above average quality. At the present moment, when there is yet a winter to be gone through, we should hesitate to give reins to our imagination to too great an extent, and we would rather err upon the right side than the other. We give, therefore, as our estimate for the coming crop, the figure of 18,000 tons, and, at the same time, hope that the quantity may be considerably exceeded. With the present supply of colored labor, it will be positively impossible to take off this 18,000 tons of sugar, except by neglecting the proper cultivation of the fields for the following season's crop. What this means to a district like Mackay all men of thought will clearly recognise, and for our part we would much prefer to see the annual output steadily increase by gradual degrees, than have alternately large and small returns such as must inevitably follow unless we can secure a steady influx of reliable labor, in suitable quantities. We do not propose to enter again into the colored labor question on this occasion, but merely point out, now that a continuance of good returns from the sugar industry depends now almost entirely upon the introduction of a sufficient supply of labor of all kinds.—*Mackay (Queensland) Standard.*

JAPAN TEA AND THE AMERICAN MARKET.

The Japanese are growing alarmed at the antiadulteration crusade against tea in America. A Japanese paper publishes a note of warning, from which we take the following extract:—

In our opinion, though Japanese green tea may still find many good customers in America, yet if the Bill proposed by Mr. Hardenbergh be practically enforced, then that will put a stop to further exportation of our green tea, that is coloured tea. Our tea merchants, therefore, cannot content themselves with the old style of tea exportation, but must make preparations for a different style of proceeding. Supposing no tea is coloured, then shall we endeavour to get profits from the sale of this tea, which we might call "original Japanese uncoloured tea." Considered from the present condition of affairs, we are not in a position to see whether this tea would suit the customers taste or not, or whether there would be any demand for it. Even supposing we could admit that this tea would find many good customers in America, it is not to be supposed for one moment that it would command such a ready sale as the present green tea. It is beyond the power of any one to change the customers taste from the old quality of tea to the new one we have just mentioned. This is a point that we are very anxious about. Our merchants may easily perceive that the sale of the green tea which has found such great favour in America, will not decrease, but increase, if our merchants will only keep from the bad practice of mixing and colouring. Our merchants know perfectly well that even the shrewd Chinese merchants cannot compete with us in the America markets. Now, however, this bill we have spoken about is the "awful object that has crossed the path of our green tea." therefore our merchants must prepare themselves for any emergency that may arise, and find some means to aboviate the difficulties that will be presented.

Look, for example, at the Chinese merchant, who is so sharp regarding his profits! There is no doubt that there are some who even now are carefully considering how they can get the upper hand, and so rule the American tea markets. If this should come to pass, how can we be sure that our merchants could afterwards enter the lists against them and come off victorious, that is, hold the same position as they do now. Indeed this is a point that requires a great deal of thought.

Now the most important duty left for our merchants is, to produce a thoroughly good tea, fit for the customer, in lieu of green tea, without regard to the prohibitive regulations, and by doing this get into the same favour with their customers as heretofore. We ourselves do not know what tea would be most likely to suit them; probably our merchants will give this matter their consideration. There are only two ways now left for us. The proposed bill contains a clause that "if teas are found to be adulterated with either colouring or other material injurious to health, then their import shall be prohibited." Well, now if the ingredients used for colouring our tea at present are really injurious to health, why not endeavour to find out some colouring substance which is not injurious. If this is found to be impossible, then there is only one resource, viz., to introduce a genuine good tea of first-class manufacture, and stamp it as such, to distinguish it from any tea that may be mixed with any leaves or otherwise coloured. Whichever plan is adopted, extreme energy and watchfulness are required to keep up our flourishing tea trade. Our merchants must use every endeavour to raise the tea manufacture to as high a standard as possible.—*Home and Colonial Mail.*

TIN TEA BOXES.

SIR,—Could any of your correspondents tell me of any cheap method of leading (covering with lead) the inner surface of the Patent japanned tin tea boxes sold by Messrs. Begg Dunlop & Co., as the tin of itself is said to be injurious to tea, and the shape of the boxes precludes the idea of lining them after they are made up? Could not Messrs. B. D. & Co. by some chemical process perform the operation of lead lining for us?—Yours, &c., BOGI TING.

[We published a letter, some time ago, from Messrs. Harvey Bros., and Tyler, in which they conclusively proved that their tin tea boxes are absolutely innocuous to tea. The following extract from another letter from the same firm goes to support the efficiency of Harvey Bros. tea boxes.—ED. *T. A.*]

"With reference to your remarks, which we have read with the greatest attention, both with regard to the tea from being packed in tin, and also as to the loss in weight owing to the way in which packages are tared at the Custom House here, we have much pleasure in informing you that in no one instance has any, or indeed can any deterioration take place, as the tin of which our boxes are made is so prepared and cleansed that every trace of grease (which is so offensive in ordinary tin) is removed.

"We have seen some of the finest teas ever sent from India, received this season in some of these boxes, and the condition was superior to anything in wood and lead boxes. The tea was as fresh and crisp as if it had just been fired. Not only is the condition on arrival excellent, but, unlike ordinary packages which undergo sad mutilation at the docks, which these boxes are exempt from, months afterwards teas packed in these air-tight boxes are found not to have undergone the usual deterioration."—*Indian Tea Gazette*, June 2.

[Granted what is here claimed, the difficulty is that of price. On an estate with reserve timber, a wooden box to hold 80 lb. can be made for the price charged for a 20 lb. tin box. If the tin boxes cannot be cheapened, our great hope is in papier mâché.—ED.]

NEW PRODUCTS AT TRINCOMALEE.

The pioneers now engaged on the rich lands on the banks of the Mahavilla Ganga are not by any means disheartened by the failures of the first growth of tobacco down here. The first pioneer has left the country, but he left behind him those who were resolved that the cultivation should have a fair and a thorough trial. With this end in view, one of the party proceeded last year to Sumatra, where he remained for six months, making himself acquainted with the growth, preparation, and packing of tobacco. Sumatra tobacco is known throughout the east as second only to the best Havannah. Not content with learning the cultivation, our pioneer brought with him a good supply of the best seed, and with this proceeded to clear and plant a dozen acres of good land adjoining that on which his predecessor had grown the plant. The attempt was thoroughly successful, and the result has been a shipment to London of upwards of fifty bales of fine leaf tobacco in prime condition. That good tobacco can be grown on these lands there is no longer any doubt, any more than there is any misgiving as to the curing of the leaf. The only problem for solution is that of value—will its market price leave any profit on the cultivation? The labor with which it is grown is Tamil, some of it old hands; but tobacco is an exhausting plant, and cannot be grown on the same land twice unless with a supply of suitable manure containing plenty of lime. The plan adopted here is to plant the ground with coconuts after cropping, though the cost of keeping off wild pigs from the young plants is considerable. Between the coconuts, plantains will be grown, in order to give a little return until the other produce begins to yield. But if tobacco yields a fairly good profit, it may be worth while to obtain coral, of which an abundant supply can be had at a low cost, and burn it for application to the land; and then, it is believed, if it can be blended with a little fish manure, also obtainable, tobacco could be grown for a number of years, if occasionally alternated with some other annual crop. On the "Lowlands" estate, cacao, athough of rather slow growth for the first year or two, comes on rapidly afterwards; the soil and climate appear to suit the plant admirably, and already the oldest trees, three and a half years old, are giving excellent promise of being heavy bearers, some of them having good-sized pods on them already. A portion of these are maturing, and appear to be well filled with beans, though perhaps a little deficient in mucilage. Thus far we have lost none of these plants whilst young, nor does any enemy as yet attack the pods. Liberian coffee is growing, but not with much vigor or rapidity, and there is as yet but little crop upon any of the plants. On one of the properties here, Ceara Rubber has been planted over fifty acres of land, the appearance of which as yet is not such as to enable any opinion to be formed of its ultimate success. Some of the trees are nearly three and a half years old, but as yet the sap does not flow very freely from them. This may be that the trees are not sufficiently matured, or that the tapping has been carried on during too dry weather, but nothing could possibly look better than some of these rubbers. These are the principal new products attempted for any length of time. There are others now in course of trial, but sufficient time has not elapsed to enable any opinion to be formed as to their ultimate success. There is no question that the soil about here is capable of producing nearly all tropical products, and that in regard to these properties, and the land generally along the banks of the river, much of the future success of cultivation will depend upon the ability to keep out the water of the Mahawilla Ganga during the floods of the north-east monsoon, and upon some means of irrigation during the dry weather of the present season. These matters will have to be considered, and no doubt if it can be shewn that the cultivation of tobacco, cacao, and other products will yield profitable returns, something may be done towards meeting these requirments by a little engineering, which, from the nature of the ground, would not present any serious difficulties.—*Cor.*, Local "Times."

MADRAS TELEGRAM FOR WEEK ENDING 9TH JUNE.

TANJORE.—Rainfall average thirteen stations ·56. Standing crops generally good. Harvest—paddy and flax, outturn below average. Cholera slight parts.

MADURA.—Rainfall average two stations ·76. Standing crops fair. Cholera slight parts.

TRAVANCORE.—Rainfall 2·685. Sowing over; paddy plants coming up well. Fever prevails.

General prospects good.

CULLODEN TEA produced at from 200 to 300 feet above sea-level and within eight miles of the sea, realizing 2s 6½d per lb. (for orange pekoe)—the valuations being much higher—shows that the lowest-situated estates in Ceylon may send a tea into the market which will fetch the highest prices. The Culloden tea, it seems, has a specially rich flavour, and it is evident that the available land in the Kalutara district can be utilized very profitably for tea. Of course, "Orange pekoe" is not to be taken as a criterim of the average, but Culloden tea is good all round.

TEA.—An ingeniously devised diagram drawn up in London shows with great accuracy the fluctuations, in price and quantity delivered, of Indian teas for five years past. Generally the diagram, which is something like a weather chart, supports by its figures the economic theory of expectancy that when prices rise consumption falls off, and *vice versa*; but it is remarkable that although since January last there has been an undoubted advance in value, no check to consumption has ensued. Prices of both Pekoe and Souchong (only with these the diagram deals) have varied considerably, for the former the highest price being one and ninepence in 1878, the lowest one shilling in 1880; while for the latter the highest price was one and threepence in 1879 and ninepence halfpenny in 1883. From last October to last April the deliveries in London were 35½ million pounds as against 27 million pounds in a corresponding period of 1881-82, or an average increase of 1¼ million pounds per month. To tell whether this will continue during the coming season is a somewhat difficult task in a purely conjectural field. The season is a late one; drought undoubtedly did damage in April; and up to that month many gardens had only yielded half the normal quantity of previous years. This diminished yield is hardly a fair premiss: for only about 5 per cent of the total gathering is collected by that time. At the beginning of May, however, prospects looked of by no means cheerful complexion; and it can hardly be said that the rains in the Cachar area have compensated for the previous deficiency. There are compensations and compensations.—*Pioneer.*

MARKET RATES FOR OLD AND NEW PRODUCTS.

(From LEWIS & PEAT's London Price Current, June 7th, 1883.)

IMPORTED FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.

"WILLUGHBEIA CEYLANICA": A SUPPOSED "CEYLON RUBBER."

Some months ago a correspondent sent you specimens of a climbing plant with its large globular fruits, 4 to 5 inches in diameter, and a bottleful of rubber collected from the plant and its fruits, and which I had no trouble in identifying as the *Willughbeia Ceylanica*, Thwaites' *Enum.*, 191. It was figured and described several years before (1848) in Wight's *Icones* of Indian plants t 1258, as the *Chilocarpus Ceylanicus*, and the late Dr. Gardner called it *Winchia chirrhifera*, Ms.* It is not an uncommon Ceylon plant from the coast up to 4,000 feet. The large handsome fruit of this species is not edible that I am aware of, but that it is a favourite food of monkeys I discovered in the forests at Delpatgedara in 1842. The plant is fully described by Sir Joseph Hooker in *Flora of British India*, 3, 624. but as the genus was named after Francis Willughby, F.R.S., a friend and pupil of Ray, and the author of some works on Natural History, it has evidently been wrongly spelt in the *Flora of British India* as *Willoughbeia*. From the seeds of the fruits sent by your correspondent at Henaratgoda, if I recollect aright, I have raised several plants in the Circular Walk, and I have now to apologize to him and to you for not sooner noticing the plant and the rubber from it, which I return you in a hardened mass in the bottle as it came. On reading Roxburgh's account of his *Willughbeia edulis* (*Fl. Ind.* 2, 57). I was discouraged by what he said about the rubber from that plant, and a friend well up in these subjects having seen the specimen of rubber and knowing the plant that produced it pronounced it as a worthless putty-like mass, but nevertheless I regret that this information and your correspondent's letters about the plant and its rubber were not published at the time.

Roxburgh's remarks on his *W. edulis* are to the effect that the milky viscid juice which flows from every part of the plant is changed into a bad or indifferent kind of elastic rubber, or caoutchouc, on exposure to the air

All this information respecting the *Willughbeia Ceylanica*, applies to the specimens of plant and fruit sent by your correspondent, J. P. Abraham. whose letter is dated Nawalapitiya, June 20th. The plant belongs to the same family, Dogbanes, or Apocynaceæ, as the Landolphias, but none of the latter are natives of India It is singular that this common Ceylon plant, with such a remarkably large fruit, does no seem to have a Sinhalese name: I know of none, and neither of your correspondents has given one for it It ought to be somewhere amongst the Mahagedi-kiriwels. W. F.

[Mr. Abraham's letter referred to is as follows.—Ed.]

Nawalapitiya, 20th June 1883.

Sir,—I send you per 6-10 a. m. train today two fruits and some leaves of the "Ceylon Rubber" "Landolphia Florida" which I plucked from a large creeper in the jungle. It resembles the L. Florida. I made incisions in the stem of the creeper and obtained a milky juice, which after a while, was hardened into rubber of a superior quality.† If you will cut the fruit you will find a quantity of milk inside which will form into rubber in a few minutes. I will send you a fair sample of this rubber if you do not succeed with the fruit I now send. Mr. Christy mentions in his "New Commercial Plants" that the fruit of L. Florida is eaten by the natives of Madagascar, and I am informed by the villagers here that this fruit is likewise eaten by them. Having examined the fruits and leaves, I am inclined to believe that this creeper is a genus of the Landolphia family. I could not get any flowers in it, being out of season. As you always take great interest on such matters I shall be glad to have your opinion on this subject.—I am, sir, yours faithfully, J. P. ABRAHAM.

RULES RESPECTING COOLIES IN ASSAM

Our coffee-planters in Ceylon have complained of Government interference and forms to be filled up, but what would they say to the Assam tea estate rules, a few specimens of which we take from the *Indian Tea Gazette*?

A new set of rules, even more voluminous and restrictive than the last, has been elaborated, and they make their appearance in a recent *Assam Gazette Extraordinary*, where the rules, schedules, and forms occupy 60 pages of print; and the Chief Commissioner's resolution introducing them sets out by saying that the same provision, in every respect, shall be made for the *dependants* of labourers as for the labourers themselves. It will be seen, thus, that the Government interference is sufficiently wide-reaching Four different registers have to be kept by the depot manager, and he has also to submit a daily report. and to fill up and forward a form to the Embarkation Agent whenever a steamer is expected to arrive. He then has to submit to the Deputy Commissioner four different forms monthly, besides a return on the arrival of any emigrants at the depot. He is to see, also, that all labourers *bathe*, on admission to the depot, and that every article of clothing that is soiled (whether new or old), shall be thoroughly washed before its re-issue. Cast-off and ragged clothes are to be destroyed at once. It is not said who is to pay for these. [We never knew of a cooly who considered his clothes sufficiently ragged not to be worn] Each man, boy, woman and girl is to be provided with a ball of soap for themselves. The depot dhobie, we presume, provides the soap for washing the clothes When necessary, food suitable for infants and invalids (fresh milk, soup, sago &c) shall be freshly prepared and regularly supplied "throughout the 24 hours," and any neglect of this on the part of the depot manager or his agent involves cancellation of the license. We should have thought however, that the manager might have been allowed his night's rest, and not keep on the watch for the whole 24 hours Chapter VI. deals with everything connected with the coolie when he is located on the estate. Every individual is to have 50 superficial feet of house accommodation; and on estates employing more than 50 labourers there must be a resident medical officer appointed When the price of rice in the local market exceeds R3 the maund, the employer is bound to supply at R3. or make good the difference. Chapter VII introduces us to the rules for employers. Each employer has to keep 11 different registers for the information of the authorities. This will, of course, involve the employment of several extra clerks as copies of these registers have to be regularly sent. The forms themselves are very elaborate. and it will require a constant supervision by the manager over his native clerks to prevent mistakes in filling up the registers and returns.

PARAGUAY AS A PLACE OF SETTLEMENT.

Sir,—I see in your paper of January 13th, a short note from a correspondent signing himself C. R. C., ridiculing my idea of a man starting in this country with a capital of £1,000, and at the same time recommending such a one to go to any other republic in South America. When C. R. C. speaks of other republics, does he mean the Banda Oriental (a nest of cut-throats), or the others farther north who are perpetually at war, and at any rate unsuitable for English settlers? Now there are three other republics left, viz. Chili, Argentine, and Paraguay. The first two (especially Chili) are very expensive countries for a man to go to with £1,000; in the River Plate the land speculators are asking from £1,000 to £2,000 per league for wild frontier lands with brackish water, and not a stick nor a stone to be seen anywhere. Now, as I am not a landowner or a speculator in any of the above-mentioned republics, I think I can say a few words with regard to my experience in South America during the last sixteen years. I have travelled in the most favoured spots of the Argentine republic, and have come to the conclusion that not one of its provinces can compare with Paraguay. We have just passed through a drought of eight months, and still the animals are in good condition on account of the permanent pasture and springs of water. I have just for amusement made a rough calculation as to what a man (aged say 40) could do here in Paraguay with a capital of £1,000. He could buy fifty acres for £5; put a house up, £10; four cows, £15; two horses, £5; corral, fencing, &c., another £5, and a few pigs, ducks, and fowls, £2; and I will guarantee that he will be able without any exertion to pass away the natural term of his life on the balance of his capital and live well. Society there is not much of, but with his gun, dog, and one or two bachelor friends, he will have a good time. The cana or rum of the country, is good and cheap, as C. R. C. probably knows, and makes an excellent punch for a cold night, flavoured with the lemons which grow wild. I am sitting, as I write this, with an estanceiro from the camps of Santa Fé, one of the best provinces in the Argentine Republic; he has bought one league of land here for £120, and intends stocking; it is naturally fenced in; he is one of a dozen who are coming up to do the same thing. The other day a gentleman arrived here from Germany to look out for a good place to colonise on a large scale. I was much amused with his account of the people he met with on his landing in Buenos Ayres; directly they heard of his intention to go and see Paraguay, they at once told him horrible accounts of the climate, snakes, mosquitoes, fevers, etc. I have lately passed two summers here, the last being the hottest; the thermometer did not touch 99° Fahr.; but by the recent accounts from below they have had it up to 109° in the shade. I have seen three snakes (small ones) during the last eighteen months, no fevers, and I sleep without a mosquito net, as the nights are always fresh and cool. I may mention that I am living about eight leagues from the capital, very comfortably; plenty of shooting, bathing, and enjoing pretty scenery. As to C. R. C.'s account of the epidemia (mal de cadera) amongst horses, I may say it is not prevalent in all parts of Paraguay, and it is dying out; I have some twenty horses, and not a case yet. C. R. C. also makes a mistake in the number of animals slaughtered in Paraguay per day. I have found out since that there are from 95,000 to 100,000 killed per year, and the population is about 350,000. The Paraguayan hide is heavier than that of the south; this is a well-known fact. The population is steadily increasing; therefore, more mouths more beef. In my letter to *The Field*, Dec. 30th, 1882, if C. R. C. turns back, he will see my account of what the country will produce. In conclusion, I may remark that it is the policy of the River Plate Governments to stop all emigration from coming up to this country, but in spite of everything people are turning their heads this way.

Asuncion, Paraguay, April 10th. El Jaguar.

—*Field.*

PLANTING ENTERPRISE IN THE WEST INDIES.

(From the *Planters' Gazette.*)

On June 8th, last a paper was read on Planting Enterprise in the West Indies at the Royal Colonial Institute by D. Morris, Esq., M. A., F. G. S., the Duke of Manchester presiding. After paying a warm tribute of praise to the usefulness of the Institute, Mr. Morris explained that by the term "British Possessions in the West Indies," he included the Bahamas, the whole of the British West India Islands, together with British Honduras (a dependency of Jamaica), and the colony of British Guiana.

With regard to the population of the West Indies, it is often believed to be either stationary or declining. This, however, is by no means the case with the creole, or negro population, or even with the whites. The population of the West Indies in 1881 was 1,493,062 as compared with 1,271,507 in 1871, and 1,107,667 in 1861. This shows an increase of population equal to 16 per cent on the returns for 10 years; and an increase of nearly 35 per cent on those for 20 years. It would appear, therefore, that the rate of increase of population in the West Indies is much greater than that of the United Kingdom, in which the rate of increase at the census of 1881 was under 11 per cent. This large increase appears to be general, and not confined to any particular locality. Moreover, it is only very slightly influenced by coolie immigration. The total number of free and indentured coolies in the West Indies according to the latest returns, viz., those for 1882, was not quite 90,000; of these more than two-thirds, or 62,000, were in British Guiana. As compared with other British colonies, the population of the West Indies is greater than that of any of the larger Australian colonies, and more than three times that of New Zealand.

The total export and import trade of the West Indies in 1881 amounted to an aggregate value of nearly 17 millions—the exact figures being, exports, £8,913,014, and imports, £7,746,470. This is an increase of nearly 3½ millions on the value of the export and import trade in 1866, and is nearly one-half of the total value of the export and import trade of British North America.

The true development of our West India possessions was to be looked for simply in the natural products and resources of the soil; and to secure the full development of these there are wanting only capital and labour, intelligently and wisely used, and proportionate and suitable to the ends in view. The staple industry of the West Indies for more than two centuries has been sugar, with its secondary products, rum and molasses. In spite of the disorganisation of the labour market, consequent upon the abolition of slavery, and in spite of the unequal competition of beet sugar, the sugar-cane still remains the chief industrial plant of our West India possessions. Not only that, but the West Indies at present produce more sugar than all the other British possessions put together. For instance, during the year 1881 the quantity of raw sugar exported from all the British possessions amounted to 7,833,504 cwts. Of this 4,697,445 cwts., or more than two-thirds, was produced by our possessions in the West Indies; the remainder, or 3,136,059 cwts., being the produce of Mauritius, India, Natal, Fiji, &c.

Mr. Horne, having given special attention for many years to the selection and cultivation of sugar-canes, was commissioned by the Chamber of Agriculture in Mauritius to make a selection of the best sugar-canes found in Australia and the islands of the Pacific, and forward them for experimental purposes to that island. This Mr. Horne did during the years 1877-78, finally closing his labours in Fiji. From the canes thus obtained, Mr. Horne, by permission of the Government of Mauritius, forwarded 44 of the best varieties to Jamaica, where all but one, No. 3, have arrived safely. In forwarding these canes Mr. Horne wrote:—"The varieties are all good strong growers, and yield a large quantity of sugar. In this latter respect I would particularly call your attention to the 'Lahina' variety. I was told, when in the Sandwich Islands that this cane yielded as much as an average of 6 tons of sugar per acre on areas as extensive as 100 acres; and 7½ tons per acre, on an average, over areas of 20 acres or less in extent. However, after the first ratoons it should be uprooted, as the second ratoons are nearly or almost worthless. The variety 'Samuri' is the favourite cane with the sugar-cane planters in Fiji. It is hardy, grows rapidly, and yields sugar freely."

Turning again to the more general question of the cultivation of sugar in the West Indies, I would mention that for most of the low rich lands of our West India possessions, where the indigenous labour is abundant and cheap, as in Barbadoes, or where coolie immigration, to supplement the indigenous labour, is carried on systematically and successfully as at British Guiana, Trinidad, Jamaica, &c., the cultivation of sugar is, and I trust always will be, a leading industry. A very common impression exists, that most of the rich soil of the West Indies has been already under cultivation, and that, in many respects, it is almost exhausted. How far this is borne out by facts will appear from the following:—In British Guiana, for instance, cultivation, so far, is wholly confined to about a dozen or 15 miles along the sea coast; while the vast, rich lands of the interior are wholly untouched. In Trinidad, according to an official estimate, "less than one-tenth of its area is cultivated, and its resources are developed only to a small extent." Out of an estimated extent of 1,280,000 acres of splendid "cohune ridge" or alluvian virgin soil in British Honduras, according to a late return only some 10,000 acres, or less than one hundredth part, is, or has been, under cultivation. Coming to the older and more settled Colonies, as they have been for the most part under cultivation in sugar, lands on the lower slopes of the hills and in the plains only, have been chiefly worked. The bulk of the hill lands, most of which possess magnificent soil and a splendid climate, have been practically untouched. For instance, in Jamaica, on the northern slopes of the Blue Mountains, there are, at the present time, about 100,000 acres of land in virgin forest, richer and finer than any now cultivated, admirably adapted for the growth of tea, coffee, and cinchona. At lower elevations, in the central districts of the island, to the west, I estimate that above the range for sugar there are fully 200,000 acres suitable for the cultivation of oranges, cacao, spices, and most tropical produce. In the neighbourhood of Spanish Town, and within easy reach of railway facilities, the Rio Cobre irrigation works embrace an extent of country equal to about 50,000 acres, now mostly in pasture and ruinate, but admirably adapted for the cultivation of bananas, oranges, cacao, and spices.

In the lesser Antilles, to the west and south, similar circumstances are found, and indeed, throughout the West Indies you will hardly find a single island without plenty of unoccupied land suitable for the growth of either sugar, cacao, coffee, spices, tobacco, or coco-nuts. Barbadoes and possibly Antigua, are the only islands of any importance which have no hill lands still available for cultivation; but with regard to the former, as I have elsewhere remarked "the rich character of the soil in Barbadoes, and the successful results of the high culture it has received," may be gathered from the fact that, while the *Sugar Planter*, a paper devoted to the intereats of the sugar industry in Australia, gravely discusses the exhauation of canefields, the *Planters' Journal*, of Barbadoes, somewhat facetiously remarks that "the land of this island, even now, shows no sign of exhaustion, although it was converted into canefields within a measurable distance of Noah's flood" (laughter.)

In Dominica, the President, Mr. Eldridge, in the Blue Book Report for 1879, refers to the facilities for obtaining land in that beautiful island, "unsurpassed in Her Majesty's dominions for fertility." Large tracts of these lands, in the interior, belong to the Crown, and they can be purchased at an upset price of £1 per acre. Another official report states that "at least on-half the total area of Dominica is availa ble for agricultural purposes, amounting to about 96,000 acres. . . . At the present moment there is not a third of that extent under cultivation."

Coming further south, Grenada has a considerable area of mountain land available forcultivation; while at Tobago probably fully two-thirds of its area are still covered byvirgin forest.

This review, necessarily rapid and general, will at least show to what a small extent really, the rich and fertile lands of tho West Indies have been so far utilised. In British Guiana alone, there is an area of country equal to two Ceylons quite untouched; in British Honduras we have more than the total rea of the Fiji Islands; to Trinidad we could add the wealth of the Straits Settlements; and with the resources of the unworked soil of Jamaica we might emulate the prosperity of, at least, for colonies of the size of Mauritius.

Next to sugar, rum, and molasses, the most important articles of production in theWest Indies are cacao and coffee. Up to within a few years ago, these two articles were almost exclusively produced by Trinidad and Jamaica, each of which had a corresponding number of acres under cultivation and an equal gross value of exports. For instance, in Trinidad, 25,188 acres were returned under cocoa, yielding a gross export value of £270,906; while, in Jamaica, 22,853 acres were returned (in 1878) under coffee, yielding a gross export valu of £271,449. Latterly, however, Grenada has become a large cacao-producing colony, and it will shortly, no doubts approach Trinidad in the value and extent of its exports. The success of the cacao industry in this island is very remarkable and suggestive. In a comparative statement, published in the Blue Book Report for 1879, the staple products of Grenada are thus shown:—

	1848.	1878.
Sugar	6,071 hhds.	2,580 hhds
Cacao	3,995 bags.	24,394 bags.
Rum	2,156 phns.	113 phns.
Spices	nil.	50,800 lbs.

From this, it appears, that while "the cane cultivation is rapidly declining in Grenada, and less sugar is made from year to year," the cacao industry is being increased tenfold. By these means Grenada, which was once in a languishing condition, has become one of the most prosperous of the Windward Islands. Again, in Dominica cacao cultivation has been greatly extended, and the quality of the produce improved by fermentation and better curing.

In Jamaica, cacao cultivation, where once it wasa flourishing industry, is now being revived and extended in connection with the cultivation of bananas for the United States.

It is estimated that about 1,000 acres are in course of being planted with cacao in Jamaica, and some 80,000 plants of the best Trinidad and Caracas varieties have been distributed from the public gardens.

As bananas and cacao thrive in exactly similar situations, and under the same system of cultivation, the returns yielded by the bananas (which bear during the first fifteen or eighteen months after planting) are more than sufficient to cover the whole cost of planting the cacao. In other words, owing to the development of the fruit trade in Jamaica, a cacao estate can be successfully established, and its working expenses entirely cleared, by the profits on the sale of bananas. Planters seeing this, are utilising their banana plants as nurses for the cacao plants, and hence, when the bananas cease to bear, the cacao plants will remain as a permanent cultivation and a source of continued wealth to the proprietor. As mentioned lately in my official report, "where bananas obtain good prices, as in Jamaica, it is no exaggeration to say that a cacao estate can be established there under more favourable conditions than in any other British possession."

For several years, and indeed up to the close of 1879, cinchona cultivation had not been taken up by private planters. The number of plants grown by private enterprise in the whole island, to 1880, would probably not have exceeded 900 or 1,000 plants; that is, a number barely sufficient to cover an acre of land. Owing, however, to the favourable results of the sales of cinchona bark grown on the Government plantations during the last three years, and to the facilities afforded by Government in rising and distributing seeds and plants on a large scale, private enterprise has now been largely enlisted in the industry.

As indicating what has been done on the Government plantations, I may mention that up to a recent date they had cost including all pioneering and experimental work about £16,000. The returns on the sale of cinchona bark and cinchona seeds and plants have yielded a return of £12,000, whilst the plantations, as they now stand, have been valued by experienced planters from Ceylom at £20,000. In my report for the year ending September 30th. 1880, mentioned that the object of the Government in maintaining these plantations was not on account of the pecuniary returns likely to be yielded by them, but for the purpose of showing that cinchona barks of good quality could be successfully grown in Jamaica; and also, that cinchona planting, as an enterprise in private hands, possessed all the elements of a sound and remunerative industry. The sales of Jamaica-grown cinchona bark, during the last three years, having fully proved both these points, the Government plantations now naturally devote chief attention to the successful introduction and cultivation, on a small scale, of all the newer and richer kind of cinchonas, for the purpose of successfully establishing them in the island; and also to such necessary experimental and scientific work relating to the industry which, for lack of means or scientific knowledge, cannot be conveniently undertaken by private enterprise. As already mentioned, much remains to be done in this respect; and as the plantations as a whole do not contain more than about 180 acres, this will not allow, on an average, more than about five acres for each of the twenty-five or thirty species, varieties, and forms of cinchona bark now the subject of careful experiment and investigation on these plantations.

In order to test the commercial value of Jamaica-grown bark, no better plan could be followed than to send it in lots, to the open market, and place it in competition with barks from other countries. That it has so satisfactorily stood this test, and brought in a large return on the outlay and, moreover, that the results of the sales have induced cinchona planting to be undertaken in the island, by private enterprise with energy and success, are matters for which the Government, no less than the general public, are to be congratulated. Three years ago, the kinds of cinchona bark under cultivation in Jamaica were only three, viz., cinchona succirubra, cinchona officinalis, and the so-called cinchona calisaya, now proved to be identical with cinchona hybrid or robusta of Ceylon and India.

Since that time, numerous kinds have been introduced which are now the subject of careful experiment to determine the most favourable circumstances of soil, elevation, rainfall, and aspect, suitable for their successful cultivation, the best methods for harvesting the bark and inducing the largest formation of alkaloids, as well as determining the simplest and most economical methods for their general treatment and management.

Among the kinds of bark now under experimental cultivation at the Government plantations in Jamaica are:—

Red Barks—Cinchona succirubra; Cinchona succirubra, var. sub pubescens.

Crown Barks—Cinchona officinalis; Cinchona officinalis, var. uritusinga; Cinchona officinalis, var. Bomplandiana; Cinchona officinalis, var. crispa. Cinchona officinalis, magnifolia: Cinchona officinalis, pubescens.

Hybrid Bark—Cinchona hybrid or robusta.

Ledgeriana Bark—Cinchona ledgeriana.

Yellow Barks—Cinchona calisaya; Cinchona calisaya, vera; Cinchona calisaya, var. Josephiana; Cinchona calisaya var. Javanica; Cinchona calisaya, verde; Cinchona calisaya, morada form.

Grey Barks—Cinchona Peruviana; Cinchona nitida; Cinchona micrantha.

Carthagena Bark—Cinchona lancifolia.

Cuprea Bark—Remija pedunculata.

The cinchona industry of Jamaica, as indicated above, has now entered upon a practical phase, and plantations are being opened by private parties on a large scale. During the last two years the Government has sold twelve patents, or runs of high forest land, containing some 5,000 acres, under conditions which involve that at least one-sixth shall be planted with cinchona at the end of five years.

Besides this, some 2,000 acres—portions of the higher coffee estates suitable for cinchona cultivation—are being gradually opened by their proprietors; so that in a few years valuable and extensive cinchona plantations will be thoroughly established in the island.

These cinchona plantations in Jamaica will probably remain for many years the only successful cinchona plantations in the New World. No cinchona can be grown in any portion of the United States territory, which is entirely outside the tropics. In all the other British West India Islands there is no suitable land, as far as I am aware, possessing the requisite elevation, soil and climate for the successful cultivation of cinchona. It is very unlikely to thrive in either British Honduras or British Guiana, and although much has been written and said respecting the systematic cultivation of cinchona in its natural home in the South American states, I have entirely failed so far, although I have met many men who have travelled through those states interested in the subject, to hear of any plantation possessing say 100 acres systematically established with this valuable tree.

The cost of establishing cinchona plantations in Jamaica is estimated at £35 per acre, which includes the purchase of land and all expenses to up the end of the fourth year, when the first crop of bark may be taken. The total yield of the plantation (deducting cost of barking, curing and shipping expenses), up to the end of the ninth year, will probably be not less than £175 per acre, against a total outlay for plantation operations for that period of about £50 per acre. The estimated cost is based upon land at about 5s per acre, and creole labour at existing rates viz. men 1s to 1s 4½d per day, women 10½ to 1s per day. The estimate of return is based on an average of 2s per pound being obtained for the bark of all ages which is practically only one-half of that actually realised by Jamaica-grown bark during the last three years. In addition to the experimental cultivation and investigations respectin cinchona plants, attempt is being made to manufacture cinchona febrifuge in the island for the purpose placing this valuable but cheap preparation within reach of Her Majesty's subjects in the West Indies. This local utilisation of the Government cinchona plantation in Jamaica is one which has long been kept in view, and should cinchona febrifuge be successfully and economically manufactured there, the plantation will be able to render an additional service in supplying on the spot the means for combating sickness and disease, and effectually coping with the scourages of fever which occasionally visit it. "This object, among others has, I believe, been always in contemplation by the Home Government in encouraging cinchona planting in the colonies; and it is an aim so noble and benevolent that it deserves the sympathy and support of all concerned." For, as one writer has well expressed it, "To England, with her numerous and extensive colonial possessions, cinchona bark is simply priceless: and it is not too much to say that if portions of her tropical empire are upheld by the bayonet, the arm that wields the weapon would be nerveless but for cinchona bark and its active principles." (Cheers).

Up to a recent date British Honduras was merely a settlement for the purpose of cutting logwood and mahogany, and it was not until 1862 that it was raised to the dignity and importance of a British Colony.

Speaking of the want of accurate scientific knowledge of the natural resources and capabilities of British Honduras, the *Colonial Guardian*, published at Belize, recently remarked:—"We have for a sufficiently long period lived without a knowledge of the capabilities of about three-fourths, and in total ignorance of even the physical configuration of more than one-half of the colony. We have been willing quietly to allow, without a contradictory murmur, the climate and soil of British Honduras to be slandered, until the civilized world has come to look on her as a vast pestiferous swamp, unworthy the habitation of civilized man. So long as mahogany was plentiful and brought good prices, little did the more wealthy colonists reck whether this continuous slandering of her soil barred the way to colonization. But fortunately mahogany is failing, and dire necessity is driving them to think of agriculture and its only hope of developement—immigration, as the true foundation of her progress. But the long lethargy has borne evil fruits, and British Honduras is only thought of in Europe as another Europeans' grave not dissimilar to the pestilential coast of Western Africa. To disabuse the world of this erroneous opinion will be no easy task, unless we can lay before it substantial proofs of our statements."

British Honduras contains an area of 7,562 square miles that is, more than four times the size of Trinidad, nearly twice the size of Jamaica, and almost equal to that of the British West India Islands proper put together. A large portion of the country is practically unknown, but excluding the low swampy ground on the bays and some portions of the coast, and allowing a large proportion of the interior rocky country as being unfit for cultivation, there remains extensive areas of magnificent virgin soils in British Honduras, equal, if not superior, to anything else in the West Indies. British Honduras has a seaboard of about 250 miles, stretching from the River Hondu on the north, abutting on Yucatan and Mexico, to the River Sarstoon on the south, bordering on the Republic of Guatemala. In general, the land rises from the sea-coast, in a gentle slope towards the west intersected by numerous deep and navigable rivers, until it meets, on the frontier line, the dividing mountain zone of Central America.

Many other interesting plants of timber and dye woods, as well as of plants of medicinal and economic value, were met, many of which I have considered are capable of being utilised both in British Honduras and in other British possessions.

For experienced planters, who have already lived in tropical countries, and especially in the East, British Honduras offers inducements superior, I believe, to those of most British Colonies. There are thousands of acres of magnificent land offered by the Government at an upset price of a dollar an acre, capable of growing nearly every tropical product. Some of those lands are either near the banks of rivers, with easy communication with the coast, or on the coast itself. There is an abundant market for bananas, plantains, cocoa-nuts, oranges, pine-apples, and all tropical fruits in demand in America, and regular direct communication, by means of mail and other steamers, with both England and the States. For the cultivation of sugar-cane, coffee, tea, cacao, spices, tobacco, vanilla, and rice, British Honduras offers special advantages. The chief drawbacks to the advancement of the Colony are:—(1.)—The scarcity and somewhat precarious nature of the labour supply, and (2)—the want of cheap and effective communication with the rich back lands of the interior. The first of these drawbacks, may in a great measure be overcome by the establishment of an effective system of cooly immigration, similar to that in force in Demerara. Trinidad, Jamaica, and more recently in Grenada. Coolies might be obtained from India at the rate of £15 per head, of which the repayment would be spread over the five years during which the engagements lasts. During this time, the wages would be fixed at the rate of 1s per diem, all things included. For light field work in the tropics the cooly is an invaluable worker. Demerara and Trinidad, without coolies, would never have attained to their present prosperous condition; and what has been done in these Colonies with coolies may likewise be done in British Honduras, which, from the richness of its natural resources, would eventually become one of the most prosperous British possessions in the West Indies. For reaching the fine rich virgin lands on the upper portions of the Sibun and Belize rivers, as well as those previously described in the South, a system of cheap and light railways might be constructed at a cost not exceeding £100,000.

Sir A. MUSGRAVE.—I have been requested to open the discussion which usually follows on these occasions, and I very willingly do so by expressing my belief that this meeting will be much indebted to Mr. Morris for his able and instructive paper which he has read; it is another of those debts we owe to him for the great interest he takes in the welfare of the West Indies, especially Jamaica. I am, myself, peculiarly interested in this question, and it is a subject which many have not looked at in the right way, and these West Indian Islands, I fear, have fallen somewhat into disrepute and not met with the respect which they deserve, and I think there has been some want of lucidity. Respecting the most important there has been misapprehension, which I think Mr. Morris's paper will do a good deal to clear up by calling people's attention to the *real* facts. I know it is very commonly supposed that Jamaica has been in a great state of decadence; everything has been going to the bad, and altogether it is going downhill as fast as ever it can. In the last years 1881-82 the colony of Jamaica has sent away the largest crop of sugar and rum, making allowances for what is known to be the difference in the size of the packages now, and this last year, fruit has been exported to the value of £138,000, and the trade was in its infancy a few years ago. Coffee is also holding its ground, and some of the Jamaica coffee is considered the finest in the world. Cocoa has been largely increasing. Cinchona cultivation is being largely undertaken by some of the residents, and will prove to be very lucrative. I think I am within bounds in saying it has reached to 2,000 lb per acre in Java, and some plants and trees in Jamaica a few years ago were almost overlooked, and when the trees matured twelve years after, they gave a splendid yield. I say that any colony that presents these facts cannot be regarded as in a state of decadence. Touching the labour question there are these facts:— The railway contractors are hard at work. I was on the lines three days before I left Jamaica six week ago, and the contractors assured me they had 5,000 persons at work and they were giving the ordinary wages; within the last eighteen months or two years nearly 900 of the labourers have gone away to the Panama canal. The largest crop, as I just now said, was reaped and exported, and during that time there were no complaints of want of labour. If time is only given, that large proportion which cannot be used for sugar labour will be used for other industries. The total population of Jamaica is 580,000, and fully 500,000 are labourers and the sugar estates cannot employ more than five per cent. The population is increasing at the rate of 7,000 a year. The question is, not to find labour for the coffee or cinchona and other industries, of which I am a cultivator myself, but I really think the true difficulty in the future is that the labourer will refuse to work on the same conditions as before. The emigration at present is 6,000, and these, I believe, will return with improved notions of the labour question.

Sir F. BARLEE:—I can quite endorse what Sir A. Musgrave has told us. I think, I can only say I am one of the very few people who can speak with good authority on that small slice of Central America which has been alluded to this evening, British Honduras, having administered the Government of that Colony for the past 6 years, it may naturally be expected that I know something about it. Before I was aware Mr. Morris was going to read a paper on the West Indies, I had placed in my hands a few rough notes on his visit to British Honduras. He alluded to the circumstances of a lethargy hanging over that colony; I may say that I found it out to my cost. The timber trade, which was the main trade of the colony, was in a state of stagnation. No new means or no active means were adopted to get the timber out, only by bullocks and large gangs of men, and the heat was so intense the timber had to be brought out at night time to the ships. I am glad attention has been called to what good really can be done in the colony, and surveys are being made at the present time for railways to run up to the timber forests. When in the colony I did persuade some people to open up new industries, and I hope I shall induce others to do the same. I wish I had been in the colony at the time Mr. Morris visited it: I should have had great pleasure in travelling with him through it. His opinion comes with great weight, and I am sure he has not exaggerated the state of the industries and the successes that have been achieved there. Another question raised by Mr. Morris was that of labour. Here I cannot quite agree with him. I don't think any difficulty will be experienced in getting labour in British Honduras; there is a large amount of labour that can come from St. Thomas where there are a large number of people ready to migrate to British Honduras and get good wages, and I am sure those who will take trouble to invest judiciously in the colony will find it yield them a handsome return. I can only add that I believe Mr. Morris's remarks will be read with great interest, not only in England, but in the United States of America and other countries.

Mr. J. OHLSON, Secretary of the West India Committee, then made some excellent practical remarks upon points raised in the paper, and we regret that pressure on our space compels us to hold these over till our next issue. He dealt chiefly with the labour question, advocating a regular system of coolie immigration from Jamaica, and remarking that in spite of what had been said to the contrary he had heard of difficulty in procuring labour for cinchona planting in that colony, though wages were paid at the rate of 4s. per day. He also suggested that Mr. Morris should, upon his return to the West Indies, prepare a memorandum of unoccupied lands and the various products for which he considered them suitable, together with particulars of the terms on which the Government would sell them. He added that if this document were deposited in some central place in London where it would be easily accessible capitalists would have an opportunity of studying it and might be induced thereby to invest.

Sir HY. BARKLY.—As a former Governor of two of the principal colonies mentioned by Mr. Morris I have listened with the greatest pleasure to the admirable sketch which he has given in his paper of the comercial positition and agricultural condition of our West Indian colonies, and I was particularly struck with the remarks on what was termed in my day the "minor products," but what are of very considerable importance, and likely to tread at no distant date on the heels of the rum and sugar trade. I was much interested in the remarks on cinchona, it is a question of the greatest importance. According to the old adage, gratitude is due to every one who causes two blades of grass to grow where only one has grown before, and therefore great praise is due to those who are opening up *new* industries like cinchona planting in the West Indies.

Mr. DYER:—With regard to the question of small products, I think that they ought not to be thought so slightly of as they sometimes are. I will make a few remarks as to these.

Dr. KIRK, of Zanzibar, discovered several important things in the West Indies, and developed the India-rubber trade to a great extent. Turn to the Ceylon statistics as compared with those of Jamaica. In Ceylon you have an island entirely dependent upon what you call small products. Cinchona planting has greatly extended, and all kinds of industries are resorted to, such as cardamoms, jalap, and other things a Ceylon planter is only too anxious to grow. The Ceylon planters having been obliged to grow Liberian coffee, which does not suit the taste of the market as well as the old Arabian coffee does, they are trying it in the United States, and why not! It is their bounden duty to make the best returns they can upon what they produce and so contribute to the welfare of the empire.

Mr. LEVY:—As a native of Jamaica, and practically interested in Jamaica planting and also some of the minor industries, I venture to say how much I appreciate Mr. Morris's paper. I think it will do Jamaica a great deal of good when we get statements put forward to the English public such as he has put before you. There are varied opinions as to the labour question in Jamaica as to our prosperity generally, but as regards sugar planting I have only come forward because I feel interested in the prosperity of Jamaica. I am a large landowner, and I say in the most unqualified way, that a small amount of capital, a matter of between £5,000 and £6,000, wisely and intelligently applied in Jamaica will, I am sure, reap better results than the same amount of money laid out in those eastern portions of the world to which Mr. Morris referred. The agricultural resources of Jamaica possess very great advantages, and are worthy the attention of any man who has money and intelligence and is willing to do his best. Personally I shall be only too glad to afford any facilities to any gentleman who think it desirable to go out to Jamaica.

Sir A. MUSGRAVE: We must now thank Mr. Morris for his extremely well-written paper, and I hope what he has read tonight will be of prominent advantage to us.

Mr. MORRIS: I am much obliged for the remarks made upon my paper, and I am most willing and happy to give any advice or information I can concerning our West Indian possessions. I have no interest to serve with regard to them except to do the duty laid before me, and to place all the circumstances before the people and improve the industry of the country. In drawing up my paper I tried to be impartial on every question. I visited the sugar plantations and did all I could to help them, and their industry I hope will always be the staple trade of the West Indies. As to the remark made about the negroes cutting down the forests and then squatting on them, I think it is much exaggerated. Respecting labour and cinchona cultivation in Jamaica, I don't think there is much difficulty. They pay 4s a day for negroes to fell the forest. Mr. Marshall went into the backwoods, but as he depended upon agents, I think he did not get the labourers he wanted. He found it a much better plan to pay them 's a chain. I say by all means let sugar plantations flourish; if planters apply for coolie labor they can get them. For two years no coolies were applied for in Jamaica, but there is an institution in Jamaica that will supply more coolies than British Guiana can supply. I am extremely obliged for the kind way you have all received my paper, and I thank you heartily for your kind reception.

THE QUANTITY OF TEA PER ACRE IN DARJILING is probably fairly represented in the latest report of the Darjiling Tea Company (Limited) The figures for five years ranged from 318 lb per acre to 369, so that the average is about 350 lb. Now, if estates between 3,000 and 5,000 feet altitude give 350 lb. per acre in 27° north there will be nothing wonderful in an an average of 500 lb. per acre at similar altitudes in Ceylon but 20° nearer to the equator and with the always more genial climate of an island.

TEA.—Recent telegrams announce that the Melbourne agents of the Tea Syndicate sold 3 500 packages at a penny of an advance. The New York agents report the sale of 1,256 packages of Syndicate teas at the equivalent of 7d to 2s 1d : average, 1s. The first sales of new season's tea were held on 31st May, when 4,173 packages were sold. The majority were Darjeeling teas, but a few arrivals from Assam and Cachar were also included. The prices compared with those, at the commencement of last season, were decidedly higher, showing an advance in the common grades, say teas ranging up to 10 annas, of from 1 to 1½ anna per lb, while on finer teas the rise may be given as quite 2 annas. The quality generally was superior to that of the first arrivals of last year. Competition was well maintained throughout, but more especially for the better class teas.—*Indigo Planters' Gazette.*

FOR FENCE POSTS.—A writer in an exchange says: "I discovered many years ago that wood could be made to last longer than iron in the ground, but thought the process so simple that it was not well to make a stir about it. I would as soon have poplar, basswood or ash as any other kind of timber for fence posts. I have taken out basswood posts after having been set seven years that were as should when taken out as when first put in the ground. Time and weather seemed to have no effect on them. The posts can be prepared for less than two cents apiece. This is the recipe: Take boiled linseed oil and stir in pulverised coal to the consistency of paint. Put a coat of this over the timber, and there is not a man that will live to see it rot."—*Scientific American.*

SUB-TROPICAL AUSTRLAIA.—The Minister for Education, South Australia, recently visited the sugar district of Mackay, and after visiting several of the best plantations, he was highly pleased with the mode of working sugar estates. He will no doubt carry away with him practical ideas for the benefit of planters in the Northern Territory, where the sugar industry is rapidly extending. Mr. Parsons received a loyal civic welcome, supported by a banquet in the Prince of Wales' Hotel, the spread being in Mr. Macpherson's best and pleasing style. Both Mr. Parsons and Mr. Hume Black, M. L. A., delivered able speeches condemning Cinghalese labour, but advocating cheap labour, and indulged in complimentary sentiments respecting the prosperity of the industry in South Australia and Queensland. The Mayor, Mr. T. Pearce, presided on the occasion.—*The Sugar Planter.*

THE MAURITIUS HEMP ESTATES COMPANY is thus reported on in the *Commercial Gazette*:—

The President laid on the table the balance sheet for the year ended December 1883, which was taken as read. He then read the Director's report and from these two papers, it appears that the expenses amounted to R39,808.17 and the receipts to R36 329.90, leaving a balance of R3 478 27 to the debit of the Company, a result which is not unfavourable when the difficulties which the Company had to deal with are considered. These difficulties are: the cost of the formation of the society, the payment of a new boiler and the unusual competition for securing fields of aloes, and sold to others at prices which it was not wise to pay. Besides the fibres unsold are accounted at the low price of £28 per ton whilst the London market price was improving. For the present year, the aloes fields bought by others last year, have been secured at suitable prices; and there are besides about 700 acres of aloe to be cut and a plot of ground of 100 acres covered with aloes and fire-wood adjoining the estate, has been purchased.

LIME-JUICE IN TREATMENT OF DIPHTHERIA.—M. Czartoryski, M. D., of Stockton, California, writes as follows to the London *Lancet*:—"During a prolonged residence in the interior of China, I became acquainted with the fact that the Chinese place great reliance during epidemics of diphtheria on the internal use of the fresh juice of limes, and of the fruit itself, which they consume in enormous quantities, in every conceivable from—as lemonade, with native spirits cut in slices, etc.—during attacks of this dreadful disease, with apparently most successful results, it hardly ever failing to effect a cure. The Chinese consider it a specific, and will, in case of need, do anything to obtain a supply. Since I have come back to California, as also in Louisana, I have used limes and their juices in my practice as a physician with most successful results in cases of diphtheria, even in the most desperate cases. As soon as I take charge of a case of diphtheria, I order limes to be administered as freely as possible, in any manner the patient can be prevailed upon to take them, especially in the form of hot lemonade, sweetened with white sugar or honey, or cut in slices with powdered white sugar. Besides lime-juice (which I suppose acts by imparting an excess of oxygen to the circulation, and thereby prevents formation of vibriones, etc., and so has almost a specific effect on disease), I prescribe whatever drug may be indicated to relieve symptoms as they develop, and impart strength by appropriate stimulants and nourishment.—*Southern Planter.*

SUGAR: MR. VINCENT'S ROSEWOOD SCHEME.

If it be true—and we are assured it is true—that the Rosewood canes have withstood the effects of frost for several winters, then a Central Mill, if managed with experience and economy, should become an undoubted success. But the farmers must not expect 30s for the ton of cane, a price which is both visionary and utopian. If the farmers get 12s per ton for their cane they will become rich in a year or two, and drive to market or church in hooded buggies or fours-in-hand. The Rosewood Scrub soil should grow 35 tons of cane to the acre, which, at 12s per ton, would give the grower a return of £21 per acre; and, if he cultivated 50 acres of cane, the annual return would amount to £1,050. The expectation of farmers making 30s per ton from 10 deg. density cane is hopeless. Evidently, Mr. Vincent or the reporters have made a mistake. Farmers, by selling their cane to the mill or refinery will not require to procure crushing mills as the growers do on the Mary and Burnett rivers. The sucrate of lime process would be the best for the Rosewood Scrub, as it would save much carting and manual labour. The Central Refinery should have a complete plant, and the Company be prepared to purchase either the cane or juice, according to the distance and position of certain farms from the mill. It would not cost a Company much to erect powerful rollers for the greater extraction of juice, or to apply pipes for conveying the juice from the farm to the millhouse.—*The Sugar Planter.*

SUGAR: CENTRAL MILLS.

It is a well known fact that central mills or sugar factories have conferred great blessings upon the small sugar-growers of Cuba, Florida and Louisiana, the French and British West Indian Islands. With the increase of population in developed countries, the increase of labour must be provided somehow or other. In sugar growing countries a large percentage of the agricultural population are now actively employed in growing sugarcane for powerful sugar mills placed in their very midst. Before the erection of such mills and the initiation of the central mill system the people had to be contented with working upon large estates. As the love of liberty and independence advanced, the lands of the large planters were let to cultivators (men who had worked for scanty wages), who succeeded in growing heavier crops and introducing a higher style of cultivation. The tenant or small freeholder devoted more care and took a greater interest in his daily avocation. The profits derived from the sale of his cane or juice to the central mill enabled the small grower to live better and acquire a larger income. The Martinique French Companies were formed to erect sugar mills of great capacity and great economical manufacturing power, as it is a truism in sugar manufacture that "the larger the crushing machinery and manufacturing power of the mill, the greater is the production of sugar from a given weight of cane." All over the French West Indian Isles the results of the central mill system has shown that more cane has been grown per acre, and more sugar has been made from a ton of cane. The division of labour and industry in this respect has produced an increase of wealth, and a wonderful amount of human happiness, comfort and content. Central mills aim to be the poor farmer's friend and the lover that lifts him along the road to industrial prosperity.—*The Maryborough (N. S. W. C.) Sugar Planter.* [The system, as we saw it in operation to some extent, in the Mackay district of Queensland, enabled white settlers of small capital to cultivate their own or rented land with sugarcane, selling the produce, about 30 tons per acre, to the owners of mills at 11s per ton, standing in the field, the purchaser cutting and carting away. In this way, all the cane might possibly be grown by Europeans, but black labour to some extent will always be necessary for cutting cane and could see the succeeding article.—ED. C. O.]

PRUNING ORANGE TREES.

Citrus seedling trees are subject to certain general laws of growth, common to all others. All seedlings have a tendency to produce a superabundance of useless spurs and branches; look at seedling pears, plums, cherrys, etc. They are all subject to the tendency I refer to. The seedling orange is no exception to that law of growth. Then to produce the best results in cultivating it: The tree should be well shortened in and thinned out each season. I believe that every tree should bear its own burden; hence when I pass an orange orchard and see a forest of poles helping to sustain its crops, I have no trouble in coming to the conclusion that the owner is ignorant of the best mode of orange management. I have long since learned the fact that a properly pruned tree requires no crops around it whatever.

Some advise never to touch a seedling or other orange, till it commences to bear fruit. I recommend instead, never to be afraid to prune off any branches which tend to destroy the symmetry or balance of the tree, no matter at what age you have to apply the knife.

There are two methods of managing the orange tree in California, either of which appears to be attended with good results. Ond is to let the branches grow near the ground to cover the trunk of the tree, and spade round it, and mulch with manure. The other and easiest method is to prune up the tree from 4 to 5 feet, so as to allow cultivation near it. The bulk of orange culturists have neither the time nor inclination to spade around their orange trees. Hence, it is necessary to prune up the tree about 4½ feet high from the ground, with one stem or trunk only.

As oranges usually grow on the terminal branches of the tree, in order to prevent them from breaking it down, or being blown off by wind-storms, it is important to head the trees in at the sides and top each season, so as to produce short stiff branches instead of long swaying arm, ready to dash the oranges about with every breeze that blows. Having pruned up and shortened in your trees as directed, it is a very easy matter to finish the necessary trimming out, and in this as in all other horticultural operations, one must be guided by circumstances: for instance, if the tree is a seedling of dense foliage, nearly one-half of the branches can be thinned out, at the first general pruning, in subsequent prunings, less will be necessary, which would greatly improve the size and market value of the orange crop; while on the other hand, if the orange tree from over bearing or any other cause has an open top and scanty covering of foliage, a simple shortening in of the branches would be all that is necessary.

To thin out the orange tree, one must commence in the middle inside, and begin by first examining the larger branches and see that none of these are crowding against each other; in that case have no hesitancy about lopping one of them off—cutting the one which is less necessary to form the future head of the tree. After having your larger branches standing at proper distances apart, continue the pruning amongst the branches, working your way out towards sunlight. I believe in opening vistas as it were, so as to let the sun at some time of the day to pay a visit to the interior of the tree. His influence in that case would do more to destroy scale bugs and other pests, than thousands of carneverous insects would. By opening the branches to let in a moderate amount of sunlight, you take away the shelter which protects the insect in its young and tender stages of existence.

THE BEST TIME TO PRUNE THE ORANGE.

If the tree is young and is not bearing fruit, any time during the winter months will do equally well. When the tree is in fruit and bearing, the usual and best time to prune it, is just after it commences to put forth its blossoms in the spring. In all cases when you have to lop off large branches, be sure to cover over the surface of the wound with grafting wax.

Following these simple directions, the way to produce the best results in cultivating the orange is so plain, that a wayfaring man, though a fool, need not err therein.—*Rural Californian.*

SUGAR IN THE LOWER BURDEKIN, QUEENSLNAD.

This sugarcane growing delta continues to assume great importance. The progress of the district since Mr. M'Millan and Mr. Mackenzie broke ground has simply been marvellous. Hard work has prevented me from writing you for some time, but I hope to be more regular in future. I purpose noting down a few items of news as they arise. The Ardmillan factory is rapidly being finished, and after Aguust will crush 800 acres of cane, exclusive of 250 acres for Mr. James Mackenzie, who has a 1,000-ton mill ordered. Mr. Spiller and Messrs. Young Bros. have each ordered 2,000-ton plants, and will be placed in position by 1884. People here are looking forward with interest to the opening of the Ardmillan mill. It will be a red-letter day for the Burdekin. I hope the *Sugar Planter* will be ably represented on that occasion. You should come yourself, knowing, as I do, your ardent spirit in advancing colonial sugar in ... sts, and I know you will have something extra to report upon. The cane-fields are looking well, but recent weather has been thoroughly planter's weather. Seaforth promises to be a compact and easily worked estate, and everybody wishes Mr. Mackenzie every success. Mr. M'Millan does not seem knocked up with his long spell of laborious and anxious work. Messrs. Young Bros., Calamia plantation, have pushed forward the work of estate forming with energy and success. The traction engines and steam ploughs (of Messrs. Fowler & Co., of Leeds), were not long in preparing a large cultivation area for cane. This estate is well managed and the young canes look magnificent. Mr. Colin Munro's plantation is also worthy of notice, as he has a splendid show of good cane, and labour done. Mr. Holland has cleared a large portion of heavy land, and ploughing will shortly begin. The Pioneer estate is rapidly developing itself into as large a plantation as Ardmillan. Mr. Masterton has exhibited good management, and has successfully carried out the experienced ideas of that veteran sugar-planter, Mr. Spiller, of Mackay. Six months cane have shown a height of six feet. A look at Ardmillan and the Pioneer, and the other Burdekin plantations throws strangers into dreamland. But the gigantic progress of the delta is a reality and no dream. There is not a lazy or inexperienced man on the Burdekin. A few more months and the Government will be compelled to give us a railway. Mr. Morey, P. M. and P. I., lately visited the plantations, when about 200 islanders were paid their wages before him; and with the exception of four boys ill with the "syphilitic," he found the kanakas all healthy. He found many whites, Chinese and Polynesians employed on the Burdekin, and the cry everywhere is "give us more." Last year from 66 to 70 inches of rain fell in this district, which is not so dry after all. In a quite ride round the plantations, I observed that Dr. Ahearne's plantation was remarkably well advanced, as well as the fine estates of Harris, and Wilson Bros. The eighteen months old canes are very healthy and heavy, and the nursery canes upon the recently-formed estates are most promising. Mr. M'Millan is experimenting with 200 acres of cane upon the irrigation system. Mr. Lionarons, who is an expert in tropical agriculture, is anxious to try a cocoa crop, whilst other planters are confident that rice and Indian gram would thrive successfully. But we need not be afraid of fodder, as a good couch grass is supplanting the original tall and tough grasses of the plain. Ayr will become a pretty township, as it is nicely situated on the Lillesmere lagoons. The township of Brandon also shows marked signs of future prosperity. Already stores, hotels and other buildings are springing up in the rival townships. Barratta Creek will always be a fair port, as, in fact, it now is. Plantation Creek will always be a port for a number of selectors and plantations.—*The Sugar Planter.* [Having visited the splendid delta of the Burdekin in its earliest, in company with Mr. Jeffray of Sloane & Co. (a firm well-known all over the colonies and largely interested in sugar), Mr. M'Millan, formerly a Government Engineer, and Mr. Graham of Lillesmere, who amongst them own 20,000 acres of sugar land, we are glad to learn of progress made. Mr. Mackenzie, who has named his place Seaforth, because he is descended from that family, was formerly a coffee planter in Coorg. "Calamia," owes its name to the reeds which abound. If science, energy and hard work can command success, then Mr. M'Millan will command success.—ED.]

THE EFFECT OF ALTITUDE ON THE ALKALOID OF RED BARK

From the *Pharmaceutical Journal*, June 9.

By J. E. HOWARD, F.R.S.

I beg to forward the enclosed published communication from Dr. Trimen, which will interest many of your readers and sustain the character of your journal as the best repertory of information on the important subjects of which it treats.

It gives me pleasure to see that "the relationship of the alkaloids" is brought under notice in Dr. Trimen's letter. It is long since I worked at this in conjunction with Dr. Herapath, and much of the information then published is probably forgotten; and much that was inferred relative to the manner in which the molecules appear to be built up in nature (bearing on the possibility or otherwise of the artificial productian of quinine) remains for further investigation. I can only remark, at present, on the universality of the relationships thus disclosed by the ray of polarized light,

The relationship is this:—

Lævogyrate.	*Dextrogyrate.*	*Feebly Dextrogyrate*
Quinine.	Quinidine.	Quinicine.
Cinchonidine.	Cinchonine.	Cinchonicine.

Dr. Herapath, in his "Researches in the Cinchona Alkaloids" ('Proceedings of the Royal Society,' November, 1857), attempted to demonstrate this relationship on chemical grounds; and even thought that quinine and cinchonidine might be mutually convertible. He observes that "closely as the quinine and cinchonidine salts agree amongst themselves, they differ widely from the quinidine and cinchonine compounds."

In order to confirm the interesting experiments instituted by Dr. Trimen, I selected specimens given me by Dr. Morris, Jamaica, of red bark grown under somewhat similar differences of altitude; that from the lower elevation having (as in India) the best appearance; that from the higher the richer produce. I shall send portions of these to the Museum.

The bark from which the second sample was taken proceeded from trees grown in the parish of Manchester at an elevation of about 2,400 feet. This is the lowest elevation at which cinchona bark trees have been cultivated in Jamaica. The trees were between eight and nine years old, growing in a sheltered situation and on a good strong red soil; the mean annual rainfall about 90 inches, and the mean annual temperature about 73° F.

As the elevation is intermediate, so the alkaloids hold a consistently intermediate position between the two samples of Ceylon bark, perhaps with a slight exception as to the amorphous alkaloid. It the circumstances of growth in other respects had been the same as in India, it is probable that the amount of quinine in the Jamaica sample of 6,000 feet would have increased at the expense of the amorphous alkaloid. As it is, the Jamaica bark at this elevation scarcely equals expectations, although the botanical samples are very true to type.

Analysis of samples of *Cinchona succirubra*, sent by Drs. Trimen and Morris, at different elevations:—

Elevatin above sea level.	Place of growth.	Quinine.	Cinchonidine.	Cinchonine.	Quinidine.	Amorphous.	Total. alkaloids.
A. 5500 ft.	Hakgala	2·06	3·47	0.61	Trcs.	0·66	6·80
5500 to 6000	Jamaica	1·76	3·17	0·75		0·75	6·43
2400	Do	1·50	0·86	3·06	0·06	1·13	6·61
B. 1500 ft.	Pr'dniya.	0·47	0·05	1·67	0·30	1·06	3·55

The *succirubra* is, however, the wrong sort to cultivate, and (except only as regards the bark *renewed* in McIvor's method) will always be found disappointing. The *shaving* process is incomplete. It is requisite that the bark should be stripped in the wet line of the cambium. The tree then begins *de novo*. An exudation is thrown out from the peeled surface, "like the perspiration from the back of the hand," as McIvor described it to me. The formation is then *radial*, and not concentric (see fig. 5 and 6 of Plate III. of my 'Quinology'), with abundance of cellular tissue and a consequent complete change in the alkaloids. I have objected to the *succirubra* from an early stage in the culture, but opposite counsels prevailed. The prices obtained of very inferior bark now sent home may perhaps show the planters that it would have been more to their interest to cultivate the better sorts—the *Patta de Gallinazo* introduced together with the *succirubra* by Cross, the *magnifolia* (Ritusinga?), the *robusta*,—known to them but neglected till lately. I have just received an account of the 1882 harvest of bark in Java, from which I learn that 763 bales of all sorts of succirubra bark gave on an average of 28 analyses 1·04 per cent of quinine; but of this two lots were of "*renewed*" bark, respectively 2·2 and 2·4 per cent. and, deducting these, the percentage falls to 0·9 of quinine. This culture can hardly be profitable for quinine manufacture,* nor yet for pharmaceutical purposes, as I have shewn first in my 'Quinologia,' 1862, and many times since, that the "red bark" contains a *distinctly noxious ingredient* not found in the barks better adapted for medicinal use.

The tests of the inferior Calisaya, Schukraft, Javanica and Anglica, are about 1 per cent of quinine. Surely this cannot pay *at present*; but, even if it does, how will such plantations compete in future with the immense cultivation commencing elsewhere. Of course, in Java the redeeming feature is the *Ledgeriana*; the *officinalis* seems also to promise well.

The result of these trials seems to prove that elevation above the sea-level is far more important than all the other factors in the problem, but why this should be so, I confess I do not see. The true home of the cinchona is in the clouds; direct scorching sunlight is fatal.

I am at this moment observing with interest the effect of light on some cinchonas. In the early part of last year I sowed, almost at the same time, seed of the true *Ledgeriana* from the Yarrow estate in Ceylon, derived from trees yielding from 7 to 12 per cent of quinine, and also seed kindly given me by Mr. Christy, from Bolivia, of the best kinds there cultivated. I watched with interest the development of the young plants, which for a considerable time entirely resembled each other—only that I found the *Ledgeriana* the more sensitive to surrounding influences. After some months' growth the Bolivian seed began to develop the characteristics of the *verde*, *morada* and the *rubra venada* of Bolivia; whilst the *Ledgeriana* showed features of difference, though at the same time of close affinity. This was shown, amongst other things, by the rich velvety surface of the leaf, marking the best Calisayas,† as also by a delicate fringe of hair at the edges of the leaves. But now that the more flourishing plants are some ten inches in height (the *rubra venada*, twenty), further diversities appear. The leaves of the *Ledgeriana* turn *red* in fading, which is said by Mr. Ledger to be characteristic of his "rojo" (*roxo*) at the flowering season, from whence it derives its name "*red*."

They are more delicately formed than the others I have named, and more easily damaged by direct sunlight. As night approaches the top leaves gradually change their position, approaching each other so as in some cases almost to fold together. This is well shown in a fine plant of true *Ledgeriana* which I have from Darjeeling, and also in the more flourishing of my plants from Ceylon. I do not notice the same in the *verde* from Mr. Christy's Bolivian seed, of which the leaves are more robust, but the above features are not *confined* to the "rojo."

These peculiarities would scarcely be seen unless the plants were well developed under glass, but once observed it is impossible to forget or to confuse these rich varieties of Calisayas which I described and figured as such from well ascertained specimens sent by M. Moens, with the plant described and figured by Dr. Trimen as "*C. Ledgeriana*, Moens," and which I should call *C. micrantha*, var. *Calisayoides*. Dr Trimen had not the opportunity of comparing the plates drawn by Fitch, in my "Quinology," with those in the *Journal of Botany*; but the distinction is most evident, as I have endeavoured to demonstrate to the Linnean Society. My figures of *C. Calisaya*, var. *Ledgeriana*, are from trees yielding respectively Pl. IV. 9·06, (Pl. V.) 9·90, and (Pl. VI.) 9·97 per cent of quinine and the fruit-bearing branch 10·90 (same plate). See the account of my herbarium, pp. 58-66. [But see also letters to *Observer* of Mr. T. N. Christie and Mr. Agar, shewing that the plant figured by Dr. Trimen was true Ledgeriana.—ED.]

The "rojo" (*roxo*), or *C. Calisaya*, var. *Ledgeriana*, is the queen of all the cinchonas; but certainly posses a delicate organization which makes the cultivation difficult. The "verde," as being a quick-growing tree, flourishing at lower elevation, is found in Bolivia more profitable to cultivate than the "morada," although the latter is richer in percentage of quinine. I do not think that the *Ledgeriana* is cultivated in Bolivia, but another sort of "rojo" is extensively planted in Coroico, in the Yungas of Bolivia "This is not so good as the Caupolicon rojo." It is the *Colorada naranjada*, or *orange peel red*, only known to me by the bark, which has a character peculiarly its own. The bark of the *Ledgeriana* is most characteristic. It is thick and composed almost entirely of cellular tissue; quite contrasted with that of the "verde," which bears the stamp of more vigorous growth and has a more fibrous structure and less alkaloid. This last has for many years been familiar to me in importation from South America.

But I must defer for the present any further remarks. From a letter from Mr. Ledger, February 7, 1881:—"I repeatedly used to joke poor Manuel when he used at first to tell me the trees from which the thick, heavy slabs of bark (in fact the *Rojo*) came from hard white flowers. The *Rojo* from Coroico and South Yungas, though with purple red leaves underside [the *morada*], are nothing to be compared with the *Rojo* of Caupolican and Apolobamba. The *Rojo* or *Ledgeriana* is very little known in Bolivia even. According to Manuel, this tree is never met with in *Manchas* (patches) like the other classes of cinchona. It is found by itself here and there. With all cascarilleros from Pelechuco a '*slab*' of *Calisaya rojo* means *uno repassado*, and is meant to say, where that is, all the rest is good or Calisaya." [Then follows Dr. Trimen's letter as given on page 864 (Vol. II. of this periodical.)

---

* See the Blue Book of Indian Government (June 18, 1866 p. 134), in which, after analysis of the first parcels sent home, I observed the great preponderance of cinchonidine, and notified to the Indian Government, "This difficulty must be looked steadily in the face, and I would suggest that it may be obviated, either by a change being wrought in the opinion of tha medical world as to the value of cinchonidine as a medicine, or by the plant being encouraged to produce quinine instead of cinchonidine." This latter, Mr. McIvor afterwards succeeded in effecting by his renewing process. The Government also acted on my former suggestion.

† See Weddell's 'Histoire.'

PLANTING ORANGES AND LEMONS.

Select trees of good, healthy growth, varieties to suit. The Naval variety and St. Michael are the best known varieties, and should be the only kinds planted—the Naval variety as the favorite, or exclusively If your trees in nursery are convenient, say not more than three miles away, and your orchard is not to exceed five or six hundred trees, two men can dig the holes for fifty to one hundred and get the irrigating ditches ready in the afternoon. In the morning, during a fog, can go and dig the trees, taking up all the roots, pack them in a wagon with wet straw about the roots and cover up well, and return home with them, planting directly from the wagon, not allowing the roots to get dry. As soon as all are planted the water should be turned on and each tree thoroughly irrigated. If there is no foggy morning it would be better to get ready in the morning and plant in the afternoons as late as possible Care should be taken to spread the fibrous roots and to pack the fresh dirt firmly around the trees, leaning them slightly towards the trade wind. We know this plan is better than to 'dobe or puddle the roots, and if all the roots are carefully taken up and properly handled in planting, keeping them moist all the time, this plan is better than sacking and less expensive.

Pruning should be attended to before removing from the nursery or immediately afterwards.

As soon as the work of planting is completed a second light irrigation of the entire orchard, followed by thorough cultivation as soon as the ground is dry enough is all that is necessary to insure a success.—*Rural Californian.*

IS SOUTH CALIFORNIA THE PLACE FOR A POOR MAN?

To illustrate the point by a practical example, we mention the name of A. P. Combs, well known to the citizens of Riverside. He came to this valley several years ago without means. He was crippled with rheumatism and could get around with great difficulty. The acute character of his disease became better, but he was left crippled for life, and well advanced in years. His family consisted of himself and wife. He rented a house and worked when able for others for wages. Three years ago he purchased a two and a half acre town block that had been partially set to orange trees. He commenced improving the same when he had time.

last year he built a nice, comfortable home and moved into it. This past year the exhibit from his place of 2½ acres, shows as follows:—

RECEIPTS.

410 seedling orange trees sold from nursery	$ 330 00
150 budded orange trees	150 00
20,200 Sultana grape cuttings	306 00
17,600 Muscat cuttings	44 50
400 other cuttings	8 00
106 boxes of raisins—net	300 00
Total receipts	$1,138 50

EXPENSES.

Cultivating	$ 29 00
Water	10 50
Irrigating	14 00
Pruning	30 00
Hoeing	4 00
Picking and handling grapes	25 00
Total expenses	$ 112 50

This gives a net income for the year of $1,026.—*Press and Horticulturist, Riverside.*

FERNS IN BOTTLES.

A most remarkable example of Fern growth was recently brought under our notice, and the circumstances are so unusual that they are well worth attention. In the garden of Mr. Raynsford at Kingston-on-Thames for the past twenty years partly damaged soda-water bottles have been employed to edge the paths. The point of the necks had been broken, and this portion was plunged into the soil to the depth of about 6 inches, thus leaving 3 or 4 inches of the base of the bottles above the surface. Some of these bottles have been in this position for the whole of the time mentioned above, and others have been placed in at intervals to within the past year.

There is nothing extraordinary in all this. In hundreds of other gardens bottles have been similarly employed, but in this case the results now to be noticed are very unusual. In the majority of the bottles young Ferns appeared soon after they were placed in the ground, and these have continued growing until in some cases they have formed a dense congested mass of vegetation completely filling the bottles. The fronds remain green during the greater portion of the year and then die, giving place to young ones in the succeeding spring; and as previously stated, some have continued thus growing for many years past practically without any exposure to air, as the amount that could pass through the soil up the neck of the bottle would be extremely small. Several different varieties of Ferns are observable, chiefly forms of Athyrium Filix-fœmina, with the Oak Fern and a few others; and it is strange that the only Fern in the garden is Scolopendrium vulgare, of which there are no examples in the bottles. The soil, too, has not been renewed since the garden was first formed, therefore the only way in which the spores can have been conveyed to the garden is by the wind.

The bottle represented in the woodcut is one of those placed in the soil within the last year or two, and was selected because the young Fern can be more clearly shown. It should be added that of the four or five hundred bottles employed nearly two-thirds contain Ferns, the other being chiefly filled with Grasses and various weeds. In all cases the fresh healthy appearance of the plants indicates that they can well dispense with ventilation.

If a few Ferns could be induced to grow in bottles like the above, they would form rather interesting [illegible], especially for windows, as they could be inverted in pots or boxes, and would at least possess the advantage of requiring little attention or trouble.—*Journal of Horticulture.*

SURFACE DRAINAGE.

Many people look upon draining as a [illegible]. The farmer [illegible] his drains [illegible] then to a certain depth from the surface, lays in the bottom stones or pipes, returns the clay, and considers the field drained. After a few years he finds the field is still clammy and wet, but consoles himself by vouching to his neighbour the information that he has spent no end of money trying to render the field dry. Knowing that there is nothing enigmatical in the art of drainning, he tries to remedy the evil, spends more money, but only to find the result of his labour most unsatisfactory. Why? Because he did not at the first set out and inquire accurately into the cause of the wetness. If, for instance, the soil was a heavy clay or loam resting on a hard "pan" or an adhesive stratum of clay, which after a couple of years or so became quite impervious to water, the subsoiling plough ought to have been put into force and the injurious "pan" broken up. A field may be wet owing to its location, being situated near a treacherous subsoil from which water is continually oozing out and stagnating in the soil. Hue-head or catch-water drains are necessary to intercept the moisture before it spreads over the field. Sometimes the redundancy of water is occasioned by bottom springs, and these should all be tapped at the fountain. Obviously if the drainer before commencing operations search for a cause, very probably he will render his work effective at one-half the outlay which it will otherwise cost by going blindly to work. Draining is very costly, and great prudence ought be exercised in laying out the money, and if this is done, no undertaking is more productive of good results. The benefits of good drainage are numerous. The land is more easily worked, and in spring may be ploughed weeks before undrained land. This in itself is not only a saving of time but also a saving of money. Every farmer is aware of the advantage of having his seed committed to the soil in proper season. Then again, when seasons are awkward such as the past two or three summers, the quick passage of water through the soil does not injure the crops. After heavy rain the surplus water speedily sinks away down through the soil, taking with it and leaving just where they will do most good, ammonia, carbonic acid, and all the other ingredients which tend to enrich the earth and make it fruitful. Obnoxious plants disappear, and the ground becomes free from germs of fatal pest among live stock. Foot rot, liver rot, and all the various diseases known by the name of "rot" among sheep and cattle are often the direct result of inattention to a proper system of thorough drainage.—D. SYM SCOTT.—*Journal of Forestry.*

UTILIZING WEEDS.

First a word of explanation, to say that I do not mean annual weeds, such as mere exposure to the sun will kill, but those with creeping stems or roots, like Squitch-grass, that are unfortunately quite impartial in their distribution and a serious source of annoyance and expense both to farmers as well as to many gardeners. In most transactions, when you have caught your hare the cooking is a secondary consideration; not so with Squitch-grass. Burning is generally set down as the most effectual means of extirpation, but I am not prepared to admit that. In numberless cases that have come under my notice in England and Ireland, the custom is to make a fire and then heap the weeds on in the fields, or in a corner of the garden. A smothered smouldering takes place, near a [illegible], and too frequently the joints escape, and as soon as scattered over the ground as charred ashes, [illegible] vigorous growth than before. This [illegible] after the organic [illegible] had been blown away into the atmosphere. I [illegible] a compost four-fifths of which [illegible] Squitch (Triticum repens) of the worst type, collected last year. A gardening friend of mine [illegible] said he wished he never had worse [illegible]." I [illegible] you how this has been obtained. I collected about 500 loads, chiefly of this noxious weed, from both the green crop [illegible] the land in which grass seeds and oats had been sowed. A fractional part consisted of that equally mischievous weed Colt's-foot, with some Docks, Thistle roots, Crow-foot, &c., in a less proportion. Those 500 loads were [illegible] in an oblong heap about this time last year, [illegible] the [illegible] crop had been sown, and the question arose, How were they to be killed, and killed immediately, so as to become available as soon as possible? I wanted the compost to soak up the oozings from the manure-heap. Had I [illegible] them, and done it effectually, my 500 loads might have left a residue of ten loads of ash. I resolved to cover the heap with lime direct from the kiln, and spread it at once, so that in slaking it should form an imp netrable air-tight external covering, underneath which there should be no plant or weed life. On the top it formed a mass, 6 inches thick, and killed everything beneath. The reason so many fail to kill weeds in this way is because they cover with clay or some other porous covering that only acts as a "top-dressing" for the weeds. I am this year going to use gas lime I have got for the dressing, and will tell you the result by-and-bye. This is a matter of importance to every farmer and gardener in Great Britain and Ireland. Recently a nurseryman told me half his profits were consumed in trying to extirpate root weeds: I proposed this plan of utilizing them in future to him. —W. T. MURPHY, Clonmel.—*Gardeners' Chronicle.*

ANOTHER WEEVIL CURE.

Attention has recently been drawn to the feasibility of protecting grain and seeds from the attacks of weevil by the use of vegetation, and it really appears as if we were about to arrive at a practical solution of this question in a simple way that will be within the reach of all. Mr. Inglis, to whom we were last year indebted for the Nilghiri coffee seed which we distributed among our subscribers, and some of which we have still on hand, has written a letter pointing out the fact that the Hindoos, or coolies as they are called here in our ignorant contempt of all dark-skinned races, have a practice of effectually protecting their products from weevil by the practice of placing leaves of the Neem tree (*Melia Indica*) amongst them. Since then Mr. Voelcker of Grafton has written to a southern paper stating that the indigenous Neem tree of Australia will answer the same purpose. He states that he has had in store a few bushels of wheat for nine months, in which are intermixed leaves of the *Melia Azedarach*, which he says grows freely in the neighbourhood of Grafton, and which is entirely free from weevil. This *Melia*, Mr. Voelcker states, to be commonly known as the white cedar, and it is therefore likely to be the white cedar of Queensland, *Melia Composita*, or a very similar variety; hence, it appears that the use of white cedar leaves will be the means of protecting grain, &c., from weevil. This tree, although not to be found everywhere, is yet by no means uncommon, and we would strongly advise our farmers to test its properties with their next crop of maize. In the meantime, it would be well if an attempt were made at the propagation of the Indian Neem in Queensland, as it appears to be a very valuable tree. It is described by Gamble, in his "Indian Timbers," as being used in the construction of carts, for ship building, making of agricultural implements and furniture. It is held sacred by the Hindoos, and idols are made of it. The bark is bitter, and is used as a febrifuge. The leaves are made into a poultice for ulcers. The gum is clear, amber-coloured, and used as a stimulant. The seeds are employed to kill insects and for washing the hair. The oil is used to burn and as a medicine. In the meantime, it would be well to ascertain whether the white cedar, an almost identical tree, has not similar properties.—*Planter and Farmer.*

SULPHATE OF AMMONIA FOR VEGETABLES.

A dressing of sulphate of ammonia given during the summer months to vegetables in free growth has a wonderful effect in advancing most crops. The present is a good time to dress such crops as Onions, both spring-planted and spring-sown. Cauliflowers may also be assisted in the same way. Any young seedlings of the Cabbage tribe which may be in a backward condition are forwarded rapidly by a dressing, which in dry weather should be preceded and followed by a watering which need only be slight, as the roots of these are best kept near the surface. The first watering at once causes the sulphate to dissolve and prepares the roots for the after watering, whilst the after supply of water carries the already partly dissolved salt down to the roots without waste, and with rapid effect. The manure is strewn broadcast over thickest crops like Onions, about $1\frac{1}{2}$ to 2 cwt per acre being a good dressing, or from an ounce to an ounce per square yard. We have found it advantageous to mix the manure with an equal part of sharp sand, crushing all lumps in the process. For planted-out crops of Cabbages and Cauliflowers the pure manure is applied, as much as lies between the first and second finger and the thumb being a sufficient dressing. Later, we have found a dressing applied to Seakale in the same way that the Onions are treated of great benefit in securing strong forcing crowns. To this crop it should be applied not later than the middle of June, in order that excitement of the plants may not be unduly prolonged in autumn. A dressing at the rate of 2 cwt. per acre is of great advantage to Celery. We have found the best way to secure crisp and sound Celery not liable to produce flower stems is to grow the crop as quickly as possible. Late sowing may safely be indulged in when means are taken to make the growth rapid in June, July, August, September, and October, according to the time the crop is wanted, and nothing secures this result so well as a dressing of this sulphate. If dry, water before and after dressing as advised for seed beds. It is better not to apply to late crops—those for use during February to May.

Dressing of this manure are of no use to such crops as Peas, Lettuces, Turnips, Artichokes, Potatoes, and fruit crops generally. Young Rhubarb may be prolonged indefinitely by two or three dressings throughtout the season. Fine-foliage plants in the flower garden are benefited, provided the beds are kept in good heart.—B.—*Journal of Horticulture.*

GRAFTING FOR ORNAMENTAL EFFECT.

The Process of Grafting may be applied to nearly all forest trees and shrubs, from the sapling in the nursery to the tree of saleable dimensions, provided that it be done at the proper season, and sufficient care be taken in the execution of the work. There is no mystery about the operation, and it can therefore be practised by any careful person; it simply consists in the joining of a shoot of one variety to that of another, in a proper manner. At one time it was considered that a graft would succeed upon and variety of stock, but this theory has long been laid aside as incorrect, and we have only to consider the matter from a physiological point of view to see the fallacy of it. The stock and the graft must be identical in regard to the periods of the movements of the sap, the falling of the leaves, and the maturing of the fruit and timber; and, unless these considerations be carefully observed, anything like success can never be realized: they may for a time appear to succeed, but will ultimately dwindle off and die, leaving the operator little credit for his work, besides in a certain degree injuring the stock for further grafting.

The principal object to be kept in view in grafting is to properly unite the liber, or inner bark, of the graft with the inner bark of the stock, and keep them together until they are perfectly united, which in most instances will occur in about three months from the time of grafting.

There are various modes adopted in grafting, but I consider the crown grafting, the best system that can be adopted when applied to forest trees, and more especially when the trees operated upon are of ordinarily large dimensions. It can be very successfully practised upon thick stocks of headed-down trees, and in this case it is accomplished in the following way:—first cut off the head of stock horizontally if preferred, taking care to have the surface of the stock quite smooth; then cut one side of the graft flat and sloping, from an inch to an inch and a half long, leaving a sort of a buldge at the top of the cut to rest on the crown of the stock; then make an incision in the bark to the required length, raising it carefully up with the handle of a budding knife, so as to admit the scion between it and the wood, place the scion with the cut side next the wood, putting it far enough down for the shoulder to rest on the head of the stock; when this has been completed the graft may be firmly bound up with a string of matting and carefully coveredover with clay to the thickness of about an inch and a half, seeing that it be effectually closed to prevent the light or weather from penetrating.

Grafting may be commenced in spring immediately before the sap has commenced its circulation, but it must be observed that the grafts should be cut some weeks before they are put on, as it is necessary that the sap of the stock should be in brisker motion than that of the scion, and its vegetation more advanced. The clay used may be either yellow or blue, and well beat up, with about a fourth of horsedung mixed in it. It should be allowed to remain on the tree until about the latter end of July or the 1st of August, at which time the grafts may be gradually relieved of their tyings, and, if need be, carefully supported, to prevent them against injury from the action of violent winds.—J. T. McLaren, Assistant Forester.—*Journal of Forestry*.

A SUGGESTED NEW AGRICULTURAL RESOURCE.

Mr. A. J. Maule, of the nurseries, Stapleton Road, Bristol, has published an experimental treatise on the *Yucca gloriosa*, or Adam's Needle, as a sugar and fibre-producing plant, which cannot fail to interest British agriculturists, landed proprietors, &c., who would be only too grateful to any person who would now point out to them some means of improving their prospects and profits from the soil—profits which in many cases are simply *nil*. Mr. Maule believes that the Yucca may be cultivated in this country with commercial success, while affording employment and light field-work for many hands; 6 lb. of the leaf of the plant producing of 1 lb. fibre and 1 lb. of sugar, the former being superior to New Zealand flax, and capable of being woven into a material almost equal in fineness to Japanese silk. To the treatise are appended two testimonials, one from Messrs. Terrell and sons, rope and twine-spinners, and another from Mr. Bond, of the Redcross Brewery. The former, who have tested the fibre, bear witness to its value commercially, if a continuous quantity could be secured at a moderate cost; and Mr. Bond, in sending the author a small cask of beer brewed from the saccharine extracted from the Yucca by Mr. Maule, pronounces it excellent. "It will not keep long (he adds), as from its crude state it contains much vegetable matter; but on testing it by the saccharometer, I find it registers two degrees more saccharine than others." Thus, two most important articles, for the supply of which we are mainly in the hands of foreigners, Mr. Maule, consider we can have at home. "The great Creator," he writes in a note which accompanies his pamphlet, "has made the world round, no doubt the purpose of giving all living things a chance, and what they get in the tropics from heat I get from cold."

The Yucca rather likes a high and dry situation, to enable it to avoid too much moisture, and is planted in rows on ridges similar to mangelwurzel.

"When once the plantation is made, there is no further trouble in digging or ploughing as with other crops, only to be kept free from weeds, and, perhaps, a little top-dressing occasionally may assist them. The previous summer's leaves are stripped off about February, but may remain on until wanted, and used through the spring as the market may require. This season is recommended for reasons hereafter mentioned, as the frost in winter playing on the foliage causes the secretion of sugar. The constant stripping off the foliage does not appear to affect the strength of the plant in the least. When I began the experiment to extract the fibre, I thought the decomposition in water, as the flax is treated, too tedious; so I resorted to boiling, and after boiling a few leaves for one hour (an experiment any one may try), I rinsed the leaves as you would a towel, laid them on grass in the open air to dry and bleach. I then found the liquor very clammy and sticky, giving off an aroma like malt and hops, and feeling certain there was a large mount of saccharine, I kept it gently simmering, when to my surprize I found an abundance of syrup of sugar. I extracted a still further quantity, and sent it to a brewer, when it produced an excellent glass of beer, and proved in its crude state, as sent in, to possess two per cent, more saccharine than the foreign sugar under the test of the saccharometer. It has been thought by scientific men that sugar cannot be grown in sufficient quantities in this country to pay, for the want of sun, and no doubt it is true as regards a summer-growing plant, but if you find a plant whose nature is saccharine that will stand frost, it gets a greater sugar-making influence from cold than it does from heat, there being no difference in the effect of extreme cold and extreme heat on substances and vegetation that are capable of enduring. The farmer turns up his land in summer to receive the benefit of the sun, and he does the same thing for the winter's frost—both of which have the same effect."

In fact, he asserts cold and frost operate on the leaf of the Yucca as the sun does on the cane, and produce more saccharine here than in the tropics.

Altogether, the idea started by Mr. Maule (who is quite a horticultural philosopher) is very interesting, and may be very important. Fancy thousands of acres of land in England laid out in Yucca plantations—half the island bristling with Adam's Needles—*breeching and beering* the population from what has hitherto been considered only a garden ornament!—*Forestry*.

SILK-INDUSTRY.

Utilization of Wild Silkworms in British-India.

Mr. Thomas Wardle, manufacturer at Leek, Staffordshire, has lately given me some interesting details about the industry of the silk obtained from silk-worms that are found in a wild state in British-India, an industry undertaken by him with devotion, and encouraged by the managers of the South-Kensington Museum.

Since long it has been an object of research to find new sorts of spinning-caterpillars for procuring silk to replace the ordinary silk-worm (Bombex Mori), which seems to degenerate more and more by prolonged culture. The Paris Acclimatisation Society, especially, has entered upon the subject with great ardour, and indeed not without cause. However the results have hitherto not been of great influence. In our country, too, many trials have been made with the Yama-Mai and Ailantus caterpillars, with little success for industry.

In British-India, however, a favourable epoch seems to have dawned for the culture of wild silk-worms, since experiments have been made on a large scale, especially by Major Coussmaker at Poonah. Most of these silk-worms feed on the leaves of trees and shrubs growing wild in British-India. The silk is mostly coarser of fibre than the common silk.

One of the principal sorts is the Tusser or Tusseh (Antheraca mylitta L.) a silk-worm which for centuries has been collected wild in British-India and in China. This caterpillar feeds on the leaves of various trees, such as the Dayeti (Lagerstroemia Indica), the Bher (Ziziphus Jujuba), the Kamnda (Carissa Carindas), the Ani (Terminalia Arjuna). The cocoons of this caterpillar are collected throughout British-India by the natives, and yield many thousand pounds of silk. The silk is mostly worked up in India to half-silken stuffs with cotton warp, in some parts also to whole silk. The cocoons are collected by natives and brought up by the traders.

The caterpillars and butterflies of this species are much larger than the mulberry-caterpillar, and the silk is thrice as thick. The Tusser caterpillar, in spinning, brings by side-movements of its head, the silk threads into a parallel, zig-zag, very closely-pressed position, it coats these fibres with a gummy matter and moreover with a hardening cement kind of moisture, by which the whole cocoon becomes firm and hard, with a dirty colour. By treatment with boiling water and alkaloid this matter is dissolved, the chrysalis killed and the cotton prepared for commerce. Yet the perforated cocoons from which the moth has already escaped, are also bought up as an article of commerce, and employed for making silk. The buyers pay from fl. 0.75 to 15 cents a hundred; the sound ones are sold to the cultivators for fl. 1.80 to fl. 2.40 per hundred.

One of the most important applications of Tusser-silk since 1880 in England, is the making of a stuff (called seal-cloth) as a substitute for seal-skin, being a Tusser silken plush on a cotton back. The use of this material for ladies' winter-cloaks has a great advantage over seal-skin, because the woven back is perfectly porous. The Tusser silk is peculiarly fitted for this manufacture, by its softness and brightness, and by the thick fibres which bear pressure capitally, whereas with common silk such long nap would soon get entangled.

Seal-cloth has a rich appearance and soon recover from the consequence of damp or pressure, by just airing it before the fire and then brushing it. For this manufacture the the Tusser silk is spun to thread, without winding it off from the cocoons, and its application to this purpose is extending more and more. The manufacture has a great chance of rivalling the *trip* (Utrecht velvet) and possesses a peculiar fitness for the uses to which woollen velvet is put especially to bear pressure, and by its soft and bright consistence it surpasses it considerably.

Another use to which Tusser silk is put, is the making of hearth-rugs, which, on account of thicker fibres forms a firmer and softer surface. The price of spun Tusser thread was in 1882 11 shill. per pound, that of organ-silk and tram of native reeled silk 7—10 shillings.

The Chinese have also availed themselves of this Tusser silk industry and are becoming dangerous rivals on account of the cheapness of manual labour with them. Most of the Tusser silk used in England and Marseilles is now imported from China.

By its gloss and strength Tusser silk is peculiarly adapted for embroidery, when reeled from the cocoons as floss-silk. Mr. Wardle has obtained excellent results by the combined operations of printing and embroidering, which the Japanese practise with so much success.

Other wild species of silk-caterpillars are the Eria (Attacus ricini) on the Ricinus, the Moenga, on the Tjempaca-trees (Michelia), the gigantic Attacus Atlas, the A. Yama-Mai, the Acteas silene, Attacus Edwardsi, Antheraea Perotheti, A. Roylei, etc.

Mr. Wardle is of opinion that also in *our colonies* wild silk might be made a profitable affair. Many of the trees, bearing these silk caterpillars in British India, growing also wild in the Dutch Indies, so that surely peculiar kinds of silk-yielding caterpillars are indigenous there too. The treatment might be effected by the natives at their leisure, as they would have nothing more to do than to take care to collect the cocoons, and then to dispose of these to the purchasers, while the manufacturing of the silk would have to take place in separate establishments on a large scale.

The culture of the Siamese and the common silk-worm has given no favourable results in Java; perhaps a better return may be expected from experiments with indigenous sorts, and especially by completely separating the culture, or collecting, from the manufacturing.

To all whom it may concern, I can earnestly recommend to make acquaintance with Mr. Wardle and with the rich collection of Indian wild silks and stuffs made therefrom, as exhibited in the Indian Department of the South-Kensington Museum, and described in the following work published by that Society: *Handbook of the Collection illustrative of the wild silks of India by Th. Wardle*, London, South-Kensington *Museum* (price 1 one shilling).

By the kindness of Mr. Wardle a presentation-copy of this book and half-a-dozen samples of silk have been received in the Colonial Museum in the pavilion at Haarlem.—F. W. VAN EEDEN. *Indian Mercury.*

TREE PRUNING.

Translated from the French of A. des Cars, by Charles S. Sargent, professor of Arboriculture in Harvard College, U. S.

Bark once injured or loosened can never attach itself again to the trunk; and whenever wounds, abrasures, or sections of loose bark exist on the trunk of a tree, the damaged part should be cut away cleanly as far as the injury extends. Careful persons have been known to nail on to a tree a piece of loosened bark, in the hope of inducing it to grow again, or at least of retaining on the young wood its natural covering. Unfortunately the result produced by this operation is exactly opposite to that intended. The decaying wood and bark attract thousands of insects, which find here safe shelter and abundant food; and, increasing rapidly, hasten the death of the tree.

In such cases, instead of re-fastening the loosened bark to the tree, it should be entirely cut away, care being taken to give the cut a regular outline, especially on the lower side; for as has been already explained, if a portion of the bark, even if adhering to the wood, is left without direct communication with the leaves, it must die and decay. A coating of coal-tar should, of course, be applied to such wounds.

Loosened Bark.—It is necessary to frequently examine the lower portions of the trunk, especially of trees beginning to grow old; for here is often found the cause of death in many trees, in the large sheets of bark entirely separated from the trunk. This condition of things, which often cannot be detected except by the hollow sound produced by striking the trunk with the back of the iron pruning knife, arrests the circulation of sap, while the cavity between the bark and the wood furnishes a safe retreat for a multitude of insects, which hasten the destruction of the tree. The dead bark should be entirely removed, even should it be necessary in so doing to make large wounds. Attention, too, should be given to injuries to the bark caused by the fall of neighbouring trees. These may remain hidden for years, and are often only detected by the peculiar sound produced by a blow of the pruning knife. Cases of this nature require the treatment recommended for the first class.

Cavities in the trunk.—Very often when a tree has been long neglected, the trunk is seriously injured by cavities caused by the decay of dead or broken branches. It is not pretended that pruning can remove defects of this nature: it can with proper application, however, arrest the progress of the evil, and in such cases should always be resorted to. The edge of the cavity should be cut smoothly and even, and all decomposed matter, or growth of new bark formed in the interior, should be carefully removed. A coating of coal-tar should be applied to the surface of the cavity, and the mouth plugged with a piece of well-seasoned oak, securely driven into place. The end of the plug should then be carefully pared smooth and covered with coal-tar, precisely as if the stump of a branch were under treatment. If the cavity is too large to be closed in this manner, a piece of thoroughly seasoned oak-board carefully fitted to it, may be securely nailed into the opening, and then covered with coal-tar. It is often advisable to guard against the attacks of insects by nailing a piece of zinc or other metal over the board, in such a way that the growth of the new wood will in time completely cover it.

These operations resemble, if such a comparison is admissible, the fillings performed by dentists, and with the same object, to check the progress of decay.

The use of Coal-tar.—Coal-tar, a waste product of gas works, is a dark-brown imperishable substance with the odour of creosote. It can be applied with an ordinary painter's brush, and may be used cold, except in very cold weather, when it should be slightly warmed before application. Coal-tar has remarkable preservative properties, and may be used with equal advantage on living and dead wood. A single application without penetrating deeper than ordinary paint forms an impervious coating to the wood cells, which would without such covering, under external influences, soon become channels of decay. This simple application then produces a sort of instantaneous cauterization, and preserves from decay wounds caused either in pruning or by accident. The odour of coal-tar drives away insects, or prevents them, by complete adherence to the wood, from injuring it. After long and expensive experiments, the director of the parks of the city of Paris finally, in 1860, adopted coal-tar in preference to other preparations used for covering treewounds, as may be seen in all the principal streets of the capital.

Employment of Coal-tar on Fruit Trees.—It is for this reason that the application of coal-tar should not be made except with considerable caution in the treatment of wounds on drupaceous fruit trees (cherries, peaches, plums, &c.), and especially on the plum tree. It has often been observed that the bark of fruit trees of this class have suffered from the application of coal-tar. This is not the case, however, with pome-bearing trees (apples, pears, &c.); to these coal-tar may be applied with perfect safety.

It must not be supposed from these remarks that coal-tar cannot be used on the plum or other trees of its class. On the contrary, there is no substance which can replace it in the treatment of large wounds on these trees, but it should be used cautiously, especially in the case of young trees, and should not be allowed to needlessly run down the trunk, and it is well to remember that the more active a remedy, the greater the care necessary in its application.

The practice of leaving a short stump to an amputated branch, adopted by some persons to prevent the loss of sap, although less objectionable in the case of coniferous trees, should never be adopted. Such stumps must be cut again the following year close to the trunk, or cushions of wood will form about their base, covering the trunk with protuberances. These greatly injure the appearance and value of the tree, and necessitate, should it be found desirable to remove later such excrescences, wounds two or three times as large as an original cut close to the trunk would have made.

The custom of pruning pines is very general in France, and is often carried to excess. The removal of all branches, with the exception of a few at the top of the tree, must greatly interfere with the growth in diameter of the trunk; and healthy branches should not be removed for the sake of creating a clean trunk of more than one-half or at the most two-thirds of the entire height of the tree. The general rule of pruning already explained in the case of deciduous trees, and which establishes a portion between the number of branches which should be removed and the size of the tree, might with advantage be more generaly applied in the treatment of pines.

THE SUN AS A SOURCE OF POWER.—Of the enormous power of the sun's rays few readers have any adequate conception; but as the time appears now to be approaching when they will be capable of being made directly available in place of coal and steam for the production of power and light, the question is beginning to assume something more than a theoretical interest. The French electrician, M. Deprez, in a recent work, makes some calculations which illustrate the enormous fund of force which the sun's heat is capable of supplying. France, he says, possesses an area of about half a million square kilometres. In one hour the sun's heat will absorb or dry up 2 lb. of water per square metre; and so on a fine summer day the quantity of water the sun is capable of absorbing in one hour over the entire area of France is not less then a thousand milliards, or a million millions of pounds avoirdupois. If we had to raise this quantity of water to boiling point in boilers we should require no less than sixty million tons of coal, which is one-fifth of the entire annual production of coal throughout the world. The sun's rays falling on France would be able to turn so much water into steam as would keep going eighty million locomotive engines of collectively forty milliards of horse-power.—BUILDER.—*Gardeners' Chronicle.*

ECONOMIC PLANTS. Under the title of *Tabellarische Uebersicht der Wichtigsten Nutzpflanzen*, &c., Dr. Goeze, of the University Botanic Garden, Greifswald, has drawn up an enumeration of the more important useful plants arranged according to their productions, and then geographically and systematically. The first thing that strikes us in turning over the pages of this useful little compilation is, that there is still a very wide field for research in determining the sources of vegetable products, and the correct names and important synonyms of the plants furnishing them. Then again the authorities for names are so uncertain, in consequence of the loose manner in which many authors immediately following Linnæus cited him and each other, and in a less degree subsequent writers. It so often happened that citations referred to works in which descriptions of the species were to be found rather than to the authors who founded and first described the species. During Linnæus' lifetime, and after his establishment of a system of universal nomenclature, other writers, Jacquin for instance, named, described and published many species, which Linnæus took up in the second edition of his *Species Plantarum*, and in other works, duly giving the authors' names and the places of publication. In spite of this a large number of such species have been and still are erroneously ascribed to Linnæus. But to return to Goeze's little book. He has divided the plants under the following heads:—1, Cereals; 2, edible tubers and bulbs; 3, edible pods and seeds; 4, edible herbs; 5, starch (Sago, Arrowroot, &c.); 6, edible fungi; 7, edible fruits; 8, plants yeilding beverages; 9 substitutes for Tea and Coffee; 10, plants yeilding sugar; 11, spices; 12, bee-plants; 13, fodder plants; 14, medicinal plants; 15, oils; 16 wax; 17, gums and gum-resins; 18, caoutchouc and gutta-percha; 19, tanning plants; 20, dye plants; 21, fibre plants; 22, plants for raising silkworms; 23, plants used in perfumery; 24, valuable woods; 25, miscellaneous, followed by an index to the natural orders and another to the substances under their popular names. It would be easy enough to point out errors of the nature indicated in the foregoing remarks. There are also a few unaccountable omissions, while other plants of comparatively little importance are included. Yet as a whole it will be found a very useful guide, of which we may expect to see successive editions. Under each category the subdivisions are indicated by numbers. Thus under plants used in perfumery we have the parts used indicated in the following way:—Flowers, 1; leaves, 2; wood, 3; root, 4; fruit 5.—*Gardeners' Chronicle.*

PUMPKIN SOUP AND PUMPKIN PIE.—From letters to a Queensland Housekeeper in the Brisbane *Planter and Farmer*, we quote as follows:—Having pumpkins you can make a most delicious soup; it is very common with the French, their favorite *potiron.* When I first ate it I could not imagine what it was made of; do try it. This is the recipe of a good French cook:—Two pounds of pumpkin cut in large dice, put it into your pan with three ounces of botter or good fat; add two teaspoonfuls of salt, the same of sugar, a little pepper, and half a pint of water; set on the fire and stew gently for twenty minutes. When in pulp add two tablespoonfuls of flour, stir round and moisten with three pints of milk or milk and water, boil ten minutes longer and serve with toasted bread cut in dice. Try also some pumpkin pies, famed in American story. They say only an American woman can make good pumpkin pies, but with care we can turn them out at least edible! Boil the pumpkin first till soft—as you would for the dinner-table, press through a collander till you have about half a pint of the pulp. Beat up three eggs, add one by one while beating a tablespoonful of butter, two tablespoonfuls of sugar, half a pint of milk and the pulp; flavour with essence of lemon and a quater of nutmeg grated, and a little cinnamon and ginger. The secret of excellence, I think, lies mainly in the flavouring; some like a preponderance of one spice over the rest, as ginger for example, but anyway the flavor of the lemon and spices should be quite perceptible, giving it a spicy, aromatic taste. Bake in shallow dishes or tin plates lined with puff paste in a slown oven.—*Planter and Farmer.*

FACTS ABOUT LEAVES.—[The following paragraph, showing the importance of a large leaf surface for tree growth, proves that the loss of leaves, as the result of *Hemileia vastatrix*, is what mainly "ails our coffee trees."—ED.] In a lecture by Professor Beal of America upon this subject, the following remarks occur:—As is well known, a tree cannot grow without leaves. These are put forth every year, and are a contrivance for vastly increasing the surface. An Oak tree of good size exposes several acres of surface to the air during the growing season. It has been estimated that the Washington Elm at Cambridge, Mass., not a very large tree, exposes about 5 acres of foliage, if we include both sides of the leaves. Leaves are more nearly comparable to stomachs than to lungs. A leaf is a laboratory for assimilating or manufacturing raw materials into plant fabric. The cellular structure of the leaves, wood, and bark of a tree is a complicated subject to treat in a popolar way. It requires a vast surface of leaves to do a little work. By countiug the leaves on a seedling Oak, and estimating the surface on both sides of each, we can see how many inches are needed to build up the roots and stem for the first year. After the first year the old stem of the Oak bears no leaves. It is dependent on the leaves of the branches, or its children, for support. A tree is a sort of community, each part having its own duties to perform. The root hairs take up most most of the nourishment. The young roots take this to the larger ones, and they in turn, like the branches of a river, pour the flood of crude sap into the trunk, which conveys it to the leaves, which are the work-shops of the plant body. The trunk and main branches also support and hold out the young branches, which put forth the leaves. The assimilated or digested sap passes from the leaves to all growing parts of the plant, and a deposit is made where most needed. If a branch is much exposed to the winds, the base of it has a certain support or certain amount of nourishment. So with the trunk of a tree. If the base of a branch or the main trunk is much exposed to the winds and storms a much thicker deposit of food is made there. The winds give a tree exercise, which seems good to help make it strong. Our toughest wood comes from the trees growing in exposed places. The limbs of a tree are all the time striving with each other to see which shall have the most room and the most sunshine. While some perish in the attempt, or meet with only very indifferent success, the strongest of the strong buds survive.—*Journal of Horticulture.*

THE ORANGE moth is committing a great deal of depredation this season, and means should be taken to destroy them. A gentleman, writing to the *Maryborough Chronicle*, says that this moth cannot be mistaken, being unlike other moths, as it never rolls its proboscis up, but keeps it straight out before it.—*Planter and Farmer*.

LARGE ORANGES.—Mr. W. J. De Shields, of Azusa, has some of the finest and largest oranges that we have seen this year. They were large, smooth, solid and handsome; one cluster of four averaged 13½ inches in circumference, and two others 14 inches in girth. The largest girthed 17 inches. They are a fair average of the product of the trees.—*Rural Californian*.

THE NEW CROP.—The Queensland crop, which has yet over three months to grow, is roughly estimated at 50,000 tons for the ensuing season. The New South Wales crop, which greatly increased last year and upset Mr. Metson's conclusions, may be set down at 15,000 tons. Crops are heavy everywhere, and the yield of sugar will probably average two tons to the acre.—*Sugar Planter*.

BLUE GUMS FOR FUEL IN SOUTH CALIFORNIA.—Mr. Nadeau is now cutting his five year old blue gums, which yield 25 cords of good hard wood per acre, worth $10 per cord on the ground or $250 per acre. This is $50 per year for the land. In the next five years the stumps from these trees will produce trees that will yield at least 50 per cent more wood or 37½ cords, worth $375 per acre; or if permitted to grow for ten years, $750, and no care or expenses to the owner except thinning out the suckers the year after cutting. The total cost of the land, planting and cultivation need not be over $100 per acre, and after the trees are large enough to cut the harvest is annual and the income perpetual. There is no possible chance to lose money. Select the right kind of land, cultivate and plant it propely, and man can provide an income for his children which will not fail.—*Rural Californian*.

HOW TO SET HENS.—Make your boxes 14 inches square, 14 inches high, nail bottom on, hang top with leather hinges for cheapness; front side make only 7 inches high—that will leave 7 inches for the hen to get in the nest. Keep the boxes well white-washed, fill the box six inches with fresh earth; form the nest with the hand, then take some fine grass or pepper leaves, just cover the dirt; put in your China or common eggs. Then take carbolic powder, sprinkle well and dust the hen; if she sticks to her business, then put your good eggs under her. After setting two weeks, take a table spoonfull of pulverized sulphur and sprinkle nest. Then you will find that your young brood will come off clean and free from vermin. Never feed your setting hen anything but whole corn; keep plenty of gravel and fresh water, feed your young chicks for the two first weeks hard boiled eggs crumbled fine with oat meal or crumbs of stale bread; keep the hen in coop for two weeks—set the coop where the little chicks can run on some grass spot; if you will do this and keep coops and houses clean your chicks will be strong and healthy.—*Rural Californian*.

PEACH PRUNING.—Mr. Downing long ago wrote that the peach bears pruning especially well; and even late in the spring, when it is unsafe to prune many trees because the fresh wounds continue to bleed. A laborer can be shown in five minutes how to prune a whole orchard, for the best course is simply to shorten back all the strongest shoots, over the top of the tree, one-half. The philosophy of this is that the later formed buds seldom set fruit, but drop off, while the best peaches are obtained from the stout triple buds that have been first formed low down on the shoot (early in the season's growth). The side-shoots that grow out of strong leaders as a second growth are not so apt to hold their fruit as the slender shoots, often covered with fruit buds alone, which have issued lower down and earlier, and which dry up after bearing, and in time drop off. This pruning enables the tree to carry its burden more safely, and facilitates picking, besides conserving the health of the tree by removing the half-ripened fruit which would be liable to disease. This principle in pruning or cutting away before the spring sap flows, all unripe wood liable to injury by the winter, is applicable to other treesthan the peach. The pear is especially safe-guarded by it, and grape-vines, Antwerp raspberries and half hardy roses will grow much better by having this source of decayed and corrupting sap removed. Its virus is comparable to that of unhealthy pus absorbed by the blood, and spreading pyæmia through every vein.—*Rural Californian*.

PROFITABLE PLANTING.—The most profitable planting I have ever seen was in Kent, where a quantity of good strong land on chalk had yielded several cuttings of hop-poles. The kind of wood was chestnut, which makes the best of hop-poles, being a far tougher wood when young than oak of the same age. As the yield was remarkable I obtained the particulars from the agent of estate (Lord Darnley's, at Cobham), and the figures may be relied on. The best chestnut underwood, cut by the buyer, sold at £63 per acre for hop-poles, the poles eleven years' growth, the underwood fifty years planted. Eleven years later the same piece sold at 12 guineas an acre, poles being cheaper.—*Forestry*.

CULTIVATION AS A TEST OF SPECIES.—It is very curious to note the opinions of cultivators as to the limits of species. At the Scientific Committee the other day, Mr. Elwes brought illustrations of Tulips and Fritillarias, to show the immense change which resulted in a comparatively short time from the cultivation of originally wild forms, and drew from them the conclusion that the number of species was very limited, but their variation great. On the other hand, such cultivator-botanists as M. Jordan, dealing with exactly the same kind of evidence, would dub each one of these forms as a separate species. Species are judgments, says Asa Gray, and the nature of the judgment in this case is to a large extent determined by the habitual frame of mind and pre-possessions of the judge.—*Gardeners' Chronicle*.

MURINGAI.—In the *Lancet* Dr. P. S. Brito mentions the leaves of the "muringai" as being used in India in the treatment of hydrophobia, and suggests whether some constituent of the leaves may modify counteract, in short, act as an antidote to the poison contained in the saliva, and asks for statistics and reliable experiments. The botanical name of the tree, which appears to be unknown to him, is *Moringa pterygosperma*, the native name having become the generic one. The tree is commonly known to European residents in India and Ceylon as the horseradish tree, from possessing similar properties to that plant. Its use in hydrophobia is unknown to Dr. Ondaatje, of Ceylon, and it is difficult to see how it could act as an antidote, unless the sulphuretted volatile oil it contains is proved to have a lethal effect on the bacillus of the disease.—*Pharmaceutical Journal*.

COMMON SALT AS A FERTILIZER.—Salt is not a direct fertilizer. Its chief value lies in the power it has of rendering various kinds of plant foods soluble, so that they can be used by the plant. Ammonia, potash, and phosphoric acid are rendered soluble by the action of salt. A prominent scientist calls salt a "soil digester." The visible effect of salt is to retard the maturity of the plant, thus lengthening the period of growth, and therefore insuring a better yield. As the ripening is naturally delayed sufficiently on heavy soils, salt in this way would there produce no beneficial effect. Light soils are almost invariably benefited by salt. It is not a successful insecticide. An entomologist writes: "I have experimented enough with salt on the cut-worm to know that you can kill your plants before you can kill the worms." Impure, unrefined salt is much to be preferred, being cheaper and containing other valuable plant foods.—L. H. B.—*American Agriculturist*.

CINCHONA.—Under the name of "cinchocerotin," Herr Kerner sent to the exhibition in Paris in 1859 a substance which had gradually been deposited in some copper tubing during the cooling of an alcoholic decoction of a dried paste of South American flat calisaya bark and milk of lime. It has been recently examined by Herr Helms, who states that the crude brown cinchocerotin yield two different constituents, one easily soluble in alcohol, white and crystalline, and a much smaller quantity of a yellowish-white substance, difficultly soluble in alcohol. The crystalline substance, for which he proposes to retain the name "cinchocerotin," melts at 130° C., sublimes with partial decomposition when heated higher, and is freely soluble in ether, chloroform and alcohol, but insoluble when boiled with water, hydrochloric acid, dilute sulphuric acid and acetic acid. Its composition is represented by the formula $C_{27}H_{44}O_2$, but the behaviour of the acid resulting from its oxidation indicates that it has possibly a higher molecular weight. From the results obtained it is evident that cinchocerotin is neither a wax nor a fat, and its properties and occurrence probably place it in the neighbourhood of betulin and cerin.—*Pharmaceutical Journal*.

CINNAMON AND CASSIA VERA.—From time to time reference has been made in this country to the advantages presented by the arrangement under which in the United States imports of drugs of inferior quality are intercepted at the custom house; but in the light of a statement in one of our exchanges this guardianship would appear to be a broken reed to lean upon. According to the *Oil, Paint and Drug Reporter* an application was made recently to the bureau of statistics at Washington for information as to the quantity of "cassia vera" annually imported into the country. The preliminary question, "What is cassia vera?" proved a stumbling block, and after it had been passed from one *employé* to another it was discovered that the sum total of the knowledge on the subject possessed by the custom-house experts was that there are two articles of a similar character, called cinnamon and cassia, the former coming from Ceylon and paying a duty of twenty cents per pound, the other coming from China and paying only half that amount of duty. Inquiries spread over a wider area raised the doubt whether the greater part of the cinnamon imported into the United States during recent years has not been entered—and passed—as cassia, payment of the higher rate of duty being thus avoided.—*Pharmaceutical Journal.*

CACAO: HOW TO GROW AND HOW TO CURE IT. By D. MORRIS, M. A., F. G. S. London: S. W. Silver and Co.—This little manual contains the substance of a lecture delivered under the auspices of the Institute of Jamaica by the indefatigable Director of Public Gardens and Plantations in that island, which had for its primary object the diffusion of information respecting the cultivation and preparation of cacoa, with a view to a further development of the industry. After historical and descriptive accounts of the cacao plant, the author deals with the methods of cultivation, the gathering of the crop, and the subsequent sweating and curing of the beans, and he also gives some information valuable to intending planters as to the cost of establishing a cacao estate and its relation to the average yield of the trees. We learn that a good cacao tree in good soil yeilds from fifty to several hundred pods per annum; the average for well cultivated trees at seven years old is between eighty and one hundred pods, about eleven pods being required to yield one pound of cured cacao. Certainly the author holds out a tempting inducement to those in a position to take up the cultivation in Jamaica, for the tells them that by combining on the same plantation the cultivation of the cacao and the banana, sufficient profit may be derived from the sale of the banana fruit to cover the entire expenditure during the first four or five years required for the maturation of the cacao plants. The book contains a considerable amount of interesting reading, though many of the details will be of use only to those who can give them practical application.—*Pharmaceutical Journal.*

SCALE INSECTS OF THE ORANGE.—Of all the insecticides which have been tried by various parties, nothing has as yet been discovered to equal a proper kerosene emulsion as the most effectual destroyer of scale insects and their eggs. The only want of complete success with this has been the failure of properly combining the ingredients and consequently the use of a very imperfect emulsion. The thorough combining of this mixture is better described as churning, and for this purpose a force pump, such as is used for spraying orange trees, is found to be the best. "Kerosene, 2 gallons; whale oil soap, or common hard soap, ½ pound; water, 1 gallon. Dissolve the soap in hot water. Add the soap solution very hot to the kerosene and churn, preferably with spray pump, at least five minutes. In use, dilute the emulsion in the proportion of 1 gallon of emulsion to 9 or 10 gallons of cold water. Apply in fine spray. The great difficulty experienced in reaching every part of the tree renders it absolutely necessary that any liquid used should be applied in one spray and with considerable force. An ordinary garden syringe does not do this, and can never be used satisfactorily to destroy scale insects. A force or spray pump will throw a constant stream of moderately fine spray with such force that the liquid is driven into close contact with the bark, and on striking the leaves and branches is dashed into fine mist, which envelops the tree and wets every leaf. The tree should always be sprayed from each of the four sides, and rather more liquid should be used than seems necessary to drench every portion."—*Rural Californian.*

THE TALLEST NURSERYMAN IN THE UNITED STATES is stated by the American *Gardeners' Monthly* to be Mr. Daniel Conger, of Walcott, New York, who stands 6 feet 6 inches.—*Gardeners' Chronicle.*

PAYABLE glucose sugar is made from "old clothes" in Germany.—Lord Houghton, a poet and Jamaica sugar-planter, has purchased a large plantation, South Florida. —*Sugar Planter.* It must be for a member of his family, for Lord Houghton is an old man now and has had a stroke of paralysis.—ED.

CINCHONA TREES are now being cultivated in the Cape de Verde Islands, especially at St. Antao and St. Thomé, where, according to Professor Henriquez (*Gard. Chronicle*, May 5, p. 585), there are already thousands of plants of *C. succirubra*, *C. [illegible]* and *Ledgeriana*, most of which have been sent from the Botanic Garden at Coimbra. Analyses of the bark of some of the trees have been made and with most satisfactory results. This is interesting as the cinchona cultivation seems to have been a failure at St. Helena.—*Pharmaceutical Journal.*

VACANT LAND IN THE UNITED STATES.—By the census of 1880 the unsettled area of the United States amounted to 1,400,000 square miles, being nearly one-half of the entire area of the country. The unsettled area east of the Appalachian range of mountains has been reduced to 10,000 square miles only, and in the original thirteen states there are less than 15,000 square miles unoccupied. Wisconsin and Michigan show 29,500 square miles as still unsettled, while Texas has no less than 137,000 square miles of vacant land. In the territory west of the Mississipi, including Minnesota, Dakota, Kansas, Nebraska, Iowa, Missouri, Arkansas, New Mexico, Arizona, Colorado, Montana, Idaho, and the Pacific States, 1,200,000 square miles are either unoccupied or inhabited only by Indians.—*Field.*

INDIARUBBER.—It does not appear to be generally known that indiarubber as now imported is a much more variable article than formerly. This is due apparently to the fact that as the indiarubber trees are destroyed near the coast line or near the banks of navigable rivers, the natives have to search further inland and become less particular as to the trees from which they take the milk. The juice of different indiarubber trees differs much in quality, as may be easily discovered by adding various reagents to it. Thus one kind will be curdled by an acid, another by salt, another by spirits of wine, and another by alum, and others again will not curdle with either of these reagents. This depends upon the body which causes the suspension of the grains of rubber in the form of milk, and which is sometimes ammonia, sometimes a compound resembling saponine, and sometimes a mucilaginous or albuminous body. Some rubbers contain a good deal of resin, and others hardly any. These differences are generally discovered in manufacturing articles from the rubber, and where the character of the rubber is altered by the admixture of different kinds, or by the use of chemicals, it deteriorates in value. This is the case with Para rubber, which of late has been found very variable in the working, and in some samples crystals of alum have been detected, showing that this substance has been used to separate it from the milk. It must be borne in mind that the milk of the tree in its natural state, simply dried by exposure to the sun or by careful evaporation at a very gentle heat, yields, as a rule, a far better and more lasting rubber than that which has had chemicals added to it. For this reason certain African and Borneo rubbers are at present much esteemed by the manufacturer. The great difference in the properties of rubber, some being useful for one purpose and some for another, should lead to careful collection of pure samples for testing and valuation. When once the best rubbers for manufacturing purposes, and at the same time for cultivation, have been ascertained, there is no doubt that there will be a wide demand for rubber of uniform quality, and that rubber of this character will hold the market against all others. Much, however, has yet to be done in the way of experiment. Sir John Rich has thrown much light upon the rubbers of Eastern Africa and similar work [illegible] with regard to the rubbers of Borneo, [illegible] imperfectly known. The gutta-percha plants [illegible] in rapid process of extermination, and [illegible] specimens of [illegible] of these trees and authentic samples of [illegible] taken from them will confer a benefit both upon science and commerce.—*Planters' Gazette.*

"PITH DISEASE" IN CINCHONAS AND JUNGLE PLANTS.

There has been some correspondence from Bogawantalawa about a kind of canker which has affected the pith of cinchonas and of a species of jungle plant used as shade for nurseries. The plant is well-known: it has a rhododendron-like leaf, and in consequence of the tenacity with which the leaves adhere to the stem it is the favourite for shading cinchona nurseries. Planters and coolies alike speak of the plant as "*shedi,*" which we, naturally enough, took to be a modification of the English word shade. But the compiler of "Ingē Vā!" assured us that this was a mistake. The coolies having this name for the plant, it is passing strange that a planter in Bogawantalawa on asking its name should receive the reply "Teriya illei," the equivalent of the Sinhalese "Dannē nœ," or the English "I don't know." The following note is from W. F.:—

"I have read the letters on diseased pith of jungle plant and cinchona, and think that it is a case of '*insidious defunction.*' I do n't see any particular disease in the pith of the jungle plant, and the other looks queer, but I do n't think the jungle plant affected the cinchona.

"The jungle plant is a very common small tree, (underwood) in the Dimbula jungles, well-known to me by the Sinhalese name of Bērōō, and is the *Sancoclinium longifolium*, WIGHT, one of the euphorbiads. I have no doubt that the Tamil name given to it to Mr. —— as '*tarrina alla*' is a fair attempt at spelling '*terrai illa,*' 'I do n't know'!! And I am sure they do n't. That is one point in the discussion cleared up. The Sinhalese use its leaves for thatching their huts. It burns fresh and makes a cracking noise.

I believe there is a great deal in what Mr. —— says about bad seed."

The allusion about bad seed is to a passage in a letter which runs thus:—

"The pith dying in cinchona is nothing new, as anyone might have seen ten years ago on the few trees that then succumbed to canker.

"The present rapid and widespread prevalence of canker I consider is entirely due to the thoughtless and indiscriminate purchase of seed from all ages of trees, healthy or otherwise and from whatever source it could be had which prevailed about three to four years ago, combined with this damp and cloudy season.

"In my own experience I could point out here the difference between plants and seed obtained from reliable sources and those that were purchased without that knowledge.

"That the Ceylon seed is and has deteriorated there can be no doubt, but this generally applies to trees under ten years of age, and our present object should be (if South American seed is not obtainable) to purchase only seed from well-known old and healthy trees."

Of course every care should be taken to obtain seed from well matured and healthy trees; but we suspect that climatic influences and nature of soil and subsoil have more to do with disease and "insidious defunction" than bad seed. We are by no means alone in this opinion, for yesterday we had the opportunity of comparing notes with a gentleman who is not only intimately connected with cinchona culture but who has written authoritatively on the subject. He has recently himself lost a good many cinchonas derived from seed regarding the goodness of which there could be no question. Cinchonas have died out in hundreds of thousands on soil which analysis proved to be excellent, but which was not mechanically free. There is not enough of gravel and sand in a great proportion of our soils. We are watching carefully and very hopefully the effect of the growth of tea on land which, although a splendid tea soil, did not suit the delicate taproots of cinchonas. But where cinchonas died off when planted as a sole culture, they are now flourishing scattered amongst tea plants. Time sufficient for a decided conclusion has not elapsed, but there is much reason to hope for success, although it seems inevitable that, in many places, a proportion, sometimes a very large proportion, of cinchonas planted out should die off at all stages up to five to ten years. But at all ages, even the most advanced, "pith disease" seems to affect them.

CEYLON: BINTENNA TO MONARAGALA.

A PASTORAL COUNTRY.

I have just been for a very interesting journey from Nugagala Gap on to within 40 miles of Batticaloa upon the new Badulla-Batticaloa road, and from thence to Bubule and on to this district. As I see you are making a map of the country most suited for various products and uses, I can not help drawing to your notice the much spoken of and little known Park Country of Ceylon; which began upon my journey within about 10 miles of Alutnuwara and extends for some 30 or 40 miles in a southerly direction, containing possibly 200 square miles of country, all admirably adapted for pastoral purposes.

I have been over a greater part of Southern India, and have seen large tracts of country, miserable to look at in every sense, and yet sheep upon it have appeared healthy and strong. In every way the Park Country of Ceylon appears superior, yet it is a waste far and wide, a desolate wilderness where once game abounded, which now has, practically speaking, been exterminated, and the land, grass and trees alone exist. Horse, sheep and cattle might surely be raised here if Government would only give encouragement and ventilation to the subject.

W. F. L.

PLANTING IN THE LOWCOUNTRY NEAR HENARATGODA.

The following dated May 1st, has been delayed, but is still of interest:—

The coffee has improved very much in appearance over the greater part of the property, and there is the promise of a considerable crop. During the long spell of dry weather the *Hemileia* almost entirely disappeared from all but the varieties on which it becomes chronic. It will seriously affect the promised crop, should we have another severe attack during the season, but we can do nothing to avert it and can only wait and hope. There are some hundreds of cacao trees in bearing: more are coming in month by month. I have used all that has come ripe hitherto for seed, but I will have some little to cure during the season. I am trying to get it up afresh on some spots where it has in individual plants done well, and I have ready to plant 12 acres on which a good deal of the jungle has been left. I cannot claim for this cultivation a great success, but it will not be a great failure: much of the soil is fit for it, but all the first clearing is exposed to wind, and no provision was made for shelter.

I am now satisfied that we can grow cardamoms, and my view is to plant them in the new clearing with cacao. The lining has been done on the triangular system, which at 13 feet gives 310 per acre. By putting a cardamom between each cacao in the three intersecting lines there will be 310 cacao and 930 cardamoms in all 1,240. The cheapest way of getting plants is to sow the seed, but the question is whether the longer time needed would not be a loss compared with paying for bulbs. I see the latter advertised at R20 per 1,000: they could probably be produced from seed for one eighth of this rate by the sacrifice of 12 months in time.

Vanilla promises to do well, and I am propogating as quickly as I can with the few plants I have rather than pay a cent an inch at the gardens where it grows like a weed. From experiments already made I believe I can grow Kew pines 6 tons to the acre. They would pay well if we could get 18 cents for a 12 lb. pine on the spot. There are a few of the pepper vines I put down twelve months ago getting on and growing quick, and having now some experience I think I can do some good with this product, but plants are preferable to cuttings, and I will get fresh seed as soon as I can obtain it. Nothing thrives here like jak, the average height of two years old trees is 15 feet and the girth of stem from 9 to 12 inches. A few acres of them would pay well when old enough for tea boxes.

I have put down the two bags of arekanuts along the lower side of the roads at three feet apart so far as they went, and I propose to plant Ceara rubber along the upper side.

The bamboo belts have certainly been of service by way of shelter, but nothing else grows within the range of its roots. I therefore propose to cut it down and destroy every shoot that subsequently comes from the roots. It is good for a boundary fence but bad everywhere else.

I have planted out 5,000 tea plants. I was deceived into planting 1,700 of these yesterday morning, by the appearance of the weather: it had thundered incessantly for three hours, and at 6 o'clock it looked so like the making of a wet day that I sent the weeders back to the lines and with the males of my gang set vigorously to planting up. Till near 10 it threatened heavy rain, when suddenly the clouds cleared away and the sun came out bright and hot; many of the plants are drooping today and though this day is gloomy there has not been a drop of rain. I find they only want a shower to settle them to be all safe so far as weather is concerned, but the crickets are at their old work and the plants are being cut both in the field and the nursery.

I have planted out the nutmegs, and they all seem to be getting on well. I find I made a mistake in putting the seeds in baskets: if I have to deal with any more I will merely put them in a well manipulated bed. If the weather is favourable they do not suffer from transplanting without balls.

I am gradually getting a few orange plants out of the danger of their numerous enemies: they get on rapidly when they reach 18 inches. The rambutan of the various fruits I have tried get on best and seem to have no enemies.

This is not a country for cotton: it is ready enough to be a weed, but the produce is not worth gathering.

CULTURE OF VANILLA.

The gentleman who sends us the notes by an experienced vanilla planter in Mauritius, of which the following is a translation, says:—"The writer of the notes had the finest vanilla in the island when I was there."

1. The first thing to do, in the formation of a vanilla plantation, is to divide the land, if this is possible, into beds about five feet apart.

2. Each bed should be about five and a-half feet wide, and dug to a depth of about *one* foot, to form a sort of drainage and prevent the water lodging too long at the feet of the vanilla plants.

3. The beds formed and dug, they must be raised if possible six inches above the soil, by means of smaller rocks or rubble arranged on both sides of each bed, and, if necessary, take the earth found in the space between the two beds to make the necessary elevation for planting the creepers.

4. Do not mix this prepared earth with strong animal manure: if possible, add to it a little compost formed of leaves and detritus of all sorts.

5. The vanilla creepers should be chosen good and in-sect: carefully avoid getting sickly creepers or those having already a yellowish color; if possible always plant creepers ... feet long: the return is quicker and the result more certain.

6. To plant the vanilla creepers supports are necessary, and if you have not natural supports, such as trees, or high walls, the plant which we prefer to employ is the *pignon d' Inde*,* a milky shrub, the foliage of which is rather dense during summer: the leaves fall in winter, just when the vanilla ripens.

7. To proceed with the planting of the vanilla cuttings you must first cut with a penknife the first leaves at the extremity of the cutting is to which be put into the earth, but not cut them too close to the woody stem. This operation completed, you bury the three joints of the cutting which have had the leaves all off, and that not too deep, about two inches, in the earth; the long creepers are then raised on their support either natural or artificial.

8. The planting finished, you must always take care to put straw or dried grass on all the beds to maintain a constant humidity about the roots which will be thrown out in a short time and which will always tend to rise to the surface of the soil. If there is the means, do not fail to water in dry seasons: it is a plant which asks for continual moisture without, however, being inundated, and on this account a good drainage in recommended in the preparation of the beds.

9. When the creepers have rooted and begin to grow never take away the suckers which give them new life if the foot be dead; and when the creeper has attained a certain length you may cut it down to the soil and operate as if for layering, bury it about two inches deep, at the same time cutting off the leaves which will be under the earth, to stimulate the roots to put forth.

10. The fertilization must always take place in the morning until 10 o'clock at the latest, and above all do not retain too many pods on the same cluster: three or four are more than enough; nevertheless it is necessary to fertilize all the flowers that appear, in order to be more certain of the complete success later on of removing the pods if all the flowers have been successfully fertilized.

11. The gathering finished, it is well to take down the creepers which are too long and also in order to cut off the new creepers to increase the plantation.

12. Never fertilize too much the flowers which appear during the first year of planting: you will weaken your vanillas, and your plants will run the risk of sickening. Your cropping must not begin until the second or third year, if you have planted creepers four or five feet in length; otherwise you must wait much longer.

13. Every year after the croping, add a little earth to the compost on the plantation to cover the roots which have come to the surface of the soil and always put a covering of straw over all, in case of drought.

These are the first principles to follow in order to have a good vanilla plantation.

ASSAFŒTIDA.—This evil-smelling but valuable product, valuable in medicine and in Indian cookery, seems to be obtained like opium, but instead of the seed bulbs it is the stem which is wounded for the drug under notice. We quote from the proceedings of the Madras Agri-Horticultural Society:—Read the following letter from Messrs. Gray Mackenzie & Co., dated Busreh, 21st December 1882:—"We duly received your letter of 10th October and delayed replying till we could give some information regarding the assafœtida plant. We are getting some seeds from Shiraz and Ispahan and when they arrive, they will be sent to you. The bush requires a damp soil and grows only where there is plenty of water. It arrives at maturity about July-August and dries up soon afterwards. The assafœtida is procured by incision in the stem of the bush from whence the gum oozes out. The finest qualities are procured in the north of Persia, those of the south being inferior. The plant grows to a height of about 5 feet, and has the appearance of a minature tree, rather than a bush."

* The *Jatropha Curcas* is called *pignon d' Inde* or *médicinier*, in Mauritius. See *Tropical Agriculturist*. Vol. I, p. 64.

Correspondence.

To the Editor,

THE YIELD OF SUGAR IN THE SANDWICH ISLANDS.

Queen's Hotel, Kandy, July 13th, 1883

SIR,—My attention having been drawn to a paragraph in your paper of the 12th instant, in which you mention the yield of sugar in the Sandwich Islands at 10 tons per acre, I write now to correct what may prove a misleading statement.

The highest yield I have heard of from reliable authorities was 7 tons per acre, and the highest yield I ever got from my own land was 227 tons from a field of 39½ acres, or not quite 6 tons per acre. From 3 to 4 tons per acre is a remarkably good average crop.—Yours faithfully, W. HERBERT PURVIS.

HOW TO RAISE TEA PLANTS.

22nd June 1882.

DEAR SIR,—A few hints as to what I consider the proper way to raise tea plants may not be out of place, especially as from what I have both seen and heard as to the way some people treat tea seed I am of opinion that a great proportion of it does not germinate because of improper treatment. This refers more particularly to seed imported from India, which, from the length of the journey, has lost some of its vitality. I believe that all tea seed ought to be germinated before it is put into the nursery beds, as tea seed is very irregular in germinating, and it is a common thing to see seeds just germinating when seeds in the same beds put in at the same time have formed plants 6 inches high. I have found the following way of germinating tea seed very successful, viz., erect sheds facing the north about four feet wide and spread the seed evenly over the bed as close as it will lie without having one seed placed *over* another, and cover the seed with about 4 inches of manure in a state of fermentation. The heat from the manure forces on germination and the manure can be turned back and all the seeds as they germinate picked out and planted in nursery beds. I water thoroughly at least once a day, *but* old seed should be watered very sparingly at first, else it will rot.

I have heard cases of germinating tea seed in cold, wet districts by heaping the tea seed in a cistern and pouring water over it. In my humble opinion this is more likely to rot the seed than to bring in fermentation.

What is your opinion as to this cry for Jât! Jât!!? I was under the impression that different jâts suit different climates, and that it would be injudicious to plant a hybrid which approaches the indigenous Assam at a high elevation.

I was informed by an old tea planter some years ago that he got more weight of leaf off the bushes with medium-sized leaves than off the bushes with very large leaves.

I have also noticed that the bushes with medium-sized leaves have far more shoots to the same surface than the type approaching the indigenous.—Yours faithfully, ORION.

[At between 5,000 and 6,000 feet altitude in Upper Dimbula what was received as seed of indigenous Assam has proved slower in growth while in no other respect that we have ever been able to see superior to first quality hybrid. The latter flourishes splendidly up to nearly 6,000 feet and flushes copiously. So, we are bound to say, does a patch of China which came from Darjiling and was sold as first-class hybrid. The Darjiling estates were all originally planted with the China plant, but all new clearings both on the hills and in the Terai, have, for the past dozen years, been planted with best hybrid Assam, than which nothing can be better, we believe for low or high elevations.—ED.]

LEDGERIANA-SUCCIRUBRA HYBRIDS.

June 28, 1883.

DEAR SIRS,—Whilst discussions have been going on as to the most valuable varieties of cinchona, it has often struck me as strange that so little allusion has been made to the hybrid originating between *ledgeriana* and *succirubra*, though *its parallel*, *C. robusta*, has—and deservedly—received so much notice. Mr. T. N. Christie was shrewd enough to recognize the probably very great value of many of the hybrids thus originating—giving it, if my memory serves me right, as his opinion that the most valuable and useful variety of all would be found here: but further than this, little or nothing, as far as I have seen, has been said as to the very important position they are eventually likely to occupy; or, in fact, regarding them. That, as in the case of *robusta*, *pubescens*, *magnifolia*, &c., they will differ amongst themselves in quality, in fact, as do *pure ledgerianas*, there can be little doubt; but that, admitting the *parent ledgers* to be of good merit, they will prove extremely valuable, there surely can be *none*? Certainly not, if *C. robusta* be accepted as a criterion: and could there be a *fairer*? My attention has been especially called to the subject by a general analysis of *mixed* hybrid and *pure* ledger bark, of between 68·70 per cent sulphate of quinine: and, though I have not the figures by me, I believe but a *decimal percentage* of other alkaloids; so that, whether the admixture of hybrid bark may have reduced the standard or not, it must, at least, have been remarkably free from other alkaloids. That the growth of the plants is, at *least*, *double*, I have proof in some raised from *mixed* hybrid and pure seed, the former being *head and shoulder* above the latter: as *robust* and hardy, in fact, as *succirubra*, which they somewhat resemble in size and shape of leaf. And there can be no doubt that they can claim the characteristic attaching to *all hybrids*, at least, among the *cinchonas*, and otherwise too, if I mistake not, both in the *animal* as well as the *vegetable* kingdom, of increased *vitality*, and strength of constitution.

All things being taken into consideration, I think there can be little doubt that, in the future, by far the most remunerative plantations on a large scale will consist of these ledger hybrids only, unless some of the new introductions from South America can claim first place. X.

[In recently noticing Mr. Cameron's splendid cinchonas, we mentioned some good-looking calisaya-succirubra hybrids we had seen on Lippakelle. We think we have also mentioned the existence of similar hybrids on Abbotsford. These latter were grown from seed of island-grown calisayas, and when the young plants were put out we could not help thinking that a mistake had been made and that the plants were pure succirubra. As they grew up, however, they put on the calisaya foliage, only that some of the leaves were equal to succirubra in size. There are shades of varieties from pure calisaya to almost succirubra. Most of the trees are robust in habit, but we have not yet tested the quality of the bark. Trees *known* to be hybrids between true ledgeriana and succirubra, we do not feel sure that we have ever seen. Information on the subject will be welcome.—ED.]

CARDAMOM CULTIVATION.

DEAR SIR,—Lest "chaff" should pass unobserved for "grain," please accept a few remarks, in the absence of more weighty criticism, on the communication of "Aberdonensis, page 76."

In the first place perhaps you can explain how "great expenditure in upkeep is to be avoided" where "Clerihew, good roads" &c. are a necessity. Also your countryman's idea of the meaning of the word "surety"—likewise Dr. Johnson's.

In the next place, we, like yourself, would like to have some description of an Indian cardamom estate. Can your correspondent show us 500 acres cultivated cardamons 8 feet × 8 feet without a vacancy? My humble idea has always been a forest containing cardamoms infested with weeds and elephants.

Our "private orchards," of 8 to 10 acres, have, as "Aberdonensis" is aware, given a profit for a series of years of 40, 60, and even 90 pounds per annum per acre and are doing so still. Can your correspondent show us anything half as good as this on his 500 and 1,000 acre blocks? and if not can he tell us of any industry in India on which "capital might be more profitably employed"?

Then what is the knowledge of "advance and wages" of which Ceylon planters (of all people in the world) are supposed to be in want?

I believe we do *not* "yet understand how cardamoms are pulled without clipping or splitting," but as long as our London friends quote "fine *well-clipped*" at 7s I think we may be satisfied.

Whilst on the subject of bulbs (the "better" "kinds" of which, by the way, can be seen growing in one out of every half dozen gardens within 20 miles of Kandy) our friend might have given us a useful piece of information. Why will planters persist in putting in bulbs at 30s per 1,000, when seedlings, 1 inch in length at as many cents. per 1,000, and with far fewer failures, will in six months equal, if not outstrip them in growth?

"No doubt there are secrets to be learnt in India," you say. "I doubt it" said the Carpenter, and so do I and you are indeed thankful for small mercies, when you ask for "more." I think the cry of the local cardamom "fancier" will more likely be "Hold enough." The experience from which we should appreciate a sermon, is not the growth of six months. Let us have the ripe fruit, not

PARTIALLY GREEN.

[The difficulty, we apprehend, is not that "Aberdonensis" has not more to tell but that as a man emdloyed by another he is not at liberty to tell, all he knows. The superior custom of Ceylon planters is freely to communicate and exchange the results of experience.—ED.]

MILKY GUM-YIELDING CREEPERS.

Udagama, July 4th, 1883.

DEAR SIR,—Regarding rubber creepers indigenous to Ceylon. Last year I not only tried a number of experiments myself, but also sent a considerable samples of milk to Dr. Trimen,—all tending to the same result: "a putty like mass." This refers to the variety mentioned, with a very handsome large fruit, the ones in this neighbourhood at any rate, I may add, growing to an immense size, often several inches in diameter, and yielding an immense quantity of milk, which too *flows freely*. But there is another and much smaller kind, with a quite different leaf, though I fancy of the same family, which I have better hopes of. The milk however is a thick creamy consistency, and in consequence difficult to collect, though apparently plenty of it. I hope to be able to speak more definitely as to quality of the rubber soon.—Yours faithfully,

R.

[Query? Might not the putty-like substance be improved by the application of cheap chemical substances?—ED.]

LEDGER-HYBRIDS.

July 5th, 1883.

DEAR SIR,—In my letter in reference to ledger-hybrids in your issue of the 2nd inst. a slight misprint occurs regarding the analysis of bark quoted. I intended it to read "between 6 and 7 per cent sulphate quinine," and on looking up correspondence I find I might have added positively "with but a *trace* of other alkaloids" and from "original bark."

The bark was taken from a number of consecutive trees, some of *pure* and some of *hybrid* type, and not from selected trees of either; all being from the same "pure ledger" seed from trees of the best origin,—as indeed I think this analysis testifies.

Even if the bark prove less rich—though this is not at all a certain result of the cross (vide McIvor's *succi.-offic.* pubescens nearly as rich as ledgeriana in quinine—and *far richer* than *either* parent)—my impression is that a hybrid of the sort offers every prospect of being found at maturity a tree of greater value than a pure ledger of the best type and analysis of similar age; with every prospect too of a more permanent growth. I recollect a striking instance of the *improved constitution* of hybrids, in the case of the mixed clearing of succirubras and officinalis, which, though well grown trees of their age, commenced at the 4th year to die out wholesale. A few *robusta* hydrids however that had crept in amongst them, it was a well-remarked fact, *continued to flourish*; though if I remember right they were cut down the next year with the remains of the clearing. X.

THE INFLUENCE OF SUNHEAT ON THE SOIL AND PLANTS.

DEAR SIR,—Mr. G. F. Walker and those who hold his convictions may be interested in the following extracts. I am with him in agreeing that we have been suffering from a want of sunpower of late years; and that it is not the rainfall we have suffered from, but the long continuance of it with little or no intermission, and the absence of the requisite sunheat.

The sun of course is a most necessary factor in the consideration of climatic influence on vegetation; and no doubt the reason why (as someone remarked) one estate bears, while another does not, may in a measure arise from the power of retention or non-retention of the soil of excess of moisture. It takes a congenial season to make a *healthy* blossom!

The extracts are as follows:—'It has been calculated by Mr. Raikes, that the temperature of the soil when drained, averages 10° higher than it does when undrained; and this is not surprising when we find that 1 lb. of water evaporated from 1,000 lb. of soil will depress the whole by 10°, owing to the latent heat which it absorbs in its conversion into vapour."

"Faraday calculated that the average amount of heat radiated in a day from the sun on each acre of earth in the latitude of London is equivalent to that which would be produced from the combustion of 13,000 lb. of coal."

"Slightly beneath the surface of the soil in the tropics, Humboldt states temperatures of 162° and 134° are frequently noted, and in white sand at Orinoco 140°, whilst at the Cape of Good Hope under the soil of a bulb garden a temperature of 150° is recorded by Herschell. In China the temperature of water of the fields was found to be by Meyer 113°, and adjacent sand much hotter. These extremes of temperature would cause the specific gravity of the air to vary from 1167 to 863, may serve as a kind of measure of the disturbing causes which interfere with the velocity and local direction of atmospheric currents and other phenomena, the calculation of which has been founded on mean results."

It would be a good thing if certain stations were supplied with sunshine recorders, but perhaps their cost would be against their institution. Earth thermometers however are moderate in price, and are made to go as deep as 120 inches. There can be no doubt that the temperature of the ground greatly affects that which is growing on or in it.—Yours faithfully,

J. V. H. OWEN.

A NUMBER OF OSTRICHES have lately been exported from South Africa to India, where it is proposed to establish the cultivation of these birds on the system which has proved so successful at the Cape. If, on the other hand, South Africa would follow the example of India in training elephants, importing, if necessary, a number of animals for the purpose of starting the enterprise, the exchange would be of great benefit to both countries.—*Colonies and India.*

COFFEE PRODUCTION IN BRAZIL.—If we may judge by recent advices, Brazilian growers of coffee are not disposed to relax their efforts in favour of other productions. Recent reports estimate the stock of coffee in Rio de Janeiro and Santos at no less than 815,000 bags, an enormous quantity, for which, of course, markets will have to be found, and a large fleet of shipping required to convey the coffee to its destination. At the same time, many articles of ordinary food required for the consumption of the people, and which could easily be grown on the spot, continued to be largely imported, notably flour. We do not say that Brazil is poorer from having this large growth of coffee—quite the contrary, but she would be both richer and more independent if much of her food was grown on the spot, for internal consumption; and that this should be the case with her new railways there can be no question. We merely notice the subject as arising out of the circumstance of this large stock of coffee on the spot. —*Brazil and River Plate Mail.* [The case requires different treatment to this milk-and-water expression of opinion. Brazil is suffering severely for having overdone coffee cultivation and neglected the raising of food products needed by her people.—ED.]

WASTE LANDS IN TAVOY.—We have received from the Land Revenue and Agricultural Department of British Burma two copies of the rules issued with the sanction of the Government of India for the grant of waste lands in the Tavoy district of British Burma suitable for the cultivation of coffee, tea, cinchona and spices; and a photographthe of Natyaydonug range, of which the lands now offered form an part. The tract destined for plantation has been surveyed and marked out in blocks, and a bridged road traversable in all seasons is being now made between the concession tract and the points of call of the British India Steam Navigation Company's steamers. A convenient and spacious furnished rest-house has been built at the foot of the range, whence any person can leisurely prospect the surrounding country; and, should a sufficient number of planters come forward, the local Government is prepared to establish a local post and telegraph office. The photograph and rules can be seen at our office. The *Friend of India* of 30th June has a letter from its Rangoon correspondent from which we quote as follows:—

A letter appears in the *Rangoon Gazette* from two pioneers of the future Tavoy coffee and cinchona industry, giving a "rosy" account of affairs in that district and the prospects of planters. That the writers are newcomers in Burmah is evident from their writing of the "detestable dorian," a fruit which nearly all Europeans who have been here anytime are enthusiastically fond of. But although they despise the Tavoy dorian, which is accounted amongst the best, these planters say the soil is excellent for coffee and cinchona, and that the climate especially on the higher lands, is all that can be desired. Mr. Duke, the Deputy Commissioner, is making a road from the plantation to the head-quarter of the district at Tavoy, when arrangements will be made for settlers receiving their letters oftener than they do now—once a week. On the whole, these pioneers seem more than satisfied with their prospects, and it is to be hoped that their account of the country and its capabilities will lead to more land being taken up and brought under cultivation, although not much can be done in cl aring until the end of the year, for the rains in Tavoy are excessively heavy during the rest of the year.

THE BURMAH COOLY TRADE.—The *Rangoon Gazette* relates an extraordinary story about a batch of coolies imported by the S. S. "Colaba," which arrived from Negapatam on the 21st ultimo. The coolies, including men, women and children, numbered four hundred, and on arrival were marched off to a shed in the bazaar, where only a quarter of the number could be properly accommodated. The matter was reported to the Deputy Commissioner, who visited the shed next morning, and found only fifty-seven left, the rest having been taken away during the night. The cooliemaistrie was arrested and fined R100 for wrongful restraint, and one of his men was fined R10. According to the statement of the *Gazette*, these coolies are only released by the maistrie if their friends will pay an exorbitant sum for them, otherwise they are sold to any one who will pay for them, and they practically become the purchasers' slaves for a time. As labour in Burmah is very dear, coolie slaves are found to be a profitable investment. In the case in question, after the coolies were lodged in the enclosed shed, the maistries and others, who purchase labour, were summoned by beat of tom-tom, and a small fee charged for admission. They then made selections of the men they wanted, and in one instance the man was found in great distress, because his son was sold in a separate batch from himself. It seems incredible that even the docile coolie should allow himself to be disposed of in this helpless fashion.—*Sind Gazette.*

CINCHONA AND QUININE.—Says the *Pharmaceutical Journal*, of June 23rd:—There appears to be a prospect of a in the bark and quinine market in this decided improvement country. We under-stand that within the last two weeks large quantities of barkhave been sold.

According to a Report on the Drug Trade of New York, drawn up by Mr. D. C. Robbins, the importations of quinine into the United States during the year ending June 30, 1882, amounted to 794,495 ounces, against 408,851 ounces in the previous year. During the year ending December, 1882, the importation of cinchona bark reached 29,200 bales, against 31,700 bales in the year 1881. This large increase in the amount of manufactured quinine imported and the decrease in the quantity of raw material are attributed to the removal of the high duty on quinine that was formerly levied.

We understand that the patent rights in kairine, the latest proposed substitute for quinine, have been acquired by the Colour Manufacturing Company in Hochst, formerly Meister, Lucius and Co., by whom it is now being made under the superintendence of Professor Laubenheimer. It appears that two kinds of the drug are to be met with, one called "karin M," which is said to present some advantages, and the other simply "kairin," which represents the substance with which the original clinical experiments were made. Whether kairin will be more successful in ousting quinine as a febrifuge than chinoline, from which so much was expected, appears very doubtful, and we are more inclined to think that the cinchona alkaloids, produced at the moderate price which the spreading cultivation of the cinchona plant appears to bring within a measurable distance, will eventually beat every competitor from the field.

Some cultivators evidently have faith in the future of cinchona cultivation in India. A writer in the *Madras Times*, who advocates a more free utilization of the assistance that chemists are able to give in selecting the most valuable varieties suitable to particular soils, prophesies that in the event of this being done the average richness of quinine in the total bark gathered, which is taken by the writer to be in that Presidency at present 1½ per cent., will possibly, by the year 2000, have reached 4½ per cent. If so, should any of the fellow-countrymen of Macaulay's oft-quoted New Zealander happen then to be engaged in the quinine manufacture, they will be within reach of a supply of good bark.

THE CAUSE OF CANKER IN CINCHONAS.

Various people of late have been giving you their ideas on canker amongst cinchonas, and if you can spare me the space I should like to say a few words on the subject. I do not believe, as one of your correspondents does, that as large a percentage of the plants obtained in the 60's from Hakgala died of canker, but that so little attention was paid to them that it was not noticed. In the first place, most of them were placed round roads—even now the most favourable spot for their growth, as the soil is loose and the wash infinitesimal—and had they died out in the same wholesale fashion that we are now accustomed to, it *must* have been noticed. The tree was not ordinarily met with on estates, and the few there were on any estate would naturally attract the attention of the manager, and any enormous death-rate would be sure to have been noted, whereas we heard of nothing of the sort. The percentage of deaths has increased with the increase of the cultivation of cinchona, and I believe, at the present moment, is far greater in clearings than in coffee or round roads. I think it pretty certain, that the plant abhors crowding, at least with others of its kind. We have made the grand mistake of supposing that cinchona would grow anywhere, and some people seem to have thought anyhow, and we are now finding out our mistake. Our bread is coming back over the waters to us. The popular idea is that wet is at the bottom of canker—either a wet soil or a wet climate. That the former is inimical to the plant no one can for a moment doubt, but that the latter is exactly true, I for one doubt very much. Rambodde, Nuwara Eliya, and Kandapolle are far wetter districts than Haputale, which is, perhaps, the driest district in Ceylon, yet *officinalis* grows far better in the former wet districts than in the latter dry district, for with the exception of one estate (Craig) officinalis refuses to grow there, at all events in clearings. How then is this? The soil of Haputale one would think must be a very heavy and close one, as compared with Kandapolla and Nuwara Eliya. But is this so? I do not think it. I know both districts fairly well, and am not prepared to say that the soil of Haputale is heavier and more clayey than the other districts referred to. I believe, therefore, that the popular idea of the cause of canker, viz., that it arises either from wet soil or a wet climate, is sufficient to account for the many contradictions to that statement that are daily to be met with around us. Irrespective of the bad soil, bad planting, &c., argument, which only refers to the plant itself, and can easily be altered in the future in any locality, the only two other things that affect the question are soil and climate. Now, if we find, as we often do, that of two fields in our climate, or two fields in *apparently* the same soil, the one is a failure and the other a success, what is the inference? That we were mistaken in supposing the soil to be similar. It may be so to all appearance, but there must be some chemical or mineral constituents in the one absent from the other, which is essential to the healthy growth of cinchonas.—*Cor.* Local "Times."

TEA PRODUCTION AND CONSUMPTION.

We have just received reports of several of the more important Indian Tea Companies. The Assam Company complains of a deficiency of crop, owing to a hailstorm of unexampled severity, and later on to a deficiency of rainfall. The Land Mortgage Bank of India have a generally satisfactory report to render, their estimated tea-crop having been realized at a considerably reduced cost per lb. Their total area in cultivation is now 6,613 acres, the capitalized cost being £46 per acre. The Directors state however that an average price of 1s 2¾d is not sufficiently remunerative when the many risks attendant upon tea-growing are taken into account and they hope to reduce the cost price to 1s per lb. In some of the districts notably Cachar, insufficiency of labour and unfavorable climatic influences are complained of. The entire cost has been taking the rupee expenditure at 2s, and including £2 000 of Calcutta charges—equal to 1s 1 3 5thd per lb., against 1s 3¼d the previous year. If the rupee were taken at exchange value, say 1s 7½d, the cost of the crop laid down in London would appear at a fraction over 11½d per lb. The following table gives an interesting résumé of the properties of this Company and the results of working them:—

Still more comprehensive and important for tea interests is the annual report just published of Messrs. W. J. and H. Thompson. This document contains so much practical information respecting the course of the tea-market and the working of Indian Tea Companies that we give it as nearly as possible in full:—

The completion of another period of twelve months, reckoning from the 1st June, 1882, affords an opportunity for reviewing the events of the past season and considering the prospects for the future. The final figures for India and Ceylon tea, are as follows:—

Imports from	1882-3.	1881-2.	1880-1.
Calcutta	55,360,000		
Imports from other ports...	1,400,000		
Total	56,760,000	49,150,000	45,380,000
12 months' consumption ...	56,620,000	46,760,000	48,320,000
Stk on June 1—	19,070,000	19,210,000	16,510,000

The China figures are as follows:—

	1882-3.	1881-2.	1880-1.
Import.............	149,000,000	161,000,000	165,000,000
Delivery—Home consumption ..	117,000,000	117,000,000	113,000,000
Export ..	41,000,000	36,000,000	47,000,900
Total ..	158,000,000	153,000,000	160,000,000
Stock June 1 ..	58,000,000	67,000,000	58,000,000

The prominent features of the season have been the heavy decline in the average value of the crop and the large increase in consumption. The fall in value, influenced by the general depression in produce, was in a measure a natural re-action from the high average maintained throughout the greater part of the previous season, and was not altogether unforeseen a year ago by those who had taken note of the decided check to consumption caused by the high prices; the fear of a much heavier crop than was actually made, assisting to bring about this result. It was also due to the policy pursued by many of making a heavier outturn, and consequently a lower grade of tea; but not, in our opinion, so much to the inferior quality of the crop as some have assumed. For although at one time there was in many cases a decided falling-off from 1881 standard, later shipments showed improvement all round; and throughout there has been a marked absence of sour, coarse, or burnt teas unsuitable for general use, which we consider a most satisfactory evidence of progress in the art of manufacture, and of more thorough appreciation by those who make tea of the tastes of those who consume it. It is to this general good character of the crop, as well as to the low rates which have ruled, that we attribute the heavy increase in deliveries —which for the past eight months have been at the rate of 60 millions per annum for the price alone would not have forced consumption had the quality been generally inferior. In many points the season just concluded has resembled that of 1880-81, and the position of the article today—viz., a moderate stock, a growing consumption, and comparatively high prices obtainable for the finer grades —is almost identical with that of two years ago. As was the case then, the prices paid for choice teas may induce some planters to return to the old plan of finer plucking —the experience of the past three seasons, however, so fully proves that a large crop of fair average quality is more easily absorbed than a smaller one of higher intrinsic value, that we cannot counsel such a general return to the policy of making fancy tea as to shorten supplies. The interests of India seem rather to lie in the direction of a continuous growth of production, accompanied by reduced expenditure, so as to bring down prime cost to a point that will discourage immoderate supplies from China and elsewhere, and thus each year make more secure the hold upon the trade of the country which Indian tea has taken. At the same time, the most careful attention must be paid to every detail in order to make good liquoring tea; and the effect of free plucking upon quality should be closely watched, especially by those who have already somewhat lowered their standard by adopting this course —for it must not be overlooked that of late years India has had to compete with very poor crops from China; while should China at any time send a fine crop, which is not impossible, the result to Indian of poor quality would be serious. It is too early to estimate with any certainty what the coming crop will be. The lateness of the season and the bad weather in many districts lead some to look for an increase of 10 per cent. only, or even less; should this be the case, and quality be fair, there should be no difficulty in dealing with it; and producers might fairly count upon last season's average if the general market be not over-borne by excess in the China supply. The diversion to other markets of nearly four million pounds is a matter of great importance if it results in creating a permanent demand. That it has done so in Australia seems sure, notwithstanding the recent severe fall in prices and consequent reshipment of several consignments to England; and we think the American trade will steadily develop, although it is disappointing to find that a considerable portion of the shipments to New York have found their way back here, owing to the teas having passed into the hands of jobbers, instead of the retail traders as was intended. The agitation which has been raised in America against the importation of spurious greens, however, is likely to create an inquiry for purer tea, and we are advised on good authority that although the sale of black tea make slow progress, there would be little difficulty of disposing of a considerable quantity of the "Nemoenah" type, which could be substituted for Oolongs now used at equivalent prices—say from 10d to 1s 4d per lb. As supply grows larger, the difficulty increases of insuring that every parcel offered for sale receives proper attention from buyers. The only practical solution that we can suggest is to continue making the breaks larger by bulking, either here or in India (to which there is no objection, providing it can be done thoroughly without injury to the flavour)—and to make fewer classes. The larger concerns have made great progress in this direction, and their produce never fails to receive due attention from buyers: the sufferers are the small proprietors, and it is generally these who send four or five different sorts in an invoice of 50 or 100 chests, when two or three kinds would suffice. Ceylon teas have this year established their claim to rank with Indian growths, and their generally useful character has brought them into favour with the trade. About 14,000 packages, containing about 800,000 lbs., have been received, and as a large area is under plant the import is likely to be heavier this season, with a rapid increase in the future. The conditions seem favourable to produce profitable results, the yield being good on well cultivated gardens which have reached maturity, with a comparatively low cost of manufacture. We give a few statistics of results realised during the past season, the returns embracing the produce of 43,815 acres, amounting to 15 million lb., showing an average of 1s 1¾d per lb. According to circulars, the quantity sold in Calcutta was 323,000 packages, say 25 million lb., the average price being R0. 8. 7., the equivalent of which to a planter is about 1s 0¾d in this market, at the current rates of exchange and freight.

Finally, we have a very cordial reference to Ceylon teas in the *Produce Markets' Review*, of June 16th, the latest to hand, as follows :—

Common sorts sold steadily, but there was a brisk demand for the finest Indian descriptions and for Ceylon growths, at firm rates. Of the latter 770 packages were offered, and as most of these were of excellent quality, the demand was unusually active. The improvement in these growths during the past season is very marked, and if those interested in the production continue to produce teas of equally satisfactory character, they are destined to become as popular and as generally used as Indian descriptions. The imports of the past season from Ceylon reached about 1,000,000 lb., and as great attention is now being paid to cultivation, a large annual increase may be looked for. If it be true that Ceylon tea can be laid down at Colombo for 6d. per lb., the industry has an immense future before it, as the quality of the finer parcels from the island is magnificent. The reports of the Indian crop continue fairly satisfactory, although the season will be later than the previous one. The demand at the public sales this week for the fine descriptions was good, and Ceylon teas sold at higher rates, while the commoner qualities met with but moderate attention at late prices. The movement in Java teas has been unimportant, as only small supplies were offered.

There is the greatest possible encouragement to the extension of tea cultivation in Ceylon. It will be observed that the highest yield of tea per acre in India was, during the last season, 9 2-5ths maunds or about 750 lb. per acre on the Talup Estate, Assam, the crop being 753,200 lb. from about 1,020 acres. Some of the Assam estates, however, go as low as from 170 to 250 lb. per acre while the average sale prices range from 11½d to 1s 3½d. In Cachar, where the yield ranged from 250 to 450 lb., the average price ranged from 11⅞d to 1s 7½d. Darjiling crops were from 220 to 410 lb., the average prices ranging from 1s 3⅓d to 1s 7d. We cannot yet show very large areas of tea in full bearing in Ceylon, but the experience gained at this early stage of a maximum yield equal to 700 lb. of manufactured tea per acre in Hewaheta and Yatiyantota, and of 800 lb. in Ambagamuwa, warrants us in considering that Ceylon is likely to beat the best districts of India in the yield of tea, as well as by-and-bye in the average prices gained in the London market.

—Just as we are closing this, we receive a letter from a well-known tea-planter who says in reference to our Yatiyantota and Awisawella districts :—"This will be a great tea region. During the last six months, I have made 400 lb. per acre off my tea all round and yet the oldest is scarcely 4 years and a portion is only 3 years old, and as far as the trees are concerned I could have got more."

REVIEW OF BOOK ON AGRICULTURE.

Agriculture: By William T. Lawrence. Edinburgh: W. & R. Chambers.

A little work of little pretensions, but of much more than ordinary merit, bearing the above simple name, has recently been issued by the above firm. For half a century this firm has been noted for the excellence of the different educational series issued by them, and this new venture should add considerably to their reputation. We have carefully read every one of the 340 paragraphs contained within the substantial cloth binding, and are constrained to say that nowhere have we met with a book, elementary or otherwise, containing so much information in so little bulk, and in such simple, easily understood language. Its author, W. T. Lawrence, Hereford, has proved himself particularly well qualified to reach the most opaque understandings. We can hardly think of boys so dull as to be incapable of understanding the science of plant-growth as here taught, and we would urge on school boards in agricultural districts the desirability of introducing this subject as one of the necessary elements as treated in this manual. It is well printed, well bound, and low-priced.

But while bearing in mind, and placing the interest of the country first, we are not forgetful of our own readers. Frequently the treatment of gardening and farming subject from a scientific standpoint necessitates the use of terms that make the writer's words less intelligible than is desirable. This is almost always unavoidable so long as the readers know little or nothing of the science of agricultural chemistry. Frequently we have been asked to recommend books to such, to enable them to master the subject so far as to enable them to grasp the meaning of the terms now so largely used by many writers. This is a somewhat thankless task, as such works are either high-priced or useless, and generally contain an amount of matter not wanted that the general reader has not the patience to wade through and pick up the grains of knowledge he is in search of. To such we can cordially recommed this manual

Our intention was to have made several quotations to show how simple, terse, yet clear and satisfactory, is the language used, but, though we had marked rather a large number of passages, we find selection rather difficult. Almost at random we select the following, which occurs under the heading "PROPERTIES OF SOILS"—"If you were to take three flower pots and fill the first with marbles, the second with sand, and the third with fine soft powdered earth, and then pour water into them, you would find that the water would run through the pot filled with marbles almost as soon as you poured it in; but that it would take a little longer to run through the one containing sand, and still longer to soak through the third. This shows that the finer the particles of the substance the longer it will hold water: and why? Because small particles lie so much closer together than large ones, and the spaces between them are too small to let the water run through quickly. Now clay consists of very fine particles (finer particles than any other kind of soil), therefore it is able to hold water for the use of plants better than any other soil. But the fine particles of clay may be pressed together so closely when damp that no water is able to get through at all; this is not good for plants. A field with an under soil of clay in this closely pressed condition would not allow the water to pass downwards, but would cause the top to remain soaked with stale water, which is poison to plants. Such land is very cold, and also very unhealthy both for people or animals to live on or near." Such a plain illustration it is impossible not to understand. Equally clear is the next paragraph quoted, which is intended to show the capacity of soils for manurial matter as the above is to show its capacity for water.

"We took three flower pots for our experiment in last lesson; we will now take two barrels with holes in their bottoms instead this time. Let them be set up so that we may be able to catch the water which comes through. We will fill the one with sand and the other with powdered clay soil well shaken down. We will next take some of the dark-brown or nearly black nasty-smelling water that runs from a manure heap and pour part of it into each barrel. We shall find that it comes through the sand first, but is not so dark in colour as it was when poured in. The part that was poured on the clay soil takes much longer to soak through, but when at length it finds its way to the bottom of the barrel it is quite clear and free from smell." Then the reason of this is explained and the value of clay in soils made clear, also the rising of water is explained.

Space will hardly permit more quotations, but we cannot help noticing the clear way the action of drains is explained. Draining is not a very well understood part of either farming or gardening practice, we should be inclined to think from the erratic way drains are often laid. Immense sums have been thus misspent. Yet here we have the whole matter in a nutshell. After reading what is here said on the subject one can hardly understand a drainer going wrong in ordinary cases, or, in extraordnary ones, proceeding at all without proper information, for like all really good books this begets a desire for more knowledge.

The manufacture of superphosphate and its after treatment is not well understood. The action of sulphuric acid is here explained in a way that has the merit of simplicity as well as some degree of novelty. As we have frequent inquiries on this subject we will give our readers the advantage of one quotation more.

"In this process"—*i. e.*, the making of superphosbate—"the bones or mineral phosphates are treated with sulphuric acid (oil of vitriol) and the change is produced in the way which is shown in the following table:—

	Base.	Acid.	Salt.
Before the change.	Lime Lime Lime	Phosphoric acid	Tricalcic phosphate.
	Water Water	Sulphuric acid Sulphuric acid	Oil of vitriol (true sulphuric acid).
After the change.	Lime Water Water	Phosphoric acid	Monocalcic phosphate.
	Lime Lime	Sulphuric acid Sulphuric acid	Sulphate of lime.

"The change is simply this: The phosphoric acid has given up two-thirds of its lime to the sulphuric acid and received water in return, and the result is a mixture of monocalcic phosphate and sulphate of lime." To this we may add that this monocalcic phosphate is only soluble so long as it remains monocalcic, and becomes insoluble the moment it meets with lime, as it always does in any ordinary soil. When this happens it becomes plain tricalcic phosphate again, but it is none the worse, but in all respects the better of the change by the time it has become by reason of its solubility well diffused through the soil. But it is quite different when this reversion takes place before application, for then the value of its solubility is gone; then it fails to diffuse itself through the soil, and is then very little, if indeed anything, superior to an impalpable powder, while it is considerably dearer. For this reason neither lime, nor ashes containing lime or other base, should be used to dilute superphosphate. Only sulphate of lime is suitable for this. Sulphuric acid displaces phosphoric acid when in combination, but the reverse action never can occur. In conclusion we advise all who are interested in the subject—and all cultivators of the soil should—to secure the book for themselves. We venture to advise the author to prepare a good index for future editions. The table of contents is insufficient for quick and ready reference to the various parts of the work.—*Journal of Horticulture and Cottage Gardener.*

CEYLON PLUMS equal in size and flavour to the best grown in England—and not unworthy of show at Covent Garden—have been grown this season on Mr. Cotton's trees on Warwick estate, New Galway. Some we have been favored with were beauties and full-flavored.

SMITH & ELLWOOD'S FIBRE MACHINE was tried on the 3rd July, at the establishment of Messrs. J. Walker & Co. and did fairly good work in preparing aloe fibre at the rate, it was calculated, of about 4 to 6 lb. of clean dry fibre per hour. That would scarcely be profitable however even at £40 a ton in the London market.

PHYLLOXERA LAWS.—It is stated that the Princess Imperial of Germany, travelling from Austria to Venice, had to submit to the gratuitous annoyance of seeing her bouquets and flowers, that had been presented by sympathizing Austrians, destroyed at the Italian frontier. Zealous *douaniers* carrying out the Phylloxera laws, properly enough made no difference for a Princess, and perhaps the exalted rank of the insulted lady may ultimately have weight in procuring the abrogation of these stupid enactments.—*Gardeners' Chronicle.*

CHICORY BEER!—This is the newest thing out We quote from the *Indigo Planters' Gazette*:—Considerable interest it seems has been taken in a new application of chicory, which has been discovered by the researches of Herr Bartels. On account of the amount of bitter principles it contains, it is said to be applicable to the manufacture of a description of beer. Should the technical researches in progress confirm this supposition, it is remarked that the growth of chicory would acquire considerably augmented importance as a branch of German agricultural industry.

GUATTERIA LONGIFOLIA.—An important discovery, was made by Col. McLeod, R. A., Superintendent of the Gun Carriage Factory, with regard to this tree. Its timber generally supposed to be valueless, and stated to be so by most of the authorities, is of very great value. It is workable, perhaps best worked, green, does not warp, and having been bent into a required shape retains the bend. For such things as sieves and drum-hoops it is unrivalled. It is closely allied to *Guatteria lanceolata*, known as Jamaica Lancewood, and to the Lancewood of Cuba and Guiana, *Duguetia quitarensis*, used by Coach-builders where they require lightness and elasticity. *Guatteria virgata* is also said to yield some of the light wood used by Coach-builders under the name of Lancewood. *Guatteria longifolia* though one of our best avenue trees, is not so common as it should be in Madras. It is exceedingly handsome, and gives an unequalled shade. Being moreover an upright grower, it is a perfect tree for the sides of narrow roads. It is not so liable as most trees to suffer from the attacks of animals, and after the first four or five years of its life is not so slow a grower as is generally believed. There are some promising young avenues of it in the neighbourhood of the Cantonments of Pallaveram and St. Thomas' Mount.—*Madras Agri-Horticultural Society's Proceedings.*

VEGETABLE OILS.

I.—CASHEW APPLE OIL.

Huile de noix de Caju	in France.
Huile d'Acajou	in France.
Cashew Apple Oil	" England.
Hijli Badam	" India.
Watn Oaju	" Ceylon.
Acajou olie	" Netherland.

The specific weight of this oil is 0·916. It is prepared from the fruit of a plant that grows in West India and South Africa. It is called the cashew or acajou tree; also the West Indian elm. This tree grows to a height of 6 ft. and bears fruit in the second year. which fruit are square and nutty. They are called Indian nuts or Cashew nuts, while they also bear the old uame of elephant-lice. They are of the size of an ordinary fowl's egg. In the dark-brown mesocarpium of the hard fruit covering, are hollows containing a black pungent oil, which causes inflammation, and blisters on the skin. This oil contains resin of cashew and other matters. Its specific weight is 1·014. After removing the fruit envelope, and washing away a kind of cone, there remains a square, edible, oily kernel, having a nutty taste. These kernels contain 40 or 50 per cent of oil, of a clear yellow colour, a sweet taste and much resembling of almonds. The Brazilians have used this oil as food for centuries. This is the oil known as Cashew Apple Oil.

A kindred oil is obtained from the fruit of the Indian ink-tree (Semecarpus Anacardium). They are known in commerce by the names of East Indian Elephant-lice and East Indian Cashew nuts. In them also a black, pungent oil is found under the hard outer-shell of the fruit, which is used in East India as an indelible ink. The etherial solution of that is used also in Germany for the same purpose, but is at present prohibited. The seeds are also edible, and contain an inferior kind of oil of 0·930 specific weight.

II.—CROTON OIL.

Oleum Crotonis, Croton Oil.
" Tiglii Jamalgotha (Hindostan).
Huile de Croton Ratov (Arabia).
" de Tilly Duud (Persia).

This oil is the produce of the seeds of the so-called granatilla tree, Purgur tree or Burgur Croton. It is a small tree, about 5 or 6 metres high, with long-stalked, serrate leaves, which exhale an unpleasant odour, and have a nauseous taste. The plant is a native of the regions about Malabar, but is also cultivated in South Asia, the Indian Archipelago and China. The seeds and the wood of this tree were introduced into Europe towards the latter end of the sixteenth century; yet the seeds and the oil were already known in the times of Herodotus. The seeds known in commerce under the names of Purger-grains, Pignons d'Inde, Graine de Tilly, Croton-seeds, are about 1 centim. long and ½ a centim. broad, and almost of a square shape, of a swallow or a drab colour, and almost black when the soft cuticle is rubbed off. In the thin, fragile, speckled shell which constitutes about ⅓ of the weight of the fruit, is a white, beautiful kernel. The taste of the fruit is first sweet and oily, but leaves a pungent burning flavour; when warmed, they emit a vapour that affects the eyes painfully. The seeds contain 30 to 35 per cent of oil, sometimes more. In pressing, every direct contact with the skin must be avoided, and as much as possible one must guard oneself against the pungent fumes entering the nose and eyes. The oil is of an orange-yellow colour, sometimes brownish yellow, very thick, and has a peculiar and disagreeable smell. In water it is completely insoluble, whereas it is easily dissolved in ether and sulphureted carbon. Croton oil is a powerful purgative, even when rubbed in on the abdomen, it causes violent purging and even bloody evacuations. Applied to the skin it is absorbed at once, causes in a few minutes a violent burning pain, the skin turns fiery red, and a strong eruption ensues. The specific weight of the oil is 0·942 to 0·955, according to its age. This increase of specific weight by age, points to the thickening of the oil, which also in other respects approaches to the siccative oils. Formerly only East Indian and English Croton oils were known to commerce: the former was yellowish, the latter brownish-yellow. Of late years a good deal of Croton oil has been produced in Germany, from seeds imported from India through Madras, Calcutta, etc., to London, and thence transported to Germany. The two houses, F. Witte, at Rostock, and Gehe & Co. at Dresden, provide all Germany, Russia, Denmark and even parts of America with Croton-oil.—*India Mercury.*

THE USE OF MANURES.

Many gardeners may be ready to say, "Give us the manure, we can show you how to use it!" It is quite true that in many districts the difficulty of obtaining manure is very great, but it is also too true that when good manure has been carted a considerable distance over difficult roads, the best is not made of it. Even the growers for market, who ought to be alive to their own interests, do not set a good example in this respect. The difficulty of carting heavy loads of manure over the country roads and lanes is enormous, and during the past winter I have frequently seen five strong horses harnessed to one waggon. Hundreds of tons of good London manure are piled upon the roadsides, where it lies for months, until the ditches are turbid with its inky juice. It is quite certain that this is the worst way to use manure. It is not always possible to cart it on to the land, but when this can be done, it ought to be done at once; and it is better to spread it over the land than to lay it down and let it lie in large or small heaps. The best manure, when it can be obtained from London or other towns, is to get equal quantities of cow and stable manure, and to throw them up together in large heaps; the cow-manure prevents the other from overheating itself, and waste is avoided in that way, which is as bad, if not worse, than allowing its essential properties to be washed away by the rains.

I consider this mixture the best of all manures; and when it can be obtained, artificial manures are not needed. I throw the two together, mixing well, and it never becomes overheated. I like it to lie in the heap ten days or a fortnight before trenching or digging it in. Excess of fermentation destroys the most useful part of the manure, reduces it to two-thirds of its original weight, and burns up, as it were, perhaps half of its fertilizing properties. In what may almost be termed the dark ages of gardening it was thought that unfermented manure imparted a disagreeable flavour to vegetables and fruits, and gardeners did not care to use the manure until it was completely decayed. In the composts recommended by the old florists, I have sometimes wondered that the quantity of manure did not kill the plants outright; and so it would have done if it had been used with all its fertilizing properties in it, but most of these have evaporated during the two or three years' exposure to summer suns and winter frosts. The dung of fowls and pigeons is very strong, and is as good as guano for most crops.

I lived for some years in a situation where a very large supply of the best vegetables and fruits was required, and no farmyard manure was allowed for the gardens; and yet we never dug or trenched any of the quarters without dressing them with manure. In that garden not a leaf of vegetable refuse was wasted; it was all laid up on a heap —mowings from the lawn. Cabbage-leaves and stalks, potato-tops, and all the leaves of trees that could be obtained; the gardener was also allowed to bring away the drainings from the farmyard, which was collected in a tank. Many cartloads of this liquid were thrown over the heap, and when the leaves and refuse were turned over together it formed a heap of good manure, which was used for everything. The vegetable refuse heap ought not to be neglected.

Green vegetable matter may also be used with advantage. On some of the large market farms it is the practice to sow with rye part of the ground that has to be cropped with potatos, and when the rye is about a foot high it is ploughed in. I have seen part of a field sown with rye to be ploughed in, and the other part left vacant. The fallow part had a good dressing of manure at planting-time, and as good a crop of potatos was obtained from the one part as the other. Rye has sometimes to be wasted when it comes on too fast in the spring; a hint that it is an excellent manure may be useful. If seaweeds can be obtained, they form an excellent manure for Asparagus, and I believe also for seakale and artichokes.

The seaweeds do not require any preparation to fit them for the use of the plants. When I lived within the sound of the breakers in Fifeshire we used to cart the seaweed direct from the beach to the Asparagus beds. The value of this manure consists in the salts it contains. Soot is a very useful agent in the kitchen-garden, and said to be "a very powerful manure" when thrown on the ground in a dry state. It is much used by growers of vegetables for the market, who find it especially useful for the onion crop. I would not like to say that it would quite prevent the attack of the onion-maggot, but in some instances, when applied at the right time, it has resulted in a good crop, free from the maggot. I have found it very useful for destroying the celery-maggot, and it also gives vigour to the Celery plant. It is best to begin dusting the plants overhead in the early stages of their growth, before the leaves are injured, and to dust them at intervals during the growth of the celery. It is also a deterrent for slugs and should be dusted over Lettuce and Cabbages in a young state.

Wood-ashes are most valuable agents in the kitchen garden, not only as a manure, but by acting mechanically on heavy soils. I do not see how the ashes can destroy wire-worm, as they are said to do, but they are used with good effect on beds of carnations and picotees, and I only wish I could get a quantity for the Broccoli, Brussels Sprouts and Cauliflower quarters. They should be spread over the surface, to be forked in lightly before planting the crop. They will also check the progress of the turnip-fly, and if persistently used from the first will save the crop. I would like here to place emphasis on the words "persistently used from the first," because in many instances such instructions as I have given are carried out in the most perfunctory manner. When the leaves of the turnips have been well riddled with the fly, a dusting of ashes may be thrown over them: and even then care may not be taken to dust all the leaves, and the operation is finished. Now the leaves must be dusted if the fly is only expected, and they must be dusted two or three times a week, until all danger of the fly attacking them is over. The leaves should be wetted before dusting them.

Lime is a most useful manurial agent in the kitchen garden, and should be used in soils deficient in calcareous matter, but should not be used as quick-lime. An old writer, who had a perfect knowledge of kitchen gardening, writing on this subject, says: "All soils which do not effervesce with acids are improved by mild lime" (that is lime which has been exposed for some time to the action of the atmosphere), "and ultimately by quicklime; sands are more improved by limes than clays." When a soil which is deficient in calcareous matter contains much soluble vegetable manure, the application of quicklime should always be avoided, as it tends either to decompose the soluble matters by uniting to them carbon and oxygen so as to become mild lime or it combines with the soluble matters and forms those compounds which have less attraction for water than the pure vegetable substances; the case is the same with respect to most animal manures, but the operation of the lime is different in various cases, and depends on the nature of the animal manure." Magnesian limestone does not answer for all classes of soil, but may be applied in quantity to peat soil. Lime ought to be at hand always in the kitchen garden, to throw over the land to destroy various grubs, slugs, &c. When our vine borders were made at Loxford Hall, I used mild lime in considerable quantity. It was mixed with our light sandy soil, and the quality of the grapes far surpassed my most sanguine expectations. I would use mild lime on the Broccoli quarters always in the same class of soils. I fancy Mr. Barron told me that he could not grow Broccoli on the Chiswick Garden soil. If lime has not been tried, I would advise its use as an experiment.—*Gardeners' Chronicle.*

THE FERNS OF INDIA.

Handbook to the Ferns of British India, Ceylon, and the Malay Peninsula. By Colonel R. H. Beddome, F. L. S., late Conservator of Forests, Madras. Large 8vo, 500 pages, with 300 illustrations. (Calcutta: Thacker & Spink; London; W. Thacker & Co., 1883.)

For something like the last thirty years, Col. Beddome has made a special study of Indian ferns under very favourable circumstances. Holding as he did till about a year ago the post of Chief Resident Conservator of the forests of the Madras presidency, he was brought into daily contact with them in his official work, and at his home at Ootacamund, he formed a large collection of them under cultivation, many of which have never reached England in a living state. About 1860 he commenced his wellknown series of illustrations of Indian ferns, in continuation of Wight's "Icones," in which the ferns had been entirely neglected. His plates, like Wight's, were in quarto, uncoloured, and were mainly executed by native artists. His "Ferns of Southern India and Ceylon" contains plates of 271 species and varieties, and was issued in parts and finished in 1863. His "Ferns of British India," which was devoted to the species not found in the southern presidency, contains 345 plates and was finished in 1868. In 1876 he published a supplementary part, containing 45 additional plates, thus raising the total number to 660, and a revised general catalogue and summary of genera and species. Now he has retired from his official position and come to England, and the present work is the first-fruits of his leisure. It contains in a handy form a full description of all the Indian genera and species, and is illustrated by 300 uncoloured plates, reduced by means of photography from those of his larger books, one full page plate, with analytical details being given for each of the ninety-eight genera he adopts, and the others of smaller size interspersed amongst the letterpress. It is the first special book of portable size and moderate price which has been devoted to Indian ferns, and is in every way deserving of the extensive circulation it is sure to obtain.

India is one of the great fern centres of the world, and it would not be an extravagant estimate to say that three-quarters of the genera and one-quarter of the whole number of ferns are known to grow within the area covered by the present work, which is precisely the same as that included in the "Flora of British India," by Sir J. D. Hooker, of which, three volumes are now completed. Europe is not a rich fern-continent, and most of the European species extend their range to the Western Himalayas. The Malay Islands are very rich in ferns, and a large proportion of the Malayan species extend to the Eastern Himalayas and the mountains of the Peninsula and Ceylon; and there are in India a considerable number of endemic species. Col. Beddome deserves full credit for not making or admitting species upon insufficient grounds, and the number described in the present work does not fall far short of six hundred, all of which are Filices in the restricted sense, the Lycopodiaceæ and Rhizocarps, which would carry up the number a hundred more, not being included.

Ferns are plants that suffer very little in the drying process, and they are generally the first plants to be collected when a new country is explored. But on the other hand they are often far too large in size to be well represented in herbarium specimens, and often so extremely variable in habit, that it is very easy to mistake a mere casual variety, for a genuine species. The first naming of Indian ferns on a large scale was in the great herbarium of Indian plants distributed by Wallich; but he gave no descriptions, simply names and numbers and localities, and very often confused together two or three totally different plants under the same number. In the five volumes of his "Species Filicum," the species were worked out and described by Sir William Hooker; and they were worked up again with abridged descriptions in the "Synopsis Filicum," which it fell to my lot to continue after his death. In England, the other botanists who had specially attended to Indian ferns were Prof. David Don and Messrs. John Smith and Thomas Moore. So that till within a comparatively recent date no one had written upon Indian ferns who had had any chance of studying them in the field. But now the matter stands upon an entirely different footing. In 1880, Mr. C. B. Clarke, who, after working for five years at Kew on the "Flora Indica," has just returned to India, and who had paid special attention to ferns whilst collecting largely in the Himalayas, published in the first volume of the new botanical series of the *Transactions of the Linnean Society*, a revision of the North Borneo species, illustrated by 36 plates; and now Col. Beddome, whose field experience has been mainly gained amongst the mountains of the Peninsula, has worked up the whole series, with a full opportunity of consulting the type-specimens of his predecessors, deposited at Kew, the Linnean Society and the British Museum.

As regards details of generic and specific limitation, of course, no two authors who work independently, but will vary considerably. In the matter of fern-genera, systematists are divided into two parties—one regarding a difference in veining as sufficient in itself to found a genus upon, and the other maintaining substantially intact the time-honoured genera of Swartz and Willdenow, which are founded entirely on characters derived from fructification. Of the first party among modern writers, Presl, Fée, Smith and Moore, are the leading representatives, of the latter, Hooker, Mettenius and Eaton. Upon this matter I differ from Col. Beddome, and the difference amounts to wishing to use different names for perhaps half the species included in his book. Of course, what he and Mr. Clarke have written about species-limitation and the distribution of the species through different parts of India will be a great accession to our knowledge; but I am rather amused to see that out of the limited number of new species which Mr. Clarke made, he refuses to admit at least half; and that he totally rejects the only material innovation that Mr. Clarke proposed on the classification of our "Synopsis Filicum," the dividing of our *Asplenium umbrosum*, to establish out of part of it a new section of Asplenium, to be called Pseudallantodia, and characterized by a sausage-shaped involucre bursting irregularly. The only points on which I feel inclined to find fault with him are two. The first, that in his key to the genera he puts Hymenophylleæ under Polypodiaceæ, without taking any notice of the difference in the structure of the sporange, but I see this is noticed in the detailed diagnosis at p. 28. It seems to me that Hymenophylleæ have excellent claims to be regarded as a distinct sub-order. The other point on which I wish to enter a decided objection is to the plan which he follows, or rather want of plan, in citing the authorities for the specific names. When he places a species under a different genus to that under which it was classified by its original describer, he moves backwards and forwards without any uniformity between four different ways of citing the authority. Sometimes he writes "*Gleichenia glauca* (Hook.)" for a plant described by Thunberg as *Polypodium glaucum*, and transferred by Hooker to Gleichenia; which is the plan usually adopted by botanists. But in many other cases he writes "*Botrychium Lunaria* (Linn. under Osmunda)" when the species was described by Linnæus as an Osmunda and transferred by Swartz to Botrychium; or "*Cyrtomium falcatum* (Sw.)" when Swartz called the plant *Aspidium falcatum* and Presl transferred it to Cyrtomium; or even "*Lastrea thelypteris* (Desv.)" for a plant published first by Linnæus as a Polypodium, transferred by Swartz to Aspidium, by Desvaux to Nephrodium, and Presl to Lastrea. And the same uncertainty vitiates his citations of books at the end of his descriptions. His citations refer to the plant, but according to the accepted usage amongst botanists they will be taken, and very often wrongly taken as referring to the binomial name as used, so that if any one copies synonymy from the book without checking it off he will often find it leads him astray. J. G. Baker. —*Nature.*

REPORT ON SOME OF THE INDIARUBBER AND GUTTAPERCHA TREES OF GUIANA.

BY THE GOVERNMENT BOTANIST, MR. G. S. JENMAN.

On the publication in *Timehri*, the Journal of the Royal Agricultural and Commercial Society of British Guiana, of my report to Government on *Hevea Spruceana*, inquiries were addressed to me by persons interested in the matter for more specific information than that report contained as to the yield of this newly-found species of *Hevea*, the age at which it might profitably be tapped for its juice, and the nature of the land best suited for its growth under cultivation. These were subjects which the time at my disposal only permitted me to investigate partially on my former journey, and on the receipt of the applications alluded to above, I deemed it important that, as far as possible, the information should be obtained. As soon, therefore, as I had the time to spare after my return from England in September, I obtained the approval of his Excellency the Governor of my design, and permission to visit the interior to acquire by personal observation and experiment the objects stated.

The journey which was the subject-matter of my former report on this species of *Hevea* was made on the Essequibo and Mazaruni rivers, where in certain creeks, and in scattered and often distant localities on the banks of the main rivers, I found, by my own investigation, and by inquiry of the Indians and other residents, the tree to prevail in more or less abundance. This being so, it appeared to me that, on this occasion, while carrying out the primary objects of my mission, I might make further acquaintance with its distribution; to accomplish which in the best way, I deemed it would be advisable not to return to the rivers with which I was already acquainted, but to visit another part of the country. It was necessary, however, to determine in advance that the region I might decide to take was not destitute of this tree; and finding, on inquiry, I could accomplish my object on the Pomeroon river, which flows through a region that was hitherto unknown to me, and divided by a wide tract of country from the rivers I have mentioned, I took this river for my operations. Mr. im Thurn, the Special Magistrate of the district, was good enough to ascertain for my assistance the situation of some of the best localities, to save me any delay in seeking this information on my arrival, and I may here acknowledge the material assistance I derived from him in this and other ways. Indeed without his aid I should have found my movements very difficult at times, with the sparse population of the region and under the bad weather which I, unfortunately, experienced.

To make the information in this report intelligible to readers who may not have the former one to refer to, it will be necessary as I proceed to touch occasionally on matter which that contained; and in this connection I may mention that the Indian* names of *Hevea Spruceana*—taking the tribes who inhabit the belt of country in which its distribution is principally embraced—are, *Arawack*, Hatie:—*Caribisi*, Poomui:—*Ackawoi*, Sibi-sibi, of which the *Arawack* name is the most generally known by the river residents, and that it is a tree very similar in general appearance to *Hevea brasiliensis* which yields the valuable Para rubber, and which is at present the most important of the caoutchouc trees worked for market. Both trees attain about the same dimensions, and appear to grow under precisely the same conditions. Indeed the description of the ground on the Amazon given by the collector Cross, would apply literally to the ground on the rivers of this colony occupied by *H. Spruceana*.

At this time of year (December), which is the height of the winter rainy season, the land is partially flooded, but the cessation of rain for a few days together makes a great difference in the quantity found diffused over it. The water lies in shallow pools between the trees, or is spread in sheets, when deeper, over wide spaces of ground, and the surface-soil generally, especially where this tree most abounds, is hardly more firm or dense than mud. It will give an idea of its character when I say that I wore a pair of high laced-up shooting boots, but with the best care in moving about, and stepping mostly on the more solid soil which is usually found in hillocks around the butts of trees, or on the fallen bits of wood which stretch between them, in spite of my care, I was constantly sinking to their tops and over, so that my socks were coated with mud. I am speaking, as I have said, of the wet season of the year, but even in the dry, the ground continues in a very moist condition. The land is usually very densely shaded, and in many places, probably in consequence, produces very little undergrowth. It appears probable that ground such as I have described is essential to the best development of *Hevea*, as where these conditions most uniformly prevail in the localities where it is found, there most of the trees occur; and to this circumstance I am disposed to ascribe its greater prevalence on the creeks than on the main rivers. On the latter the banks are rather higher than they are on the former and in many instances higher than the land within them, The surface drainage of the country is in the first instance into the creeks, and their banks are intersected with numerous and near channels,—a feature which the banks of the

* "Indian": of course natives of South America are in every case meant. That the term "Indian" should still attach to these people is only a lesser blunder than that of naming the western world, which Columbus discovered America—Ed.]

main rivers do not so characteristically exhibit. So prevalent is water on the land abutting the creeks, that on one occasion on this journey I travelled the greater part of a day before I found a place I could land, where the ground was sufficiently dry to allow of my moving about. In using the word creek, which is applied in this colony to all the tributaries of a main river, some of which are very large, and even navigable to large craft for many miles, I speak of the smaller ones over which the trees on each hand more or less meet, for on these I have found the Hatie to most abound.

I have taken the occasion to describe rather fully the character of the land, as it is important that persons contemplating the cultivation of this species of *Hevea* should be well informed as to the conditions which prevail in its native haunts. Doubtless the tree might be grown on dry land, or land dry comparatively to what I have described, but the conditions which accompany its distribution in a state of nature are the most reliable guide as to what it requires for its best development in the shortest time; and these favour the presumption that the growth would be slower on such land than on land most approximating in character to that on which it is found spontaneous. In this as in other similar cases, the nearer the natural conditions are copied in cultivation the greater the probablitity of accomplishing the highest success. I have had unquestionable evidence from observation of plants in the Botanic Gardens of the sensitive nature of this tree under conditions which diverge materially from those which I have described, though I must acknowledge that the *Hevea* among trees inhabiting the same low alluvium is not singular in this particular.

As to the rate at which the Hatie grows, I can only adduce the evidence gathered from residents of the rivers and forests of colony. A very intelligent half-breed, who has been acquainted with this tree from his youth, and for many years resided on the Essequibo where it is particularly common, described it to be of very quick growth, though it is always slender in proportion to its height, and appears, comparatively, more so by the absence which it uniformly exhibits of branches while young, of which, it makes very few at any period of its life. He estimated speaking of it, of course, in its native habitats, that it attains a diameter of eight or nine inches in five or six years. If this be correct, I think it must be its extreme rate of development under the most favourable conditions, for from what has been experienced of the growth of *Hevea Brasiliensis*, which, as I have said is a very similar plant, under cultivation in the several countries where it has been tried, under, however, I believe, generally, conditions which conform but little to those which prevail in its native haunts, one would infer it not to be so great. Yet I feel convinced that had the Brazilian plant been tried on alluvial ground, well sheltered from wind, with a very moist atmosphere, and shaded by large trees, their growth would have been much greater; and perhaps, so much improved as, considering the relative very medium dimensions of the members of the genus, to be regarded as rapied.

My experience on the Pomeroon of the ultimate development of *Hevea Spruceana* agrees with the conclusions I arrived at regarding it on the Essequibo and Mazaruni rivers. At its best it is not a large tree, and rarely, I believe, exceeds twenty inches in diameter, squaring for timber to about fourteen or fifteen inches. The wood is hard, but how durable I do not know, and it appears to be of a character to be easily worked. The sap wood is white, but large trees have a few inches of dark centre, and its specific gravity is less than that of water. The bark is rather thin and smooth, and it adheres tenaciously to the wood. On trees a foot or more in diameter, it is not a quarter of an inch thick. When found in high forest, surrounded by others, the trees are quite straight and erect and attain a height of sixty feet or more, with a few branches at the head. The upright trees are more conveniently tapped than those which, standing on the banks, lean out over the water; the position of which is both awkward for cutting the bark and catching the flowing juice.

I may here again call attention to the facilities which this colony affords on all its rivers—and on that portion of them too which is accessible without difficulty or much expense, i.e., that below the falls—for the cultivation of *Hevea*. To have the trees close together, as they would be under a state of cultivation, for the convenience of the collector, would be an important desideratum and reduce the cost of collecting to a minimum. The waste of time which the most systematic collectors experience when the trees are growing in a natural state, scattered as they are through the forest, must very considerably enhance the cost of the labour. The cultivation might be successfully pursued, not only where the trees are found spontaneous but, as well, on land of a similar, or identical, character, though on which, through other circumstances, they are not naturally established. The labour required would be very inconsiderable, and a few hundred acres, treated with care and intelligence, would prove in the course of years a source of considerable means to the proprietor. If planters in Ceylon and India speak hopefully, as they do, of the eventual success of *Hevea* cultivation in those countries, here, possessing all the natural conditions, and the advantages derived from an intimate acquaintance with these under the actual occupation of the trees, the success should be assured. Wherever the tree is found, in the fruiting season—April to June—seed may be procured in fair abundance. If sown at once under the trees in nursery beds prepared from the lighter soil and leaf-mould which the forest affords in places the plants would spring up rapidly, when they might be carefully lifted, with their rootlets unbroken, and planted at intervals under the other trees. Where the latter are too close to admit the amount of light required, they should be thinned out first; and it might be necessary to carry this on with care from time to time with the increasing requirements, both for room and light, of the planted trees. In some seasons and places it would be unnecessary to collect and sow seeds as natural seedlings may be gathered under the trees. I think, though my opportunities of observation have not been extensive on the matter, that the spontaneous production of seedlings depends very much on the character of the season when the seeds fall. If the rains have been very heavy and the land is flooded, they lie in the water where they drop and decay, but if the season has been light, or if the water has subsided, they drop into the muddy surface and germinate. This, too, is the only way I can account for their abundance in one place and almost entire absence in another where the parent trees equally prevail. A good many seeds are consumed by animals, for fish and birds, and probably such quadrupeds as Acourie and Labba, are fond of them. The *Hevea* cultivator should be prepared to wait for his crop, but meanwhile any trees already on the ground might be utilised and the produce sold. Seeing the increasing demand for indiarubber, with the daily extension of its application, and, particularly, the value of *Hevea* rubber, as compared with other kinds, the results of the enterprise might be looked forward to with the utmost confidence. Manufacturers will take all they can obtain, and were it only more abundant in the market and cheaper, many new uses might be found for it. To give an idea of the importance of the Brazilian trade in rubber, I may mention that the export from Para for the half-year ended June last reach the value of $12,350,000. It illustrates, as well, the value of the industry which is within our reach. The present market value of Para rubber is 4/6 per lb. The cultivation might be carried on in conjunction with woodcutting, plantain growing, or any other immediately remunerative industry which would enable the cultivator to tide over the time till the trees reached the age of production.

With regard to the question of the yield of *Hevea Spruceana*, it seems to me from my late experience and what I have been able to gather of the yield of *H. brasiliensis*, to be not less productive than that species. It must be remembered that though the Para tree has gained so great a commercial reputation and importance, its yield of milk is exceedingly small. Cross, the collector for the India Office, to whom I have already alluded, says that fifteen of the cups used on the Amazon by, the collectors make an English Imperial pint. Rarely however, a cut produces a cupful, for he adds, "the quantity of milk that flows from each cut varies, but if the tree is large and has not been much tapped the majority of cups will be more than half full; and occasionally a few may be filled to the brim." And of trees which have been wrought in previous years he says: "though tapped in only two or three places, the quantity of milk obtained is surprisingly little." Now I came to the conclusion while experimenting on the Hatie that the yield of good trees was hardly, if any, less than this. The chief difficulty experienced is in the method and means of collecting the juice; every drop is of value, and it is important that there should be no waste either by imperfection of contrivance for catching it as it issues from the bark, or by the employment of unsuitable vessels. The instant an incision is made, the milk begins to run, and it naturally runs faster at first than it does later, so that the collector must be prepared to immediately apply, in a dexterous and effectual manner, his means of catching it. Again, if unsuitable vessels are used as to character or size, waste will be experienced by the diffusion of the milk over unnecessary surface, to which it adheres in a very surprising manner. The little loss or reduction which occurs in drying in the change from milk to rubber, and the considerable bulk of the latter resulting from the process, also strike one, though it is probable that the quality of the milk, as well as its quantity, depends upon the age of the tree. I was under the impression that the character of the vessels employed in collecting the juice was a matter of little consequence, and therefore I prepared none of a definite character. I shall have occasion to speak further on of another mode of collecting, but for this which I am describing I am disposed to approve of the kind of cups used on the Amazon, and also of the method there practised in the operation. These cups are round or flat or slightly concave; the latter forms being most in use, as they fit more closely when pressed against the tree. They are made of burnt clay. Our Caribisi Indians, who are potters to themselves and the various other tribes, would no doubt produce similar vessels at a very cheap rate. They are stuck to the tree immediately under the incision made in the bark by the collector's axe, by a small lump of well wrought clay. On the Pomeroon where the trees grow, in the banks of the creeks, I found a very suitable clay, which I employed in my operations. It is necessary to smooth a little of it over the edge of the cup so as to direct the juice in. For gashing the bark, I think a small axe with a short handle for use with one hand would be the best adapted instrument. This could be used with ease, and it is of very material importance in carrying out the work that everything employed should be of a character to enable the operator to manipulate it with dexterity. The Para plan of making a single circle of incisions each day is, too, I consider, the best to pursue. Nothing is gained by making numerous cuts close together: the flow of juice should be allowed to take place by a few rather than several exudations. If it occurs from too many for a certain area, so little is obtained from each as to be a mere drop or two in a vessel, which, diffused over the large surface of the several receptacles, involves a proportionately large loss by surface adhesion, in addition to the time and labour taken up by the extra work. A circle of incisions is made each day, extending from as high as one can reach and working downwards day by day to the base of the tree. They should be made about six or eight inches apart; the incisions in the circles being in quincunx order.

I recommend this system as the most economical for collecting the fresh juice, but were the waste of the trees not a vital consideration, a less conservative plan might be practised. Much more is obtained in one operation by cutting the tree down and tapping its bark the full length of the trunk, than by the above method. The yield I found in this way several times greater as the immediate result. But to the permanent loss of the tree as a rubber producing agent, though the timber might perhaps be turned to account, must be added the considerable waste which occurs in collecting the milk by the number of vessels or wide leaf surface required to catch it. I employed banana or pieces of trooly (*Manicaria saccifera*) leaves, from which in part the men, as well, made the cups which were used when the trees were tapped standing, laid under the postrate trunk which I ringed at intervals of ten or twelve inches. But as I have said, it is a wasteful method, so much of the milk adheres to the leaf surface. Yet I fear that when the collectors turn their attention to Hatie and other indiarubber trees, this will be the system they will adopt, as it is already established by practice in the colony wherever balata is gathered. From large trees thus destroyed a pound of rubber might be obtained on an average each, but I do not think more. The market value of this, supposing to be of the same quality as Para rubber, and cleanly gathered, would be from three shillings to four shillings and six pence; which, though it may be urged with some truth as regards the present as a paying price, the timber possessing no commercial value, seems an insignificant sum to destroy a tree for. I doubt, however, considering the low relative price which balata fetches, though the trees which produces it is so much more prolific in milk, and so much larger than the Hatie, whether the trees destroyed by balata collectors return, for balata alone, so much as three and sixpence each on an average.

In my former report, guided by certain leading evidence, I expressed belief that other species of *Hevea* might be found in Guiana: but up to now none has directly come under my personal notice. I have been informed, however, that there grows on the Mazaruni, in that part where the rise in the country first begins, above the first falls, a tree which the Arawack Indians call Hatie-balli, from its resemblance to the Hatie, producing a similar but smaller fruit. From what I can gather, and the inference which may justly be drawn from the usual acuteness of Indians as to the affinity of plants, I am under the impression that this will prove to be a second species of *Hevea*.

I have now to speak of another indiarubber tree which I became acquainted with on this journey, the discovery of which I regard as of great interest and importance. While carrying out my investigations with the Hatie, Mr. im Thurn informed me that he had seen in the coreal of some Caribisi Indians at his waterside, two or three small balls of indiarubber, which were exceedingly elastic. This appeared to me to accord with the stories brought home by the early travellers in the West Indies, when the islands were occupied by Caribs, and which also some existing travellers in this colony have told me they had witnessed, of indiarubber balls used in the festive games of the Indians when assembled at paiwarie feasts, an instance of which I had never met with in my own travels. I therefore determined at once to visit the country where these Indians described their residence to be, and gather what information they might be able to give as to this rubber and the tree which produced it. I was not certain, however, that it was not the production of the Hatie; but I thought this improbable as I had met no Indians anywhere who possessed any knowledge of the rubber produced by the Hatie. The weather at this time was exceedingly wet and the downfall of rain nearly continuous. On reaching the waterside on Myrack Creek just before midnight, after a wet day and a tedious pull for several hours through the darkness, I found the land flooded within the banks, and the sheets of water bridged over by long logs. Most of these sylvan bridges were covered six or eight inches deep with water, and the footing was, to me, in the profound darkness of the forest treacherous and uncertain to a degree. A walk of about four miles through deep forest on an Indian trail brought us to the settlement, only to discover that my guide had mistaken the creek and, consequently, come to the wrong people. This was, however, I found the neighbourhood of the tree I was in search of, and the next day the collector of the gum, as the river inhabitants term every substance which exudes from a tree, was found at Comageguru, the next creek. He had in his possession seven or eight balls of various sizes, the larger ones weighing nearly a pound and a half. I could not discover that he had had any definite object in view in gathering them. The larger balls were, I should think, too big for employment in any Indian games. His object may have been merely the speculation that he might barter them on the river, or down at the coast, as they do balata, considering it an analogous substance. In the afternoon when the rain stopped he took me to the same trees from which he had collected the rubber in the balls. They were situated near a newly-made clearing intended for a provision ground, about an hour and a half's walk through the forest from the landing place on the creek to which I had come the night before. Passing over the cleared ground on which the bush had not yet been burned, we had to dive again into the forest to reach the trees. I have noticed a good deal of destruction in places of valuable timber in the clearings made for provision grounds, and this more particularly with the half-breeds who live on the lower parts of the rivers and grow plantains, which acquire a stiff soil upon which some of the better woods grow. Only recently I came on a bit of forest which had been underbushed for a provision field, the standing timber of which consisted of greenheart and other valuable trees. Whether any of this new rubber tree had perished in this clearing it did not occur to me at the time to ascertain, but it is not improbable, as those I examined stood on the skirt of the ground

The trees were large individuals, four or five feet in diameter of trunk, and one hundred and twenty or more feet high. Their trunks were long, straight and unbranched for sixty or seventy feet from the ground. The lowest six feet of one had been scarred, and from the scars the milk had run and was dried in tears or strings several inches long on the bark. Most of the congealed rubber was, however, contained in the fissures made by the cutlass cuts, from which places it was rather hard to extract it because of the tenacity with which it held to the inner bark from which it had oozed. I gathered and made a ball, following the Indian plan of winding it up like twine, of what was on this trunk. They scar the trunk and then leave it, the milk oozes from the wounds, trickles down the bark and coagulates and becomes dry in a few days. My guide said it took three days to dry, but I should have supposed a shorter time might accomplish the change, the little rivulets are so very thin. That which was in the old cuts—cuts probably a year or more old—had turned black, but that in those recently made was nearly milk-white. The Indian boys, who are perhaps accustomed to play with the balls, as I noticed from several which they brought me they never make them large, stripped the dry strings very dexterously from the bark, taking good care to extract the larger portion to which I have alluded partly concealed in the incisions, and stretching it with a good deal of tension, wound it up. These balls have wonderful elasticity and bound with very little impulsion several feet off the ground. The rubber too seems exceedingly tenacious and strong. This method of collecting is that pursued in Ceara, the province of Brazil which produces *Manihot Glaziovii*. It is very economical of time, for it saves the tedious operation of catching the milk in a vessel as it issues from the wound, which is the most bothersome of all the operations. The principal objection to it is, that the rubber becomes soiled by the dirt adhering to the bark, a little of which it retains, and no doubt this would deteriorate its market value; but this cause of depreciation might be reduced to a minimum by carefully brushing the surface down prior to commencing collecting operations. Rubber which has foreign matter incorporated with it, is classed under the term negrohead in the market, though its value depends on the measure of its freedom from dirt or other substance having regard of course to the quality of the rubber itself when clean.

The branches of the trees I saw were so high that the character of the foliage could not be distinguished from the ground, and, as there was no means of ascending trunks so stout, I had to resort to the aid of a gun, and with this shot some branchlets off. It was, I was sorry to find, not the flowering season, but judging from the foliage alone, the trees appear to be a species of *Ficus* or *Urostigma*, but in the absence of flowers and fruit its could only be identified conjecturally. The colony abounds in different plants of the above genera, of which, presumably, other species to this are also valuable. Some of them are known to attain large dimensions. The seeds are dispersed by birds and other animals and they germinate on other kinds of trees, principally palms, among the leaves, from whence they throw a root to the ground which again emits branches, and these with the main root in course of time amalgamate and form the base of the tree. It is curious to notice how these root-branches fuse together and form eventually a concrete trunk. I regard the discovery of this tree of great interest and probable importance, attaining as it does such a vast size, and producing a material of apparently excellent quality. The Indians know it under two names, the *Carabisi* calling it Touckpong and the *Arawacks* Cumakaballi. Noble in all its proportions, spreading and lifting its massive head above its neighbours, it is one of the largest trees of the forest, and has a wide and general distribution over the deep belt of low country in the colony. Samples of the rubber of both this and the Hatie I have sent to England to be tested as to their probable commercial value.

Attempts have been made to extract caoutchouc by chemical means from the bark containing it. If this could be carried out successfully, and with playing results, every part of the bark might be utilised, just as the bark of *Cinchona* is in the production of quinine. The milk vessels abound all over a tree, as may be seen alike by cutting the bark of the stem, or that of a twig, and in breaking off a leaf; though they are proportionately more plentiful in any given species the thicker the bark is. Seeing this, it has always appeared to me a loss that so small a portion of the surface is operated upon. Where the tree is not cut down, only about eight feet of the trunk is utilized; and even when a tree is felled it is not thought worth while by collectors to spend time tapping the less productive parts which can be devoted to the best parts of fresh ones. I speak of existing circumstances; they might act differently if the trees were less plentiful. I gathered samples of the bark of Hatie and Touckpong, and also of the Balata or bullet-tree, for the Government Analyst, Mr. Francis, to make trial of; but, as the following extract from a letter he has sent me shows, he does not regard, from the single experiment which he describes, the object as feasible from a commercial point of view. He writes:—

"I found no difficulty in extracting the indiarubber from the sample of bark you sent me called Touckpong. I placed eight ounces (3,500 grains) of the finely broken bark in a glass vessel, and just covered it with a liquid called bisulphide of carbon. After standing for twelve hours, the bisulphide of carbon was squeezed out from the bark through a cloth. The partially exhausted bark was again treated with bisulphide of carbon in the same way, and then the whole of the latter was evaporated down to dryness in a porcelain basin, and left a residue consisting of about 100 grains of indiarubber. The result barely represents three per cent of rubber in the bark, and it is doubtful whether such a small quantity would pay for extraction.

"I should recommend petroleum ether as being a better solvent to use in this process than bisulphide of carbon. The latter would contaminate the indiarubber with free sulphur that is nearly always present in it as an impurity.

"Petroleum ether is a cheap—almost a waste—product, but unfortunately owing to its great inflammability it cannot be imported into this colony except under a duty of three dollars a gallon.

"Of course, in the practical working of a process like this, the solvent employed—whether bisulphide of carbon or petroleum ether—would be recovered by distillation from the indiarubber and so could be used over and over again."

In face of this unfavourable result, it would be worth while to experiment with all the indiarubber and guttapercha barks produced in the colony. If no other good came of it, it would determine the relative yield of the different trees.

In a few places I met with the bullet or balata tree and the Indians told me it was scattered sparsely over a wide extent of the banks of the river and its creeks. I was surprised to hear that the trees were being filled by the Indians for the balata they yield at the instance of traders who travel on the river purchasing the products procurable from the native inhabitants. The privilege Indians are allowed in regard to cutting timber of a specified limit as to size "so to be used by them or to be disposed of by them in the shape of a squared timber," appears to confer no right to cut for this purpose, and therefore in felling, or in tapping trees for the juice of their barks, they are committing a depredation for which they should be held responsible on detection. Much more should the men who instigate them to it for their own profit, knowing that they could not do it with impunity themselves, be severely punished for their villainy. As to this however, there seems to exist some difficulty. In response to a communication which I addressed to him on the subject, Mr. im Thurn writes:—

"The bullet-tree (Mimusops balata) appears to be widely but somewhat thinly scattered throughout the Pomeroon District as a whole; but in places it occurs in great plenty. One of the places is said to be at the head of the Akaiwini creek, which runs into the Pomeroon just opposite Hackney. And that this information is correct is apparent from the large amount of balata which is collected and brought down from the Crown lands up that creek. I have myself seen a bateau coming from there with over 300 lb. of this substance. It is collected by the most injurious method of felling the trees, chiefly by one man, a coloured man from the coast, who makes his living, and it is apparently no bad one, by collecting this balata and a small quantity of locust gum. This is of course wholesale robbery and wilful destruction of Crown property; and I am the Superintendent of Crown lands in this district. But though I can lay my hands on this robber and perhaps on others, almost any day, I have no power to deal with such cases."

Having had my special attention called to this matter by his Excellency the Governor, I availed myself of every opportunity either for inquiry or of observation. On the very limited ground I was able to cover on the main river, as I have said, I met with very few balata trees, and no tree that had been destroyed. The creek mentioned by Mr. im Thurn I ascended as far as the time at my disposal would permit, but, unfortunately, as the land was everywhere flooded, I could land in very few places. The Akaiwini is, in fact, however, a very considerable river, and the whole period of my leave, could I have spared it, might have been occupied in its exploration. Only its higher reaches appear to be occupied by Indians, and here the balata tree is said to be more plentiful. So far as I can ascertain, none of this gum is gathered on the Essequibo or any of its tributary rivers. A wonderful impetus must have been given to the trade in Berbice within the last two years. In 1881 93,578 lb. was exported, or more than double the quantity of any previous year. From the products of our forest which are utilised, important as they undoubtedly are, the colony derives hardly any profit, while the forests are impoverished by wonton waste and the depredations of the dishonest, and the trade is in the hands of a few merchants. As to the balata trade, unless some efficient method of utilising the whole of the bark be discovered, felling should be prohibited, and, if, with this rule, an export tax were imposed, and every package containing the gum required to bear a special brand belonging to the grant on which it was gathered, which would show the production of each grant, a very salutary change would be effected in the trade.

As the privileges accorded to the aboriginal Indians are now under review by the Government, it may be hoped that the damage done by the nefarious acts of traders and others, which they are enable to perpetrate by means of these people, will not much louger continue; though only a new and comprehensive forest law will meet the whole forest question of the country. G. S. JENMAN.

TAN AS A MANURE.—Probably most persons would laugh at the idea of this; but in some instances tan has been used with good effect; and it has been used to destroy the Gooseberry caterpillar by placing it under the bushes when the larvæ are issuing from the ground. Most plants root freely into tan-beds when that material is used as a medium to plunge in, and that they are benefitted by it I am certain. I would not waste any spent tan; after it was past using as a plunging material it could be used freely on heavy soils. J. DOUGLAS. —*Gardeners' Chronicle.*

INSECTICIDES.—Few plant cultivators will deny that the question of insecticides for plant pests is one of great importance, and one on which there is much variety of opinion as to the relative merits of the many preparations supposed to possess the power of destroying the various insects to which plants are subject without injury to the plants themselves. There exists, however, a pretty generally held opinion that a perfect insecticide for plants is still a desideratum, and therefore it is to be hoped that the intention of analysing the various insecticides in the market and opening up a discussion, out of which we may gain much more information than we at present possess of the nature of the insects themselves, may result in the discovery of an insecticide that shall prove efficacious in all cases without injury to the health of the plants operated upon. Here, at Kew, where the requirements of the establishment are such as to make the collection much more subject to the attacks of insects than in ordinary cases, the necessity of keeping so many totally different plants growing together—different in many cases both as regards the temperature, moisture, and light required—we are sorely tried in our efforts to keep the pests under. As in the case of animals so it is with plants, ill-health generally being the signal for the visitation of vermin, and where plants are crowded together under such untavourable conditions as those I have mentioned the growth and increase of insect pests is often simply alarming. It is only by continual sponging, syringing, dipping and other such means that we can hope to keep the plants anything like clean, and there is no establishment where the discovery of some easy means of total eradication of all plant vermin would prove a greater boon than in the botanical garden. We have tried so many insecticides, and on so many different subjects, that I venture to offer a few remarks on one or two of them, and as much importance seems to be attached to the useful qualities said to be possessed by the Pyrethrum powder perhaps what I know of it as an insecticide may be worth recording. A box of beetle powder, which is, I suppose [On what grounds?], nothing but Pyrethrum powder, was got for experiment, and used as directed for various plants and on various insects. Impatiens Sultani before it flowered was sorely infested by ants which, in addition to sapping the life out of the young leaves, exercised themselves by establishing a colony of bugs all over the plant. We washed off all the bug, and then submerged the whole plant in a tank of water, where it remained for two hours. This drove out all the ants from the soil. After the plant was dry we dusted it all over with the powder, and placed a ridge of the powder all round the stem of the plant. It was of no use; the ants were as busy as ever in a day, and carried their loads over the "poisonous" powder without showing the slightest alarm. We also dusted Abutilons infested with red-spider, Pelargoniums infested with greenfly, and some Crinums with thrips, as well as various other plants on which scale and bug were at home. "We might as well have thrown sugar at them; perhaps better, for this stuff may hurt the plants." So said the man who assisted me. For horticultural purposes the beetle powder proved with me to be perfectly useless. It may be that Professor Riley's experiments were made with a much more powerful preparation than that I used, but so little was the effect this powder had on the insects it came in contact with that I am inclined to doubt the insecticidal powers of Pyrethrum powder in any form. An insecticide of which I have heard much both for and against was tried here some two years ago. [We omit the name till analysis has been made.] In this case the vendor himself prepared the mixture and dipped the plants selected: a good-sized Palm, some small ones troubled with bug at the root, some Bambusas on which red-spider was in strong force, and several Ferns infested with scale were tried. The Palms were submerged, root and all, as the mixture was said to be not only a first-rate insecticide but a good fertiliser also! The gentleman called about a fortnight after the dipping operation and saw for himself, the Palms quite dead, the Bamboos much injured, and the Ferns curled up like scorched Bracken, while the insects seemed to be no fewer nor yet even more sick than before the operation. Since then I have heard the opinion of others as to the merits of the liquid, and it is only fair to say that in some cases the verdict was as favourable as mine was unfavourable. Fowler's insecticide, Gishurst Compound, and other insecticides are only useful in those cases where tobacco fumigation is not convenient, as aphides, red-spider and thrips seem to be the only insects that fall victims to them. Paraffin is an effective yet a dangerous insecticide to use for plant pests. Bad oil, carelessness in applying the mixture, or the injurious effect paraffin, however much diluted, has on many plants, make the use of this insect destroyer not always safe. Here at Kew, however, a great deal of paraffin is used, Palms, Cycads, and many hard-leaved dicotyledonous plants proving capable of standing a dose of diluted paraffin without showing any ill effect. Soft-soap and tobacco-water are generally mixed along with the paraffin. We want something that will destroy bugs, scale, and those other hard-to-kill insects without injury to any plant however delicate it may be —something one may syringe down into the heart of a bulbous plant, and destroy the bugs nesting there without destroying or seriously injuring the bulbs as paraffin does—a mixture one may use for Ferns, young Cycad leaves, Orchid, &c., without having pounds worth of loss as the result of its use. If Pyrethrum will do it then the question of its cultivation in quantity can soon be solved; but whatever the desideratum may discover itself as, the great service such an insecticide would be to horticulturists may be seen in the many inquiries for insecticides, and the thousands of pounds worth of stuffs sold as such. W. WATSON, Kew. *Gardeners' Chronicle.*

CULTIVATION OF THE TEA PLANT IN THE CAUCASUS.

(Translated from the *Journal de St. Petersbourg*, [illegible] March [illegible].)

The question of the cultivation of the tea-plant in the Caucasus has been started by the E[illegible] society of our capital. According to the information of the *Nouveau Temps* some plantations of the tea-plant have been already made at Soukhoum both in the Botanical Garden and in that of Mr. Wedenshy. The plants of [illegible] qualities that have been cultivated there have matured perfectly. The question therefore of the possibility of the culture of the tea-plant in the open air is practically solved, and the only thing that remains to be done is to ameliorate the methods of such cultivation.

The establishment of tea plantations is equally feasible in other parts of the Caucasus region; for example, in the western part of Trans-Caucasia, especially in the valley of Alazan, where the climate resembles that of China. Everything depends now on the method of preparing the leaves of tea-plant, and as yet this is not well known in the Caucasus. The Agricultural Society of the Caucasus has therefore solicited that a specialist in the cultivation of tea may be sent to that district. It is surprising that no serious effort has yet been made to cultivate the tea-plant in Southern Russia, principally in Caucasia. After the English and the Americans no people consume as much tea as the Russians, for they import annually to the extent of sixty millions of roubles worth of this article, and yet they neglect to develope the cultivation of tea in their own country. China has no longer the monpoly of the production of tea. Japan provides the United States with a lage quantity, and India sends enormous quantities to England. The Indian produce which was commenced in the last century has greatly developed, especially in the district of Assam, during the past thirty years. Indian tea costs a great deal more in England than Chinese tea, the consumption of which is diminishing yearly. Generally speaking forty per cent. of the tea consumed in Europe is from other countries than China. Even the Java tea is used in spite of its bad quality. That of Ceylon which is excellent, is getting into vogue. The production of tea has been also introduced into Borneo, the Phillipines, Brazil, and the South of California. Why should not Caucasia follow the example of all these countries? Even admitting that the quality of tea produced there were of inferior quality at the beginning, there is no reason why it should not be used for making brick tea of which the consumption is considerable. This inferior quality of tea costs us annually five millions of roubles, which we now pay to China. *Nouveau Temps* proposes to attract an emigration of Chinese to Caucasia so as to introduce the proper cultivation of the tea-plant and the fabrication of tea there. Our Consuls at Hankow and Foochow can make contracts to bring those specialists from China who thoroughly understand the whole tea process, and without having recourse to the proprietors of the Russo-Chinese tea plantations in China, whose interests might suffer from the eventual development of the cultivation of the tea-plant in Russia itself.—*N.-C. Herald.*

TRANSPLANTING TREES.

Save for the presence of a wrapping of canvas around the stems—a wrapping, by the way, for which hay-bands kept wet might advantageously be substituted—few persons would imagine that the fine symmetrical trees which now border the Place d'Armes at Ghent had only recently been planted; yet such is the case. It appears that the square had, many years ago, been planted with Lime trees for which no suitable provision had been made at the time of planting. The consequence was that the trees had a [illegible] appearance, and shed their leaves in early summer, just when shade is most grateful. It was therefore decided to remove the Limes, about 100 in number and replace them by some [illegible] Elms, each measuring 18–20 inches in circumference at 3 feet from the soil.

[illegible] it did not discourage M. Van Hulle [illegible] the middle of January of the present year [illegible] commenced, the soil of the square was trenched to a depth of 5 feet or so, the old soil, where dry and [illegible] being removed. M. Van Hulle, however, [illegible] even more importance to the depth and sufficiency of the trenching than to the quality of the soil. The Elms were moved by the aid of a transplanting machine, so as to allow of a ball of earth being raised with the roots 1 m. 90 in diameter (6 feet).

A trench was excavated round the trees of an oval form, so as to include the longer roots on two sides of the tree. Planks were fastened around the ball to keep the soil in place and to prevent injury to the roots. Supports were placed underneath the ball and connected by chains with a windlass arrangement on each side, by which the ball could be raised or lowered at pleasure. The ball thus supported rested on a truck, which was drawn by three horses, and thus each of the ninety-nine trees was safely removed and conveyed to the site prepared for it, the ball being gently lowered on to the top of a slight mound projecting from the base of the hole, the planks were removed, and the planting finished. Watering to settle the soil around the roots, and the ordinary cares in the way of tree guards were provided. Wire guy lines or other means of support may become necessary, at present they have not been required, but watering during the summer is almost sure to be required. The total cost of the proceedings is given as follows, nothing being set down for the use of the transplanting machine, which was lent by the City of Antwerp:—

	Francs.
Trenching, about	2000.00
Removal of bad soil and substitution of good, about	1300.00
Preparation, removal, and replanting of the trees	2100.00
Gratings around the roots... ...	2800.00
Tree guards	1000.00
	9200.00

—or, in round numbers, the expenses of transplanting each of the ninety-nine trees amounted to 93 francs (say £3 15s).

No doubt other trees, such as Planes, some of the Poplars, and Pyruses would do even better than Elms.—*Gardeners' Chronicle.*

PLANTERS AND COOLIES ON THE ASSAM TEA ESTATES.

The *Indigo Planters' Gazette* thus notices the nature and effect of the elaborate code of rules regarding the treatment of coolies on Assam tea estates. In Ceylon we are perfectly familiar with the process by which coolies *improve* the best built and best ventilated lines:—

It is the usual practice of the coolies, if the manager builds a substantial line with a nice verandah, to alter and improve upon it according to his ideas; the first of these alterations is to carefully enclose the verandah with a *tattee* (an *ekur* or mat wall). This is then carefully plastered over so that not a crevice is left nor can a breath of air penetrate it. After this he carefully subdivides the interior into a number of small apartments or pigeonholes, so that when finished according to his ideas to the European eye, it presents on examination more the character of a "*rabbit warren*" than a human habitation. This of course is a direct contradiction to the Chief Commissioner's ideas, but what is a manager to do? If he obeys the Chief Commissioner he offends his coolie, who takes his departure at the end of his time, as he considers any interference with his ideas of house arrangements to be great *dook*, and very naturally too, for does not every one consider his house *his castle!* And if he chooses to have his dearly beloved cow in his house, who is to interfere with him, for is not his cow his own, and not the *sirkar's?* And if he has a *penchant* for unripe fruit, why should he not eat thereof, and give to his infant son or daughter, no doubt often entailing grievous after-consequences and an application to that necessary ornament of a tea garden, the *Doctor Baboo*; but to preach and tell him so, is like throwing pearls before swine. It seems, too, a most extraordinary thing how this said coolie existed previous to his arrival in the tea districts. Why were not all those precautions now taken necessary to keep him alive before he arrived on a tea garden? May we ask how many of them ever before in their lives had a dose of quinine administered to them for fever? Are we to suppose that they lived a charmed life before, or what explanation can we expect to have? We are at a loss to understand why so much wet and dry-nursing is necessary to a coolie the moment he sets foot on a tea garden. Does the Chief Commissioner think that coolies are imported to be killed off wholesale for the gratification of the brutal planter? Can it not be brought home to him that the very existence, the very bread and butter of a tea planter to a great measure depends upon the successful handling of his coolie force, and that the first consideration is their health, for although a large bonus may tempt a few straggling coolies to an unhealthy garden, it will not be sufficient attraction to them, provided on a healthy estate provisions are cheap and a fair wage is given, with a few days' leave now and again when the inevitable *poojah* is on. The very sinews of a man's success are now fully put to the test when gardens must be worked cheaply, and at the same time keep their coolie force up to the requisite strength. Unless the coolies are well cared for, and all their little complaints listened to depend upon it they will not remain when other gardens alongside are holding out tempting baits of a high bonus and low nerricks. That rates have risen in the different tea districts within the last few years is an established fact, and that they will rise further and thus deprive the long suffering shareholder of his due in the way of a dividend, sometimes many years waited for, we doubt not; and the only way to remedy this is to give a clear field to free labour and put no obstructions in the way. This millennium is far off, judging by the restrictions laid down in the Gazette we refer to, and our only hope rests in the proposed Railway. Whether this will be in the present generation or not we cannot forecast.

WYNAAD PLANTING AND MINING ASSOCIATION.

Notes of a Committee meeting held at the Pookote Club, Vythery, on Wednesday the 6th June 1883.

New Products.—Read the following letter from Sir Joseph Hooker. Royal Gardens, Kew, March 31st, 1883.

G. L. Yonge, Vythery, South Wynaad.

Sir,—I am directed by Sir Joseph Hooker to acknowledge the receipt of your letter of March 2nd, and to say that he has much pleasure in transmitting to you five copies of the report on the progress and condition of the Royal Gardens for 1881 (the last published).

With regard to your further application for seeds Sir Joseph Hooker regrets that having regard to the calls made upon the Royal Gardens by the numerous botanical establishments of other parts of the Empire he is unable to accede to your request.

It appears to him, however, that the time has come when Southern India should possess a proper Botanical Department of its own similar to those existing for example in Ceylon and Jamaica. With such a department Sir Joseph Hooker would be prepared to co-operate and correspond and it would be the proper means of meeting such requests as you now address to Kew.

A memorandum is being prepared at Kew for communication to the Madras Government in the matter and it appears to Sir Joseph Hooker that your Association might usefully move in the same direction.

I am sir, your most obedient servant,

W. T. Thiselton Dyer,

Assistant Director, R. G. K.

Resolved that Sir Joseph Hooker be thanked for his letter and the copies of the report on the Royal Gardens of Kew and that the Madras Government be addressed on the subject of the proposal for a proper Botanical Department in Southern India. A copy of Sir Joseph Hooker's letter to be forwarded to Government.

Read also letter from the manager of the Sydapett farm to the Collector of Malabar re the despatch of the seed of the Reana Luxurians The Honorary Secretary announced that 14 lb. of the seed had been received and was ready for distribution.

Mr. Winterbothan read the following letter on the subject of cinchona shaving.

London, 2nd March 1883.

Messrs. Croysdale & Co. Madras.

Dear Sirs,—In continuation of our remarks in a previous letter upon the subject of slicing cinchonas, we must remind you that the data upon which we base our views have been collected from the entire field of our experience in this article which extends from the first shipment of E. I. cinchona to this country.

In the interests of cinchona planting we deem it our duty to place the following result of our observations before our friends in India.

To touch upon the facts of the subject slicing claims to largely increase the percentage of Quinine, by discarding that portion of the bark containing the inferior Alkaloids and taking the portion only, which contains the Quinine. We find that the Analysis of the first and perhaps second crop thus taken, shows a slight improvement in the Quinine contents compared with the same bark taken previously by the mossing and stripping process but we also find that this same bark upon subsequent renewals shews not, as claimed a yearly increase in Quinine contents but on the contrary a *marked decrease* in fact we find that the bark languishes and weakens. Slicing claims to give larger crops to keep the tree in a healthier condition and to avoid the expense of mossing. As regards the first our experience tends to show the contrary, but the second is probably true, the third is a very doubtful advantage. The average weight of bark slices compared with the weight of the entire thickness of the bark taken in strips, we think we can take at not more than a third, thus to produce the same quantity, three times the area will have to be taken, while we find that the Quinine percentage is not permanently improved, but rather the reverse. our friends know better than we, whether they can by gathering oftener, by the slicing system produce the same weight of slices as they could of strips of the entire thickness of the bark. To test the comparative merits of the two systems from the points of view of both quality and quantity, it is manifestly necessary to compare and watch the results of both systems on the same bark and under similar circumstances; this we believe has very rarely been done. Permit us to imagine a Chinchona proprietor making a trial on this slicing system upon a small scale the analysis of the first crop has shown some improvement, the trees have exhibited exceptional vigour and have quickly recovered from the taking. The advantages of the system have been taken as demonstrated and the proprietor orders all his produce to be treated by the same method. We dare prophesy that in the course of 4 or 5 crops the quantity of his produce will exhibit a very practical decrease and the quantity will have largely diminished, possibly in both cases to the extent of 25 per cent. to 50 per cent. his trees will however exhibit every sign of health and vigour. This is no mere hypothesis on our part.

We may remark that the effect on young trees may not be so pronounced, that with such trees the bark in spite of slicing may go on improving even in quality as it naturally should, it being possible that the effect on the bark may be imperceptible as long as the tree has not attained maturity but we are perfectly persuaded that slicing a mature tree is fatal, probably the change from slicing to mossing and stripping would be discouraging for the first season or perhaps longer as the waste will have taken place from the bark left on the tree after taking the slice and it will only be after new bark has been grown entirely under the stripping process that the benefit will be reaped of trees that have been sliced.

We are thoroughly convinced that were the two systems to be tested side by side and under similar circumstances the slicing fallacy would quickly explode and we submit that the facts of the case were known do not recommend its adoption. We advise all our friends to look into the matter thoroughly before slicing a single tree Red or Crown.

Drying Bark at a high temperature.—The convenience and economy of the expeditious drying of the bark has raised the question, whether bark could not be dried as well at a high temperature, on a tea drying machine as at a low temperature in the usual drying house.

We have the highest authority for saying that the effect of drying at a high temperature is simply destructive to the Alka loids.—We are, Dear Sirs, yours faitfully,

(Signed) FRANÇOIS LE MAIR AND RIVERS STICKS.

Mr. Winterbotham said: In referenceo to the above expression of opinion I would observe that the question is one of the greatest moment to Planters in Wynaad, for in a year or two a considerable quantity of Cinchona as almost every Estate will come of age to yield something in the way of a return.

In the shaving or "slicing" operation we fondly hoped that a very efficacious simple and altogether satisfactory method of gathering in our harvest had been devised. If this idea is upset and it is true that the method is destructive we shall have to take to "coppicing" or if we prefer to export renewed bark we must go in for the plan pursued on the Government Gardens for some years past and take off strips of bark in alternate years, with the inconvenience of mossing, or covering the trees in some way.

Any how I think we ought to have the matter settled as soon as possible, and to have as much light as can be obtained thrown upon the question.

And proposed "that a copy of the letter be sent to the Government of Madras with the request that it would ask the opinion of its Cinchona authorities on the subject, and supply us with any information, or statistics of the results obtained by the shaving process over a series of years as may be available in India, or in Java where the process is said to have originated, and that a copy be sent through Mr. Guard to Capt. Cox now in England with a request that he would be kind enough to satisfy himself as to the value of the opinion expressed in the above letter and to give us the benefit of his great experience. The subject was afterwards discussed at great length and with much interest [We should think so, and we have no doubt planters in Ceylon will give their opinions. The balance of testimony, we believe, will be dead against the dogmatic assertions of Messrs. Le Mair and Rivers *Sticks*! We know that the bark from the Nilgiri gardens, dried by strong furnace heat, always sold at high prices.—ED.]

Coast Charges on Coffee.—Read the following letter from Messrs. Parry & Co. of Madras.

Madras, 17th April 1883.

G. L. Yonge, Esq., Honorary Secretary.

Wynaad Planting and Mining Association, Vythery.

Dear Sir,—We have to apologise for so long delaying an answer to your Association's letter addressed to us and other coffee curers in Calicut in regard to a reduction in the rate now charged.

The matter has had our best attention, and we have resolved to reduce our charges to

Coffee in bags R35 per ton of 20 cwt F. O. B.
Do cases R40 ,, ,, ,,

which will we trust meet the expectations of yourself and the members of the Association. We believe that we are the only coffee curers who have accepted the desirability of meeting the wishes of the planters, and we trust to receive a solid recognition from the planters in the form of crops to cure. We enclose a copy of the notice we are issuing and will be obliged by your giving to it the utmost publicity.—We are, dear sir, your faithfully, PARRY & Co.

Resolved that Messrs. Parry & Co. be thanked for their public spirit in thus meeting the necessities of the Planting interest and that the attention of the other Coast Firms be drawn to the reduction in the curing charges with the hope that they will be able to reconsider their decision expressed in December last and lower their rates to the same standard.

CAOUTCHOUC.

Letter from W. T. THESELTON DYER, Esq., to Sir LOUIS MALET, C. B., India Office, dated Royal Gardens, Kew, 7th March 1883, No. R. S. and C. 584-83.

I am desired by Sir Joseph Hooker to draw your attention to the enclosed extract from the Kew report for 1881, pages 47-48, with reference to *Parameria glandulifera*, an apocynaceous plant believed to be common in Southern India, but which appears to have been hitherto overlooked as a sourco of caoutchouc.

Extract from Kew Report 1881, *pp.* 47-48.

Chinese collections of materia medica often contain specimens of a drug consisting of blackened fragments of bark and small pieces of twigs. These when broken across are seen to contain an abundance of caoutchouc which can be drawn out in fine elastic threads as in the East African Landolphias. Specimens have reached the Kew Museum from the Paris Exhibition of 1878 (with the Chinese name tuchung) and from the Smithsonian Institution, Washington. The botanical origin has been hitherto altogether uncertain. It seems, however, probable from a notice by M. L. Pierre, Director of the Botanic Gardens, Saigon (Excursions et Reconnaissances No. 11, Saigon), that this drug is the produce of *Parameria glandulifera*. This is an apocynaceous climber ascending to the summits of the highest trees; it is common in the forests of Cochin China. Specimens which M. Pierre has obligingly communicated to Kew prove that the plant is identical with a species which abounds in Southern India. M. Pierre states "that the sap which flows from the stem has exactly the appearance of milk, and may even be used as a subsutute for it, it has a slight nutty flavor. In the liquid state it is often employed in medicine by the Annamites and the Cambodians The bark after being dried ordinarily in smoke is sold at 20 to 25 francs the picul (= 133⅓ lb.) and exported to China. The bark is a medicinal product esteemed by the Chinese."

The method of extracting the caoutchouc is exceedingly simple. The liquor obtained from the bane either from incisions or by cutting it into short lengths (if it is wished to obtain at once a larger quantity) is poured into a basin filled with water at a temperature of 104°–122° Fah. On agitating the mixture with a stick the milk immediately coagulates into pure caoutchouc of excellent quality. The plant may be propagated by cuttings with great facility, and M. Pierre suggests that it may be planted in forest reserves where the trees are not less than ten years old. If this method were thought practicable by the Indian Forest Department it might be extended to the African Landolphias and in this way a forest product of great importance might be secured.

WHAT BRITISH CAPITAL AND ENTERPRIZE HAVE DONE FOR ASSAM

was thus forcibly stated at "the Assam dinner" in London :—

Surgeon General De Renzy, C. B., in proposing the toast of "Prosperity to the Tea Industry of Assam," spoke as follows : "Of the many benefits which British rule has conferred on India there are few more remarkable or likely to be of more permanent value than the creation of the Tea Industry. This industry has already conferred immense advantages on the Government and the people of India. Fifty years ago Assam was as little known in the commercial world as Central Africa is to-day. The Tea Industry has made it one of the most productive and flourishing provinces of the Empire ; a waste of jungle and swamp has been converted into a fertile garden. Considering the difficulties that had to be surmounted, the rapid progress of the industry has been astonishing. Forty years ago there was no traffic whatever on the Brahmaputra. The noble river knew only the dominion of the alligators that swarmed on its banks. The scanty populations of the province hardly held its ground before the terrible unhealthiness of the climate. There being very little labour available in the province, the task of clearing away the jungle and fitting the ground for tea had to be done by imported labour, and the food required by those labourers had to be imported. Who could believe that, with such enormous difficulties to be surmounted, when just forty-five years ago Assam sent to England its first small consignment, consisting of twelve chests of tea, we should now be within measureable distance of the time when the Province would be in a position to contest the supremacy of the tea market with China, a country in which the cultivation of tea has been carried on for thousands of years? The tea industry, like other industries, has had its ups and downs. In 1866 it seemed for a time as if it would end in disastrous failure; and it is mainly owing to the courage and shrewdness of Mr. Roberts, now the managing director of the Jorhat Company, who will reply to this toast, that the industry weathered the dangers of that period. The prospects of the industry at present look very bright. The taste for Assam tea has become widely diffused in England. Large sections of the population will use no other tea. The population of the province has grown immensely, and, with the improvement effected in the public health, promises to increase very rapidly ; food staples are largely produced in the province, and the communications by land and water have improved immensely. Thirty years ago Dibrugarh was a three months' journey from Calcutta. To-day it is a fifteen days' journey. The opening of the Dibrugarh railway this year will undoubtedly mark a new era in the history of the industry. This enterprise will not merely supply cheap carriage for the produce of the gardens through which it passes to the Brahmaputra highway ; but by opening the Makum coalfield, it will provide coal of the very best quality at the head of that great river in unlimited supply at very cheap rates. Consider what this means. It means cheap carriage of produce to the sea board ; it means reduction in the cost of manufacturing tea, by supplying coke to be used instead of charcoal, thus rendering available for cultivation the establishments now employed in making charcoal. It probably means the final solution of the labour difficulty by facilitating immigration for the over-populated districts of Bengal. And here mention may be made of the immense benefits which the tea industry has conferred on the congested districts by affording an outlet for the surplus population of Bengal." The Surgeon General went on to say that he had seen, in the course of his inspections as sanitary commissioner, thousands of coolies who had risen, since their arrival in the province, from a state of extreme poverty, having hardly a rag to cover them, to comparative affluence and comfort, many of them having become the owners of large droves of cattle. It is very gratifying to note the improvement that has occurred in the health of this class within the last few years—a change due to the intelligent forethought and kindly care of the planters. A few years ago the death rate of the coolies ranged from 6 to 9 per cent. It is now actually lower than that of the village population of the old settled provinces, and is little over 3 per cent. There can be no doubt that when the improvements in progress have been completed their condition will be still better, and will be far superior to that of the population of Bengal.

Then,—Mr. William Roberts, in responding to the toast of the Tea Industry, said: Our thanks are due to Surgeon General De Renzy for the very able and eloquent speech in which he has proposed the toast. When I look back some thirty-five years ago, when I first became interested in tea cultivation in Assam and compare the state of the industry then with what it has attained to at the present time, I can realize the vast progress that has been made. In those bye-gone days the old Assam Company was the pioneer and only tea company. We had to perform a tedious journey of two months from Calcutta to Gauhati, and proceed on by dug-out boats to the remote district of Sibsagor. Almost everything in these days belonged to the Assam Company, and for many years it was believed by many of the leading men connected with that company that it possessed a monopoly, and that the cultivation of tea could not be undertaken by others. (Laughter and cheers.) What vast strides have been made in the cultivation of the plant since that remote period. We have seen it extended throughout Assam : it has been established in Cachar and Sylhet, in the Darjeeling district, the Terai and Doars in the remote North Western Provinces in British Burmah, in the Neilgherries, and in Ceylon, and as far as these vast extensions are considered it must be admitted that prosperity has followed the industry for many years past. But, Sir, I fear it will not be so readily admitted that the pecuniary results have been equally prosperous. There have been "leaps and bounds," great prosperity and great depression. But probably if we were to take a fair average of the whole, the result would be considered satisfactory by ... men of moderate ideas. (Cheers.) Steam communication between Calcutta and the tea districts, and between Calcutta and London, has assisted most materially in developing the industry, and with equitable laws in India, and the preservation of our bright ... of trial by our own countrymen—(loud cheers)—there is no doubt, but that the great Indian tea industry will continue to flourish. (Cheers.)

Mr. Burnett proposed the toast of "The Mining and Railway Industries of Assam," and coupled with it the name of Mr. Benjamin Piercy, M. I. C. E., the Engineer-in-Chief of the Assam Railways and Trading Company.

Mr. Piercy, in responding, spoke as follows : * * * From the banks of the Brahmaputra, which you know is navigable through that rising capital Dibrugarh, and the intervening succession of villages and tea plantations to Doom Dooma, some fifty miles the rails have been laid ; and locomotives with trains of passenger carriages and goods trucks are running over it. (Cheers.) On to Talup, the end of the main line, the formation is complete, excepting one bridge ; and the rails are being laid upon it. The fork to Makum and on to the coalfields of the Naga Hills is progressing with great rapidity from its junction, south of Doom Dooma, with the main line. Over the whole length, the jungles of massive trees, with a thick foliage on intervening branches which nearly shut out the light of Heaven, have been cleared: the formation is nearly completed, as well as the long bridge over the river Dehing, and the rails have been laid with despatch. Simultaneously with the construction of the railways, the coalfields in the Naga Hills beyond the Dehing are being opened up energetically and effectively under able and experienced chiefs sent out from Italy and the Staffordshire and North Wales coalfields, and immense quantities of coal have been stacked all ready for transport by the time the railways are finished. So that in a few months, trains of coal will be sent from the Naga Hills for distribution along the line of plantations in Assam, and for transportation down the great Brahmaputra River for supplying the stations on either bank; the railway termini including those of Goalunda and Calcutta itself. That this is the position you may feel absolutely certain. Considering that we have only been at work two seasons, this being the second, I trust these results will be deemed satisfactory to the Indian Government, who, with a wise liberality, considering the great benefits railways and coal will bestow on the Assam Provinces, guaranteed 5 per cent. on the railway capital and also to the public. Some tons of coal have been sent to this country for analysis, and the coal has been tested out there by practical men. And the analysis here, coupled with the reports from Assam, establish beyond doubt that the quality of the coal is equal to British coal and admirably suited for all purposes. It is fully equal to the coal hitherto imported into India from this country and Australia. As regards quantity it is practically unlimited, and easy to get, as it comes to the surface in seams varying from 5 to about 40 feet in thickness. It can easily be imagined what an influence this tapping of such rich coal deposits will have upon India and the glorious future that is in store for Assam. I have just been speaking to an enterprising traveller (Mr. Lepper) who has thoroughly explored Assam and the, as yet, little known regions beyond, where there are precious stones and gold in abundance; and from what he has told me tonight, as well as the maps I have examined, there is no doubt on my mind and there can be no doubt but that Assam is the gate of the Chinese and Burmese Empires; and I believe that over the railways we are making and future extensions of them advancing civilization will flow through the country you all take such an interest in into the heart of China and Burmah, and then Assam will become a province of surpassing interest.

INSECTS ON FLOWERS.—Says a correspondent of the *Garden*: "The best insecticide, and the safest I have ever met with, is nicotine soap, which, from containing the active properties of tobacco with other ingredients, is fatal to insects, and has a marvellously cleansing effect on the bark of trees, which it frees from all parasites in very quick time. For using on the stems of vines and peach trees it is quite unrivalled, as with a brush and a slight scrub, followed directly after by a dash of water from the syringe, it leaves them bright and polished, free from all slimy deposits and other confervæ. At one time peaches and vines used to be daubed with a coat of liquid clay and other mixtures to smother scale, but with nicotine soap there is no need of this, and anyone who is troubled with that insect, or red spider, or thrip, has only to apply the wash to be rid of the pest. If on the young shoots of peaches, the best way is to syringe it on at a strength of four ounces to the gallon of water used at a temperature of 90° or 100°, and immediately afterwards the stems of the trees should be scrubbed and the whole rinsed off at once.—*Gardener's Monthly Horticulturist.*—[We confess to never before having heard of nicotine soap. Has diluted tobacco juice ever been tried as an insecticide or a fungicide in Ceylon?—ED.]

POWDERED SULPHUR AS AN INSECTICIDE is thus noticed in the proceedings of the Madras Horticultural Society:—

Read the following letter from Messrs. H. Prudhomme & Co., dated Madras, 13th April 1883.

"We beg to send you per bearer a small quantity of a composition of powdered sulphur for disinfecting plants and trees from noxious insects, and request you will be good enough to give a fair trial to this for the said purpose, and kindly submit to us your opinion and report at your convenience, whether it proves successful for the end for which it has been intended.

"We may here add for your information that this composition has been largely used in Egypt for cotton trees for preventing the leaves from being tainted and destroyed by insects or natural causes, in which place it has succeeded in keeping the leaves fresh and luxuriant, it has also been used in France for the Vine, and has also shared the same success."

The composition kindly sent by Messrs. Prudhomme & Co. is apparently useful. It has to some extent checked the plague of insects on the Cycas plants and with the assistance of muslin coverings has enabled some of them to send out fairly good whorls of leaves.

Messrs. Prudhomme & Co. have been written to for further information.

Read the following reply from Messrs. Prudhomme & Co., dated Madras, 25th April 1883.

"We have the honor to acknowledge the receipt of your favor of the 25th instant, and we are glad to hear of the powdered sulphur seeming to be promising for destroying insects. We shall send you another supply of the powder for further experiment after you have exhausted the quantity we have already sent you.

"This composition is a manufacture of Marseilles, principally of sulphur of a peculiar kind termed in French 'Mineral de Souffre' sold at the rate of R12 per cwt.; should your experiment prove successful, as we hope, shall be glad to receive your orders for the same." Rupees 240 per ton seems rather a heavy price for the substance.

THE COCONUT AS FOOD is thus noticed in an article in the *Fiji Times* on rations for labourers:—Before closing this list of the natural food supplies of Fiji, belonging to the vegetable kingdom, it may be well to call attention to the great staple, the value of which, as a food, seems not to be appreciated. We allude to the coconut. The distribution of a few coconuts weekly to any of the various tribes of recruits is immensely valued. Especially as a Sunday treat, it is accepted with gratitude, and the interest shown in making up the *rakalolo*, very often of bush foods gathered by themselves, in unemployed time, will show any one who has the charge of them that it is not thrown away. The cost of the quantity required is trifling, and the addition to the content of the labourers invaluable. It is not too much to say it will often make up for a hard week's work or short rations. As to the nutritive value of this food doctors may have doubts, but one or two examplea will show that the use of the coconut alone for some time was not adverse to the good health of those who lived on it solely. Many years ago a vessel, (the "New World",) left San Francisco with 400 passengers. These were what were known as "Sydney Ducks" in California and were sent back by order of the Vigilance Committee. Making a long passage, she ran short of stores and had to put in at Samoa. But a small quantity of pork or beef could be obtained there, and the captain was advised to fill up the ample space he had, there being no cargo, with coconuts. Soon after leaving Samoa they encountered heavy weather and became water-logged, the result of which was a very long passage to Sydney, during which time they were forced to live on these coconuts alone. Men, women, some of them in a delicate way, and children, of all ages, had no other food for something like eighty days, and, while supplied *ad libitum* in the first inatance, were reduced to one coconut each per diem, for adults, and a proportionate quantity for the younger passengers, long ere they reached Sydney. Not one life was lost, there was scarcely any sickness, and on landing all were stout and hearty. Another case happened where two men cast away in a whale boat drifted on Quaris Island. There they had to remain seven years ere they were taken off, and, during all that time, had only a few chance flying fish beyond coconuts to eat. When rescued they were in excellent condition and had gained weight. These instances can be verified, but others might be quoted, which, though true, cannot be completely proved. These practical experiments show how important the coconut might become as food and how much more valuable it might be in that way than exported as coperah.

TEAK.—A very large trade is done in the Central Provinces in wood, particularly teak, which is so plentiful in Nagpore and adjoining towns that it is used even in the most common carpentery for the most trivial want. I do not know, says a correspondent any reason why the Central Provinces should not supply a great portion of this wood to the markets of the world, and why Burmah should have the monopoly of supply, when there are hundreds of square miles of teak wood available in these territories, size and quality equal to the best Moulmein. Thousands of squared beams are brought in from the outlying forests from 1 to 2 feet square and sold at at an average of from 8 annas to 12 annas per foot, and as the cost of carriage from here is dear, are wasted principally in supplying sleepers to the railways. Such misuse should be officially prohibited at once, more especially as great forests of the other strong and durable woods exist, chiefly *sal*, more convenient to the railway lines than the supplies of teak.—*Indian Agriculturist.*

FLORAL AND AGRICULTURAL RESOURCES OF BRITISH HONDURAS.—A preliminary Report from the Director of Public Gardens in Jamaica, showing the general results of his visit to British Honduras at the request of that Government, to examine the flora and agricultural resources of the Colony, and also the results of his collections of plants, &c., for the Public Gardens of Jamaica, is published as a supplement to the *Jamaica Gazette* of 19th April. Mr. Morris left Jamaica on 8th November 1882, and returned on the 26th December. He first travelled through the southern settlements, making valuable collections of seeds and plants for the Public Gardens of Jamaica. The chief plants of interest gathered were several species of palms (Chamædoreas, Bactris Sabal, Chamærops, &c.) which were not previously in the Jamaica Gardens; seeds of numerous timber trees and flowering plants; and a valuable collection of decorative orchids, including the indigenous large growing vanilla of Central America. This latter has pods much larger and more aromatic than the ordinary vanilla cultivated in Jamaica. After returning from the south, Mr. Morris visited the central and western districts of the colony. He says:—"The country generally (with the exception of a few isolated ranges) rises so very gradually from the sea coast to the interior that points on the western frontier, nearly one hundred miles from the coast, are only three hundred feet high. This low, gently-sloping land, is plentifully intersected by deep navigable rivers which flow slowly towards the sea. Along the banks of these rivers, the characteristics of the soil and climate were of a most favorable character, and the vegetation essentially tropical and luxuriant. Passing across the country from one river district to another, a section was traversed composed of a poor quartzy soil supporting only a sparse vegetation of pine (pitch pine), evergreen oaks, and a low shrubby palm (Chamærops sp.) On further acquaintance with the interior portions of the country I found that the alluvial deposits along the river banks extending some five or six, or, in some instances, some ten miles on each side contained, chiefly, the rich valuable soils of the colony. Beyond these were 'broken lands' and 'pine ridges.' I estimate that fully one-third of the area of the colony is composed of 'pine ridge.' The most important as well as the richest river valley in the colony is that of the Old River sometimes called the Belize River. This extends in a wide sinuous course from the town of Belize at the sea coast to the western frontier: in the upper portions, the valley widens into broad expanses of rich fertile plains covered by cohune palm, in some cases, thirty or forty miles in breadth. I carefully examined this district and worked my way to the frontier station—the Cayo—near which a coffee plantation has recently been established. With the exception of some six sugar estates, and the same number of banana plantations, this coffee plantation is the only attempt, hitherto made, to establish a systematic course of culture in the colony—the bulk of the people being employed, and the chief trade of the colony depending upon mahogany and logwood cutting which, when good prices are ruling, are apparently very remunerative industries. In the forests of the western districts, I found the rubber-tree of Central America (Castilloa elastica) very abundant. This tree (a member of the breadfruit family) is specially suitable for cultivation on account of its preferring a loamy sandy soil; and being a deep feeder it might be utilized as a shade tree in cultivated areas with great advantage. I spent two days with a rubber gatherer in order to observe the methods for bleeding the trees and preparing the rubber: and I have brought with me botanical specimens of the tree, some seed, as well as a sample of the rubber. I hope soon to make a special report on this tree and its produce. I am, also, making arrangements to procure a large quantity of the seed, when ripe, for distribution amongst cacao planters in this island. Trees at ten years old yield from four to seven pounds of rubber, which is valued at from 2s 3d to 3s per pound. If carefully managed the trees can be bled every three or four years. Another interesting plant found wild in these forests was the indigenous cacao of Central America: this differed from all kinds I had met previously. After careful inquiry, I found that it was the 'Tampasco cacao' of the Atlantic slopes and identical with the celebrated 'Socunusco cacao' of the Pacific coast. In habit and character, the trees approach those of the *Cacao Criollo* and an examination of the pods which are of a golden-yellow colour led me to the conclusion that this 'Tampasco' or 'Socunusco' cacao is the yellow form of the celebrated 'Caracas cacao. Should such prove to be the case, there is little doubt that this yellow variety will prove as much superior to the red (Caracas) form, as the yellow Forastero does to the red (Trinidad) cacao. Many other interesting plants of timber and dye woods, as well as, of plants of medicinal and economic value, were met, many of which I have no doubt are capable of being utilized both in British Honduras and in other British possessions. A detailed account of these will more fittingly be included in a report which I am now preparing on the scientific results of my visit." In returning from British Honduras, Mr. Morris had to take steamer to New Orleans, and was detained there nine days waiting for a steamer for Jamaica. He took advantage of this opportunity to visit the sugar estates on the river Mississippi; and among other kinds, he found that the celebrated Lahaina cane of the Sandwich Islands (lately introduced to Jamaica from Mauritius) was under cultivation on one estate and was very favourably reported upon. He brought with him specimens of the best canes from Louisiana which were established at the Hope Plantation. He also visited several orange groves in Louisiana and brought fruits of kinds not already under cultivation in Jamaica.

OPINIONS ON THE NEW TARIFF IN AMERICA.

QUININE MANUFACTURE A THREATENED BRANCH OF INDUSTRY.

The quinine manufacturers of America are very much depressed by the action of Congress upon the tariff question. This feeling is shown by the following statement of Mr. C. A. Robbins of the firm of McKesson & Robbins.

The action of Congress seems to have been an endeavour to give the final blow to the manufacture of the cinchona products in this country by abolishing the duty of 40 per cent on cinchonidia. This is a product obtained by the manufacture of quinine, and it was brought to general notice by the largest manufacturing house in the country, who, thinking that this substance was of value for the cure of malarious fevers, advertised it extensively and created a demand for it. Now foreign makers will supply it. To go back however to quinine. The effect of the removal of duty was to divert the richest bark to Europe, where the manufacturers of quinine were not hampered with duties or taxes on the materials they employed.

The one grain of comfort the American manufacturer enjoyed was in the making of cinchonidia from the low grades of bark. On that there was some protection, and it balanced in some slight way, the difficulties under which the manufacturers laboured. This duty Congress has repealed. They have also seen fit to place a higer duty on imported bottles in which quinine and cinchonidia were packed. What effect that will have is not known, but generally the effort has been made to crush out the manufacture of quinine in the United States and to throw the entire business into the hands of the European manufacturers. I question very much the wisdom of this proceeding. It must be borne in mind that the United States consumes one-third of the whole quinine of the world, and that, should we be cut off from the supply of the bark, as was the case during the civil war, terrible distress might arise. Considering the position of the United States in relation to the bark-producing countries in South America, and the chances of our returning them the value of their bark in goods made by us, we are positively destroying that special line of trade. We cannot now buy the bark on the same footing as other countries. The essential substances necessary for the manufacture of quinine are still taxed. Soda pays 25 per cent; fusel-oil is taxed \$ 2 a gallon. What quinine manufacturers asked for was a duty of 10 per cent, and either ten or twenty per cent per ounce on the sulphate of cinchonidia.

At the present price it would have enhanced the cost of quinine some 15 or 16 cents, and sulphate of cinchonidia 9 to 18 cents per ounce, barley sufficient to counterbalance the burdens we were weighted with.

This discussion on quinine has never been met in the same spirit as were other manufactured products. We have always been met with the cry. "You are rich! You are taking blood money" etc. There was a howl of this kind which did the business, when, under suspension of the rules, Congress without debate removed the duty on quinine. What will be the effect on quinine according to the new tariff? So far, it has brought about the bankruptcy of one of the oldest and most respectable firms of the country, and a very serious curtailment in the working of other manufacturers. It has already started three new factories in Europe which will supply the American demand. It has increased, of course, the consignment of bark to European ports, and more foreign goods will be sent to those countries which make the bark-shipments. In fact, every thing favours the foreign manufacturer. Of course you will hear it repeated over and over again that quinine was \$3 before the removal of the duty, and that it is today \$ 1·70. The duty accounts for that. It has been said that should the duty be re-imposed the price of quinine would advance to a figure were it stood before the duty wasremoved. It might be the case, or might not be. Quinine may rise and fall in figures according to the bark supply, European combinations, or the demand for the alkaloid. But no sane man would think that a duty of 16 cents an ounce would today force the price up to \$ 1.50 or \$ 1 30 an ounce. What will be the outcome in the future noone can prophesy. The plantations of Ceylon, India, and Jamaica, opened by the money derived from the British Government, are making tremendous return of very rich bark, and their products will go on increasing every year in bulk and quality. To meet this supply of raw material from these quarters, new European combinations are being made with the idea of controlling these products. They will have it all in their own hands, and will fix the price of the article. One thing is quite certain, that the quinine makers of this country have been made the scapegoats for the high protectionists, and that we, without any fault of our own, must take the conseqeuence.—*N. Y. Times.*

SOME OBSERVATIONS ABOUT THE VEGETABLE KINGDOM OF SOUTH-AFRICA,

AND ABOUT THE FITNESS OF THE SOIL FOR NEW CULTURES.

It is a peculiarity of South African soil that in February no woods have to be cleared, nor swamps drained. It only requires tillage and rain.

At present South Africa produces in the South cereals wine and fruits; in the North, the same with the exception, of grapes, besides Maize and Kaffer-corn.

Maize or Indian corn, especially, originally introduced from India, thrives everywhere in South Africa, even in soils where irrigation is impossible; the only requisite for an unlimited sowing being stiff enclosure to keep off cattle and horses. The utility of this plant is enormous; the seed affords excellent food for man and beasts, and retains its virtue for years when kept in dry places; the stalk when cut down immediately after harvest, affords capital fodder, while the leaves are a good material for the manufacturing of paper, besides, that the corn abounds in fecula, and therefore the best material for the manufacture of starch.

Kaffer-corn, the only agricultural product originally found among the Kaffer and Negro tribes, has this advautage over maize, that it can bear drought still better, but is wanting in all the other advantages.

A third article, which can be cultivated everywhere, but has as yet been little tried, is the Beetroot. This may be cultivated on any patch of ground that is unfit for finer tillage, and it affords excellent food for cattle in winter.

To these three productions follows, as far as regards its independence of climate, Barley. This can also bear a tolerable deal of drought.

Of late a new species of corn has been tried in several places, the so-called Egyptian-corn, with the best success, growing much faster than the common Dutch corn (wheat) and requiring moreover much less moisture.

In the southern parts of South Africa the soil is found overgrown with a kind of ligneous herbage, while the northern parts are distinguished for their extensive grassy plains. Now it has been observed that since droughts have become more common in the North, the grass in the pasturages makes way for this herbage; and consequently some landowners in these northern districts, have been induced by several succeeding years of drought, to plant these herbs, called *Karoo*-bushes in various plots, which has succeeded very well, propagating from the seed. These plants can bear drought throughout the year. Others have made a similar trial with the Lucern plant, which affords very good fodder for sheep, though not so well able to bear drought. At Bloemfontein, the Director of the Botanical Gardens of that place has had grass-seed over from Australia, and placed it at the disposal of the public of the Vrijstaat. From experience he asserts that this grass will retain its vigour for a whole year without moisture.

For the rest all vegetables, introduced from Europe, thrive very well in the South African soil, as the Botanical Garden at Graaf Reinet and Graham's town can testify; in this case irrigation is a *sine qua non.*

As for trees, those which best repay the trouble of introduction are the poplar, the beech-tree and the birch; the oak will not thrive. The blue gum-tree on the contrary has become completely naturalized.

Of the regions in South Africa, inhabited by Europeans, Natal, and the parts beyond the Vaal are most fit for new cultures.

Natal already cultivates a small quantity of sugar, but this culture is susceptible of immense extension. Besides this, the climate is very favourable for the cultivation of cotton.

The part of the Transvaal North of the Mountains has hitherto proved most favourable. Coffee, sugar and cotton have been tried, and these three articles thrive wonderfully; but notwithstanding this great success, the culture has never been extended or continued, though enough is grown for private use.

The pomegranate-tree, too, thrives exceedingly well wherever it is planted, without the aid of manure. The utility of the tree needs no comment. A plantation of such trees would, in my opinion, pay well, and is practicable anywhere.

But then the blue gum-tree has a great future in the North of the Transvaal. In the district of Waterberg (as large as Netherland) there are a multitude of open spaces, with excellent soil and abundance of water, but dangerous to health, on account of prevailing agues. Now this tree possesses a febrifugal property; a trial made to see if the tree would thrive there, was completely successful; it throve as well as in its native soil.

Now to return once more to colonial productions. It has been found that coffee, sugar and cotton, as likewise oranges and lemons are of an inferior quality to those of all the other colonies. It is only in tobacco that South Africa can bear away the palm and compete with the best as to quality. However this can be said only of tobacco grown North of the Vaal, as the Cape Colony also grows tobacco. The soil of the Cape Colony being much heavier and less saltpetrous, the tobacco produced there is much stronger and less odoriferous, and more fit for chewing; while the light, sandy soil of the North produces a tobacco, which if it does not surpass that of the West and East-Indian islands, is at any rate equal to it. Most places in the Transvaal yield three crops in one season. The tobacco of the last crop, which is of course of an inferior quality, stands on a par with inferior sorts of the Kimbolingo of Java.

The only colonial produce that South Africa cannot produce is rice, but maize can be regarded as its substitute; it has also been jestingly termed African rice.

In the future, exports from South Africa may be thus divided: Cape-Colony wool, hides and ostrich feathers; Grigaalland-West diamonds; Orange Free-State wool and hides; Natal coffee, sugar and cotton; Transvaal coffee, sugar and cotton, but chiefly tobacco.

These cultures can only be effected by a good co-operation of trader and husbandman. About this we shall have more to say in a following chapter after a short notice of the disasters to which, especially there, agriculture is exposed.

DISASTERS TO WHICH AGRICULTURE IN SOUTH AFRICA IS EXPOSED.

The first disaster to be dreaded is the failure of rains at the usual period. The best remedies against droughts are, of course, preventing ones; such are, the making of large dams which will for a long time preserve a sufficient supply of water; or, if the ground is situated near a constant watercourse, then a pumping machine is more expedient, as the waterlevel will, during a long drought fall far below the banks (the Mooi-rivier is the only exception). The next drawback is that game, such as spring-bucks, bles-bucks, or the cattle of neighbours, may consume the crops, but a brick wall about 6 ft. high, will suffice to keep them off.

Sometimes, though but once in ten years, locusts come swarming from the North, and devour all the verdure. Nature has provided her own remedy in the locust-birds, which follow in their wake and sometimes succeed in exterminating them. The only human remedy is to have recourse to an insurance company.

More frequent is the plague of caterpillars; these, however, mostly confine themselves to low herbage, such as grains, greens or vegetables, etc. The great difference is that the locusts devour everything, whereas the caterpillars leave the stalks and nerves of the leaves. This calamity only ceases when the caterpillars assume their larval form, so that it lasts about two months; after the lapse of this time the plants have still a chance of recovering themselves. If practicable, strewing powdered brimstone is a capital remedy. Further drawbacks such as mildew, blight, etc. are common to this as any other country.

In the North, an animal called the [illegible]-*haas* (spring-hare) gives the most trouble to the planter, by browsing on all the tender plants [illegible]. The remedy is traps.

But the greatest calamity to the farmer is, as in Europe, hail. As an illustration [illegible] we read in the South African [illegible] of the 23rd of February 1883:—

Bethuly, O. F. S., 11th February.

"We had on Monday 7th Feb. [illegible] hailstorm. Many gardens are destroyed; in some places the damage amounts to £400. In the village a blue gum-tree 80 ft. high was uprooted. I hear that the hailstorm extended over a distance of ten hours' ride.

"The hailstorms are remarkable for their narrow limits. Over a tract where they have passed, a path 400 yards broad is formed, between the limits of which every thing is beaten down the hail."

In conclusion it may be remarked that cattle, horses and mules, are all subject to the same maladies as in Europe; asses alone die of old age, or by the accident.

After this short sketch, we must examine what the cooperation of the trader and the husbandman can do for the extension of cultures. Last year sundry magistrates in the colony and in the chief places of their districts, convened meetings of the shop-keepers and traders of the district, to set on foot for next year an Agricultural Exhibition, and to discuss the best means for the encouragement of commerce and agriculture. Indeed these are much in decline in South-Africa.—*India Mercury.*

ORANGE CULTURE.—Does orange culture pay on pine land? Yes. Mr. J. L. Chandler living three miles from town netted from half an acre, consisting of 32 trees, between $400 and $500 the past season, and yet the crop was a short one. Sixteen of his trees are twelve-year old seedlings, and the remaining sixteen, seven-year old buds. The croakers who say that oranges will not pay on pine land may digest this if they please.—*Florida Agriculturist.*

LABOUR IN FIJI.—It is very evident that the planters of Fiji are now experiencing a crisis in their labor supply that must entirely revolutionise the working of plantations. The cost of Polynesians has, within three years past, increased so rapidly in every particular, that it is impossible to grow produce at the rates which, as an example, were contracted for on the Rewa a year or two ago with the Colonial Sugar Company. Even then the price given for cane was not considered quite just to the planter, and now, with the increased cost which a fresh supply of laborers at current rates involves, it is hopeless to think of making any return, out of even large areas, at the prices then fixed on. It is almost beyond a doubt that Fiji employers will be driven to try to obtain laborers from some other country. The experiment of bringing coolies from India has not been thoroughly satisfactory, and the cost is now as fully prohibitory as it is for Polynesians. The trial of Chinese has yet to be made, and it seems not unlikely that they may be, after all, really the best and cheapest for Agricultural work. The letter, in another column, from Mr. Boyd, whom our readers will remember as not long ago a resident in Fiji, gives some information, derived from practical knowledge, which seems to indicate that they may be found well fitted for Fiji. At all events, if, by employing these, the harrassment from Government interference could be avoided, that of itself would be a great gain in every way.—*Fiji Times.*

ORANGES IMPORTED AND GROWN IN FLORIDA.—The importation of Mediterranean fruit at the port of New York from Sicily, Italy and Spain during the year 1882, comprised 953,837 boxes and cases of oranges and 1,052,874 boxes of lemons. The importation of oranges from the West Indies, Central and South America consisted of five full cargoes and parts of several cargoes by sailing vessels, and 83,587 barrels by 111 steamers. The total number imported comprised 31,260,587 oranges, of which 11,217,811 perished on the voyage, a loss of 36 per cent. The hundreds of thousands (it may be millions of trees heretofore transplanted are annually arriving at a bearing state, and a large crop of fine oranges the past season has amply rewarded the labor bestowed upon their cultivation. Perseverance and more experience will insure lasting results, so far as the permanence of the fruit-growing industry is concerned, and constantly increasing [illegible] to its promoters. The writer predicts that the products of the orange groves of Florida [illegible] will be [illegible] to supply the whole [illegible] with an [illegible] oranges. About [illegible] boxes and barrels of oranges were shipped to this city [illegible] and found a ready market, and about [illegible] boxes and barrels of oranges were distributed through the West, South and South-west from the [illegible] trade [illegible] oranges the past year [illegible] both unsatisfactory and unprofitable.—*Florida Agriculturist.*

A GENERAL INSECT PREVENTIVE.

Some would call it "Insecticide," but the truth "Prevention is better than cure" never had a more direct application than in relation to plants and their insect enemies. Each season the latter re-appear, although deciduous trees during winter have clean burnished stems which one would be tempted to think could never be tainted by aphides-scale, red spider, mealy bug, or any of the numerous pests to which vegetation is subject. Insecticides, *i.e.*, substances, whether liquid or solid, that will kill insects, are happily numerous; Gishurst compound, an infusion of tobacco or quassia, common soapsuds, soft soap in solution, lye of woodashes, kerosene, and compounds out of number which are sold by the trade, will each and all kill insects which frequent vegetation, the difficulty is in applying them so that every portion of the plant shall be reached. Kerosene is a favourite insecticide, because its effects are immediately apparent, and partly also because it is always at hand. It is, however, as generally used, a most dangerous remedy; the application intended only to compass the destruction of the enemies of the tree involves also the life of the tree itself. Kerosene may, however, be used with complete safety if diluted or incorporated with water in certain proportions. To mix oil and water an alkali is, of course, required, and a little fatty matter serves to keep the fluid in a homogeneous condition. The method of proceeding is this:—In a common washing copper boil 4 gallons of water, 1 lb. of soft soap, and 4 oz. washing soda until thoroughly mixed. Then add a pint and a quarter of kerosene, and stir freely until the liquor is of uniform consistency. To this should be added 12 gallons of water, making 16 gallons altogether. Any smaller quantity can, of course, be made by proportioning the ingredients accordingly. The whole need not be used at once, indeed a supply of this should always be kept on hand, so that a dose may be applied through a fine syringe wherever the presence of a single insect is observed; to destroy the first marauder is the most important matter of all. When no remedy is ready prepared, insects are frequently allowed to increase until they have attained unmanageable numbers and the plants have lost vigour. It is, therefore, expedient to have the preventive always at hand.—*Australasian.*

COFFEE SENT TO EUROPE IN PARCHMENT SKIN.

TO THE EDITOR OF THE "INDIA MERCURY."

SIR,—I beg you will have the kindness to insert the following in your next number of the *India Mercury*, in consequence of the paper communicated to you by Mr. van Gorkom, in your January number, in which this gentleman endeavours to refute the article sent to you by Mr. John Smid, from a letter of one of the greatest coffee-planters of Java, about the drawbacks of sending coffee in the parchment to Holland. In the interest of many planters here in Java, I am induced to discuss these lines, nay to refute the arguments, of Mr. v. G. though I cannot presume to enter into the lists with him as regards argument, style and theoretical knowledge.

Though I am fully persuaded that the esteemed writer has been led to send in the lines quoted, in the interest of the planters, yet I verily believe that if that gentleman were better acquainted with the practical part of the coffee-business, which no one can attain to unless he has been a considerable time employed, *not* as a government official, but as a steward or administrator, he would have given a different view of the matter.

Every official is well aware that wherever he may travel in Java, to examine the various cultures, whether rice, or coffee (the cinchona culture excepted) every native chief —from the Regent to the Loerah, will seldom express his opinion and mostly answers in the so characteristic expression of the Soundance language: Koemaha Djoeragan . . . . waes which interpreted means: "As Mr. —— likes." It speaks, of itself that though a European Government official be willing to give himself ever so much trouble to master the details of laying out, planting, preparing etc. etc. he can seldom succeed under such circumstances. Many firms here, and a still greater number in Holland, take for granted whatever a government official writes or says, as they are supposed to be acquainted with the affair, which has frequently been to the detriment both of the farmer and of the planters. Could measures be devised by which the government need not be planters themselves, we should be spared articles often productive of much mischief.

Mr. John Smid, whose acquirements as a planter are universally known, would not have sent in such an article, if it did not express his full conviction.

But let us examine the arguments of Mr. v. G. This gentleman is much opposed to the shipping of coffee to foreign parts, and adduces as an instance that tea formerly sold to England, is now, since the grievances have been partially removed, shipped to Holland, and so recommends the same for coffee.

Now a few days ago, three of the greatest tea-producers here in Preanger assured me that the former grievances do exist still, and that all their tea is shipped to England.

The English Brokers send every year samples to the planters, give instructions respecting selection, flavour, etc. A cargo or invoice of tea, prepared agreeably to those samples, is often no sooner in the Thames than all is sold off and the cash paid down. None of these gentlemen ever knew of such a thing being attempted in Holland, but they did know that there they had to wait long for a settlement of accounts. With the coffee it is much the same; sometimes there is no knowing what to keep to; frequently stale white coffee fetches a higher market than better qualities, and what encumbers the sale in Holland to a great degree, is the re-sorting. Formerly most of the private coffee was brought to market and disposed of immediately after unshipping; at present this is of rare occurrence, which greatly impedes the sale in Holland. There is no reason to suppose that a better control was kept on the sorting formerly than now, when the great competition which induces every one to render the commodity prime as possible. The charges of a repeated sorting in Holland are in most cases much higher than the whole cost of sorting in an undertaking here. That coffee, invoiced from here to Marseilles, has sometimes fetched better prices in Holland, may be attributable to their ignorance of the mark, as Marseilles and Trieste are eager to buy Java-coffee, provided they know the marks; when once known a telegram is sent hence, the coffee is readily disposed of without further sorting, and the money is at hand—a very pleasant way of doing business. America takes chiefly Padang coffee from here, and will have none of West India curing. The Padang coffee is coarse of bean, of a yellow colour soon turning brown, a consequence of the curing which we shall not go into now; this coffee sells there off-hand nor requires any re-sorting. If we can make such coffee at Java—the trials are already being made—then this is also preferable to Holland.

As to sending coffee in the parchment, which Mr. v. G. recommends so strongly, this has many drawbacks. As I said before, in Holland coffee is always sold on colour, most in demand is the W. I. cured, dark-green, coarse bean; if this is sent out well-dried, in the parchment, it discolours and becomes mottled within a few days after peeling in Holland, and has much less market-value. Then one's article, on the ready sale of which often the very existence of a dear-bought and carefully administered undertaking depends, is entrusted to strangers for curing. The greater charges from here to Holland, from the landing-place to the mill, the storing, sometimes long lying, by which the coffee in your damp climate deteriorates rapidly, the discolouring, the passing through the mill, the sorting, the insurance anew, the bags, etc. etc. make together an awful amount, compared with the expenses of the processes here and selling elsewhere, while the quality must needs be very inferior. As a proof that coffee sent in the shell is not everywhere approved of, last year a Swiss and a German Firm wired to Amsterdam: "Never send any more samples of coffee peeled in Holland, as the colour of the lot differs entirely from the sample."

It is no wonder that this novel industry is smiled upon in Holland, as it affords subsistence to thousands, as Mr. v. G. justly observes, but will it in the long run prove profitable to the planters in Java, who, on account of taxes, chargeable export duties, poundage, etc. are already under many vexations for the coffee they ship to Europe.

The esteemed writer, I presume, meant to write in the interest of the planters and not of the peelers in Holland?

That the trials made by the Government have failed, is not to be wondered at, considering how their coffee is maltreated; coffee, to be peeled in Holland, must be of very first-rate quality otherwise it is all loss.

That Government should have to pronounce its "veto" on this industry (according to Mr. v. G.) is, with the notorious ill-treatment, absurd.

Government has been going on planting for years, and though at the time a Manual was published on the subject, it is not adhered to, especially as to curing, which is the main thing for procuring fine coffee, a very few sorts excepted. One need only compare the prices with private invoices.

It is a strange thing that Government, who has pocketed so many millions by these very beans, and might have profited as much again, with better management, should not have applied themselves to the application of machinery and mills, which after all are not so very expensive—the native and the balance would both have gained by it. But no; it is private enterprise grown wise by experience in Ceylon and elsewhere, that takes the initiative, and regards no expense to produce on the market the best article possible.* Mr. v. G. assures us that some undertakings have sent coffee in the parchment with very good results; probably those undertakings lacked hands, and then it would be of some importance; yet even in that case peeling-works in the chief towns of Java would be very useful and would throw off positive profits.

As regards the after-drying of coffee as practised in the establishments of Gardiola, van Maanen and others, this is very recommendable, as then every bean undergoes the same process, which is not always the case on the ordinary drying-pans, one bean being occassionally more exposed to the sun than another, which is apt to produce a difference in colour after peeling; yet one respect I agree perfectly with Mr. v. G. "that it must be very cautiously treated" otherwise, and that gentleman says very rightly, it will be apt to turn rusty, which is less desirable both for colour and quality.

Then, if such an arrangement exists on the premises of the undertaking, the drying and temperature is inspected *personally*, which requires the utmost care. If however, this must be left again to the peelers in Holland, it would again add to the bill of charges, which are not unimportant, considering the price of fuel, etc. whereas in the undertakings all this can be had almost for nothing; but what is worse, as the process requires such prodigious care one exposes oneself to the risk of having shipped off good coffee, which on its arrival on the market is unsaleable. The peelers in Holland, moreover, are paid for their work, but not according to the quality of the article delivered, which has also its drawbacks.

When the crop is entirely cured in the undertaking itself, one knows what article is brought to market; but, besides the above-mentioned draw-backs, to leave the drying also to the peelers (which is indispensable for speedy change of colour, or sending it in the parchment to Holland) is strongly to be condemned. Anybody at all acquainted with the process in a drying-room, will admit this, and knows what the article looks like when dried too fast or too slowly.

Mr. v. G., ever since he set foot on Java's ground, has evinced an interest for every thing regarding the cultures, and has endeavoured in all directions to master the subject. I need only refer to the still new and very comprehensive publication—and has also thought to perform a useful act in the passage quoted; we must be thankful that he has done so. There are so few, who come out boldly for their opinion, as regards their own experience. Were this more frequently done, Government and private industry would be much advantaged; friction of ideas is always beneficial. This was my object in writing these lines.

Thanking you, Mr. Editor for the space afforded.—Your very humble servant. P. ZEFER, Jr., Preanger, Java.

NATAL (VICTORIA) PLANTERS' ASSOCIATION.

(*From the Annual Report for* 1882-83.)

SUGAR-CANE—TOBACCO—COTTON.

A disease called smut, in the sugarcane had been for some time doing considerable damage to the variety called China cane. It was extending its damage to other canes, when Mr. J. M. Wood, the curator of the Botanical Gardens, forwarded many valuable communications on the subject. You finally appointed a Committee to consider the report, and the Committee gave much time and thought to the question. The Chairman, Mr. Leo. Acutt brought up a very valuable report, one which has secured considerable attention and consideration in this and other sugar-growing countries. You caused that report to be printed and circulated amongst members and others. It is no exaggeration to say that your action checked the advance of the disease, everyone's attention was called to the desirability of stamping out the pest with the result, that at the most favourable period of the year, thousands of diseased plants were dug up and burnt. The disease is still to be found in our cane fields to a limited extent. Constant and sustained action on the lines laid down in your report will eventually exterminate it. At several meetings the cultivation of fibres was discussed. Valuable samples were exhibited, a pamphlet was read by Mr. de Chazal, and finally a Committee was appointed, which has yet to make its report. It is a matter of great regret that the co-operation arranged with the Chamber of Commerce for securing the representation of the colony at the Amsterdam Exhibition was not required, and that this colony was unrepresented. You decided to consider the Government Bill for remedying the Pollution of Streams cl. by cl., and drafted a measure which seemed in every way to meet the requirements of the subject. Your Bill was adopted by the Government, but was held over by the Legislative Council to the next session. A paper on subjects relating to the successful growth of sugarcane was raised by Mr. Labistour. The labour questions referred to therein were handed to the Coolie Committee to report on. Your Committee proposed that a deputation from all Associations should wait on the Indian Immigration Board, pointing out that unless active measures were taken to fund the indents in hand a serious scarcity of labour would result when the men, whose time expires during the year, claim their discharge. The interview was satisfactory, the instructions given and powers granted by the Board to their commissioner, Col. Mitchell, are of a character which, taken with the wellknown energy and ability of our Colonial Secretary, cannot fail to attain substantial results. You devoted considerable time and attention to the question of fencing. The final division shows that here on the coast, as well as upcountry, there is considerable difference of opinion, the majority of the Association being of opinion that a compulsory measure was not required. Mr. Wilkinson, who has devoted much time to the study of meteorology on the coast, read an able paper on "Tree planting in its relation to the rainfall of the country, and the trees best adapted to the coast climate." He proved: 1st. That the deforesting of the land induces long droughts 2nd. That tree planting increases and more equally distributes the year's rainfall. It is not necessary, in a Society mainly composed of sugar-planters, to point out the advantages an increased rainfall would confer on the country. The report of the Committee on the subject of Mr. Wilkinson's paper says that tree-planting should be made compulsory on occupiers of land, and that the Government should conserve the forests. The immediate result of the paper and the discussion will probably be increased activity in tree-planting for the future. Mr. Binns brought forward a motion urging the extension of the North Coast line, and asking for surveys of branch lines in thickly populated districts. The Association was unanimously in favour of the extension, but opinion was divided upon the necessity for branch lines, until the North Coast line reached the Tugela. It struck the gentlemen, during the discussion on the desirability of at once pushing on the railway from Verulam to Stanger, that the point that this line was urgently needed for the better defence of the whole colony was omitted. This line ranks in importance with the trunk lines of the country, for the reason that it would form the base for the defence of the most vulnerable part of Natal- the Zulu border. Many other subjects were treated by you during the year, principal among them being aid and support to the Botanical Gardens, the cultivation of cotton by coolies, introduction of cane from Inhambane, coolie holidays, Outspan and Pound Laws, quarantine, Maritzburg Agricultural Show, bye-roads, several important labour questions, and the introduction of fresh varieties of cane. Of subjects which call for your attention during the ensuing year, I think there will be no lack. You have to receive the reports of the Fibre and Fresh Varieties of Cane Committees. You have the labour question ever present and pressing; the extension of railways, local councils, the best system of increasing the yield of your fields by manuring; agricultural shows on the coast; tree-planting; the pound, outspan and fencing laws; the railway rates for

* £5,000 worth of machinery chiefly coffee-curing) was sent from Colombo to Java in 1882.—ED.

goods; the erection of custom houses on the border by the Cape Government; the formation of a central chamber of agriculture, are all subjects which are intimately connected with the welfare of the country. The sister Societies of the Tugela division of the county and of Alexandria have expressed a desire to co-operate with this Association on several important questions. This Association recognize the desirability of unity of action amongst the agricultural community. I trust, gentlemen, that during the coming year it will be possible to form a Chamber of Agriculture, embracing not only the coast, but the upcountry districts as well. The time, in my opinion, has arrived when the formation of such a chamber is practicable; communication will soon be rapid; meetings could be held quarterly, alternately at Durban and Maritzburg. The upcountry farmers are large employers of coolies; the question of land tax in payment of railway expenditure will soon be upon us. The rates of carriage of agricultural produce on the railways, the pound, fencing and outspan laws, the registration of native labourers, rebate of custom dues as affecting the incidence of taxation, and a few of the subjects which are common to all agriculturists. In referring to the progress made by agriculture in the past, it has struck me most forcibly how much that progress depends upon a bountiful rainfall. In the eight seasons from 1866-67 to 1873-74 the average rainfall was 43·30 in., thus each crop of cane during that period received 86·60 in. of rain; in the eight seasons 1874-75 to 1881-82 the average rainfall was 35·84, thus each of the crops of cane during this period only received 71·68 in., an average loss of 14·92 in. per crop. The heavy crop of 1880-81 was in a great measure caused by the splendid rainfall of 1879-80. The outturn of sugar during the first eight seasons referred to was 56,850 tons, during the latter 71,746 tons, an increase only of 14,896 tons. During the first period named, the acreage under cultivation was less. We had not emerged from the period when errors of judgment in manufacture sent much of the sugar to waste; cultivation was of the most primitive kind, labour was scarce, and manuring unknown. The increase of crop during the latter period would have trebled 14,896 tons had the rainfall been equal. If, then, by any known means, we can increase the rainfall, it follows that great progress in agriculture must be the certain result. That this result can be attained has been clearly shown. It remains for us to adopt the means which have proved successful in other countries—in a few words, to take up with energy tree-planting. The progress made in the cultivation of the cane has been most marked. Never, perhaps, has greater care been bestowed upon the same area of plant canes as has been the rule this year. Manuring is being adopted by all our prominent planters. The dunder and refuse from all mills prove to be a most valuable fertilizer, thus by its application to the soil, not only benefitting the country by increased fertility, but preventing the noxious exhalations and pollutions of streams which have hitherto been a blot on the country. We see magnificent fields of cane growing, with the aid of manure and cultivation, on the oldest and of the poorest sugar lands in the country. The question of manuring deserves the most careful consideration. It is possible, as was proved in the West Indies, to grow magnificent crops of cane, but only limited crops of sugar. It is thought by some that manuring will take the place of cultivation but I think I am speaking with authority when I state we shall never possess a manure that will enable us to dispense with cultivation, in fact, that the cultivation of the soil is more important than the application of manure. If the two go together, then the happiest results may be expected. I think that this would form a most interesting subject for a Committee to consider and report upon. The analysis of artificial manures imported into the colony is a subject also that the Association will no doubt in time turn its attention to. It has been found that the action of Agricultural Societies in England on this question has elicited the wholesale fraud and robbery which for a time seemed inseparable from the business. Through the kindness of Mr. Hunter, the general manager of the railway, and of Mr. Rutherford, the Collector of Customs, I am enabled to give you some reliable statistics regarding the past crop of 1882-83. The total quantity of sugar exported from Natal from the 30th of June 1882, to the 28th of February 1883, amounts to 4,125 tons. The railway has carried to Maritzburg during the same period 2,692 tons. We have thus reliable data for 6,907 tons. I estimate that wagons have carried upcountry (say) 500 tons, that local consumption stocks in hand on the 20th of February will equal 600 tons, thus we have a total of 8,007 tons, worth £200,000, as the result of the past crop. It is divided as follows:—Victoria County has sent in by rail (very little, if any, has gone by road) 5,494 tons, leaving 2,513 tons as the produce of Alexandria and Durban Counties. It is interesting to note that only a trifle over half the crops has gone over the bar. It has been customary to reckon local consumption and country trade at only 1,500 to 2,000 tons. The progress of agriculture in the past has, as you well know, been beset with difficulties; but, gentlemen, the future is brighter. In a large and well cultivated average of cane, of mealies, of tobacco, magnificent rains have fallen. The rainfall since the 29th of November last, when the drought broke up, now reaches 27 in. The sugar industry was never on a better footing than it now is, the manufacture of the crop which in many years gone by was little understood, now leaves very little to be desired, the yield per gallon of juice is no longer an uncertainty, and compares most favourably with the yield in the most advanced sugar-growing countries. Cultivation (and, by cultivation I mean something more than holing and weeding) is daily receiving more attention, thus increasing the yield per acre. The labour difficulty will be overcome if a constant stream of Indian immigration is kept up. The Central Mill system has found a firm footing, and is working satisfactorily. There is one thing we lack, namely, financial facilities, but given average seasons, with the advantages named, a greater capital must flow to support an enterprize which is in itself remunerative and of vast benefit to the country. I estimate the crop for the coming season at 11,000 tons, 8,000 for Victoria County, and 3,000 for Alexandria and Durban, and valued at £279,000. Never, perhaps has the oldest inhabitant seen such a bountiful mealie crop. In this county alone, I estimate the surplus crop to reach 10,000 tons, worth in the English market £7 per ton. The question arises, what can be done with this surplus? The high rate of carriage on our railway prevents any thought of exporting this staple except from districts a few miles from the port. It is a question worthy of your consideration, whether rates of carriage for agricultural produce should not be materially reduced, to encourage production, and if necessary, a land tax imposed to meet the deficiency in railway revenue. It seems manifestly unfair to make the occupier and producer pay for the interest and working expenses of the railway; whilst owners of unoccupied land are earning the yearly increment caused by the railway and the industry of the occupier, without contributing to the revenue in any way. It is a question vitally affecting upcountry interests. The carriage of a ton of mealies from Pietermaritzburg to Durban is equal to the freight now offered from the Durban wharf to London. Can we compete with other countries with such rates of land carriage? The size and quality of the leaf of the tobacco grown always inspires the hope that ere long this article may figure in our export list. There will be a large crop of tobacco this season, and a considerable surplus. The re-introduction of cotton has caused considerable discussion; very little advance has been made; where coolies have tried it they have smothered it with mealies. It is possible that the immense crop of mealies may induce farmers to turn their attention to growing an exportable product like cotton, a crop realized quickly and for which there is a certain market. In conclusion, it is satisfactory to note that the thinking inhabitants of the colony are awaking to the fact that on the development of agricultural industry must the future wealth of South Africa depend. Wars, gold and diamond mines may for a time give an impetus to trade, but unless the soil is made to give forth her increase, true prosperity will be wanting. We are blessed with a fruitful soil, a genial climate and boundless tracts of unoccupied lands. We lack population, capital, cheap transport and sound legislation to develop the capabilities of as fair a land as any possessed by the Crown of Great Britain.

Report of the Committee appointed to consider the question of the introduction of fresh varieties of cane:—

Your Committee beg to report that it has considered the question referred to it, and is of opinion that it is desirable that fresh varieties of cane and fresh plants of some of the old kinds should be at once introduced into the colony. Your Committee is of opinion that the best way to accomplish this end would be to send a commissioner to various places to personally select and dispatch likely varieties. With the object of testing public feeling on this question, your Committee drew up the accompanying circular, with the intention of sending a copy to every sugar-planter in the colony. On second thoughts, however, it occurred to the Committee that in so doing they might possibly be going beyond their legitimate duties, and decided to obtain the sanction of the Association before putting the matter before the outside public. Should the action here indicated be sanctioned by the Association, the Committee will be prepared to go on with the matter. It will be seen that in the proposed circular, Government assistance is mentioned; this assistance your Committee has reason to hope would be granted.—W. R. Cowley, Convener of Committee.

February 12th, 1883.

Dear Sir,—The Victoria Planters' Association has appointed a Committee to consider and report on the best method of introducing fresh varieties of sugarcane. This Committee is of opinion, that the best way would be to send a commissioner to the following places;—Madagascar, Queensland and the Eastern Coast of this Continent. The Committee is of opinion that from these places almost every variety of cane can be obtained.

It is estimated that the cost of introducing enough canes from these places to start a large nursery would be about £400, and the cost of establishing and maintaining this nursery would, for two years, be about £300. It is proposed that this sum be raised as follows:—£10 each from 35 persons interested in sugar, and £350 from the Government.

It is suggested that the subscribers to this fund should retain the management of the enterprize, and be the first to secure plants from the nursery. After two seasons plants could be sold to anyone at cost price.

I am desired by the Committee to ask if you would (provisionally) promise to be one of the 35 subscribers to this fund. A meeting of contributors would be held before any steps were taken.—I am, dear sir, yours truly,

W. R. Cowley, for Committee.

—*Natal Mercury.*

[For the Committee's Report on Fibres, see index for page.]

Orange Cake.—Two cups of sugar, two of flour, four eggs, the white of one left out, two oranges, one grated for the cake, the other for icing, three table spoonfuls of melted butter, poured on the flour, one half cup of cold water put in alternatively with the flour. Table spoonful cream tartar, one-half teaspoonful of soda, rind and juice of remaining oranges, white of eggs and sugar beaten together for the top and between the cakes. [*Send us a slice.* —Ed.]—*Florida Agriculturist.*

Dogwood.—Though a plant of not large growth, it is commercially of great value. It is indigenous to North America, but it thrives best in New Jersey, Maryland and Virginia. Where the soil is gravelly and shaded, it grows well in Tennessee. The wood is hard, close grained, and takes a fine polish. It is used principally in the manufacture of mallet handles, toys, hames, shuttles, harrow teeth, and shoeing for sleds. The bark is bitter, contains many of the qualities of the Peruvian bark, and is often used as a substitute for it.—*Artisan.*

Baron Liebig has once more made a most important discovery, and this time it nearly affects all possible cocoa-nut growing countries. This is his Malto-Legumine. What this is I cannot tell you. Its preparation is a strict secret, and when the manufacture commences here, this process will only be known to two persons, who will be bound under heavy penalties not to disclose the secret. Suffice it to say that cocoa comes largely into its composition. It is said that 90 per cent, of this Malto-Legumine is easily assimilated by the weakest digestion. The 44 per cent. of water and the 22 per cent of fat in butchers' meat are replaced in this valuable discovery by 65 per cent. of easily assimilated carbohydrates, thus giving both meat and bread in a form unsurpassed. Baron Leibig's leguminous cocoa appears to be nearly perfect food. The objectionable preponderance of fat found in the bean is reduced, but the flesh forming quality is increased by judiciously using a meat rich in those bodies deficient in cocoa. Undoubtedly the consumption of cocoa is increasing in this country. In 1878 the number of tons entered for home consumption was 4,445 tons; in 1879, 4,514 tons; in 1880, 4,717 tons; and in 1881, 4,685 tons. 1882 also shows a proportionate increase. The machinery for manufacturing this Malto-Legumine will be up in February; at present all supplies come from Germany. I should say there is little doubt, from the advantage which it has in being much cheaper than other cocoas in the market, thus reaching the lower classes, that is will command very large sales and much increase the consumption of cocoa in Great Britain and all her dependencies.—*Fiji Times.*

Value of the Sunflower.—It is the best egg-producing food known for poultry, keeping them in a thriving condition and largely increasing the production of eggs. Every poultry raiser who tries it will find that this seed is the best known food for glossing the plumage of fowls, and is almost indispensable to those who want to fit their birds for exhibition to the best advantage. The Russian sunflower is easily raised, requires very little care, can be grown in fence corners or other places difficult to cultivate. Its production of seed is immense, yielding often at the rate of one hundred bushels to the acre. It should be planted in hills four feet apart, any time from the 10th of May to the 1st of July. Three quarts of seed will plant an acre.—*Iowa Homestead.*

Artificial Incubators.—The possibilities of the artificial incubator are attracting much attention in the United States. Successful experimenters have found that as the size of the machine is increased, the percentage of hatch is decreased. This is accounted for by the fact that an enclosed surface of four feet square can be so heated that there is no apparent variation of temperature in any part of it; but when that surface is increased, say to eight square feet, there will be a decided variation in the outside edges. Professor J. Hasbruck, who has devoted much time to the question of artificial hatching names uniformity of temperature as the most important condition; and a trustworthy regulator is thus the first essential of a good incubator. Mr. Hasbruck finds, after repeated experiments, that eggs hatch equally well, other things being the same, if held fixedly at any point between 102 and 105 degrees, or if the heat varies from 98 to 106 degrees, without remaining long at the extremes. Very few eggs, he observes, will start below 102 degrees, none at 100; and for the first half of the incubating period few will endure 106 degrees many hours. Some operators advise a considerable increase of heat at about the middle of the hatching; and others advise a reduction of temperature during the latter half of hatching. But all will go well, whether the temperature be varied or kept just at it was at the beginning, so long as the heat is kept well within the safe lines—viz., between 102 and 105 degrees.—*Colonies and India.*

Canker in Cinchona.—A correspondent writes as follows on this subject:—There seems to me to be no rule at all in the matter. For a long time I believed in acclimatised seed as against imported, and was inclined to believe that the former was lesss liable to canker, but I confess in view of my later experience that I must somewhat modify my former opinion. I don't say that imported seed is perferable to our own, but I do not think it one whit the more liable to canker. There is no difference I am sure between them. I certainly believe canker is more or less contagious. If not, how is it that, in the seed beds, when it commences to go out in rings, this stops, if the whole of the ring, together with some of the surrounding seedlings, is dug out? I tried an experiment the other day in connection with this subject which confirmed my previous views of the disease. In a seed bed which had been very unsuccessful, and more than half of which had died out in rings, I inserted a glass tumbler, the bottom of which I had previously knocked out, and pressed it down till the tops of the young seedlings that were inside it were about level with the the rim of the glass. *Outside* the rim of the glass were similar seedlings as thick as inside, but the cankered ring was encroaching on this space daily, and in a short space of time all the seedlings round about the glass tumbler had died off, the cankered ring having enveloped it and passed it by harmless, for all the seedlings within the glass were alive and well. This led me to believe thoroughly that canker is contagious.—"Times of Ceylon."

THEORY AND PRACTICE IN TROPICAL AGRICULTURE: WEEDS ON PLANTATIONS.

(*By an old Ceylon Planter.*)

The irrepressible advocate of weeds, Mr. Halliley, has in a letter of ten lines, run full tilt into two scientific theories, resting on bases of long careful patient experiment. The bulk of scientific evidence goes to shew that *few if any* plants derive *any part* of their nitrates from the atmosphere. Again nitrates do not evaporate but are lost by percolation beyond the region of roots.

If weeds obtain from the soil, all the nitrates they contain, is it not wasted labour to grow them for the mere purpose of restoring to the soil, what they have abstracted from it?

If those, the latest and best supported theories be scientifically correct then the practice must be scientifically correct, of keeping the ground occupied by a cultivated plant, free of all other vegetation.

As for keeping the soil moist the great complaint of Ceylon in the current cycle is superabundance of moisture and the paucity of sunshine. The Ceylon planter is the most modest of truth-seekers: he reads earnestly such pages of the book of nature as are open to his lights, and he listens with the confidence and reverence of a true disciple to the teachings of masters whose studies have enabled them to turn over leaves that have remained sealed to him. The consequence of such a temper is that the slovenly and perfunctory are abhorrent to his habits. In whatever he undertakes he aims high, and the records of his successes are written in the market reports of Mincing Lane. Be it coffee, tea, cinchona, cacao, cardamoms, the newest as the oldest of his products assume at once a place in the first rank and keep it. It is to be hoped that no utterance of any apostle of the slovenly, however brilliant, may ever move him, from his chosen ground of careful culture and manipulation of whatever he produces. Let other lands keep their secrets if they have any and laugh at their own wit, if they have any, the Ceylon planter will never remain long in the background when he earnestly sets about creating a superior quality of tropically grown produce.

BALMER, LAWRIE & CO.'S INDIAN TEA AND WEATHER REPORT: SEASON 1883-84.

CALCUTTA, 7th July, 1883.

Our last Report was dated 23rd June; for the past fortnight the weather in the tea-growing districts, has on the whole been satisfactory. On the whole there still seems to be a general want of rain, and though some gardens are picking up for some time lost, most are considerably behind last year

All those connected with Indian tea will learn with pleasure that the Indian Tea Association have gained the concessions respecting the weighing of tea in bond, that it has been so long striving for; the Association is to be heartily congratulated on the satisfactory result of it efforts, and it only rests with the planters now to make the new system one of practical advantage.

ASSAM.—Dibrughar. Prospects are improving in this locality, rain having fallen more or less daily: the Brahmaputra overflowed its banks at some points but fortunately the waters soon subsided, and caused little damage. The plants were flushing nicely and beginning to lose the charred look they have had for some time; but the chilly nights complained of still by a few managers retards the rapid progress that the gardens should be making; there is slight indications of Thrips, and red spider and blight are on some gardens. JAIPUR.—The gardens here are doing well in tea, and some are ahead of last year in outturn. SIBSAGAR.—The weather has been favorable for growth in this part lately, a moderate amount of rain being accompanied with sun heat. Blight is disappearing and good flushes as coming out so that gardens that are greatly behind last year, have a chance now for picking up a little. JORHAT.—Hot and dry weather still prevails in this part, with only occasional showers that do but little good; leaf is thin and outturn very deficient LAKHIMPORE.—The weather here continues favorable and fair flushes of leaf have come out; red spider and green fly seem less vigorous, probably owing to the prevalent damp heat; on three mornings there was an unusual fog noticeable. Most gardens are much behind in outturn. MUNGLEDIE.—The regular rains have not yet set in, and the weather is very hot; red spider is bad everywhere which shows there is no growth in the bushes. Unless the regular rains set in soon, prospects will be gloomy, and the manufacture will probably fall short of the estimates. GOWHATI.—The weather is too cool still to be seasonable and prevents heavy flushes; most gardens will not be able to make up for the quantity lost at the beginning of the season.

CACHAR.—Good growing weather has favored most parts of the district, but on some estates constant rain has impeded the progress of manufacture; blight is very bad in all parts of the district.

SOUTH WEST SYLHET.—The rainfall here has been inadequate and the weather cloudy and cold; leaf which had been coming on well, was very much checked by these unfavorable conditions; on 29th ultimo however a change set in and $2\frac{1}{2}$ inches of rain fell in one night.

DARJEELING.—Since the heavy rains reported in our last, this district has had favorable weather for tea. but a good deal of sickness is prevalent, and cholera has appeared causing much anxiety.

The temperature has been very changeable. the thermometer being sometimes as low as 62° in the day; the mornings have been mostly warm and sunny followed by cloudy afternoons. A peculiarity in the leaf produced lately on some gardens is a long piece of stalk between each leaf, which may be the result of recent unfavourable weather. From the Dooars we hear that the weather lately has been showery, and everyone very busy trying to get off their flushes before they are too matured; the late continued rains had brought such a heavy show of leaf.

KUMAON.—The monsoon seems to have burst over this district on 29th ultimo, about a fortnight later than usual. Many gardens are so far behind last year in outturn that there is little chance now of them picking up, for the previous rain had come down in heavy but very partial showers.

KANGRA VALLEY.—In this district the monsoon burst on 26th ultimo and the flushes have since run out very well, so that the outturn is equal to last year on some gardens; the quality of tea also is better than the average.

CHITTAGONG.—The rainfall has now far exceeded last year, three quarters of the average of the year having been already registered in the northern part of the district; sunshine would be very welcome, manufacture being still behind and impeded by the rains.

NEW PRODUCTS IN CEYLON: GENERAL PLANTING REPORT.

REPORT, JUNE 1883, ON A LOWCOUNTRY ESTATE, NEAR HENARATGODA.

We have had a good deal of rain in June, but hardly any planting weather: sharp showers lasting five to fifteen minutes, followed by some hours of bright sun; planting was consequently carried on under difficulty an hour or two at a time, and from the 15th the rain stopped altogether. Had weather permitted, I would have cleared out my tea nursery: as it is, I have more than one-third of the plants remaining. Of the 23,000 I managed to get out during the month, there is not one per cent of failures. The percentage of failure in the planting done earlier in the season is large, partly from cricket-cutting, though many of those cut are growing again, but chiefly from the eighteen days of dry weather that followed the great rain-storm of May 8th and 9th.

It appeared to me in the early days of May that the coffee fungus was on the increase, but the character of the weather since has not suited it, and the greater part of the coffee, seems absolutely free from it, and looks well and healthy while all the trees that werenot heavily mauled by the disease last year are carrying a satisfactory crop.

Had the whole of the land here being equally well suited for cacao in soil and exposure, we would now have had 10,000 trees bearing at the average rate of one pound per tree. As it is I have less than 2,000 tolerably promising but the best are real beauties, branching at three feet, and presenting a dense mass of foliage eight feet in height, and twelve feet in width,in three years,and I have four months ago gatheree 50 ripe pods from one tree. On the other hand I havd not 200 plants remaining on 28 acres planted three times and not one of those remaining promise any good. On another 20 acres, the greater part of the plants live, but what they gain in six months of south-west-monsoon, they lose in six months of the north-east. The new fields I am getting up, are well sheltered and, though the soil in some spots, is not quite up to the mark, I expect better results from the 4 000 odd plants I have now in hand, than any I have hitherto achieved. They are very lucky people, who get one plant up out of ten seeds. I used, from three to four years ago 1,200 pods, averaging 30 seeds, 36,000, and my living and dying plants are 2,500. On the present occasion, I think I will do better. I began to plant at *stake* when the April rains came, but I was cramped in my operations, by the pods on my trees not ripening so fast as I wanted them. I had nurseries in baskets, nearly equal to the requirements, but cacao plants are so eminently precarious that I wanted two strings to my bow, and hence I planted some 3,000 at stake, one-half of which will probably succeed, and as two seeds were put to each stake I will have plants enough for the vacancies, unless the white ants become very industrious, or an unusually long spell of dry weather should occur.

I put down 3,000 of the highly recommended jat of arekanuts, as soon as they came to hand, along the lower side of the roads. Some few of them are putting in their appearance above ground, but I have ascertained that by far the greater number are failures. It is the same tale that has to be told of all imported seeds. It may be well for those who propose to cultivate palms, to learn that the seeds should be put at once where the tree is to remain, and the seeds should be as a rule covered to a depth of three or four inches. The monocotyledon is slow of germination, but can make way through a depth of earth in which a dicotyledon would perish: it is, therefore, right to put the seeds of the former at a depth that an ordinary spell of dry weather will not reach. The wax-palm seeds send down a tap root of three feet, while above ground it makes no more show than a large blade of grass. I made holes two feet deep, and drove an alavanga a foot deeper, so that the root might have full justice, but I have not succeeded in saving a single transplant. The talipot palm has the same habit, but I have succeeded in transplanting it. The sago palm seed should be put down under an inch of water, and that will never get dry in the longest drought. The areka palm should be planted four inches deep, under partial shade, and the coconut nursery should be covered up under six inches of earth. This is a frightful heresy in a country where coconut planting is the royal road to fortune and every goviya believes that he knows all about pol. No doubt, with half the nut above ground, the fittest lives, but fittest would be more fit, and many would become plants, if properly treated, that never grow in the usual style of forming nurseries.

TROPICAL AGRICULTURE.

The Tropical Agriculturist: a Monthly Record of Information for Planters of Coffee, Tea, Cocoa, Cinchona, Sugar, Rubber, Palms, Rice, and other products suited for cultivation in the Tropics. A. M. and J. Ferguson, *Observer* office, Colombo, Ceylon: sqre. 8vo. London: J. Haddon and Co., 3, Bouverie-Street, G. Street and Co., Trübner and Co., &c.

Two numbers of Vol. II of this most useful *olla podrida* are before us. Its subject matter is very extended, and the long list of its agents all over the world shows that an equally extensive area of circulation is aimed at. In Ceylon, the yearly subscription is twelve rupees, and in Europe and India £1. Prof. Hæckel, in his book on Ceylon, reviewed in No. 1589, permits himself (p. 107) the following observations with regard to the publisher of the well-known *Ceylon Observer*: "This paper is conducted by him in the spirit of stern and gloomy orthodoxy and conservative rigidity which unfortunately characterises so many professedly liberal English journals." Seeing, as one cannot well help doing, the evident desire to extend practical knowledge, the freedom of discussion, and the attention to minute points of detail as well as to larger interests shown by Messrs. Ferguson, it is difficult to understas in what way they can have raised the ire of this wise man of Gotha. They can probably, however, afford to ignore the harsh criticism, having raised Ceylon to the highest rank in the scale of publishing colonies, The Ceylon Directory and Handbook, the daily and weekly issue of the *Observer*, the monthly periodical now being noticed, the Manualsd on coffee, Rubber Cinchona, Cocoa Nut, &c., issuetioby this firm, exhibit anything but the congested act on implied by Prof. Hæckel's remarks, and will convey instruction to many beyond the island in which they are printed.

The explanatory words in the title sufficiently shew the scope of this monthly issue; but, so far from being exclusively local, we see notes, extracts, and observations on the like subjects of industry in Brazil, Java, France, St. Helena, Fiji, Texas, North Borneo, Madras, Coorg, Colombia, Madagascar, Jamaica and elsewhere. These are, of course, primarily inserted as bearing on Ceylonese interests; but the results thas with a good index a year's issue of this "Tropical Agriculture" must become a valuable work of reference. The different papers and communications bear upon the botanical, agricultural, chemical, or commercial aspects of known plants, with occasional suggestions, for new industries or novel applications of old ones; whilst such papers as those by Mr. Von Donop on his journeys in the North Borneo Company's Territory and Mr. Cottam's notes on the Straits Settlements partake of a geographical interest.—*Field*, June 23rd.

NOTES ON THE STRAITS SETTLEMENTS BY H. COTTAM.

THE TIN MINES OF LARUT—MACHINERY—TIN WASHING—DRAINING THE MINES—COST OF CHINESE LABOUR—CHINESE HABITS OF EXCLUSIVENESS—SUPERSTITION—DISEASES—SMELTING THE TIN AND SMELTING HOUSES—EUROPEANS INTRODUCING AND FIXING UP STEAM ENGINES FOR CHINESE MINERS—VISITS TO ASSAM—KUMBENG, TUPAI, AND KAMUNTING MINING DISTRICTS—LARUT—PERAK—NEW ARRIVALS FOR THE KINTA MINING DISTRICT AND DISCOVERY OF TIN ON CAPTAIN SCHUTZE'S PROPERTY.

Perak being chiefly supported in its revenue by the tin mines of Larut and not as yet an agricultural country, those employed here are therefore directly or indirectly interested in tin. The salaries of officials depend on tin, public buildings rise up from tin, hospitals filled with tin miners (700 patients said to be there at present). Troops and police, jails, offices, public works all kept up by tin. As coffee was to Ceylon, so is tin to Perak, and take away your coffee, you become a miserable people, so take away Perak tin, and the result would be equivalent to letting the air out of a balloon or the collapse of a bladder: *Perak would be nothing at all.* Europeans could not find rice and curry in any other enterprize unless they brought the money to plant tropical products and could afford to wait years for uncertain results.

Perak in Malay means silver, so perhaps silver in quantity may have been found here in days gone by, but meanwhile tin mining is the staple product, and very difficult is it to obtain and prepare it for export, as the following description will show.

Like all mining operations, the scene of action is ugly and unsightly, though the motto is "Never mind the appearance and discomfort as long as the dollars are forthcoming," so the Chinese swarm like bees in a hive in the Larut tin mines, near Thaipeng.

The flourishing little city of Thaipeng is in the centre of the Larut tin mines, and supplies stores to the miners; many of the Chinese storekeepers, having also an interest in the tin mines, keep their miners or rather mining coolies together by keeping them in debt, and, whilst to all appearance paying them very highly for their labour, squeeze a good profit out of them in the distribution of stores and by giving long credit.

The Chinese mine owners, however, are getting more liberal-minded from necessity: they have made the discovery that European appliances in machinery of a first-class order work their mines like magic compared to the old jog-trot *modus operandi*. For instance, instead of their oldfashioned wooden waterwheel and chain pumps, they are substituting large steam engines, the Perak Government allowing them a paid official to supervise the working thereof, and right well and disinterestedly does Mr. Givan do his duty by them.

On his daily rounds, Mr. Givan of the P. W. D. would call for me at 5 o'clock in the morning, drive en route to the tin mines called "Kamunting" to the north of the township of Thaipeng, dismount from the pony chaise, and wending our way through cooly lines, piggeries, duck-houses and caddies or Chinese shops find ourselves surrounded on all sides by a series of terraced pits, varying in dimensions from one acre to four or five in extent, and varying in depth of cutting according to the length of time the tin mine had been in working, the coolies employed carrying wet earth and sand on their heads and on sticks weighted at end with tin washings. There was a vast difference in the work performed by the coolies in different mines: in some workings they carried only half baskets, in others their baskets well full or nearly so, and it strikes the casual observer that either Johnny China is loafing or else there must be adifference in the weight of the stuff in the respective tin mines under operation. Whichever it may be, there is little doubt that more work might be done than at present, and the tin mine owners must know by comparison, that one mine pays better than another, not because there is more tin taken out of it, but because the crowd of Chinese coolies are better superintended on one mine than they are on another. Machinery will to some extent cheapen labour and hurry up the sleepy-headed-opium-eating-heathen Chinee.

I accompanied Mr. Givan to many of the engine-rooms and saw the water being pumped up from below in fine style, but will not tire your readers with Chinese names given to their varied arrangements nor intrude on your space with particulars of how the men are paid and what they do with their money: suffice it to say that a great number of Chinese coolies are employed in the pits digging and terracing and a great number carrying the rich deposit of tin dust mixed with sand and clay up a notched log and shunting their loads into the place where others are employed puddling and washing the tin; that the engines should be kept working is obvious, for the rains are heavy in Larut, and with an annual rainfall of about 300 inches all mining operations would be brought to a standstill unless the mines are pumped nearly dry, yet should dry weather set in, water is used to drive out water by the Chinese chain pump and water-wheel where the owner is not in possession of a steam engine and centrifugal pumps, therefore without some certain quantity of water to drive their wheels and chain pumps it would be next to impossible to efficiently drain their mines constantly producing water by percolation and covering the bottom of the mine where the men want to get at the tin dust deposit.

Gwynne's centrifugal pumps are in use here, and if I remember correctly Mr. Givan informed me that no less than eighteen steam engines are daily working on the Kamunting mines alone.

The Chinese miners though giving way to Europeans' ideas of working their mines stick religiously to their own yellow-skins as labourers and won't have "Ramasamy" for love or money. They said he offended their gods by appearing in their mines with only a crupper on! Ramasamy would do the work as well and perhaps better than Johnny Amo, though his dress is reduced to a minimum: however, Chinese habits of exclusiveness added to their superstition account for this difference of opinion and it was clever to say the least of it to draw the line at trousers, like the old Colonel of the 15th when he asked Swan to look him up at the mess and enquiries were made as to how he should dress, the jolly old Colonel replied: "Come as you like, but mind you have breeches on, for we draw the line at breeches!"

There is no doubt that the heathen Chinee, so engaging in his habits, especially when flocking as they do to our tin mines in thousands, must stir up the mud in the water a bit and the rubbish in the shape of decomposed vegetables, dead dogs, and what not mixed up with worst impurities would tend to breed disease. To grapple with this contingency, a dollar per head was charged to maintain the hospitals and large staff of medical men, and as before mentioned 700 are now indoor patients. Cholera broke out last week, and 40 cases died out of 72 reported. Small-pox is always hanging about, and a disease resembling your Ceylon elephantiasis called beriberi disables many. Bad water is doubtless the cause of much misery at the tin mines, but everyone knows where dollars are dug out of the ground in the form of tin or any other mineral there will always be men ready to face the *old gentleman* himself rather than not try their luck.

The Chinese, looking remarkably happy, may be seen daily travelling backwards and forwards between the shipping port at Matang and the mines, they don't walk, oh dear no! they ride, bless you. Even the ordinary cooly, when off duty, sports a fine straw hat with ribbons, silk suit of clothes and pair of wooden shoes, his face beaming with smiles, and a cheroot, a kind of penny pick-wick, in his mouth occasionally—his cares in this world of trouble ascending with the smoke to the wind.

To return to the subject of the tin mines—we next enter the smelting-house, and to explain to you the number of ingenious contrivances here to be seen puzzles the brain of your correspondent. The Chinese furnace for smelting is a cylindrical shaped arrangement about a man's height and made of yellow clay with a piston-rod and bellows made of wood. Charcoal is used to get up the required heat, and the tin may be seen flowing out in a bright glittering stream. It is put up in moulds of a certain weight, passed through the Treasury, and the duty paid, and Government stamp put on each block: then it is free for shipment for Penang or elsewhere. I could enlarge on this subject but fear to make my letters too long and tire your readers with statistics of dollars and cents, piculs, bharas and katties, with other Chinese measurements and currency in Perak.

The tin enterprize has attracted the attention of Australian miners, and several are here prospecting the country and in some cases putting up their machinery to commence operations. Johnny Chinaman has been making his pile, and thinks nothing of producing champagne when Europeans call to see him. Captain Ah Quee was offered $500,000, or a sum equal to £100,000 (one hundred thousand pounds), to sell out, and refused!!

Most of these wealthy Chinese rent the gambling farm, spirit farm, pawnbroking, opium farm and other paying speculations, and by strict attention to business and honesty in their dealings gain the confidence of both natives and Europeans both at home and abroad. From the writer's first voyage in 1862 to Shanghai and in 1863 to Hongkong down to the present date, nearly twenty-two years, he has always had a favourable opinion of the Chinese, and individually they appear to like us, though of course always jealous of our getting the eggs out of the nest they may happen to find before us.

Europeans here do their best to advise them well in mining matters. Messrs. Scott and Givan, the former Inspector of Mines for the Government of Perak, settle their daily disputes about watercourses, boundaries, building sites, squabbling amongst the working miners, &c., and it speaks well for Mr. Scott and his management of Chinee affairs to find he has given satisfaction to both the Government of Perak and also the Chinese themselves. He was a gold miner from Melbourne, Victoria. Mr. Scott promised me specimens to send to you.

More machinery is ordered out for the Larut mines, and the railway will materially cheapen transport of engines, pumps &c. required.

There are three large mines in full swing in Larut, they are called Kamunting, Assam Kumbeng and Tupai. The first mentioned is to the north of Thaipeng (the commercial capital of Perak) and extends over a vast tract of flat country below Bukit Janah range and Bukit AssamKumbeng with the mines of that name to the west of Thaipeng with Tupai mines to the south of Thaipeng city. So much for the geography of the mining districts of Larut, Perak, a place your readers upcountry in Ceylon perhaps never heard of before and probably will forget now though nevertheless teeming with life and enterprise, and the money being turned over in a most wonderful manner. "Nothing venture, nothing win" is the motto; "Heads you win, tails you lose." Like the gamingtable put down a dollar and take up three or nothing! Europeans would "rush" these fields if not for the tropical climate and open-air labour. With gold it is different, because the miners burrow like rabbits (only a good deal deeper): In these lands of the sun, Johnny China has everything his own way. He can buy and sell cheaper than the European in both provisions and clothes, and although one would prefer dealing with one's own countrymen anywhere and everywhere, however, when we find our own countrymen charging sometimes double the amount the Chinese charge for the same articles, it is a temptation to discontinue dealing with European storekeepers and go to the Chinese with dollars in hand for a direct saving of fifty per cent, and sometimes one hundred per cent. The writer speaks from personal experience, having dealt with both, and although at present not mentioning names of any firm may have to touch on this subject in a future letter and give some proof of the difference in the charges for clothing in particular between what is called a good house in Penang and Chinese storekeepers. What has this got to do with mining? *Everything* in the world, because it under-*mines* one's health and robs us of our *tin*, and what can anyone do in this world without *tin*, we should like to know.

A French gentleman representing a French Mining Company has just arrived in Perak, and goes, we believe, to far off Kinta district, where their mining interest is situated. Mr. Towgood and family went there last month. A very lively place Kinta from all accounts.

Messrs. Scott and McIntyre found tin on Capt. Schutze's estate near Gapis, at the foot of Sara. It is to be hoped good will result from this discovery, and that Schutze will get his estate off his hands with his vast territory of 5,000 acres. We shall speak of soils and agricultural prospects, cost of labour, contracts, &c., in a future letter. Meanwhile chinchin.

COCOA PLUM.—It is very common in Portland and Carpenter's Mountains; seems to thrive best in a cool, moist soil. It grows to the height of 6 or 7 feet, and bears a fruit not unlike the English plum in size and shape. Of these some are red, some white, and others black, without any essential difference in the shrubs of either sort. The fruit is perfectly insipid, but contains a large nut, inclosing a kernel of very delicious flavor, which makes up abundantly for the insipidity of the pulp. The fruit of the several complexions mentioned have been preserved with sugar, and sent by way of presents to Europe; but the red and black kinds are generally preferred.—BROWNE.—*Hortus Jamaicensis.*

THE COMPOSITION OF TEA is thus noticed in a notice to correspondents in the *Queenslander*:—

EXPERIMENTS.—(1) The tea plant can hardly be expected to thrive over a very wide range in Queensland, owing to the fact that the rainfall in most places is inadequate. (2) Pure tea, when analysed, is a wholesome beverage, said to contain in itself the constituents of the finest mineral springs. In the ash, magnesia, potash, lime, iron, and chloride of sodium are found; while the extractive matter is nearly half albumen, showing that the leaves contain a nourishing food almost equal to beans and peas. (3) The invigorating power of tea is caused by a volatile oil called *theine.* (4) Black-lead and gypsum are used in China for the purposes of adulteration.

CHOCOLATE MANGE.—One box gelatine dissolved in one pint milk; pour this by degrees, while boiling hot, on five ounces grated chocolate, stirring it all the time; when cool, add four well-beaten eggs, pouring this into a kettle with one quart cream, in which has been dissolved one pound sugar, let it boil till the chocolate is thoroughly melted and smooth, and the mixture has become much thickened; pour into moulds, and eat with whipped cream.—*Southern Planter.*

FOOCHOW TEA has now for some years been deteriorating, and it is naturally losing its hold on the English market, where Indian teas are greatly preferred. Every year sees a decline in the consumption of Foochow tea in England; every year witnesses a large and steady increment in the import of Indian tea. Nor can this be wondered at. The Indian planters bring science and care to bear upon their cultivation of the tea plant; the Chinaman, either through ignorance or carelessness, takes no trouble to improve the stock, and the consequence is that it becomes poor and degenerate. In future the Foochow producers will have to make up their minds to accept much lower prices and to pay some attention to the improvement of the stock, or they must be prepared to see a rapid annual decline in the foreign demand for their teas. A good quantity of Foochow tea goes to Australia at present, but the Indian teas are finding their way freely to Melbourne and Sydney, and great efforts are being made to popularise them by the Indian Tea Syndicate. The Indian teas are most carefully cultivated and picked, and the yield goes on increasing to the extent of more than a million pounds every season. Unless the China teas are materially improved, and the prices for them greatly reduced, it will be a question of time only when they will be altogether superseded in British markets by the Indian teas. Having regard, then, to these facts, it is the rankest folly for Chinese producers to hold out for prices which can give the foreign merchant no margin of profit and may instead involve him in heavy loss. The Chinese producers will not only have to surrender a portion of their profit, but the authorities will have to reduce the duty upon the staple, if they wish to long retain their hold on the British market. The question is one that will have to be faced soon, and the sooner the better for the Chinese producer.—*N.-C. Herald.*

NEW PRODUCTS AT COONOOR.—During the past fortnight we have had decidedly cool weather, with glimpses of the monsoon over the Koondahs; but very little rain has fallen in or about Coonoor. However, some planters are hard at work getting out cinchona, as experience shows an early planting is everything. I lately had the pleasure of visiting the Chelmsford Estate, situated at Kullar, where during the past year and a half, considerable experiments have been made with rubber, cocoa, Liberian coffee and fibres. The rubber (ceara) was imported as seed about a year ago, and some acres planted 6' by 6' now average a growth of upwards of 20 feet with sturdy stems which will support a man's weight some feet from the ground. The tree and leaf somewhat resemble, the Castor-oil plant, and the stem branches at a some 10 feet. This tends to thicken the trunk by checking the growth in height, which entirely caps anything I have seen in blue gums. The trees are expected to yield a return after the third year. The cocoa and Liberian coffee are slow growers, but a three year old tree of the latter was full of cherry, which appeared very large to my eyes, used to the Mocha variety. Both cocoa and Liberian coffee must be grown from seed, but the rubber grows from cuttings which are perhaps more easily propagated and certainly less expensive with a product promising such good returns; and growing best at an elevation of 1,000 feet, it bids fair to rival coffee cultivation in the planting future, more especially as it requires little attention after a few months. As the Tongas change horses at the entrance to the estate, it is well worth a passenger's while to alight and inspect the different products. A great deal of attention is given to the extraction of fibre from aloes and machinery has been imported, which worked by bullocks can treat a large quantity per diem.—*South of India Observer.*

COFFEE AND THE GENERAL PLANTING ENTERPRIZE OF CEYLON.

At a general meeting of the Maskeliya Planters' Association, held at Bloomfield Reading-room on the 18th July, Mr. W. D. BOSANQUET, read the following paper :—

GENTLEMEN,—The subject of my address to you today is coffee and the general cultivation of the same. But as coffee in this district promises in time to become a secondary cultivation, I trust that I shall be pardoned for digressing from the strict consideration of the subject to glance at the general aspect of the planting enterprize as now carried on in Ceylon.

At the present time we are very much in the position of pioneers opening up a new country: we are groping more or less in the dark to discover what product may be most profitably cultivated not only on certain estates but on different portions of those estates. Cinchona we have found on most properties to fail us in many portions; cocoa, rubber, and cardamoms require each special conditions of soil and climate; and though tea will grow everywhere it is hardly probable that everywhere will it be found to pay. There are some men who, when their coffee or cinchona fails, give up all attempt to experiment with other cultivations but cry out forthwith for abandonment. It is my own belief that every acre of the country will be found to grow something to a profit if we can only discover what. The energy displayed by so many planters in trying new cultivations on their estates and of which this district and Association furnishes many examples, is the true spirit which will lead Ceylon to a sound and prosperous future. It may be that some of us will have to succumb during the struggle, and that the benefit of our labors will be reaped by future proprietors, but let each one do at his best for his own estate and so will he be best promoting the general welfare of the country.

I think that the recent years have done much good in training the minds of planters in a more mercantile groove and in teaching them that questions of cultivation are after all a consideration between profit and loss. To be conducted profitably agriculture like mercantle affairs must be guided by the balance of probabilities. I would therefore take as my text today 'the law of probabilities,' urging upon each one to take into his consideration as regards the working of his estate the question whether certain portions are most likely to return the best profits from tea, cinchona, coffee, or other cultivation, whether some portions are more likely than others to respond to a system of high cultivation *i.e.*, manuring or whether a particular method of pruning and handling is not calculated to put crop on the trees: in fact to reason out things for yourselves instead of doing a thing simply because your neighbours are doing it and testing everything first on th small scale;—thus let everyone use his judgment to the best of his ability and, if he does not feel sufficient reliance upon himself, consult those in whose judgment he has more confidence.

The questions of cultivation are not such as any one man can be dogmatic upon, but if in my address to you today I am able to offer any suggestions which may help others to judge better themselves, my object will have been attained.

I have been asked to consider the questions of leaf-disease and seasons and how far the present infertility of coffee is due to one or the other. I will endeavour to make my own views on the subject clear and to give my reasons for holding them. In the first place then I look upon leaf-disease as the primary cause of our present distress, and think that if it was absent we should find our coffee trees giving remunerative crops in even doubtful seasons; but that coffee, even with leaf-disease present, would be able to return paying crops had we really favourable seasons, Uva is I consider a standing proof. I have seen leaf-disease in Uva worse than I have ever witnessed in the high districts on the Kandy side, but in Uva the leaves do not so quickly drop off and the trees recover themselves sooner. This is not by reason of its better soil, for on this side we have many soils equal to Uva ones, but in consequence I hold of its drier and more forcing climate. One reason however why Uva crops in spite of leaf disease is that it is blossoming more or less all the year round and is therefore capable of turning to account any period of comparative relief from the attacks. It is the time therefore of the attacks that is with us as important a factor as the disease itself. If an outbreak of leaf-disease comes upon our coffee just at the commencement of the blossoming season the trees are naturally weakened just at a time when they are required to be most vigorous. The seasons are however I think largely responsible for the time and virulence of an attack, and if the coffee has been weakened by any long continuance of rain and low temperature, they are more open to the assaults of the enemy and less able to throw it off; and here I think a writer in the *Observer* has well called attention to the unfavorable character of the north-east monsoons of late and to the amount of rain which has fallen in the latter months of the year, which has kept the trees back from hardening and preparing the wood for the ensuing period of blossom. As I shall notice later on under the subject of Pruning, it is the early blossoms that we want to prepare our wood for, but last year at any rate I can answer for it that the wood in our higher districts was kept green and unripe up to the middle of February, when at length the weather became fair. That the effect of seasons, in Ceylon alone of all countries in the world, should be by some ignored and ridiculed, has seemed to me most extraordinary, and the reasons frequently given in the papers for ridiculing the arguments of those who hold that seasons have had their share in producing the falling-off in crop production are truly absurd. If it be admitted, and everywhere else it is not denied, that the effect of too much moisture, combined with unusually low temperature, is weakening to vegetation in generally causing a cessation of root development, then is it not reasonable to attribute the various indications of weakness as much to seasons as to leaf-disease. We have most of us noticed how, if a constantly running stream bursts its bounds, or there is a steady leak from a coffee spout, the coffee trees coming under the influence of the unaccustomed moisture speedily die, and in a modified degree the effect of long continued rain is the same: what wonder then if branches die back, or crop drops off in such seasons as that of last year. Mr. Giles Walker's valuable statistics prove what unusual rainfall and low temperature Bogawantalawa has suffered from of late, and the estate journals I consulted show that, from 1870 to the end of the blossoming season of 1876, the weather was invariably favorable for blossoming during the months of January, February, March and the beginning of April, being hot and dry with occasional days of rain. It should not be forgotten also that the effect of long-continued rain is to wash the fertilizing matters of the surface soil into the subsoil and therefore out of reach of the feeding rootlets, while if a soil becomes water-logged, as it practically did last year on many estates, the effect is to destroy the nitrates present and evolve nitrogen as gas, then causing a very considerable loss of plant food.

This brings me to the subject of cultivation.

The main resource at our command for combating leaf-disease is manure. I do not however propose to consider the whole subject of manuring, which would take up too much of your time and be mostly a recapitulation of what I have already written in the *Observer*, but merely to give a few suggestions for the general guidance of those who are desirous of trying the effect of manure upon their estates. And here the law of probability must be taken largely into consideration. It requires in the first place some faith in the future to give one confidence to make the required outlay of capital, for the effect of weather upon crops is greater than the influence of manure, and you may therefore lose your return through the effect of an adverse blossoming season; in a doubtful season however the soil best furnished with plant food will yield the best results. Another point to be considered is that unless the soil is in proper condition for the reception of manure its effect will be reduced to a minimum. To put the soil into condition there are two means, viz. tillage, and liming. By tillage, that is in our case freeing the soil with the fork, the surface soil is kept in an open condition favorable for the distribution of roots, while lime has the effect of sweetening it and enabling it to retain the fertilizing matters added thereto. A soil in good condition is able to absorb ammonia from the atmosphere if sufficient clay is present, in which respect few of our upcountry districts are deficient. The solvent power of the water in a soil is greatly increased by the carbonic acid it holds in solution, and if lime is added to a soil it attacks the humus present and forms carbonic acid. Lime without being itself a manure is therefore the proper foundation for all subsequent manuring, but to sandy soil it should not be applied, as it is then liable to use up the humus too rapidly, and in such soil gypsum, *i. e.* sulphate of lime is the best application. In my own practice, I have always used air-slaked lime, that is the Colombo coral lime in the condition in which it usually arrives on the estate, at the rate of 1 lb. for each tree. Lime should be followed up by manure at an interval of about 6 months.

The most certain of all manures in its effect upon coffee is cattle manure when combined with bones: in my own experience cattle manure when applied alone has been found occasionally to add nothing to the subsequent crop, but when combined with bones the increase was more than doubled.

Artificial manures require for their most economical application considerable study of the character of the soil or knowledge of the previous history of the manuring that may have been carried out; thus, if cattle manure has been previously applied, an application of bones by itself may be sufficient to produce the highest degree of fertility. In low-lying districts nitrogenous manures which do not give up their nitrogen to the soil too rapidly are the best to make use of, of which cattle manure and rape cake are the best examples, though for certain objects such as pulling a crop through or putting wood on trees deficient in leaf such manures as sulphate of ammonia in small quantities may be cometimes used with success. The mode of application of one's manure is also a chief consideration, and the great point is to diffuse the manure through the soil as much as possible within reach of the crop feeding rootlets. It is I believe a fact known to fruit-growers at home that there are three kinds of roots—the taproot which supports the tree in an upright position, the leading roots, the function of which is mainly to supply the tree with foliage, and the network of rootlets which radiate from the tree for a distance of 2½ or 3 feet which contribute to the crop production, and it is therefore of importance to apply your manure within reach of these latter, that is fairly close to the tree and round as much of its circumference as possible. In my own practice I always fork in the manure after scattering it round the tree at a distance of about 18 inches from the stem, disturbing the leading roots as little as possible. A semicircular shallow, hole if the manure is well mixed with the soil will produce much the same effect, and in rather light soils may have the advantage of retaining the manure longer, but it is a more costly and troublesome process and therefore less likely to be well carried out unless the supervision is very close. Manuring in my opinion is best done to good coffee which is accustomed to crop and it is I believe a waste of money to attempt to renovate old worn-out coffee from which the surface soil has been washed away, if the framework of the tree is still left it may be done but at a cost which renders it unprofitable.

When we come to the question of pruning, I confess that I have great difficulty in ex pressing an opinion and it is difficult to apply what I have called the 'law of probability.' In giving the considerations which guide my usual instructions, I may, however induce some of you to reason out the matter for yourselves and thus we may all reap some future benefit. What I think we have to aim at in these days as far as possible and the system by which we shall attain the best average results, is the preparation of our wood for the early blossoms. In the high districts the wood takes from 9 months to a year, sometimes even more, to arrive at maturity. In the days before leaf-disease the difference of opinion was one between pruning before and after the blossoming season with the object of assisting the wood either to increase its blossom or else to bring its crop on after the blossom had set. Now our main endeavour is to help the trees to set their blossom, and if this is attained we can help the trees by the aid of manure. The effect of pruning is to cause the trees to throw out a fresh flush of wood, and from this wood is selected in the ordinary course that which is to bear the following crop. Now if your pruning is done early, *i.e.*, before the 15th say of April, and your wood is accustomed to mature in 9 months, you are really just at the right time, whereas by pruning after the blossoms are over the wood subsequently formed would still be green in the beginning of the following year. If a late pruning is adopted systematically then it must be necessary at the time of pruning to leave on the trees such wood as has formed before the blossoming season commenced, as in an ordinary blossoming season the formation of new wood should be checked, and the old wood be hardening: your late pruning is therefore adopted with the view of giving your wood at least 12 months in which to mature. In the majority of cases I should give my verdict for early pruning and for this reason, that where coffee is intended by nature to grow, there it will in ordinary seasons mature its wood in nine months at the most; still if I had to deal with an estate where the longer period was required I should then prune late, but, guided by the balance of probability, I should at the same time hasten to substitute for the coffee some cultivation better suited to the climate.

Whether the pruning should be heavy or light is a very important question, and I feel here that I am treading on delicate ground. It is certainly necessary that the pruning should be adjusted according to the power of the tree to make root, for it is to this power of the tree to make root beow ground that it will owe its ability to form wood above, and in these days of leaf-disease and wet seasons the root development is only too much checked already. The amount of leaf on the tree mainly determines the development of root, for the evaporation or transpiration from the leaves is the cause of the suction exercised by the roots on the soil. If therefore you unduly reduce your foliage you reduce the power of the tree to nourish itself from the fertilizing matters of the soil. In a strong soil this is not so much the case and may be an advantage as the upward flow is not immediately checked by the reduction of the foliage and consequently there may be a concentration of food material in the roots which when fresh foliage has formed itself will afford extra nourishment to the tree if carefully regulated by the subsequent handling. Prune therefore according to the strength of your soil as evidenced by the vigour of the tree and pay the utmost attention to the after handling.

Handling I look upon as the most important work upon the estate as being the real regulator of the crop. Too often I notice the inferior labor of the estate turned on to do this work. By the handling you direct the strength of the tree into right wood. The handling after the pruning is the time when you select the wood which is to bear the following crop, and no more wood should be left on the tree than it has the power to bring the crop of to maturity. At this time therefore you cannot give too much attention to the work, and all your subsequent handlings should be directed towards the same object, viz., turning the strength of the tree into the wood you have reserved for crop. In conclusion, what we require is the training of our faculties of observation: a few simple observations such as marking the branches at the time of blossoming or the watching of the wood from the time of its formation to the time when it has borne its crop and the noting down the result will lead on to making further observations, and the comparison of notes among ourselves will add to the mass of general information. But above all things have in you a reason for what you do founded upon accurate experiment.

The Chairman then asked Mr. GILES WALKER to give the meeting the result of the very careful observations of the seasons and temperature that he has made during the past ten years, and to tell the meeting whether the views held by Mr. Bosanquet were endorsed by him.

Mr. WALKER in a short speech said that he had for many years kept the daily temperature and rainfall, and had observed the weather carefully; that he had undoubtedly PROVED that during the past few years he had had unfavorable blossoming seasons in Bogawantalawa; that he considered that want of sunheat during January, February and March was one of the great causes of our not getting good crops; that it was a well known fact that morning sun was particularly necessary to force out blossom, and that he had very carefully noticed that during the past blossoming season we had had continuous cloudy and hazy days, and that in saying this he was stating certain facts and not making assertions he was unable to prove, and that it was his belief that if we again got favorable seasons, notwithstanding leaf-disease, good and cultivated coffee would give remunerative crops.

The CHAIRMAN then asked if any member wished to make any remarks or ask any questions.

Mr. BLACKLAW, who was called on, stated that his observations were in accordance with Mr. Bosanquet's and Mr. Walker's, and his views were the same as theirs; that he was glad to see two gentlemen who still had the pluck to stand up for coffee; that if Colombo merchants would listen to men like Messrs. Bosanquet and Walker, who proved their correctness by profitable returns in the one case and indisputable figures in the other, the future of Ceylon would be a brighter and more hopeful one. When V. A.'s publicly condemn coffee and say they think Ceylon is played out, it cannot be expected that superintendents will have their heart in their work or be successful in pulling round their estates. In his opinion Ceylon requires hopeful men at the helm instead of detractors during the present crisis.

The CHAIRMAN then in the name of the Association thanked Mr. Bosanquet for his address, and added that to speak in favor of coffee in these days was a bold thing to do, but coffee was the mainstay of Ceylon still, and likely to remain so for a long time. Cinchona certainly would never take its place, and it would be a long time before the export of tea approached even the coffee export of the late unfavorable seasons.

CINCHONA.

Mr. CHRISTIE was then asked to give his opinion on cinchona cultivation and mortality at present compared with that of the past. In a short address he said:—The chief question at present being discussed was whether or not the vitality of the stock had seriously deteriorated, and whether that was the cause of the non-success which attended so much of the last three or four years' planting. While he admitted that such a thing was possible he did not think it was likely or in any way proved. Those who argue that the stock has deteriorated quote, almost as a proof, the case of English vegetables, which as we all know become worthless in two or three generations, but on the other hand we have lantana, white-weed, Mauritius grass, and many other exotics, all thoroughly at home in Ceylon. And in fact nearly all the great economic vegetable products of the world are most largely and successfully grown in countries to which they are not indigenous. Therefore it by no means follows that the cinchona stock must degenerate because the plant is not indigenous to Ceylon. If the cinchona stock had deterioriated, he supposed it would do so in all the varieties, but he had calisayas grown from local Emelina seed and also from S. American imported seed and both stocks lived and died equally. To what therefore are we to attribute the undoubted fact that cinchona is more difficult to mature now than it was? He, the speaker, thought that close planting had much to do with the failure; we planted what we expected to grow to trees at distances apart more suited to cabbages. Then our soil was older, and much of it had previously been more or less studded with cinchonas. Lastly but not leastly he thought that the same adverse conditions of climate to which Messrs. Bosanquet and Walker attributed in a great measure our short coffee crops in the high districts had been equally adverse to cinchona plants. Our soil for the last four years had never been out of a damp sodden condition, and there had been far too little sunshine and warmth for any vegetation: even weeds had not grown during these years as they used to do.

After a considerable discussion on this subject Mr. A. E. WRIGHT gave some information as to the returns tea on Mariawatta and Rookwood were giving, and Mr. MULLENS was asked to give a few particulars about tea in Maskeliya, but preferred to wait until next meeting, as he had not come prepared.

Major TRANCHELL proposed a vote of thanks to the Chairman, especially thanking him for the information he had given about cinchona. This was unanimously carried, and the meeting then closed.

THE BRITISH NORTH BORNEO COMPANY.

The adjourned half-yearly general meeting of the British North Borneo Company was held yesterday at the City Terminus Hotel. Sir Rutherford Alcock, K.C.B., the Chairman, presided, and in moving the adoption of the report reminded them that the principal object of the adjournment of the meeting had been to change the date of the half-yearly meeting so that the accounts might be received in time to be presented to the shareholders. Although on the present occasion it had been found impossible to obtain the detailed accounts required for the preparation of a complete balance-sheet, still the information placed before the shareholders would, it was believed, fully enable them to see the financial position of the Company on the 31st of December last. Another six months, however, had elapsed since these accounts were rendered, and much additional information had been received of great interest and importance, showing the rapid progress which had been made in the interval. After reminding them of the circumstances in which the Company took over the territory from the British North Borneo Provisional Association (Limited), with all the rights, titles, and property previously acquired, he alluded to the steps which the directors had taken to ascertain the liabilities which were existing, referring to the despatch of the managing director (Mr. Alfred Dent) to the territory to make such arrangements as might seem necessary to place the administration on a satisfactory basis, and to establish a system of accounts which should secure to the court the full control over expenditure. As Mr. Dent had not yet returned, and the court had received no final report from him, they were not able to state how far he had succeeded in giving effect to his instructions, as regarded more especially the scale of expenditure and the effective control of the court. According, however, to a telegram received on the 25th ult. from Governor Treacher, the corrected estimate of revenue and expenditure for 1883 was as follows:—Expenditure $328,000, revenue $158,000, or in sterling £65,600 and £31,600 respectively, leaving a total required from the Company of £34,000. This amount the court had already sanctioned in fixing the limit of the drafts to be made on them. What their policy should be required careful consideration before it could be definitely determined. They had the option of becoming traders as well as rulers; but after consultation with the Governor, and others experienced in the administration and development of colonies in the Eastern Seas, the directors came to the conclusion that it was unadvisable, in the best interest of the Company and the colony, taking the territory as a whole, to enter into any rivalry, or otherwise interfere with the trade in process of rapid development. They were convinced that greater results would accrue with less risk by the Company confining itself to the administration of the country, and, as the owners of the soil, throwing open the acquisition of land to all applicants on favourable terms, and, if not declaring their ports free, yet to limit all import duties to four or five articles, such as opium, tobacco, spirits, &c.; and on exports in like manner, to a royalty of 10 per cent. on natural produce, such as gutta, indiarubber, camphor, rattans, &c. They had felt assured that by giving security to life and property under their charter, such as was enjoyed in the British colonies in the same region, with the offer of cheap land eminently adapted to all tropical produce, they would best succeed in securing the two important conditions of prosperity—the rapid inflow of an industrious population from China and the adjoining territories of Sulu and Brunei, which would supply cheap labour; and a large investment of capital for its profitable employment in plantations and in many other ways. From Mr. Von Donop, their superintendent of agriculture, a very interesting report to the end of last year had been received, "on the agricultural prospects of North Borneo," giving the results of his personal observation of the various kinds of soil and the natural products, which could not fail to be useful to planters, with a selection of land for the cultivation of different crops. The soundness of the policy pursued by the directors had been fully demonstrated. While there was no prospect of large profits for the Company either by mining or trading on their own account, there was every probability of an immigration securing at no distant period a very large Chinese population, supplying cheap labour for planters, and a source of revenue to the Company. This had now become a certainty, and everything tended to encourage it. North Borneo was not only in close proximity to Hongkong and the southern coast of China, but it was a healthy country, as Dr. Walker, the Company's principal officer, in his official report had satisfactorily shown. Although it was not their intention to make North Borneo a Chinese colony—and he should be sorry to think that that was the destiny reserved for it—there was an obvious necessity for encouraging, in the first instance, a large immigration of Chinese to supply the artisan and agricultural labour which the natives could not at present afford. Of course many unforeseen contingencies arose in such an enterprise as the founding of a new colony in the far East, which not only interfered with its progress, but strained all the powers of those engaged in the arduous work on the spot. The Company had within the last few months lost three of the most efficient of their staff, two by misadventure and one by sickness. A wave of cholera also swept over the island last autumn, which raged with great violence over the whole archipelago. Fortunately it was very transitory, and not as serious in North Borneo as elsewhere, nor did any European fall a victim. But while present it paralyzed trade among the natives and work in the jungle, and otherwise greatly interfered with their progress. Notwithstanding these trials, the onward progress of the Company had been marked, and each mail for some months had brought fresh intelligence of the most encouraging character, of new Companies forming in China and Australia, and fresh applications for large blocks of forest or waste lands. With all this capital and labour immediately available for the full development of the territory and in so many different directions, the shareholders might assume that if their own capital subscribed at this time should seem at any time to fall short of the large demands which such an enterprise created, more would be forthcoming from other sources. Now that Australian legislation, expelling the Chinese, had rendered sugar growing more difficult for want of cheap labour, and that American legislation had equally tended to close the field for their labour on the Pacific coast, this surplus labour must find an outlet. After quoting from an article in the *Times* on the "Resources of Madagascar," he stated that with these prospects before them, so full of promise for the profitable and peaceful occupation of a new territory, so lately given up to jungle and a few scattered tribes of natives—promise of a good return in the immediate future and evidence of active progress in the present—the directors could feel no serious doubt as to the success of the Company and the prosperity of the colony. Its national importance, either in peace or in war, he had never doubted. For British interests it was essential that its magnificent harbours should be accessible to our fleets, and afford sure harbours of refuge to our merchant ships, lying as these ports did right in the fairway of the great trade between China, India, and Australia. Maruda Bay in the north, and Sandakan in the east, were not more than five days from Port Darwin, in the North Australian territory, and a similar distance from Hongkong and Singapore, the two great *entrepots* of the trade carried on between India, China, and Great Britain. If any lingering doubt could remain on this view of the great future in store for this country, it must, he said, yield to the most cursory review of the progress made in the last few years by other colonies in the same seas. The prospects of North Borneo were therefore bright, but the development of a new country, in the most favourable circumstances, must be a work of time. A large revenue depended almost entirely on the population, and at the present rate of increase a year or two should balance their revenue and expenditure. Lord Elphinstone, the vice-chairman, seconded the motion, and the chairman, in reply to questions, stated that the directors saw no reason to doubt that they had quite sufficient capital, having regard to the influx of capital from outside, to work the colony as rapidly as circumstances would permit. They had made no application to the Stock Exchange for a quotation, and they were not in a position to apply. The report was then unanimously adopted, and the auditors, Messrs. Turquand, Youngs, and Co., were afterwards re-elected. In reply to a vote of thanks to the chairman and directors, the chairman again alluded to the political importance of North Borneo to England.—London *Times*.

BOTANICAL TRANSGRESSORS.

Impersonification is a comparatively innocuous offence. Graver charges may be brought against the seemingly peaceful denizens of our fields and hedgerows. It is often noticed that special varieties of plants grow in special districts, and the guide books which find their way into the hands of autumn wanderers generally contain some account of such local varieties. These variations are often ascribed to differences of soil and climate, and certainly both have a good deal to do with the well-being and the perpetuation of specially varied forms. But many facts show that the potency of soil and climate is by no means so great as it is popularly supposed to be. Cultivated plants, for instance, plants which are under the care of man, grow equally well and produce equally abundant fruit in very varying soils and climates. Wheat ripens in Siberia and in Egypt, in Southern Russia as well as in North-West Canada. The soil and the climate of Europe is sufficiently like to that of temperate North American to lead us to suppose that the flora of both would be the same, but in fact it is not. We might suppose that plants would flourish best in their native soil and in their native climate, and here again facts falsify many of our suppositions. English watercress (*Nasturtium officinale*) was unknown in New Zealand, but when introduced there it took so kindly to its new home that it is not unfrequently found with stems 12 feet in length. This prodigality of growth was not only found inconveniently large for the breakfast table, but it made watercress a formidable impediment to river navigation, it blocks up river courses, and costs the New Zealand Government some hundreds of pounds yearly to keep it from altogether choking up the water way. Similarly the American water weed or ditch moss (*Anacharis canadensis*), although harmless enough in America, has spread with such rapidity in this country since its introduction about 1840, that there are few rowing men whose sweet serenity of temper has not been occasionally ruffled by it. The fact seems to be that plants depend not only on the soil and climate, but also, to an extent hardly as yet sufficiently appreciated upon the good-will and forbearance of other plants. Plants grow, it has been epigrammatically observed, not where they like so much as where other plants will let them. No idea seems more fittingly associated with the quiet beauty of foliage and of flower than that of tranquillity and peace, and yet this seeming peacefulness only veils to the passer by an internecine war which is ever going on. It almost seems a mere rhetorical flourish to assert that war, bitter and unsparing and to the very death, is carried on by the silent beauties of our fields and meadows. But war there is. Many species have faded away and have become quite extinct in certain localities, not because the soil was unsuitable or the climate too rigorous, but because they have been overpowered and crushed out of existence by their floral rivals. Warfare among plants is carried on in various ways. In park lands it is often noticed that no flowers bloom under the shade of the trees, although outside the shaded circle the grass is studded with gaily-coloured dots and patches. The ground beneath a fir-tree or a yew is not only devoid of flowers, but as a rule the toughest grasses, tenacious of life as they are, have been choked and throttled out of existence by the layers of fallen leaves which cover the ground and shut out light and air. It is not the soil, but the absence of sunlight which is fatal. The leaves of the tree, by intercepting the light, deprive the germinating seeds of one of the main sources of their well being. Many large-leaved plants war in this way upon their less favoured fellows; but to equalise the conditions of the combat a little, many plants are especially equipped to fight with large leaved foes. Some, like the Convolvulus, are enabled to obtain a sufficient quantity of air and light by climbing; others, like the *Potentilla reptans*, which have not learnt how to climb and are in danger of being left too much in the shade, sent out long trailing stems which throw out roots at every node or joint, and find compensation in this way. Annuals, plants, which die down each autumn and are grown from seed, fight at a great disadvantage when they have to contend with perennials. Perennials, when once they have their roots embedded in the soil, are prepared at each successive approach of spring to push up their fresh shoots through the moistened ground, and they supply their nurslings with nourishment from already existing stores. But annuals have to begin at the beginning. Supposing the seed to have fallen by good chance on suitable soil, it has still many dangers to run when it begins to push its rootlet downwards and to expand its first pair of little leaves to sun and air. Taller plants may overshadow it, shutting out light and warmth; quick-growing grasses may draw away from its immediate neighbourhood the moisture which it needs, and its story is soon told. It dies in early infancy, and by a death which may be termed violent. Although the plants which are falling into the sere and yellow leaf cannot be said exactly to watch over the rising generation, there are many species which show some kind of parental fore-thought for the welfare of the seeds they bring to maturity. They are not content with allowing the seeds when ripe to fall down and grow up beside them, but they send them away to seek their fortunes in far off fields and lanes and road sides. Some seed are provided with an apparatus not unlike an open umbrella, an umbrella with many ribs and no covering. The round feathered heads of the dandelion are examples of this, and children who blow them to pieces to see the individual seeds sail away steadily on the still summer air have no idea of the start they are giving these seeds in their struggle for life. All seeds do not start life so quietly. There is a little bitter-cress (*Cardamine impatiens*) which grows in North Wales, whose erect linear-shaped seed pods as they dry up contract unequally, and by this unequal contraction cause the shells to burst and curl up gracefully above the summit of the pod. This violent bursting of the pod causes the seeds to fly out to a distance of 3 or 4 feet. An American species of witch-hazel (*Hamamelis virginiana*) shoots out its seeds to a distance of 14 feet and more—but when anything done here is also done in America, it is naturally done on a larger scale. The yellow balsam (*Impatiens noli-me-tangere*), now rather rare as a wild plant in England, gets its botanical name from its propensity to fire off its seeds when touched or shaken by the wind. This scattering of the seeds gives them a fairer chance of finding unoccupied soil than they would otherwise have, and it is not so usual to find these species growing so close together as we find daisies, for instance. In spite of its mild and placid appearance the Daisy is a great warrior, its close low lying leaves shut out light and air from any unhappy seeds that chance to be underneath them, and field botanists soon get to know that there is little chance of finding many varieties where daisies grow plentifully. Grass and masses hold their own against most antagonists, but grass is not so very successful in its battles with the daisy, as those who try to preserve the unbroken green of a favourite lawn often experience. Curiously enough it is not always the seemingly strongest plants, plants with the toughest fibre and hardest texture of leaf, which win these floral contests. The small white or Dutch clover (*Trifolium repens*), with a weakly creeping stem, usually not much more than a foot in length, when introduced into New Zealand attacked and defeated an indigenous species of flax, an exceedingly tough, robust plant with strong leaves over 6 feet high. The vegetable Goliath had to succumb to the floral David, and the little clover is actually driving the big flax out of existence. This struggle for life among plants shows that the farmers' antipathy to "weeds" is extremely well founded. Especially in the case of varieties cultivated by man; when his protecting hand is withdrawn it is found that they are in great danger of being swept away by their many competitors for a livelihood. One result to which this botanical warfare largely contributes is that the flora of a district changes. Some species die out, and "colonists" come to take their place. Anyone looking through an English flora will find that the number of plants marked "a colonist," "an alien," or "native ?" is not inconsiderable. And this is true not only of shrubs and small plants, but also of forest trees. The remains of the Hyrcinian forest, which in the time of Cæsar was composed of trees which annually shed their leaves, is now mainly made up of pines and firs. But with respect to forests, there seems to be a rotation of various kinds of trees, the kind of tree which grows up to take the place of those decaying, depending upon the light and air and other conditions which are afforded to the young saplings by the kind of tree already existing.—*Month.*

THROUGH THE TEA DISTRICTS OF NORTHERN INDIA: No. I.

(*By a Ceylon Planter.*)

Sampling Ceylon and Indian Teas.
The Importance of Jat and of only Using Good Seed.

S. S. "Agra," River Brahmaputra.

To a Ceylon man, the air of prosperity and of profitable business which pervades Calcutta is very reassuring. The tea industry is of course only one of several sources of business, but it is the only planting enterprise in which European interests in a large scale are involved, indigo excepted. It is not till Calcutta is reached that the difficulties of a journey to Assam are understood. The greater portion of the journey is by river steamer on the Brahmaputra, a very slow and tedious way of travelling, especially when against the stream. The steamers run weekly, and I was most unfortunate in just missing one and having to wait almost a week in Calcutta.

I took advantage of this opportunity to spend a little time at the office of one of the leading tea brokers, where I gained much valuable information. We sampled some teas, both lowcountry and hill, which I had brought from Ceylon with me, and tried them against numerous representative Indian teas. In manufacture, the Ceylon teas (two samples excepted, which were under-fermented) were perfect and compared favourably with anything which was put against them. The appearance of the liquor was also a point in which the

Ceylon samples carried off the palm, more especially a lowcountry broken pekoe. When, however, we began to taste the teas, it was evident that both in strength and in flavour, the best Darjiling and Assam teas were greatly superior. One set of the samples from the estate in the Doars, distinguished by a fine *malty* flavour, was wonderfully fine, beyond anything that has yet been made in Ceylon. This particular estate, it appears, is magnificent alluvial soil of the richest quality, and consists entirely of indigenous Assam plants. Several other teas, distinguished by this *malty* flavour, and which fetched prices up to R1 11 annas, both from the Darjiling and Assam districts, were all described as being of indigenous Assam plants, or of a hybrid jât very closely approaching this. In fact, the influence of jât on the quality of the manufactured tea was most remarkable, and I do not think that in Ceylon we are as yet sufficiently impressed with this fact. The indigenous Assam plant will of course only succeed at low elevations, but the importance of planting it, or a hybrid closely approaching it in character, is evidently a matter for consideration to those opening gardens in the low country of Ceylon.

The general opinion of the brokers was that we should be able to compete successfully in regard to *quality* with Cachar teas, but that we could not compete with the *best* Assam and Darjiling gardens. What the result will be of trying plantations of the very highest class of plant possible, in the Ceylon lowcountry, remains to be seen; but the paramount importance of paying every attention that the highest jât of plant alone shall be propagated is evident, and economy in the purchase of tea seed is to be deprecated. The area of tea in India is now being very largely extended: this fact, with the rapid extension of the enterprise in Ceylon, is a promise of keen competition in the future. That loss has been incurred by many, in the case of cinchona, through carelessness or ignorance in the selection of seed, is a fact patent to all; and it will be well to take warning by the past and not admit the possibility of futuredis appointment in the case of tea. It is to be feared that in Ceylon we are prone to be in too great a hurry, to endeavour to make our acreages large at the expense of the quality of our work: with cinchona the result was very serious, with tea it would perhaps be less so, but it would certainly mean a permanently lessened yield from the plantation.

There are two routes from Calcutta to Assam: one via Goalundo, the other via Dhubir. The steamers leave Calcutta every week or so, but are somewhat irregular in their times of starting; they go down the Hooghly round the Sunderland, and up the Brahmaputra. Goalundo, a station on the river, is one night's run from Calcutta by train Dhubir, a station at which the steamer calls a few days later, is about 24 hours from Calcutta by train. Being unable to catch the previous steamer at Dhubir, I had caught this one at Goalundo Steaming up stream is most tedious work: the vessel scarcely moves at all sometimes when the current is strong, and I should think three miles an hour must be her average speed at the outside. This run from Goalundo to Tejpore in Assam, which will take us 14 or 15 days gives an idea of the difficulty of transport. The labour difficulty, every cooly costing R100 to secure on the estate, has been a great drawback in Assam, but Government are doing all they can by constructing roads from the labour districts to encourage free emigration. These steamers are very comfortable but expensive. The advertised fare, which seems moderate, having been paid in Calcutta, you discover when you embark,that it does not include board, and that for this you have to pay the captain so much a day: this does not tend to lessen one's annoyance at the slow rate of travelling. Such necessaries as soap and towels are also not provided, and in my case it was not till after embarkation that I discovered this interesting fact. These steamers, driven by paddles not screws, only take a small amount of cargo themselves: the bulk of it is carried by "flats," large barges, which are lashed to the sides of the steamer and not towed; one flat on each side is the usual complement, but this steamer, being an old vessel and not very powerful, only has one. The country along the banks of the river above Goalundo is a very rich one, the soil is very fine, and even with the primitive method of cultivation in vogue amongst the natives large crops are raised, principally of jute. The country is too dry for tea here, and is liable to being flooded. T. C. OWEN.

ECONOMIC BOTANY.

At the last meeting of the Linnæan Society (21st June) Mr. W. T. Thiselton Dyer exhibited several interesting vegetable economic products, and made remarks thereon. Of a species of wax extracted by Mr. D. Morris of Jamaica from *Myrica microcarpa*, it was stated that while the berries are used for obtaining wax in South Africa, the West Indian fruits had not hitherto been used for this purpose. Of a grey camphor like substance the product of *Artemisa noxa*, he mentiond such to be a rare example among the compositœ; and there was a probability that this camphor was that used in the production of Indian ink by the Chinese, and which gave the peculiar aromatic odour to the true China ink. A rosary made of fruits of *Trapa verbanensis* de Not, (locally called Frutti di Lago) from the Lago di Varese, Italy, had been purchased for one franc. These fruits were supposed to be a variety of the above species. Specimen of wax and candles made from *Rhus vernicifera* of Japan; the latter preparation is quite a local industy, which unfortunately is now ceasing on account of the rivalry of the cheap American oils.—*Planters' Gazette*, July 2nd.

GROWING OYSTERS ON TREES IN AMERICA.

Poquonnc River is a broad arm of Long Island Sound, penetrating the Connecticut coast a few miles east of New London, dividing the great level sea meadows for three or four miles inland. Around the head of the river, where a trout-stream tumbles over a mill-wheel into the sluggish waters of the estuary, are the scattered farm-houses of Poquonoc hamlet. The tide rises the whole length of the river. For years the waters of Poquonoc River have been noted has producing the most delicious oysters known in the world. They out-ranked the famous "Blue Points," selling readily in New York restaurants at 10 dollars a barrel when the latter might be bought for 5 dollars. The demand was far in excess of the supply. On account of the thick black mud that plastered the bed of the river, and which is fatal to oyster-culture, only a small margin of the bottom, a rocky strip far in shore, could be utilized by the oyster-growers. Annually the oysters that had attached themselves to the rocks and other obstructions over this district were knocked off and sold at tempting prices, but there were not enough of them. It was not until three or four years ago (says the *New York Times*) that a speculative and inventive Yankee devised a plan for extending the oyster cultivation upon the mud bottoms. He cut down a forest of tough, wiry white birches, dragged them to the bank, bore them in his boat upon the river, and dumped them over board, taking care that they should be left at proper intervals on the bottom. He had an idea that the oyster spawn would come sailing along in the season, catch hold of the birch boughs, and grow into a fabulous fortune for him. He allowed the birches to lie a suitable time, and then pulled them up. Every bough and twig was thick with half grown bivalves but the weight of the growing shells had dragged the bush down into the fatal mud, and the oysters had perished by the million. Enlightened by his failure he made another trial. He planted the birches right up on the bottom, setting them at an angle with the current. Their tops just pricked through the waves at low tide. In the breeding season that followed the planting of the birch trees, billions of spat came floating down the current. It was just what they wanted, a ready-made home. They drifted as thick as snow-flakes to the bending boughs and pliant twigs. It requires two years for an oyster spawn or spat to reach maturity. The trees bowed under their load of growing shells, but the elastic wood kept the fruit clear of mud. At the end of a few months it was seen that the oyster orchards promised an astonishing harvest, and all the oyster men along the river were anxious to try their hand at the new style of oyster farming. Soon both sides of Pequonoc River, from its head for a long way towards the sea, was bristling with sunken birches waving and ebbing and flowering welcome to the drifting spat. In consequence of an epidemic of scarlet fever and diphtheria, which broke out in the village and neighbourhood, it was ordered that the brush should be taken up out of the river, as it was believed the epidemic was caused by the decayed wood. This was done, and the trees were found to be covered with oysters in all stages of growth. They were thrown in a rattling heap on the shore, where they froze and died by the cart-loads. This led to a law suit by the owners of the oyster trees against the local authority, which is still in progress. —London "*Times*".

THE FIG TREE.

Much misapprehension exists in various parts of the world respecting the fig tree, especially as regards the process of what is termed caprification, which is that branches of a wild fig are placed over the fruit-bearing varieties, in order to cause the fruit to mature earlier. The male and female organs of the fig exist in different flowers, and in the wild, or Caprifig, the flowers are nearly all males, while in the cultivated fig few of the varieties contain any but female flowers, consequently they are unable to perfect seeds until fertilized by pollen from the wild fig; and thus it is that figs, away from their native country, or from where the wild fig grows, although they ripen their fruit perfectly, produce no seed, although abundance of seed is found in dried figs from Asia Minor, where the wild fig is used. It is generally known that the flowers of the fig are inside the fruit, but the opening is very narrow, and pollen floating in the air could hardly obtain access; but it so happens that the true fruits of the fig, which are the small fleshy bodies found inside the fruit, the outer portion of which is only a receptacle, are liable to be infested with a small insect resembling a gnat, named Blastophaga grossorum, the eggs of which are deposited in the fruit, and caprification consists in the female insects, when they have attained maturity, emerging from the orifice of the fig in a fecundated condition—both male and female insects being bred in the same receptacle, but only the female is winged. She then enters and deposits her eggs in the next crop of the same season that is coming forward; but in emerging from the fig in which she was bred she brushes the pollen off the male flowers, nearly the whole of which are situated near, or in the mouth of the orifice, and carrying it into the fruit of the cultivated trees on which the wild fig branches were laid, the female flowers are thereby fertilized, and thus the presence of seed in the Smyrna and other dried figs from the East is accounted for. The insect also produces another effect upon the cultivated fig besides fertilizing its flowers; she lays an egg in each of the small fruits inside, and the ovary of each being pierced, the irritation caused by the piercing induces a rapid and voluminous gall-formation, without preventing the further development of the ovule into a seed. It is well known that worm-eaten apples ripen earlier than those not infested, and the same effect is produced in figs in which the maggots of the Blastophaga exist, they ripen a week or a fortnight earlier; but, as it has been asked—who would have either his apples or his figs worm-eaten merely that they might ripen a fortnight earlier? The practice of caprification is being gradually given up, it is not found to be necessary anywhere, and even in Asia Minor, where it has been the custom for ages, it is being gradually given up. The facts appear to be that the cultivated fig is the result of selection; the fruit of the wild fig hardly ever swells and becomes fleshy, but occasionally a tree is found on which the fruit swells to some extent: and by breeding from such a tree gradually, and in course of time, by cultivation and selection of the best varieties, the fruit has attained the condition in which it now exists. Proof of this may be obtained through an examination of seeding figs, of which it is found that a large proportion do not produce fruit of the juicy and succulent character of the cultivated fig, but merely a dry husk; while in others the fruit is partially swelled, thus showing the same tendency to reversion as in the case of apples, pears and other fruits. From the same causes—selection and cultivation—the fig, like the banana and several other fruits, ceases either entirely, or nearly so, to produce seed.

A few words anent the pruning of the fig tree. It is almost a proverb that the fig tree should not be pruned at all, and pruning is therefore rarely practised; hence the ugly forms under which the trees are generally seen, and the stunted appearance they present. It is quite true that by pruning the crop of fruit is lessened, and may be altogether destroyed; but it is decidedly better to maintain a tree in health, vigor and pleasing shape than to allow it to become gnarled and old before its time, even though producing a great number of fruit, which must of necessity be comparatively poor; while that of a tree that has been pruned, and thus prevented from bearing to excess, is, if less numerous, superior in size and quality. The shoots of the fig, however, should rarely be shortened, and never only when they are of extreme length, but when the trees are young, they may, for the sake of proper formation, have the shoots shortened, as in trees of other kinds, and afterwards, should growths of unequal strength be made, they ought to be equalised by pruning, and the best period to perform the operation is when the shoots to be operated upon is in full growth, and the best method is to merely pinch out its point. Fig trees ought to be more generally cultivated against walls or trellises; main branches may be trained fan-shaped, and their laterals to grow outwards, instead of being laid in to the wall, as in the case of the peach and other trees; but they need not be allowed to extend beyond what growth they make in a year; which may be effected by cutting out the alternate ones annually; thus, a young shoot will produce an autumn crop, and being allowed to remain, will bear another crop the following spring, but its extension may be prevented by pinching out its point; at pruning time in autumn this shoot is to be cut down almost to the base, from which one or more shoots will proceed the following season, of which the best must be chosen, and will make its growth, while the alternate shoots are bearing their spring crops, and which are afterwards to be treated in the same manner as the first.—*Melbourne Leader.*

CASUARINA PLANTING.

The failures that attended the attempts made by some enterprising people to grow casuarina for purposes of fuel, have not altogether thrown a damper upon small capitalists, for we learn that in a large part of the Madras district between Avady and Trivellore, on land not far from the railway line, extensive plots have just been planted with casuarina. Some of the plantations near the railway are about two or three years old, so that in the course of a few years these plantations will be fit to be cut down and the wood sold for fuel purposes. The Madras Railway and the different cotton and other mills are large purchasers of wood, and with the continued demand for domestic purposes, casuarina plantations ought to thrive and their number increase so as to form large and extensive plantations which it is well known have a great effect upon the rainfall and otherwise improve sterile soils. In the Madras district there are large plots of land within easy distance of the railway lying waste: they may be unfitted for grain cultivation owing to the nature of the soil thereabouts, but casuarina may be grown on land where it is difficult to rear any other tree or plant and such being the case a few enterprising people with the money and will might form plantations, obtain land on very easy terms and plant and work them in a manner that will lead to success. In a letter, to which we directed attention a few weeks ago, Dr. Bidie, writing of sand-binding plants, stated that casuarina was very useful in this way and that extensive plots of land on the Madras coast gave place to casuarina, and that in addition to the benefits derived by the owners, the plantations had a very good effect upon cultivable land by protecting it from severe wet or dry weather. The Government have resolved to direct the attention of the Forest Department to this subject and the Conservators will shortly report what steps are to be taken in this direction and where plantations on the sea-coast between Madras and the Northern and Southern districts may be opened up. If the Government intends to move in the matter there is no reason why private enterprise should not do likkewise and some small well-managed joint stock companies established to increase casuarina planting not only on the seacost, but in the districts within very easy reach of the railway. By the establishment of the railway line, the gravel quarries of Umbatoor and the huge boulders of Sholingur granite have come into extensive use, the former in connection with the harbour works and the latter with other public buildings. The easy access afforded by the railway may also give an impetus to an industry, the successful working of which will be of very great advantage.—*Madras Standard*.

COFFEE LEAF DISEASE IN INDIA.

TO THE EDITOR "MADRAS MAIL."

Nellore, 8th May 1883.

Sir,—May not the growth of one universal plant over a given area continuously or for a length of time be the cause of the leaf-disease? It is a well known fact that in course of time forest soil becomes impoverished for the class of tree that predominates. In forests, trees fall and decay, and various other classes fill their places and become fine trees and keep up an advantageous state of soil, and for this reason, it is advantageous to have other trees on a plantation. One universal plant over a given area, must take from its immediate soil all the chemical properties required to perfect the said plant, and then it is that disease sets in. To keep land in a clean and fertile state, a rotation of crops is adopted in all civilized countries, besides manuring. The following observations of Professor Anderson are appropriate:—"The necessity for a rotation has been usually attributed to different crops removing different inorganic constituents from the soil. Thus certain plants require for their luxuriant growth a large quantity of potash: and they must be followed in the rotation by some other plant which does not extract that element from the soil, or at least only in a comparatively small quantity, and each individual crop can only be successfully repeated when, by the lapse of time, a sufficient quantity of its characteristic constituents has been liberated from some inert form of combination, in which, it exists in the soil." If a certain crop is cultivated year after year on the same piece of ground, it will ultimately remove such a quantity of the particular plant food it delights in as to render the raising a remunerative crop of this particular plant a matter of great difficulty. By careful manuring the elements of plant food taken up by a certain crop, can be regularly returned to the soil, and the food which would support other kinds of crops would then remain unused, but certain insects prey on particular crops and plants, and if these crops or plants are repeated too frequently, they increase to such an extent as to interfere very seriously with profitable culture of those particular crops or plants. And therein, perhaps, lies the chief cause of the leaf-disease in coffee or other plants grown continuously or for a great length of time on the same area of ground. The wet crop or paddy lands in India have by the continuous growth of paddy on them already impoverished the Indian peasant, necessitating the sales of holdings for the recovery of the land revenue, and large annual remissions of the revenue. Independent of this growing infertility of the soil, these paddy crops from their universal adoption over the same lands are now regularly subject to blight and other distempers which no amount of maturing can remove. It is time that Government should bestir itself and remedy the growing evil. By regulating the supply of water and insisting on a rotation of crops, the peasant will be eventually rescued from his present abject poverty, and the Government revenues will be collected with facility. But to return from this slight digression. By taking a hint and planting in coffee, tea, cinchona, cocoa, &c., estates, other trees, such as the wood-apple, jak-fruit, mangoe, divi-divi, &c., trees, and palmyra, coconut, nut, &e., palms, planters will benefit, and in most probability the progress of the leaf-disease will be checked and ultimately eradicated. When a tree gets too old, or is affected in any way, it should bo cut down and burned, and another of a different kind planted in its stead. The leaves of trees in plantations should also be raked or ploughed up before the rains, that the heavy and obnoxious gases may escape or get sucked up in the soil, for the leaves get wet and flattened down in such a way as to prevent this. This will not only make the the place healthy but keep the soil in a profitable state for future work. Much has been said of a "wally coating"—a species of fungus that covers the under parts of the coffee leaf. Would it not be advisable to ascertain by chemical test what proportions would not only suit the coffee plant, but at the same time destroy this fungus. In some countries on the continent the mustard and bhang plants are sown in rows between the standard trees, and in other crops, to keep them in a healthy state, they besides giving a profitable return. A.

THE INDIA-RUBBER AND GUTTA PERCHA TREES OF BRITISH GUI

At a meeting of the Royal Agricultural and Commercial Society of British Guiana, held in May last, the Secretary laid over a communication he had received from Mr. Jenman with regard to the India-rubber trees in Demerara. The letter is as follows:—

My Dear Sir,—I enclose herewith for the Museum of the Royal Agricultural and Commercial Society, samples [vulcanised] of india-rubber, produced respectively by the Hatie and Cumatraballi of this colony. The raw rubber from which these samples were manufactured, I collected on the Pomeroon River, and sent to Kew, to be tested a few months ago; which resulted [with other correspondence] in the following report, communicated through the Secretary of State for the Colonies and published in the *Official Gazette* of the 18th instant:

"The india-rubber made on the Pomeroon River, British Guiana, from the *Hevea Spruceana* contains caoutchouc, but is impregnated with other principles which destroy its properties for any manufacturing purposes involving the process of vulcanizing. Since most of the species of *Hevea* have been described as yielding good india-rubber, including the *Hevea Spruceana* growing several miles north of the Amazon, it would be important to determine whether in this case the deteriorating principles are foreign [? belonging] to the tree, or whether they arise from injudicious incision. The rubber smells very strongly of the oily matter which goes off in the smoke from the burning of the nuts of the Uracapi palm, which also has the effect of softening and rendering the rubber dark.

"The loss on washing and drying is 11·75 o o. The soft and sticky character would appear to be due to a volatile, or perhaps easily carbonised substance. When mixed with sulphur and submitted to the vulcanizing process, it vulcanizes, but becomes spongy. The caoutchouc vulcanizes so completely, that it would be worth while to try whether, by any chemical treatment its sponginess can be prevented. Such treatment however, prevents its being used extensively.

"The [Cumatraballi] india-rubber on washing and drying yields a loss of 11·96 o o, and when mixed with the suitable proportions of sulphur, vulcanizes perfectly. Its firmness and freedom from stickness are in favour of its manipulation.

The passage in the report,—"it would be important to determine whether in this case the deteriorating principles are *foreign* to the tree, or whether they arise from *injudicious incision*" is not very clear in its meaning. Injudicious incision, so far as it affected the character of the milk, would be "foreign" to the tree; but I do not see how any method of tapping could be injudicious in this sense. In collecting this rubber, the incisions were made with a cutlass; and an axe or this instrument must necessarily be used in the operation. It is true the juice was dried in the smoke of burning palm nuts, but this system is very largely practised in coagulating Para india-rubber. It hastens the process, but is not essential, and need not be pursued if disadvantage pertains to it.

It is disappointing, however, that as *Hevea Spruceana*, is so abundant in the colony, and such a near ally botanically of the valuable *Hevea brasilensis* its rubber should be, apparently, of such inferior quality. I say apparently advisedly, for I think this cannot be regarded as determined till the nature of the deleterious principle, which prevents its perfect induration when vulcanized, is ascertained, and whether it was accidental in this sample or is inherent in the juice of this species of *Hevea*. It is possible, too, that if the sponginess cannot be prevented in its manufacture, considering the multiplicity of the applications which are being found for india-rubber, certain uses may be discovered for which this character will specially recommend it; which seems not improbable, for it is certainly a very peculiar and characteristic substance.

As I anticipated in my report of the discovery of the Cumatraballi,* its rubber has proved to be an excellent material; and considering the great size of the tree, its thickness of bark and prolificness in milk, the price [2/3—2/6 per lb] it is estimated as worth in the market is very satisfactory and encouraging; and I have no doubt that in the future both the trees and the rubber which it yields will be in considerable demand. I hope in the interval, steps may be taken to prevent collectors from felling and destroying a tree so valuable, and of much interest for its grand proportions as a woodland feature, and thus ensure its abundant perpetuity in tho colony.—Very faithfully yours,—G. S. Jenman.

W. H. Campbell Esq.,

Secretary, Royal Agricultural and Commercial Society.

Small Industries.

Mr. Jones laid on the table a sample of coconut fibre he had received from the works of Mr. Smith at Mahaicony. As he required the samples for this purpose he had endeavoured to present a special sample being prepared, and that laid on the table was what was turned out, and he had no doubt but that a better sample could be obtained if it was required for an exhibition. The President was aware that Mr. Smith had imported a very fine set of machinery for making oil and dressing the fibre of the coconut, and he deserved very great credit indeed for an advance in what might be called "one of the small industries." He had not the smallest doubt that it would pay. Formerly, when coconuts, were sold at from $20 to $24 a thousand, it did not pay to carry on this industry, but if it was sold at about $12 per thousand it would be a successful enterprise. Mr. Jones also laid on the table a sample of the *accovrie* palm nut oil. He obtained it from a black man in the Berbice River, who prepared it for his own use, but as to its value as a commercial oil he did not know. Mr. Williams asked that the sample of oil be forwarded to Mr. Francis, and that gentleman be asked to report upon it. This was agreed to.

* Report of the Government Botanist and Superintendent of the Botanic Gardens on some of the India-rubber and Guttapercha trees of British Guiana.—*Gazette* Office, 1883.

THE DIVI-DIVI TREE IN MASULIPATAM, MADRAS PRESIDENCY,

is thus noticed by Mr. C. M. Smith, Public Works Department:—

1.—Under head *Cæsalpinia*, p. 356 of Roxburgh's "Flora Indica" (kindly lent me by the Forest Officer, Mr. Boileau, from whom I learn that the Divi-Divi belongs to this family), I find a number of varieties described, none of which seems to correspond with the variety growing in this garden. 2.—I should describe the variety growing here as follows:— Height of tree, 15 feet; *boughs* commencing at about 3 feet from the ground, straggling and widespreading, from 10 to 15 feet in length; unarmed; *bark* of a dark brown-grey color and very rugged. *Leaves*—bipinnate, three or four on a twig, 6 inches in length, with from six to eight pairs of *pinnæ*—pinnæ being 2 to 3 inches long; *leaflets* paired and numerous—sa many as twenty-eight pairs to a pinna, but varying in number in different leaves and on the several pinnæ; length ¼ inch, breadth 1/16 inch. *Flowers*—in clusters, of a pale green-yellow; very strong, but agreeable scent. Blossom in the cold weather;* *seed* ripens in March (second crop). *Pods*—curly, of a dark red-brown colour and hard; an average pod contains five or six *seeds*, small, oblong, smooth and of a tawny color. The length of such a pod is 2½ inches, and breadth over ¾ inch. I should have mentioned that the leaves commonly have one terminal pinna, but frequently terminate in two, *i.e.*, in a pair of pinnæ. 3.—There are ninety trees of different sizes in this garden, most of which are producing seed, besides two or three young self-sown plants. There is no difficulty in propagating the tree: it comes up readily self-sown. The trees in this garden are, I am informed, about 38 years of age, having been planted by a Mr. (?), Port Officer. The soil is almost pure sand; the roots of the trees probably reach good water, which is found not far from the surface. The poor nature of the soil probably accounts for the small size of the trees—I say "partly" because the small size is, I think, mainly due to the trees being planted too close together —in many instances there being little more than 6 feet space between the trunks. The girth of the best-grown trees at a height of one foot from the ground I find to be about 2 feet 6 inches. The trees, however, are mean in appearance, though luxuriantly covered with foliage at the right season of the year. They never entirely lose their foliage. 4.—With regard to the produce of the trees, I note as follows:—The total quantity of seed in pod produced in the one crop which I have lately had collected amounts to 43 sacks of 70lb. each, or 3010 1·33 tons. I find that ⅞ oz. seed is obtained from 1lb. of full average-sized pods, *i.e.*, the seed bears a proportion in weight to the pod of 1: 18 nearly. In one average-sized well-developed pod I find seven seeds, in another six. Eight hundred seeds nearly to go to the ounce, *i.e.*, 12,800 to the lb. of 16 ounces. A 70-lb. sack of pods occupies in bulk a space 28 × 18 inches diameter — nearly 4 cubic feet, and thirty-two sacks = 128 cubic feet = 1 ton. 5.—In regard to the value, I have never systematically endeavoured to sell the seeds and pods. There is no great demand for them here I believe. I believe they are not exported. They are, I know, used to a limited extent by the local chucklers or leather-workers in tanning and colouring leather.

Endorsement by J. G. Horsfall, Esq., Collector of Kistna dated Masulipatam, 19th April 1883. No. 1202.

The above note, kindly furnished by Mr. C. M. Smith, is submitted for the information of the Board of Revenue. Mr. Boileau, my Forest Assistant, has been directed to commence planting up one of the forest tops with the Divi-Divi. The tree grows fairly well in this district, both close to the sea on sandy soil and inland. Our avenue trees on the Hyderabad Road seems to have flourished better than those in Mr. Smith's compound in Masulipatam. I expect that it will be largely grown as soon as its value becomes generally known, and I am informed that plantations of it are being started by some enterprising natives in the Bapatla Taluk, who had taken up lands for casuarina plantations after witnessing the result of the casuarina plantations started under the Jungle Conservancy. I see no reason why in a few years this district should not be able to supply any quantity of the pods. The tree, however, is a slow-gowing one, and I regret I cannot state from personal observation at what age it first begins to yield.

* Twice, from November to February.

THE CULTIVATION OF TEA IN NATAL.

The supply of tea is likely to keep pace with the demand. The cultivation of the plant in Ceylon is being followed in other colonies, and it is necessary for Indian planters, if they wish to hold their own, to do all in their power to maintain the excellence of Indian tea, and to do this upon the most economic terms. From the following extract taken from a Natal paper, it is evident that the Natalians are turning their attention to tea cultivation. Mr. L. Leigh Hulett, J. P., gives the following account of his experience. He says:—

"Permit me to lay before the public the present condition and prospects of the tea enterprize as far as I am concerned. Considerable interest was taken last year in the matter, and the twelve months mean the addition of considerable experience.

"I am more and more convinced that tea-growing in Natal is certain to succeed, and that it will prove a mine of wealth to the colony, far beyond any gold mine that may be opened out in the interior. The result of my experience is at all times at the service of all. The more pointed the questions put to me regarding the *modus operandi* and results, the better. There is nothing to keep back and nothing to be afraid of. Some friends express astonishment that I endeavour to induce others to enter upon the cultivation of tea, when, by pushing my own forward, and keeping quiet, I may command for a longer period a kind of monopoly, and thus the sooner obtain an independency. Well, there is something in that; but it appears to be shortsighted policy. I might gain in the beginning, and the colony would lose. The sooner we occupy our waste lands with industrious settlers, the sooner we shall all be benefitted. If whilst helping myself I can assist others, I am satisfied. If the colony holds back from investing in what must prove a blessing, it has itself to blame; my personal benefit will not suffer.

"To return. The prospect for the future appears to be exceedingly good. My area has increased from thirty-two to fifty acres during the past season. Of these fifty acres, only three-fifths of an acre consists of the originally imported plants, planted out in November and December 1877—consequently now nearly five-and-a-half years old. My present picking is from $5\frac{1}{2}$ acres, planted in November, 1880, and three-fifths of an acre unplanted plants, with a slight picking from plants eighteen months planted out. My return from this will, I confidently believe, reach 2,000 lb. by the end of the season, in May. To define it more distinctly: say $5\frac{1}{2}$ acres under $2\frac{1}{2}$ years old at 250 lb. per acre = 1,375 lb. and three-fifths of an acre ($5\frac{1}{2}$ years) say 500 lb. (or over 800 lb. per acre), and the balance of 125 lb. from a few plants in the 18 months' olds. Such yields as these, or anything approaching thereto, cannot be surpassed in the world. The colony possesses thousands of acres of land that may yield an average return from good culture of 800 lb. per acre, and the cost of that tea delivered in London need not be more than 10d per lb. I am certain that tea can be grown in Natal at less than 8d per lb.; that the class we shall produce need not average less than 1s 4d per lb. in bond in London; that if in the future planters can be certain of 1s per lb. in Durban, the enterprize is one that means wealth to the colony. The question is frequently put to me, 'What weight of green leaf can coolies pick per diem.' During the past month I have weighed each picker's leaf at noon and evening. The following is the result of my last picking, February 26th and 27th. On the 26th, 15 men, 2 girls and 2 boys (coolies)—19 hands—noon, weighing 180 lb. leaf; evening, 171 lb.; total 361 lb.; average, 19 lb. each hand. The largest picker gave $28\frac{3}{4}$ lb. and the lowest, a little boy, $8\frac{1}{2}$ lb. On the 27th, 13 pickers—noon, 167 lb.; evening, 124 lb.; total, 291 lb. of leaf; average, nearly 23 lb. per hand. The two days' 652 lb. green leaf turned out 148 lb. of made tea. N.B.—Early and late in the season the yield of made tea to green leaf is 1 lb. to 4 lb.; at the present time leaf and stalk are very full of sap, and it takes a little more than 4 lb. of green leaf to give 1 lb. of dry tea. The cost of picking this leaf comes to $2\frac{1}{4}$d per lb. of made tea. The cost of rolling and drying came to the same as the picking—total, $4\frac{1}{2}$d per lb. of manufactured tea. Had women only been employed to pick, the cost would have been reduced by $\frac{1}{2}$d per lb. Had I possessed a rolling mill and drying furnace, it would have been reduced $1\frac{1}{4}$d more. Thus, with adequate appliances the cost will be considerably lessened; say picking and making to 3d per lb.; however, under present circumstances, a cost of $4\frac{1}{2}$d per lb. The culture of land will not under any circumstances be over £5 per acre per annum (it should be considerably less). This includes weeding, cultivating, manuring, pruning and cartage of manure, tools, &c., which, allowing 800 lb. of tea per acre (when five years old and above), will give $1\frac{1}{2}$d per lb. for the annual growth of the tea—total, 6d per lb. This will not include interest on capital and personal expenses.

"From the foregoing, those interested can draw their own conclusions. My opinion is that an enterprize is before the colony well adopted to the requirements of those possessing but small capital, from £500 and upwards. Especially is this the case when ten or twelve can grow for a central factory. The advantages are such that proper appliances erected in a convenient position to receive the leaf as picked, from a radius of three miles, could manufacture tea of more even and reliable quality than can be done by several individual makers. In India, estate belonging to large Companies have from 300 to 2,000 acres to pick over. Here the individual owner of from 10 to 50 acres of tea can bring such to a position of bearing power which no large concern can possibly do, and consequently, by merely picking leaf and selling it at once, a large amount of trouble is avoided. Indeed, I should be very glad to know that ten or a dozen people were disposed to settle down in this neighbourhood for the purpose of tea-planting. I am quite prepared to purchase their leaf in the green state, and give, until export becomes a necessity, not less than 3d per pound for the leaf direct from the tree, and afterwards a price based upon the result in the English market. Will tea-growing be remunerative to grow in the Midlands? I see no reason why it should not, but I do not believe the yield of leaf will equal that obtained on the Coast. Until someone fairly settles the question by trial, we must rely on facts obtained.

"The importance of this matter, in a social, political and commercial sense, is my apology for thus intruding upon the columns of the colonial papers.

"Kearnsey Tea Plantation, March, 1886."

—*Home and Colonial Mail.*

ON AGRICULTURAL EXPERIMENTS.

BY DR. JOHN R. PAGE.

The importance of accurate experiments in agriculture cannot be over-estimated, and it is a subject which is attracting a great deal of attention in all agricultural and scientific circles at the present time.

Having had some experience in conducting agricultural experiments, I am free to state that the difficulties attending them are far greater than they are commonly supposed to be. The factors which enter into the subject are numerous and intricate. In the first place, the mere observation and record of the facts involved, from day to day, is difficult, while the analysis and collation of all the facts accumulated, so as to be formulated into principles, requires a trained intellect. In the second place, it is difficult to find land of uniform quality and to make experiments of general application, from the fact that soils differ, climatic influences vary, and seasons are unlike, while it is still more difficult to estimate the extent to which these influences operate as factors in producing given results.

Great stress is laid now-a-days on the importance of teaching students the art of conducting experiments. I agree with Professor White, of Perdue University, Indiana, "that experiments should have a prominent place in agricultural instruction, but that they should be taught as a means of *investigation and training*." It should be borne in mind that experimental farming and practical farming are very different processes. Experiment, like experience, is a dear school, and experimental farming is no exception. Common sense and a thorough scientific training are necessary, as a means of preparation, for experiment in agriculture, in order to reach valuable results of general application. To insure this, the soils, plants, animal implements and plots of an experimental farm should be made as much a part and parcel of the "*teaching aids*" as are the blackboards, diagrams and microscope in the lecture-room. A common and very faulty idea exists in the minds of many farmers, that *science* is an *entity*, that it can create and make anew, and in this way they expect too much from its teachings. They fail to realize the common sense idea that science can accomplish *nothing* of itself; an idea well expressed by Dr. Oliver Wendell Holmes, in regard to the science and practice of medicine, when he said:—"Science is a first-rate piece of *furniture* for a man's upper chamber, if he has common sense on the ground floor. But, if a man hasn't got a plenty of good common sense, the more science he has, the worse for the patient." This is especially true in regard to the experimenters in agriculture. It must be admitted, that however much help we may get from the applied sciences as contributions to our social life, their help to our agriculture will never cause a revolutionary change. For, after all that we can do to the soil by the addition of the best manures which experimental research and the knowledge of the chemist can point out: after we have drained with the greatest skill and tilled with the most effective implements which mechanical art can produce; after the scientific skill of the botanist has been enlisted and exercised in the selection of the best seeds and the most suitable plants; after the application of the knowledge of the entomologist in the destruction of insect pests: aye, after all these things have been done wisely and well, the experimenter, like the farmer, can do *nothing* but to trust that the controlling influence—*the seasons*—will be favourable to his work and enable him to reap a good reward for all his labour and expenditure of time and money.

Science enables us to accomplish many things, but it cannot help us warm the too cold earth with the telegraph wire; nor can it enable us to command sunshine with the mighty steam engine.

Having settled the purpose and scope of an experiment, the experimenter should, in the next place, consider how far the character of the soil and the prevailing climate are suitable to the natural habits and requirements of the crops upon which he wishes to experiment. Thus, it would be of little use to try field experiments on roots on a stiff, imperfectly-drained clay soil which has never been brought under the ameliorating influence of thorough drainage and autumn cultivation, nor would there be any use in trying to grow wheat continuously, from year to year, on a soil so little suited for wheat as a poor fertile sand.—*Southern Planter.*

INDIAN TEA IN AMERICA.

[The following letter, which we take from the *Indian Tea Gazette*, is very lengthy but exceedingly interesting. The exhibitions of prejudice by interested dealers and honest tea drinkers in America are repetitions of what had to be contended against in Australia.—Ed.]

New Jersey, U. S. A., 31st March.

After careful consideration and sufficient experience of American men and manners to permit an opinion being expressed, your correspondent has deduced as follows, viz.: *No people as a nation are so appreciative of a good cup of tea as the Americans, and yet not one in a hundred knows the true taste of pure tea, or the difference between tea leaf and a willow, or any other leaf.*

The cuteness attributed to our "cousins" by those who have not lived among them, often exists only in fancy; and any one who has spent his life amongst other people, particularly in the East, will be truly astonished at the childlike innocence and ignorance evinced by untravelled Americans, whose only information is gathered from books. These remarks, of course, only refer generally to all classes, exceptions proving the rule. To commence with, the often-ventilated and well-worn question of *what tea* is required to suit the American taste and market? I humbly submit that no definite rule can be laid down as to what sort of Indian teas will suit the taste of the American tea-drinking public. The general taste is so vitiated by drinking and enjoying decoctions of rank poison under the name of *Japan* and *China* teas, that when the pure unadulterated teas of Assam or Cachar are tasted, these are actually regarded as spurious imitations of their cherished *Oolongs* and highly coloured "*green*" *teas.* As an old Indian planter, used to the honest productions of Assam, Cachar, and other districts, I can only say I am astonished and disgusted at the productions I have seen sold in this country under the name of "Tea."

Some months ago, I happened to be in a Grocer's "Store," in one of our large towns, and was making a few enquiries about some kinds of "Japans" exposed for sale. A "mercantile" gentleman (bagman) addressed me and remarked that I evidently knew something about tea, and asked if I would look at his box of samples. I consented, and he produced a sm ll box containing something that appeared to me like leaden-pellets or buck-shot. I pronounced it to be, as I imagined, "Gunpowder." "Yes, sir, a vrey fine kind indeed." He then produced another sample whiech reminded me of No. 2 shot, very leady-looking. "That, sir, is our finest kind of tea," said he proudly. I humbly asked if I could express my opinion without offence, nd permission being granted, I said that all his teas were olored, and faced with some matter, either *Black lead, Indigo*, or *Prussian blue.* "No sir," said this truthful commercial, "*they are coloured with copperas.*" I expressed my horror and surprise, and he then added, "*but the people will have it.*"

I sampled these teas and fairly tried them; the infusions were disgusting and sickening, and utterly undrinkable as tea, and yet a high price was paid for these "teas" (!!)

I subsequently procured other high-priced "*uncolored Japans*," tried them, and reported that they consisted of "*some tea leaves* highly colored with some blue substance—mixed with leaves of *other trees* than tea, as also *some old tea leaves*, which had evidently been once used and remade." Yet this "Tea" (!) is sold publicly in packets bearing the name of a New York firm; *poison* is a mild name for it.

Being convinced that an erroneous opinion exists in this country as to the merits of Indian teas, I determined to find out for myself what is thought of the teas forwarded from India, through your Syndicate or other channels, and accordingly I called upon several of the largest wholesale tea firms in one of our most important cities. Entering one large store filled with dozens of gaudily painted China and Japan tea boxes, I politely enquired of the owner if he would purchase a few chests of "Assam" teas, manufactured by myself. "No, sir, I don't want your Assam teas." "But," said I, "perhaps you would like to try it?" "No, sir, we have heard of 'Assam teas,' and don't want any new kinds of *China teas.* Good morning, sir." Scotched, but uncrushed, I called on another large 'importer.' Would he buy "Assam" tea? Here education shone forth, and the "head" told me that they had already several chests of "Assams" procured from the "Syndicate" Agents in New York, but that they could not sell them, *as it cost more to introduce* and change the public taste, than it was worth. This gentleman added, that "*half what we get from China, is not tea at all*"; and further, that '*we never drink anything but Assam tea ourselves.*" This from a firm whose stock-in-trade consisted of boxes of "Chinas" and "Japans" by hundreds. Entering another house, and having picked my way through matted chests from "Foochoo," "Amoy," "Formosa," and other ports, all "via Suez Canal," I found myself face to face with an august personage, ensconced behind a barrier at his desk. I introduced myself as a planter, and asked if he would buy a few chests of "Assam" tea? This consequential "*Boss*," answered me *ex dem*, "*Don't want your Assam tea. Every day some fellow comes along claiming to sell Assam teas. Who do you represent?*" I simply replied, I only represented "*myself*," and wished this gentleman (!) good morning.

After several such interviews I finally entered one large establishment, introduced myself and my business—"Would they buy Assam tea?" I was requested to sit down, and was asked many questions about teas, and was then told that they had a great deal of "*Assam*" *tea* in stock, which they would be glad to sell at *any price almost.* Hereupon I was asked to taste some "Assam" teas, which I accordingly did, and tasted some of *the* loveliest samples of teas I ever saw. On referring to records to find what factory *in* "*Assam*" could make *such* tea, I found we had been drinking superb "*Darjeelings*" and "*Chittagongs*."—*yclept Assams.* On asking the prices these teas would be likely to bring, I was shown the 'sale'-book, and learned that these splendid teas would probably be sold at from 27 to 35 cents per pound (or about 9 to 12 annas),—and this was for Pekoes. Mortification and disgust were my feelings, and muttering some remarks about "pearls" and "swine," I thanked these gentlemen, and left sadder, but wiser, as to the prices *first-class Indian teas* will go for. Observing an advertisement in a certain town, of "*Assam*" *teas for sale*, I "interviewed" the "storekeeper" and asked to see it, and was shown a 20-seer box of tea marked "*Chittagong.*" The tea was a splendid "Pekoe" full of tips, and he told me he sold it for 80 cents a pound *when he did sell it*, but *no one would buy it*, and so he was *mixing it with China* to *pass it off.* I pointed out *Assam* was not *Chittagong*, and he has never since that time advertised "*Assam*" *teas.* Now it is a great mistake to imagine that cheap teas are what are most needed to introduce Indian teas into the American market. By market I mean the *people* who are the consumers, and *not* the *merchants* or *brokers.* From observations and experience, I venture to say that the only sure way to introduce and popularize Indian teas in this country, is to place a *fair class* of tea at a *fair price direct* into the hands of tea-drinking classes. Once reach the *consumers, even at a sacrifice,* and as a sequence the merchants and purveyors will follow suit in self-defence, and compete for Indian teas as they do now for Japan and China trash, in order to meet competition and the public taste.

Being fully aware of the conclusion arrived at years since that the public taste must be educated to the flavour of Indian teas, your correspondent still differs with the means adopted to further this object. The agents of the Syndicate in New York undoubtedly do their best in the interest of their principals, so far as selling off their consignments wholesale. But it is not by this means that a taste will be inculcated *into the masses,* to insure whose appreciation is the Indian tea grower's *sole aim.* My reference to the statements made by large tea importers supports this view, as *it costs more to introduce it than it is worth,* conveys volumes. Japan and China teas can be sold, but Indian teas *cannot,* and it therefore pays best to leave well alone. I saw chests of splendid teas of every class, from Pekoes downwards; and from my own knowledge of their cost and present selling value, some sacrifices have been made, and much money lost, as also valuable work, as no one appreciates these magnificent teas here,—teas that have turned managers' hair grey to produce so carefully; *to show Americans what Indian teas are,* will be characterized here by tea-drinkers as *poor kinds of black tea,* (fact,) and yet the same class will readily pay 75 to 80 cents a pound for *rank poison called colored Japan or Oolongs,* but would not pay 35 cents for a *splendid Indian* drinking tea. *Americans do not object to* pay for *value,* and will pay one dollar or even more, for a tea they *know to be pure, unadulterated* and *uncolored.* I have met dozens of people who are real lovers of good teas, and ready to pay *any price* to procure such, and yet these say, that they have not drank tea for years, simply because they were afraid of it. Plenty of these *now drink nothing but Assam tea, which they procure direct from me,* and repeatedly thank me for placing them in a position to drink such splendid tea *so cheap.* The price charged is that of the finest *Oolong,* (or Caper) kinds, and it is readily paid for, and acknowledged to be *more economical* than teas costing *one-third* of the price. If the price was fixed at the rate of cheap teas, they would *not* buy it, the reason being that they have been so often swindled, but knowing that its excellence and purity *are guaranteed* by the seller (in the present case), price becomes only a secondary consideration. Swindling *Prize packet Tea Companies* have lately been prosecuted and suppressed, and it is only the other day that agents have been exposed in this neighbourhood itself for selling teas in packets, offering as inducements various prizes, according to quantity purchased. For example, any one who purchased \$5·00 worth, would receive a suite of furniture, or a Sewing-machine, which of course never arrived, leaving the purchaser with a stock of rubbish called *tea* to console himself with. These "premium" tea concerns are the outcome of the thousands *of chests of China teas shut out last year as "impure," and "spurious" by the British Customs authorities,* these same having in due course arrived in this country, where at *that time* no prohibition existed against their import. This state of affairs at length has brought its own deserts—the climax being a combined petition to Congress from several of the largest importers of teas in the States, including *Messrs. Catherwood & Co., Colburn & Co.,* and others. At a meeting of the Philadelphia [Penn] Chamber of Commerce held lately, the whole affair was ventilated and discussed, and resulted in a bill being placed before Congress, to prevent the *importation of spurious* or *poisonous teas.* It met with some opposition, it was stated, *principally from English firms or their representatives,* or, who are materially affected *as importers.* Virtue however was rewarded, and the Bill was passed only last month; so now for *pure teas,* or none.

The question arises, *how is the taste for Indian teas to be introduced to the masses upon whose appreciation its future success is dependent, in this country.* An opinion is ventured that it will *not* be by *wholesale* means, as no one here will buy even a half chest of tea, but hundreds *will* and *do* buy *quarter pound packets* on trial; and if they drink that amount, will return again and again for *Assam tea.* Many, however, taste it and don't like it, call it *herby,* and drink no more; many dislike its taste from its sheer strength, as they put in as much as they would of trashy China from ignorance, and are surprised to be nearly knocked down by its great strength. No quantity less than ¼ pound should be sold, for this reason, that having paid, say, 20 cents for it, they *don't like to lose it,* and so will try and drink it again, and when they have finished that ¼ pound, they will come again for more. Now if people can get a "pinch" or ½ ounce on trial, there are hundreds who will "try it," as if it were "Senna" tea, spit it out, and never try it again. To properly and successfully introduce Indian teas in the States and Canada, I am convinced that the "*packet*" system is the one to be instituted. Agents should be appointed in all large cities, with controlling powers over certain States or districts, and having powers vested as to appointing sub-agents in all minor towns. These agents should be essentially the servants of any Syndicate or combination, being properly salaried and *treated* as if they were simply factory Managers. It may of course be urged that it would not pay to give an agent, say R300 or R200 a month, simply on the chance of selling a few pounds of teas, but this is the *sacrifice,* or the "sprat" to catch the mackerel. Contingent expenses, such as office, advertizing, travelling, &c., would of course, have to be estimated for, and the agents should be required to engage *in no other business* than that of pushing forward *Indian teas.* The Syndicate would, through its New York agents, arrange for keeping up continuous supplies in such quantities as needed according to periodical indents. The leading representative periodical of American Industries animadverts *strongly* on the point of the universal consumption of Indian teas, and recognizes America as a vast field for the future of Indian teas; and your correspondent ventures an opinion that there are thousands of people in these States who will gladly drink Indian teas if they only taste them *properly at a moderate* (*not cheap*) price, and obtain regular supplies under guarantee of purity. A custom exists almost universally in America of *boiling* tea as if it were coffee, and this not unfrequently in copper kettles. The expression of the Tannic acid and the sequent effects of their combined action, has, in some cases I am certain, led to cases of suspicious malicious poisoning, and three such cases are now fresh in my mind, where arrests have been made in suspected cases of arsenical poisoning.

As to the means and ways to be followed in order to carry out the foregoing hints, these are open to discussion and suggestions, and the statements and ideas are founded upon practical experience and not upon theoretic assumptions.

I shall have more to say upon this subject at a future day. "STAR SPANGLED."

TOBACCO CULTIVATION AND CURING.

Memorandum on Tobacco Cultivation and Curing at Gazipur in contrast with the French system described by Kumar Gozendra Narayan, Jr., of Kuch Behar, in his Memorandum, page 19 of his Report on the Cultivation and Manufacture of Tobacco in France, 1881.

Shelter for field.—The tobacco fields are usually sheltered from the hot west winds by a high crop on that side, or, in the absence of this, by sowing a line of castor-oil plants or any other fast and high-growing crop. The cultivation commences in July. In France in October.

Rotation of crops.—We follow the American system, and tobacco is grown on the same land only once, or on rich land twice, in three years. The land usually lies fallow the third year, or should do, and in America a crop of oats is often sown, which crop is ploughed into the land just as the ears commence to form. In France tobacco is grown on the same land only once in from five to seven years.

Manure.—The manure at Gazipur and Poosa consists principally of cowdung and vegetable manure, such as leaves, indigo *seet,* &c.; at Gazipur a good deal of night-soil and poppy trash. The land is manured yearly.

Soil.—Lands suitable for sugarcane and poppy are selected as being the richest. The land is ploughed from commencement of rains to time of planting, or earlier if feasible.

Seed-bed.—A piece of good high land is selected, well ploughed, cleaned and manured with good old manure (low ground would swamp.) The ground, when soil has become well pulverised, is now marked off into beds four feet broad and running the whole length of the ground. The bed is slightly raised in the centre as a protection against heavy rain. A small ditch is cut between the beds to drain off the rain. Tatties made of straw or *arhar* twigs are put over the beds, and are raised 3 feet from the ground. The seed is sown in July, and a second sowing is made in August in case of accidents. The seed is sown at a different season to the French season and differs in soil, and in not having a stony hard under-surface which would not drain off well.

Sowing in seed beds.—Two table-spoonfuls of seed are sown over 100 square feet of seed beds. It is sown mixed with ashes. It is not left to germinate before being sown as in France (this plan has not yet been tried.) It is sown by a man who stands in the ditch running between the seed beds. After the seed is sown, the bed is beaten down gently with a plank or the naked feet of coolies. The seed germinates in eight days. The land is kept clean from weeds. The tatties are kept on for at least a fortnight. They are left off gradually, that is to say, they are first taken off for a few hours daily, in the morning and evening and at night, till the young plants get accustomed to the sun. They are a protection to the plants from the sun and also from heavy rain which often washes out the earth from the roots of unprotected seedling. This is also done in France. The tatties must not be left on until the young plants are transplanted, or else the plants will be weak and unable to bear the sun.

Transplanting.—The land having been well ploughed and cleaned from the middle of June to the middle of August, is smoothed over with a *henga* (harrow), and the young plants being now large enough, they are transplanted when the leaves are not quite the size of a rupee. A cloudy or rainy afternoon is selected for the planting (the afternoon is better than the morning, as it gives the plants the whole night in which to take hold.)

The field is either marked out beforehand, by means of a long rope laid on the field, along and on which a few coolies are made to walk, and which leaves a clearly defined line marked on the field; these lines are made first down the field and then across, each line being the same distance apart, or else a lighter rope marked with knots is thus laid on the field at the time of planting, and a plant is put in opposite each knot. It is very necessary for facilitating the after working of the tobacco that the plants should be equidistant from each other. In rich land the plants are put three feet apart. In poorer soils they are only two feet and two and-a-half feet apart. No plants whose stems have become at all hard should be planted; they will certainly be stunted. Grubs should be looked for in the roots and stems and all affected plants thrown away. If the ground is hard and clayey it is desirable to stir the earth with a *khurpee* a little round the young plants three or four days after the planting.

Hoeing and earthing up.—The land is usually hoed about 10 days after planting. When the plants are from a foot to $1\frac{1}{2}$ feet high, the earth is thrown up round the roots of each plant. This is the same process apparently as that described as ridging by Kumar Gozendra Narayan junr., in his memorandum.

Irrigation.—This is carried on whenever, from the appearance of the plants, it is required. The ground is hoed and the plants earthed up after each watering until the plants become too big to allow of men working in the field.

Tapping and pulling off suckers.—When the plants are about 3 feet high, or, if weakly-looking, 2 feet, the top shoot is plucked off (this shoot is plucked off directly it makes its appearance in small or sickly plants), also the lower leaves which are dirty and draggled, and from 7 to 14 leaves are left, according to the strength and growth of the plant, the principal object being to get a few large and well-developed leaves in preference to a quantity of small ones. The side shoots or suckers are plucked off the instant they appear, and are left on the field for manure.

Frenching and grubs in the plants.—In frenching, the leaf puckers up and is only fit for the native market. If a grub be found in a large plant, it should be cut off with all the affected part and all the portion of the plant above it—a side shoot may be allowed to grow which will give a fairly good plant.

Signs of maturity.—Tobacco ripens in about three months' time. It is cut during the months of November, December, January, February, to the middle of March. A ripe leaf has yellow spots on it. It has a crumply look, and if bent between the finger and thumb will break.

The cutting and curing of the tobacco as described in Kumar Gozendra Narayan's memorandum, pages 22 and 23, is totally different to the system pursued at Gazipur. Does not Kumar Gozendra Narayan's memorandum refer to cutting and curing for cigar tobacco only?

Cutting or harvesting.—The cutting commences directly there are sufficient plants ripe in a field to fill a curing barn. The plants are cut off bodily at the stem just below the lowest leaves of the plant. The plants when cut are left lying with their butts towards the sun in the field to wilt. The time a plant takes to wilt depends on the heat of the sun. Usually half an hour is sufficient. When wilted the plants are either carried or carted to the curing barn. There they are spiked on split bamboos. In the French system the leaves are plucked off the stem and hung in the barn on strings.

Spiking and hanging in the barn.—Each coolie is provided with an iron spike which he fixes like a spear head on to the bamboo stick, he then takes a plant of tobacco in his hand fixing first the other end of the stich into a hole in a block of wood provided for the purpose which he holds between his toes. The plant is placed with the butt on the spike about 5 or 6 inches from the end and the plant forced down over the spike on to the stick. From 6 to 10 plants according to size are hung on one stick which is 4 feet long. These sticks are then hung in the barn, the stick should be hung so that the leaves may touch each other slightly, but should not press against each other. The barn is fitted up with a scaffolding of bamboos. The bamboos are 3 feet 6 inches apart and 4 feet above each other, the lowest tier of bamboos being 6 feet at least from the ground (where the tobacco is intended to be cured by fires.) The barn is provided with as many doors as possible, those on the west side being made as airtight as possible. Ventilators in the roof made to open and shut are advantageous. Rooms can be made any size. A room from 35 to 40 feet high and 30 yards long by 15 yards broad is preferable, as it can be filled rapidly and will hold sufficient tobacco to cure well.

Curing and Drying.—When the barn is full (it should be filled as rapidly as possible in order to prevent the tobacco drying out in hanging) all the doors are closed and also the ventilators, if any. It is left for two or three days. The planter can now tell whether the tobacco is drying up too rapidly or not fast enough. If the tails of the leaves curl up and break when handled, it shows that the tobacco is going up too fast, on the other hand if there is a sour smell in the room and the plants sweat, the tobacco requires air and perhaps fires. In the first case the doors and ventilators are still kept closed and fires are lighted in different parts of the room, or if the house is filled with flues (which are preferable to open fires) hot air is carried through the room in the flues. The temperature will probably be raised to 80° Fahrenheit, but this can only be told by experience. The tobacco must be carefully watched and if drying too fast, the temperature lowered and water sprinkled on the floor. Raising the temperature causes the tobacco to sweat and the moisture thus created in the house makes the colour run in the leaves. The leaves should turn gradually yellow and then brown. If dried too rapidly it retains its original green colour. If it is intended to cure golden leaf the temperature is raised to 140° Fahrenheit or higher at the stage in which the tobacco has changed to a yellow, but this curing cannot be attempted in a hot climate, except by an experienced curer. Golden leaf realises double the price that dark leaf does. The plants should originally all be in the stages of ripeness to ensure success in bright or golden leaf curing. In the above, curing in a hot, dry climate like Ghazipur is referred to; in Tirhoot, in mild weather tobacco can be cured without any fires. This process will now be described. If, as in the second case stated above, after two or three days hanging in the barn the tobacco feels soft and there is a sour smell in the room and the plants may or may not sweat, then all the doors and ventilators should be opened and kept so until the sour smell is gone and the sweating has stopped; if that is not effectual then fires must be lighted. The curer must now be guided by the weather and must carefully watch the tobacco. If the tips of the leaves begin to curl, it is going too fast, and the doors must be shut during the day and opened only at night to allow the cold air to circulate through the room, the main object being to make the tobacco dry up gradually to yellow, and the greater part of it will turn to reddish yellow called medium bright. The temperature must be regulated by the doors and ventilators. This air curing makes a lighter brown than the firing process, and can only be adopted in a climate in which there is a certain amount of moisture in the air. If the tobacco sweats badly, doors and ventilators must be opened and fires lighted and the heat raised till it stops. Green tobacco is preferable to sweated. There is another process followed in some parts of America called sun-curing. In this process a scaffolding is erected under the shade of a tree after the plants are hung up, the whole is covered around and on the top with straw. The straw is opened out when it is found necessary to quicken the drying. This style of curing is hardly adaptable to the plains of India.

Flues.—Flues are iron pipes, fitted up a little above the floor. The hot smoke carried through them finds its exit in a chimney at the end of the room. The fires are lighted in furnaces outside the building or just inside with the furnace opening outside. It has many advantages over the open fires, as no smoke stagnates in the room to taint the tobacco and the risk of fire to the building is reduced to a minimum. The temperature can also be regulated better. For a room 30 yards long by 15 yards broad you would require three furnaces; these furnaces are built of pukka masonry. The pipes should be 15 inches in diameter. The pipes should be arranged so as to spread the heat equally through the room. Tobacco should not be hung directly over the furnace as the heat would dry it up too rapidly.

The higher the barn is the better it is for curing purposes. The highest tobacco in a room is usually the best colour, if you have a thick roof, otherwise the centre is the best.

Bulking, sorting and banding.—The tobacco is generally cured, so far as its colour goes, in a fortnight or three weeks. It is left to hang through the hot weather in the barns, as the heat makes it too dry to handle. Early tobacco may be ready to bulk down in the Christmas rains. No tobacco should be bulked until the sap is entirely dried out. This can be seen by breaking the stem of the leaf. If bulked with sap in it it will rot.

Directly the rains commence in June and the tobacco has become soft and pliable, it is bulked down in heaps in the curing room in which it is hung. The heaps are raised some 8 inches off the ground by a small scaffolding made up of bamboos and sticks, so that air can circulate underneath, and are covered over with straw or matting. The tobacco should not be bulked down in too moist a condition. The best order for bulking is when the tobacco is just soft enough to handle without breaking. If too soft it must be fired and allowed to come in order again. When all the tobacco is bulked down, the bulks must be opened and the leaves stripped from the stem and tied in "bands" or "bundles" with about 50 leaves in each band. The band is tied round with a leaf of tobacco tied round the upper ends of the leaves and tucked in at the centre of the bundle; these bands are now carried to the head barn or sorting room. They are re-bulked here in the same way as before. When all the tobacco is in the sorting room, the bulks are again opened and the bands being untied, the leaves must be sorted. They should be sorted into 1, long leaf dark, 2, short leaf dark, 3, long leaf bright, 4, short leaf dark, 5, lugs, that is, all torn or dirty and very small leaves, red and bright, being banded separately and 6, green—six varieties in all. The sorting is most important and requires strict supervision. Care must be taken that the coolies do not make unnecessary breakage in handling the leaves. They should be tied in bands of from 15 to 20 leaves. These bands are again bulked and left in bulk till packed. The bright is divided into four varieties, should there be any golden leaf. Golden leaf is pure yellow. In this case you have 1, bright long leaf (that is golden leaf), 2, bright short leaf, 3, medium bright long leaf, 4, medium bright short leaf. Lugs are often made into strips by taking out the thickest portion of the stem midrib; two-third is taken out, one-third of the way from the tail of the leaf. It sometimes sells best in this form.

Packing.—The tobacco is packed in hogsheads made of thin staves. The hogsheads are made 4 feet in height and about 3 feet in diameter for despatch to Europe, or else after the native custom in bales. The tobacco should be packed as dry as it can possibly be packed without breaking it. It is generally necessary to hang it again in a barn, the bands just slung across the the stick, and fire it till sufficiently dry. If too dry the doors may be left open at night, when it will probably be found in the right order on the following morning. The bands are packed with the butts outwards and the tails inwards. There are three lines in each row, two with their butts at the edge of the hogshead and tails meeting in the centre of hogshead, and one in centre of hogshead. The next row is commenced from the other side of the hogshead. When the hogshead is filled it is pressed down with powerful screws and refilled till it can hold no more. It should contain 900 lb of leaf as nearly as possible.

G. Caine.

Poultry.—Sprinkle a little flour sulphur in nests of sitting hens. Put sitting hens in quiet dark places, away from disturbance. Sprinkle eggs that are about to hatch, with lukewarm water. Select the best shaped eggs from best layers, for hatching.—*Rural Californian.*

To Prevent Potatoes Rotting in the Cellar.—When potatoes are first put into the cellar they exhale an unpleasant odor. To absorb this, and also to exclude the light and air, they may be covered with a little dry sand, and if there is any tendency to rot, this can be counteracted by a sprinkling of air-slaked lime.—*Southern Planter.*

Whitewash.—Whitewash should be applied as often as once a year to cellars, outbuildings and to rough board fences that cannot be painted. Take a lump of lime and slack it with boiling water; cover it during the process; strain it, and add a little salt dissolved in warm water half a pound of Spanish whiting, two ounces of glue This is good for ceilings, walls, wood, brick or stone.—*Southern Planter.*

An Ostrich Farm in Egypt.—The ostrich farm in Cairo extends from the Virgin's tree to the desert and comprises several acres of land surrounded by high mud walls. The greater part of the farm is desert, the loose pebbly sand being essential to the well-being of the ostrich. There are at present on the farm 120 birds of more than a year's growth, and of these 15 are female and 12 are male adults —that is to say, they are more than three years old, the age at which they commence to lay. Twelve of the adults are now laying, and three are engaged in hatching—one being upon 22, one upon 14, and one upon 11 eggs. Strange to say, the male bird attends more to the hatching part of the business than the female, especially in cold or rainy weather, and, in fact, often undertakes the whole of that tedious duty himself, being only relieved by his better half at meal hours.—*British Mercantile Gazette.*

Peaches, in spite of several successive bad seasons, are still cultivated extensively on the open walls in Kent, and in some instances with good success. It is very rarely that the peaches in the garden of the Rev. Canon Jeffreys fail to perfect valuable crops of fruit. Last season they were very good, and there is every prospect of an average crop being secured this season. Old half-dead trees are not relied on, but one or two young trees are planted every year, and these, in addition to being sufficiently vigorous, are rooted and encouraged by mulchings and a clear space. Under these conditions a healthy root-action is maintained, and without which the proper ripening of the wood cannot be reasonably anticipated. Peach houses or cases, although highly serviceable where there is a good water supply, are not absolutely necessary in peach and nectarine culture, and proprietors of gardens and gardeners should not too readily give up open air culture. No particular varieties of peaches are considered indispensable. For instance, the presumably delicate Noblesse perfects excellent crops, Barringtons, is usually very fine, and Princess of Wales proves profitable. Royal George, although there, as everywhere else, is very liable to mildew, is grown, and has been for many years, on account of its superior quality; while for the earliest crops the small but highly coloured Early Alfred bears well, and is of excellent quality.—*Journal of Horticulture.*

Correspondence.

To the Editor, Ceylon Observer.

FUNGI—LIME—CANKER.

Dear Sir,—Of some copies of the *Observer*, overland and daily" which I occasionally send home to my friends, one containing an article on leaf-disease was shown to a gardener, and he was asked to write to me his opinion on the subject, and as it may interest you I send you his ideas on the subject. I may add that he has carried off every certificate and testimonial at home and elsewhere for practical and theoretical horticulture. He writes:—" ——— very kindly gave me a Ceylon newspaper to read which contained an article upon 'Fungoid Diseases in Forest Trees,' and wished that I should write if I knew of any remedy for it. I read the article carefully and agree with the editor upon many points, especially that rotten wood causes fungi. I have found some fungi destroying vine roots, and even the roots of pot plants; and have applied *lime water* to pot plants, which always destroys fungi, even once watered; but it is more difficult to apply lime water with effect to the roots of vines or coffee trees; but I would suggest that in making a new plantation lime should be mixed with the soil, and it can be done without the least injury to the roots for they have the power to reject the acetate of lime, and it assists germination and luxuriance; although with small seeds lime should be used cautiously in a caustic state. The editor of the paper suggests that the trees should be taken up, washed and cleaned of all diseased roots, but I disagree with him on that point; it would be far better to lift the trees up, prune the diseased roots and apply a few canfuls of lime water to it for it would not only destroy the fungi upon them but also act as a preventive for years to come. When the fungi appear on the leaves and branches it is easier still to apply this simple lime water remedy, by the use of a syringe; and the trees if syringed for 3 or 4 evenings will be clear of these epiphytes. The editor is perfectly right when he says that cankered roots are symptoms of debility, but canker has no connection with the fungi, for iron causes any plant to canker, but it will destroy fungi. There are many remedies offered for the destruction of fungi such as divided powdered arsenic, crushed soda &c., but the most effectual and simple according to the testimony of the most experienced gardeners (I have searched all my books, and the *Gardeners' Chronicle* on the subject) is the application of lime in a caustic state to the roots when planted or dissolved in water. In making a mushroom bed we always take great care that no lime gets mixed with the soil for it will always destroy the mycelium; and as rotten wood in the soil is the great cause of fungi, I would think it best to burn all branches and twigs about when making a plantation; there is not much danger when the roots are on the surface, but when covered with soil in damp water the fungi will appear in a very short time." You are at liberty to print the above if you think fit, and let me be known as

CYMRU BYTH.

THE RESOURCES OF CEYLON.

Uva Province, 6th July 1883.

Dear Sirs,—You never hit the mark better than when you had the map sketched showing the cultivations, forests, &c., of our "tight little island," and I hope you will give the readers of the *Tropical* the benefit of it, showing as it does I suppose the various areas and productions of the different provinces.

I have travelled Ceylon pretty considerably, and have had impression on impression confirmed as regards the island's resources, and the peculiar agricultural capabilities of each province showing a different kind of land, a different climate, and a different elevation; and Ceylon may well be compared to a quilt of most wonderful patchwork. You have a multitude of designs, all nature's handwork, quaint, arabesque and elaborate. How necessary then that our new Governor should be a travelling Rex, for seeing is believing, and how important that Government Agents should be requested to develop the agricultural resources and arboricultural capacities of their respective provinces and that each province should have an experimental Government garden. I am tolerably sure that such products as ginger, aloes, white poppy, West India yams, and perhaps indigo, may yet be profitably cultivated in Ceylon; and why not the opium plant, is it worse than the alcoholic plants—barley, coconut-flowers, &c. When perverted into ardent spirits—I wonder which of the two, alcohol or opium, is the more dangerous. I am also persuaded in my own mind that the sugarcane can in some dry parts of Ceylon be profitably grown on fine soil and in a dry climate. I have myself four kinds growing here: they would yield lots of juice but little sugar, for the obvious reason that we have no protracted spells of hot dry weather to sweeten the juices of the cane. May I beg of you to give us in the *Tropical* in what climate and land the aloe flourishes in, as also indigo, ginger, white poppy, and West India yams.

PLANTER.

COFFEE, TEA AND CINCHONA IN CEYLON.

18th July 1883.

Dear Sir,—Someone has defined "life" as "matter that has become conscious of itself": a feeble definition this at best for a series of emotions acting and reacting one on another with regular irregularity; one would almost prefer to speak of "being" as the passing through a constant series of emotions and sensations, of the which mental unreliability, as the cause of most of one's bodily actions—mostly foolish,—stands out in boldest relief.

This preamble to introduce the recognition—which even itself condemns itself—that today's wisdom will and must become the folly of tomorrow, and from this again my acknowledgment that in some rather recent writings I have allowed myself to "croak" in a manner which at this date appears to have been unnecessary. *Coffee* was the country the hordes of my distrust overran; leaf-disease, grub and abnormal seasons were my generals. At the time I was convinced of the wisdom of what I wrote. But it has been permitted me to peer through the arch of experience, and what I now remember in the immediate past to have seen in this dip into the future I will here set down.

But first for the present:—In spite of the foes I have named, which have not yet left the field (so flatly contradicting my earlier convictions) coffee is still in many parts being cultivated at a profit.

My wanderings these last few days have taken me through districts that, from all I hear, have not been favoured with normal proportions of sun-heat and rain, and at these—in especial on one estate that ranges from 3,000 to 5,000 feet and that cannot boast the blessed inheritance of eastern aspect I find that where upkeep has been continued in any degree in accordance with our ideas of liberality coffee has a very gratifying show of berries upon it; and where the land gets the benefit of morning sun the yield is most satisfactory. It is right to mention Meddecoombera, as a passer through in a late impression of the *Observer* recorded that on that property crop was to be seen on the lower fields only; let your correspondent take a walk as I have done through the upper parts of the estate, and I think he will see substantial reason for amending his previous report).

Only let us have the old style of sunshine in the early months of the coming year, and I venture to predict that coffee will once more mount his throne, his old sovereignty indeed, but minified by his foes and the follies of soi-distant allies, (much in the proportion that the united Italy of today stands to the splendid Roman empire of the anti-Christian era) but his dominion will only endure so long as his parliament of planters is a liberal-conservative one and strong to act up to the spirit of their scientific convictions. Let it not be supposed that experience has yet taught us everything: much, too much remains to learn. So much for the old staple.

Cinchona appears to be teaching us its own lesson in its own way: no comment is necessary on the sickly tree that has supervened since the pseudo gentle, grasping blade of the shaver was introduced. This evil and a glutted market, bid fair to expel Ceylon bark from the pulpits of the Lane in a very few years.

It is a real pleasure to turn from these to *tea*, to note the steady demand that has arisen and is arising for all but reckless, haphazard manufactures, the pretty prices that all carefully-prepared parcels bring, and above all the earnest way in which this enterprize is at last being taken up.

For my part I regard the lands available for the profitable cultivation of tea in Ceylon to be equal to any demand, even without the many thousand acres of lowlying lands that could be utilized therefor with irrigation's artful aid in times of drought.

That too fondly nurtured and coddled infant, the fear of fever in corners yclept forbiddingly "white men's graves," will, fed on the pap of commonsense, be transformed into the healthy embodiment of *thrift*, exemplified in the lives of steady, prudent planters, owning no such laws as those that call that man capable who treads upon his coolies' heels, priding himself, as if that were much, on knowing each individual's names (not to mention the problematic pedigree of his or her cousins and aunts), appearing in the field, wet or fine, at periods regular as the proverbial clockwork; whose *management* consists in this and method:cal:sms as inane and as intellectual as his own kangani's existence! This is not the man to succeed; method is much, grant you, but it is not all. The mind must come into play, and experience that will certainly *not* be gained by too *honesty* remaining on the tottam from year's end to year's end.

Well-tried systems will be introduced from further eastern lands, which will in process of time yield the Palm to Lanka's improvements thereon.

Most important is it in tea growing, as in other agricultural matters, that the stock should be sound and the rearing thereof as careful as the training of a Derby favorite.

The silver streak broadens from the vast bank of cloud, broadens daily. On many, who appeared totally incapable of perception, its light has now beamed, and this light will grow brighter and brighter.

Too long has the good barque "Ceylon Investments" been tempest-tost, and well-nigh sinking 'neath the waves of doubt and distrust. The storm is almost worn out; we are making way now and before long the watch will be able to make out the light that marks the haven of prosperity, the haven where she would be.

She carries her complement of passengers; through your columns their friends and relations will learn the glad tidings of her safety. A protracted absence from any loved object is surely worth the endurance, when we regard how the joy of meeting gathers strength in proportion to the duration of such separation.

"Love all its joys of today assuredly borrows
From yesterday's cares; as all of tomorrow's
Cares lose their sting from yesterday's sorrows."

—Faithfully yours,

P. T. L.

HARVESTING CINCHONA BARK.

July 23rd, 1883.

DEAR SIR,—Sufficient experience should now have been gained in the harvesting of cinchona bark, to enable some decision to be arrived at as to the best and most profitable method to adopt.

For my own part I am of the opinion that coppicing will soon became more general than at present and to a great extent take the place of shaving.

In carrying out the latter method I have found:—

1st. That trees beyond a certain age, say eight years and upwards, renew very slowly and in many instances hardly at all.

2nd. That young trees of whatever age will not stand repeated shavings at short intervals without injury to their growth and health, especially the former.

If you attempt to shave oftener than once in 12 months the quantity of renewed bark obtained does not much exceed ⅔ of the previous weight.

3rd. That shoots from the stools of coppiced trees renew their bark more readily after shaving than original trees of the same age and size, and do not appear to feel the operation so much. This may be accounted for by their greater root-power.

4th. That officinalis and calisayas are better adapted than succirubras and hybrids for the shaving process, as the bark appears to renew faster.

5th. That if the present favorite method of harvesting (shaving) be persisted in, it must be accompanied by liberal manuring to maintain the vitality of the trees.

I submit with some diffidence these points to your readers, but in the hope that others of your numerous correspondents will throw more light on the subject by detailing their own experience.—Yours truly,

A. W.

NEW PRODUCTS.—Messrs. Lee Hedges & Co. have introduced the seeds of further new products, the Tonca bean (*dipteryx odorata*), *copaifera sp.* and Dragon's Blood, which are cultivated profitably in South America and which ought to succeed in Ceylon. We have been favored with a few of the seeds of each and they appear to be fresh and in good condition. We trust the introduction of all three will prove a success. There is nothing like multiplying the strings to the bow of the future.

TEA.—The following appears in the letter of the commercial correspondent of the *Times of India*:—The Indian tea planters are to be told it appears, that the customs are not to blame for the bulking of the tea which inflicts so serious a burden on the trade. The reason for the process is that the weight and tare of the packages for India are so very irregular that no average can be struck. The remedy for this—so the customs authorities will suggest—is for the Indian planters to take another leaf out of the Chinese book. "The Chinese," says a writer of authority, "carry on their tea business on true commercial principles, while the Indian planters are still in the wasteful stages of a half developed industry and have not yet learned the full advantage of the division of labour. The planter is or tries to be, merchant, carpenter, and engineer as well, and one meets with persons holding shares in tea estates who harbour the delusion that they can not only send their tea to Calcutta for sale, but ship it to London and, passing over the machinery of Mincing Lane, follow their pounds of tea into the consumers' pot."

PLANTING ACTIVITY IN THE WEST.

Mr. D. Morris's paper read before the Royal Colonial Institute made very plain the revival of planting activity in the tropical West, notably in Jamaica and in the splendid but hitherto comparatively unknown lands of British Honduras. A good deal of this revival is due to Mr. Morris himself, for we (in Ceylon) well know his keen interest and marvellous energy in promoting Tropical Agriculture and Economic Botany, and in this connection we cannot help saying that but scant justice has been done Mr. Morris for what he, at least honestly and earnestly, tried to do for the Ceylon planters in connection with the Coffee Leaf Disease. We are apt to forget in the disappointment that ensued that, practically, Mr. Morris was at work for only some three months on this subject, two of these being months taken from his engagement in Jamaica. Remembering the difficulties he had to contend with in opening the campaign, that the conditions of the disease as we now know, are greatly affected by seasons, and that Mr. Morris's description and terms may very possibly have been misunderstood, we think there is reason for hesitating to condemn Mr. Morris and his work even in this direction in Ceylon. In other respects, we need not say that Mr. Morris did an abundance of good work here; but he has had more power and greater scope in Jamaica under a Governor so enlightened and progressive as Sir Arthur Musgrave. In spite of what the West Indian Committee and others in London who clamour for everything in the interest of the sugar planters and nothing for "new products," we are assured that Sir Anthony is admitted to be the best Governor Jamaica ever had. We certainly know nothing in Ceylon of "consignee's lien" and the many influences which oppose encouragement to "new industries" in the West Indies. A Governor who dares to speak out and to act independently incurs the most inveterate opposition of the holders of vested sugar interests who are resident in London and whose sole object is to maintain the *status quo* as regards the sugar industry, to devote all available labour to this and this alone, and to sacrifice everything else to "sugar"!

After leaving Jamaica lately Mr. Morris visited the United States on his way to Europe, and he is now, we suppose, busy over his special mission to St. Helena, on which he has been asked to prepare a report with reference to its capabilities for cinchona and other "new products." After this is done, Mr. Morris returns to continue the important work he has in hand in the tropical West. At the discussion which followed the reading of his Paper, testimony to the value of that work was borne by one ex-Ceylon planter, we find (from *Colonies and India*,) in the following terms:—

"MR. R. C. HALDANE: I am an old Ceylon planter who lately paid a visit to Jamaica, and was much struck with what I saw there, especially in the cultivation of cinchona and coffee, products with which I have been engaged for a good many years of my life. Mr. Morris has done me the honour to allude to a few remarks which I lately made to him in a letter. I can say that the cinchona I saw in Jamaica was perhaps the finest I have ever seen; and there is room on the Blue Mountains of Jamaica to produce the "100,000 acres of cinchona" which some gentleman said has not yet been seen anywhere. But I have seen something like 50,000 acres of it: and why Jamaica should not have its 100,000 acres in time I cannot tell. One of the chief products of Jamaica which has not been alluded to at any great length is coffee. The climate and soil for coffee are simply perfect, and there is still a considerable amount of virgin land to be had, and the usual plagues of the coffee planters are there unknown. The Blue Mountain coffee is the finest sample of coffee I have ever seen. I lately brought home a little from the estate of Sir Anthony Musgrave, and showed it to some gentlemen in the city, one a Ceylon merchant, another a Ceylon planter of great experience, and the other was a South Indian planter, and they told me they had never seen anything to equal it, as it was a larger and bolder bean of finer colour than any they had met with before. A remark was made by Mr. Ohlson about a friend of mine who is opening land on the Blue Mountains, and who found great difficulty in obtaining labour. Two months ago, when I left Jamaica, he said it was quite heart-breaking to find the negroes refuse to work for him; however, lately I had a letter, by which I learn that, after thinking the matter over, the negroes had come to him with a rush, and he is able to obtain a hundred men a day. Clearing land is always expensive; in Ceylon, where labour is cheap, an axeman made 2s. 6d. a day, and a man who does such hard work is entitled to good pay. After all, it is a primary charge, which, once done, has not to be done over again. I must say I would like to have seen some coolies on a Jamaica property; perhaps because I have been accustomed to them, and like them as labourers. I have travelled a good deal in the world, and seen other countries beside Jamaica and Ceylon, and I think that in no British Colony is there the same opening for a man with small capital say, 1,000*l*. to 6,000*l*., provided he is steady and energetic, that there is in Jamaica. (Hear, hear.")

AGRICULTURE IN REMOTE DISTRICTS OF CEYLON: FROM BINTENNA TO MONARAGALA.

About 10 years ago I went to Bintenna on a shooting expedition with a few friends. It was very shortly after the Horaborawewa tank was restored, and I expected to see some efforts had been made in the extension of paddy cultivation and where jungle once stood and all was wild and unproductive, "the wilderness would blossom as the rose."

I have been down again, and I see no progress, unless it be that a portion of the dagoba has fallen away and most of the palmyra trees are gone, which were once a feature of these parts. It seems a great pity that some kind of patriarchial pressure cannot be brought to bear upon the natives in outlying districts to take the place of the stronger means in force before the English took Ceylon, for wherever I go far away from Government centres it appears to me that Ceylon is going backward. The palmyra palm in Southern India is becoming a great source of wealth to the natives, and large quantities of jaggery are being exported to Europe, to be refined and converted into white loaf sugar. Chenaing goes on pretty briskly, around Bintenna, and surely it would [illegible] no great trouble to a cultivator to plant a few [illegible] [illegible] many of these would in time [illegible] no way of rewarding the [illegible] headmen, so as to induce at least [illegible] existing perennial trees which are from year to year becoming fewer? Sir Hercules Robinson was quite right when he spoke of the indolence of the native, yet the native can and does work when encouraged and sufficient pressure is brought to bear upon him. Doubtless under the old dispensation he was made to work a certain number of days in the year and thus famine and scarcity were better provided against. What is most apparent to a casual observer is the total disregard for any permanent crop, something which if planted once would be a stand-by for years, but throughout my journey from Bintenna to Wellawaya there was nothing of the kind or practically nothing. It appeared as though when the existing coconut trees were (as they soon will be) defunct that even a kurumba would be unprocurable. There is little or no effort to supply the places of dying trees: no mangoes of an eatable kind or other fruit trees are to be met with. Is this may I ask in accordance or at all consistent with the jails in our chief towns, the pay of the officials, or even the elaborateness of our Lunatic Asylum? Let those who pressed upon the planting community the attenuated system of medical aid where men are well-fed, housed and tended just send the flying contingent through these parts and the Wanni and let them honestly state where medical assistance is most needed, and if they say the coffee districts, I will for ever hold my peace.

From Bintenna we passed through many miles of uncultivated country, finer soil and richer than those parts of Southern India where the palmyra grows, but no effort at cultivation, save the everlasting chean-aring. Fine stretches of grass and lightly wooded country extended for miles; death-like stillness all around save the occasional harsh cry of the drongo; even the game appeared to have been destroyed. What a charm would a sheep-bell have been, even a live animal of any description—yea an enemy! Nothing however appeared and we finally rested our weary limbs in the exciting resthouse at Kaladi. From this we went to Mahaoya, saw the hot springs at Medawewa and heard much talk of a rogue elephant which had killed one man, and frequently stops the tappal runners.

At Mahaoya a tank had been restored, irrigating some very rich paddy fields, but they were shamefully cultivated, so bad indeed that not more than half their produce was paddy; the remainder were weeds and *iluk*. The soil was rich and fine, but the native as elsewhere appeared untended and uncared-for, so unlike his sleek brother of the towns. I was told, as he becomes educated, he prefers clerk's work to agriculture—the clean white cloths, the umbrella and the effeminate hands. I am not sure that natives are far wrong, in an agricultural country where everything appears to receive more encouragement than agriculture itself. There are scholarships and colleges capable of supplying doctors and proctors, and all the paraphernalia that lives upon the food-makers of the world, but no special inducement given to those who form the backbone of the land. Can Ceylon employ all the material of this sort it produces? If not, surely it would be better to turn out a few of a more really useful kind. I can understand why the native village boy prefers the clerk's occupation to the *goyigas*. It requires less extraneous thought and he takes a position where, if he does not work he will lose his situation, and he runs like an engine upon rails knowing nothing beyond. Any question upon the simplest thing around, and the reply is "I don't know," with particular emphasis (truthfully though incorrectly) upon the "I." The agriculturist is just the same individual as his town compatriot except that he wanders untrammelled by an employer and boylike, is more careless about his meals and often the victim to fever. There was a time when the system of forced labour existed and he was then obliged to work, and the headman was responsible for his well-being. Now no one is, so he feasts in plenty, starves in scarcity and then if fevers come when his larder is short, he dies unknown and uncared-for as thousands have done the last few years in the Wanni. Whatever my own opinions may be, it would be barbarous to suggest a return to the old pre-British system; immaculate though it be of harm, and good in this respect—neither vicious nor sympathetic—all principle and no practice—mere words without action. Such is not quite suited to the Eastern mind, or I read it wrongly. Determined idleness can scarcely be brought to native charge; a system has existed which shows great industry. Heaps of bricks are lying about Mahaoya of great antiquity shewing that this neighbourhood was not always what it is now; and surely with all our national conceit, we might endeavour to discover first the main causes of the early prosperity and then of its decay.

One of the grandest sights I ever beheld was upon the banks of the Mahaoya. The Moratuwa tree (*Lagerstræmia Reginæ*) I had hitherto seen either singly or in a group but never I think over 40 feet high; there the whole western side of the river from 30 to 60 feet high, shone forth in the morning sun a perfect blaze of purple from a background of dense green. As far as the eye could reach this gorgeous sight extended; below amongst a bed of yellow sand ran the river.

From Mahaoya we returned to Kaladi (Palagama by the Directory road list) and from thence to Ekeriyankumbura (Aralupitiya by the list) where we noticed a great falling-off in the condition of the resthouses. I cannot pass by without a good word for the Powers-that-be in the Eastern Province. The resthouses were clean and a porch of inexpensive materials shaded the front of the house from the mid-day glare. There were wells that would have shamed even the Colombo Municipality, built up fully 3 feet above the surface, and so preventing all polluted surface wash from draining into the drinking water. Where a road went off a large stone was erected stating the millege to Bintenna and to Kandy. Upon entering the Central Province a great change: the resthouses were dirty, the wells dangerous looking, and my companion at Bibile found a woman with sores upon her legs standing in the shallow well from whence the drinking water was obtained. Altogether things were unsatisfactory: possibly too much attention to the comforts and luxuries of the more centralized parts. There is nothing to be said in favour of Ekeryankumbura, nor do I think Bibile any better. The climate was dry and the pasturage appeared good on the road between these places, the land undulated, and here as had been the case throughout our trip, rocky hills rose some abrupt, some scarped and wild from the undulating plains forming bold features in the landscape; which park-like spread out with its sprinkled trees among grass glades and mana-filled ravines. Tavalam bullocks passed by us or were picketed at the numerous stations along the route being quite as frequent as the heavily laden carts taking coffee or bringing rice from Batticaloa. Both were far more numerous than I anticipated and I could only regret that so many thousands of acres of valuable land should lie unsought, unknown and uncared for, where every human being in the island, from the highest to the poorest *goya* would be benefited by the advantages, its occupation would entail. The magnificent road uniting Badulla and Batticaloa would become a thriving and populous thoroughfare, and those old ancient bricks would take useful forms again.

W. F. L.

CEYLON AND HER PLANTING INDUSTRY.

(*By a Java Proprietor.*)

Valuable Practical Hints.

Personally connected as I am with Ceylon and bound up in the welfare of its planting interests

I trust my numerous friends will not think it presumption of me, if I, in a few words, note down the impressions made on me, during my late flying visit upcountry, premising beforehand that I am not a practical planter, but have merely gleaned my views from what I have seen both here and in Java, so that I make suggestions and put forward my opinions with all due diffidence.

Since visiting Ceylon in 1879, coffee has continued to suffer from the terrible *H. V.*, and planters having turned to cinchona, only to meet with disappointment in the majority of cases, are now pinning their faith on tea, and it is of these three articles therefore that I propose to write. Of coffee I would merely state that looking back to October last, when I was in the Pussellawa district, and comparing its state then, with what I saw this time, I cannot help thinking that I do see an improvement and that where the estates are given a chance the trees are looking healthier and more vigorous, and leaf disease is showing signs of disappearing, or rather of being checked. Going on to Udapussellawa and Uva, I saw this more plainly, while in Haputale there was little or no disease observable, so that I should not be surprized if, in time, you get rid of it altogether, at any rate in the younger districts, where the soil is not so worked out. There is one thing, which your planters here do not seem to set so much store by, and which I would strongly advocate, and that is, the system of "*air*"-*holes*, as we call them in Java—a name more appropriate, methinks, having regard to their object, than that you employ here namely, "*water*"-*holes* These we make 2 feet deep by two long and ten inches or so broad, between every four plants, filling them with dead leaves, twigs, &c, which serve as a natural manure, while the bottom soil is spread over the field and tends materially to keep down weeds and our enemy the "alang-alang" or "lalang" grass, your "illook." With us they cost about R2 the 100, and we adopt them freely in cinchona and tea plantations

Regarding cinchona, I must confess I was not prepared to hear such gloomy accounts, for in 1879, I do not recollect hearing of canker. I have no desire to enter into a dissertation as to the causes of this diseased or "damping out," as I have heard it called; broadly speaking, I think we may take it for granted that poorness or exhaustion of soil is chiefly at the bottom of it. In Java such wholesale dying out is unknown but then we have soil such as cannot bedreamt of here, where yours is granitic as against ours, volcanic.

I think that your want of success has been due chiefly to the quality of the soil, but I feel convinced that with more attention to your seed, being sure that the same is from matured trees, and more care with your nurseries, not being in too great a hurry to put out puny weakly plants, your failures would not come up to 66 per cent, as I am told they do all round, whilst proper holing and not mere dibbling is with us considered a "sine qua non." We in Java can afford the waiting game, for we can depend on our soil supporting trees to a good old age: hence we do not attempt to shave our trees so young as you do, nor do we lop them, until the branches are matured, which then form our first crop. We plant closely—generally four by four,—thin out as required, and only shave when the trees are six or seven years old Mr. Van Romunde, successor of Mr. Moens, advocates only shaving half round the one year, half the next, and giving the tree a rest the third year, and his idea is that old trees may be sawn down to about sixteen feet, shaving being carried up to twelve or thirteen feet, thus leaving a bare pole, from which one should allow two suckers to shoot, to be cropped when seemed fit. You however in Ceylon, with your soil, are I think wise in adopting your present system of "sweating" the ground or taking as much out of it in a short space of time as possible, apart from all monetary considerations. There is one thing, however, not to be overlooked, and that is the future of cinchona cultivation, and I think there can be no doubt, that, in view of the enormous production looming in the distance, an estate of the very best kinds only will, in the face of low prices, prove remunerative, and it should therefore be everybody's endeavour to propagate from seedlings or cuttings of tried and duly analyzed trees of the ledger, verde and other approved types, employing the succirubra, hybrid and others sorts as means for providing the sinews of war. Where ledgers or other sorts, rich in sulphate of quinine, I mean of 10 per cent and over, will not grow so as to form a permanent plantation I would not advise anyone to to go on with cinchona cultivation, and when talking of the above good kinds I would point out that hybrids between succirubra and ledger, found among ledger seedlings, have been found to contain 10 to 12 per cent sulphate of quinine, so that while possessing the robustness of the one they have been blessed with the richness of the other. Of these hybrids, you must surely also have specimens among your Yarrow and other ledger seedlings to be brought to light only on analyses, in which direction we all have to work, if we want to do any good in the long-run. While on the subject of ledger, I may mention what is not generally known here, that one can tell the superiority in a tree by the acute angle the twigs or branches form in shooting, from the stem, the acuter, the angle, the richer, the tree, and vice versa. Of tea, I have but little to say, beyond the pleasure it has given me to learn of its success. It will stand a poor soil, so has a better chance of life in played-out coffee estates than cinchona. Still I would advocate the air-holes already allued to. Tea costs the planters in Java if I am not mistaken 10d a lb. to sell all round—anything under that leaving them a loss.—I am, etc., G. P. T.

Australian Trees on the Nilgiris.—Dr. Brandis, the Inspector General of Forests, wrote as follows in a note to Government in May 1882:—"The plantations of Australian trees on the Nilgiris now cover a considerable area, and some of them have been already cut over. The oldest of these plantations date back as far as 1857, and, considering the extremely rapid growth of the Blue-gum and the large Accacia, it is time now that the rate of growth, and tables of growing stock per acre, at different ages, be drawn up. These tables must be based upon the examination in detail of most of the existing plantations on the plateau, and they will furnish data for estimating the outturn of thinnings, and the final crop at different ages. The enquiries which must be made for this purpose will probably also lead to clearer views regarding the principles by which thinnings, the formation, and the treatment of these plantations generally should be regulated It will doubtless be found necessary, sooner or later, considerably to extend these plantations on the plateau, and the results, which the enquiries here suggested will furnish, will be found useful in arranging these operations in a systematic manner." The Government of Madras concurred with Dr. Brandis in these views, and the services of Mr. Hutchins, of the Mysore Forest Department, were made available for this duty. He devoted 4½ months to the work, and has submitted to Government a most exhaustive report, which contain full details of the methods adopted and the results. These include reliable data as to the average annual increment per acre or individual tree, and the reducing factor necessary for calculating the same.—*S. I. Observer.*

AGRICULTURE IN INDIA.

Field and Garden Crops of the North-Western Provinces and Oudh. Part I. With illustrations. By J. F. Duthie, B.A., Superintendent of the Saharanpur Botanic Gardens, and J. B. Fuller, Assistant Director of Agriculture and Commerce, North-West Provinces and Oudh.

This *brochure* is the first of a short series in which it is proposed to describe the cultivated products of the North-West Provinces of India. With the exception of an introduction of considerable length, treating generally of the physical, social, and agricultural peculiarities of the North-Western Provinces, the volume is chiefly devoted to a description of farm crops. Many of these, such as wheat, barley, oats, maize, hemp, tobacco, millet, and poppy, are as familiar to European cultivators as to Asiatics. Others, such as opium, rice, sugarcane, and cotton, betoken the tropical nature of at least a portion of the season.

The text is not free from remarks betokening a want of knowledge as to the progress of research on certain points. When, for example, treating of the enemies which affect the wheat crop, the author (presumably Mr. Fuller) writes as follows:—"But by far the most extraordinary disease to which wheat is liable is *sehwan*, in which the young wheat-grains are found to be filled with minute worms. . . . The most extraordinary fact connected with this disease is, however, that the worms can retain their vitality for a long time." &c. A footnote is then added as follows:—"Since the above was written, the worms have been identified as belonging to the order *Nematoidea*, and are apparently of the genus *Tyleuchus*"! This is really too gross and wilful ignorance. The wellknown and often-described "pepper brand" or "ear-cockle" attributable to the *Vibrio tritici*, now known as the *Tyleuchus tritici*, is paraded as a "most extraordinary" disease, the precise nature of which has been ascertained "since the above was written." If such is the fact, the figures 1882 should be withdrawn from the title-page, and 1828 be substituted in their place. Neither do the authors appear to be at home in treating of the varieties of the cultivated plants. The varieties of rice, we are told, are more numerous and more strongly marked than those of any other crop. Forty-seven distinct varieties are announced, in support of this statement, as existing in Barcilly, although the writer proceeds somewhat naively to add "Probably in the Provinces their number considerably exceeds 100." Now, as 300 varieties of wheat have been propagated by one naturalist, the forty-seven varieties of rice do not strike us as bearing out the statement as to the extraordinary variability of the plant.

An alluvial soil and a climate by which the year is divided into two complete seasons certainly are conditions highly favourable to vegetation and to agriculture. In the colder season, wheat, barley, and oats are brought to perfection, while in the kharif, or hot season, rice, cotton, sugarcane, and maize thrive. Not only do these highly-favoured provinces enjoy a temperate and a tropical climate, but each half of the year is again divided into two definite sub-seasons fitted for producing crops peculiar to it. We cannot but wonder whether the strange climatal vagaries to which the western world has latterly been exposed have disturbed the pleasant division of the year into kharif and rati in the North-West Provinces of India: but on this point our authors are silent.

—*Nature*, July 13. JOHN WRIGHTSON.

THE COIR YARN INDUSTRY IN TRAVANCORE.

We are not specialists in the coir yarn trade, and don't know the difference by miles between fair Alapat and middling Vyome, but we claim to note a remarkable innovation in this branch of industry, which is calculated to work some influence on the local and home markets. During the last sixteen years, we have been much up and down the Travancore and Cochin backwaters, and in the course of our journeys we noticed one thing remarkable; and that was, while Anjengo produced the best coir yarn known to the commercial world, Trevandrum, but 25 miles south of this noted coir yarn market, produced hardly a skein. In Trevandrum, for the last sixteen years, so blind have the people been to the importance of an industry that might have been pursued with golden results, that they have actually all along used the crude coconut fibre as fuel. Trevandrum possesses millions and millions of coconut trees standing in compounds of varied dimensions, but beyond using the nut for oil and the leaves for thatching, the fibre and the shells are put to no other use but fuel. We search the list of Trevandrum tradesmen in vain for an exporter of oil or a manufacturer of yarn. All these years, lakhs and lakhs of rupees worth of valuable fibre has simply been wasted in smoke. We noticed this lamentable callousness on the part of the benighted Trevandrumites, and suggested to some of our mercantile friends that engagements in the coir yarn trade at Trevandrum would probably be a profitable undertaking; but our shrewd friends turned up their eyes, and seemed to think that the fact that the Trevandrum people burned their fibre for fuel sufficiently proved that any attempt in bringing the fibre to marketable use must prove delusive and a failure. We are glad, however, to note that within a few—very few—months this branch of trade has actually attracted the attention of that shrewd and enterprizing merchant, Mr. James Darragh, of Cochin and Alleppey. That melancholy litigation between Dow & Sons and Archer & Bull took Mr. Darragh oftener to Trevandrum, we expect, than he at first liked; but he is a man, who is not accustomed to letting the grass grow under his feet, and he kept his eyes well open to such commercial attractions as might present themselves to him in his journeys up and down. A week or two ago we noticed what to us was an undoubted phenomenon, hundreds and hundreds of carts laden with green coir fibre travelling towards the Chakay landing place and emptying their contents into the large cargo boats which have already begun to ply freely between Quilon and Trevandrum. On enquiry, we were told that the fibre was being conveyed to Anjengo to be converted into yarn to supply the requirements of Mr. Darragh's firms at Alleppey and Cochin. It may not be a fact that Mr. Darragh has himself any interest in the exportation of the fibre from Trevandrum; but the significant fact remains that at last the coir fibre of Trevandrum is to be converted into something marketable instead of being consigned to the flames as in times of yore. There are many spots in Trevandrum, where we are sure the coir yarn industry might be opened with splendid results, say, for instance Valley, Covellum, Poonnora, Valiathoray, Shereinkil, Vellenjum and a host of other places. All these places enjoy exactly the advantages which Anjengo possesses, and with Trevandrum, as the head quarters of an establishment, the Anjengo manufacturers would easily be attracted to give their labour for the development of a really enormous scheme. The sleepy owners of coconut gardens thereabouts might be induced for a mere song to part with the fibre, which they now fling into the fire; the monopoly of all the available fibre could easily be so cured by any one merchant; and we leave it to our long-headed mercantile friends here to calculate what might be the eventual harvest of an enterprize such as we indicate. The Scottish India Coffee Company is nearest the scene; it is already on the track of the coir yarn trade; and it might be profitable if this enterprizing body of investors put out their hands at once in the direction which we have pointed out.—*Madras Mail.*

PALMS IN TRAVANCORE.

Some recent notes from India state that the cultivation of the cocoa-nut extends over the whole of Travancore, which has hence been facetiously called "Cocoa-nut Core." Forty-four years ago the total number of cocoa-nut trees was 11,100,000, and the increase since has been so considerable, much waste land having been planted with this valuable palm, that the present number cannot be estimated at less than 15,000,000. These are almost invariably too closely planted to obtain full advantage of sun and air; but suppose they stood at the moderate distance of 20 feet apart (which is 109 to the acre), the area covered would amount to 137,000 acres. It is well known that the situations best suited for cocoa-nut cultivation is near the seashore, the banks and alluvium of rivers, and level lands exposed to the sea breezes, which conditions abound in Travancore. Inland, on the mountains, the cocoa-nut grows, but does not bear fruit. The young plants generally require watering for the first two or three years, and must be protected from the inroads of cattle until they rise some feet above the ground. Ashes are applied as manure at the beginning of the wet season, and the ground opened about the roots of the trees, which come into bearing some eight or ten years after planting. A cocoa-nut plantation is one of the most easily managed and most remunerative products of the country. The natives have but to put down the nuts, and guard the trees more or less while attending to their other employments, and in due course a permanent and profitable plantation is created. Europeans, however, seldom attempt such an investment, and few who have done so have succeeded in it. For new plantations, waste lands are usually taken up. Within the last twenty or thirty years much land otherwise worthless has been reclaimed along the sandy sea coast, and many trees have been planted on either side of new roads opening up into the interior. The produce of the trees vary much in different soils and climates. The average of a good tree in full bearing has been stated at 120 nuts per annum, while in low and sandy soils it will amount to 200, and in gravel or laterite under sixty.* The dried kernels, under the name of "copra," are exported to other parts of India, for the expression of oil; and the coir, or fibre, which composes the husk, is sent in enormous quantities to Europe and America. The annual value of the products of this palm exported—nuts, dried kernel or "copra," oil and fibre—amounts to 42 lacs of rupees, besides oil, nuts, timber, and leaves for home use. It has been estimated that 60,000,000 of nuts are annually consumed in the country. The timber is not exported, but split up and used for rafters, and, leaves are in great demand for thatching. The trees are sometimes tapped for a few mouths to produce the sweet juice, which, boiled while fresh, gives a palm-sugar, and, kept a day or two till it ferments becomes toddy—a slightly intoxicating drink, somewhat like beer. The toddy is also distilled into "arrack," or native spirits. The Palmyra Palm (Borassus flabelliformis) stands next in importance to the cocoa-nut. It is grown only in the driest districts towards Cape Comorin. This palm, with its sweet sap and sugar, leaves, timber and fruit, furnishes a living to a great number of the Shanar caste in Travancore and in Tinnevelly. The number of trees in 1880 was about 6,000,000. It is probable that no considerable increase has taken place since, as old trees are in demand for their timber, and the slow growth of this palm discourages planting. From 16,000 to 24,000 cwt. of the sugar ("jaggery") of this palm are annually exported, worth something over 3½ rupees per cwt. The beautiful Areca Palm (Areca Catechu) is planted in damp clayey soil on the banks of tanks and rivers. Unlike the cocoa-nut, it will thrive at a distance from the sea, and on the hills. It is grown very largely in North Travancore, whence the nuts are carried to the south by traders. The trees will grow 2 or 3 feet apart. The Areca begins to bear in five years, and continues to produce fruit for twenty-five years. The nuts are sold wholesale at six or eight chuckrams per thousand, and retail in Trevandrum at from eight to thirty-two for a chuckram, according to season and demand; 3,500 candies are annually exported to Bombay and other ports, the value of which is about 4½ lacs of rupees.—*Indian Agriculturist.*

PLANTAIN CULTIVATION FOR INDIA.

Class, MONOCOTYLEDONÆ; *Natural Order*, MUSACEÆ.

Scientific typical names:
- *Musa Cavendishii*, Lambert.
- ,, *Paradisiaca*, Linne.

- ,, *Troglodytarum*, Linne.
- ,, *Simiarum*, Rumph.
- ,, *Livingstonia*, Kirk.
- ,, *Ensete*, Gmelin.
- ,, *Corniculata*, Linne.

English general names ... Plantain and Banana.
Bengalee ,, ,, ... Kola gach.
Hindustani ,, ,, ... Keyla ka per, or darakht.

INTRODUCTION.

The name of the plantain plant is quite familiar to every one in India; and every one knows that variety of this plant which grows where he is located, and values it accordingly. For instance, the people of lower Bengal, Bombay and Madras (in India); and Burmah, China and Japan, on the other side of India, will hail the plantain plant, because they know it is an excellent and very useful fruit plant. The people of other parts of India and other countries, meaning the masses of the people, however, where plantain is unknown, or where an inferior variety exists, which does not fruit well, whose fruit is insipid or unpalatable, and not so nutritious and cheap as other fruits are, do not and cannot appreciate this highly-prized plant. As applied to India, this remark is applicable to such places as Oudh, N.-W. Province, the Punjab, Sind, Central Provinces, and some other parts of India,—hence the unequal appreciation of this very valuable plant all over India.

CLASSIFICATION OF PLANTAIN.

The foregoing, at the beginning of this article, is the general classification of edible plantains; the following are the names of the principal species and varieties of plantain I have cultivated, and which are found growing in Lower Bengal, Madras and Bombay. All of these have been introduced in other parts of India, chiefly in the Government Botanical Gardens and those of the Agri-Horticultural Societies; but have not as yet been diseminated among the masses of the people owning garden, orchards, &c., easily known by there being not a single good variety of plantain fruit in any of the markets of India, other than those of the places where the plant, which bore it, is indigenous, or where the plants is in extensive cultivation from a long time.

Musa Cavendishii: the Chinese banana; *cheenee champa*, Ben.; *Hazara keyla*, Hin. (so-called from profuse fruiting of this plant, the word *hazara* being derived from *hazar*, meaning thousand).—This plant is extensively cultivated in Lower Bengal, and in the South Sea Islands. The stem is pretty thick; height not exceeding 6 feet. The flavour of the fruit is excellent, as every one in Calcutta, and other cities and villages in Lower Bengal, who has eaten it, can certify. Baron Mueller states that so many as 200 to 300 ripe fruits are obtained from one spike (*kandi*, Ben.; *ghoud*, Hin.). In the present state, however, of this plant in Bengal, the ripe and fully developed fruit-yield per plant or spike is very small. I have examined several fruit-spikes of this banana both on the plants and in the markets of Calcutta, but found no more than 80 to 200 fruits on each spike. This diminished number of fully developed fruits per spike or plant is no doubt owing to want of proper cultivation and the fertilizing elements in the soil.

Musa paradisiaca.—This species is that which supplies the varities most extensively cultivated all over Lower Bengal, and various other parts of India. The Bengalee names of the varieties are:—*Champa kola*, *mortoman kola*, and *chatim kola*; and the variety found in Madras called *madrajee kola*, Ben.; *kela*, Hin. These are the principal cultivated varieties. *M. paradisiaca* is believed to have originated from *M. sapientum*. (Baron Mueller.)

Musa sapientum.—This species, which undoubtedly is the type from which have sprung most of the cultivated edible plantains of India, furnishes three well-known varieties:—One in Bengal called *kantali kola*, so named on account of the smell, taste and flabbiness of the fruit of this plant resembling those of the jack fruit (*kantal*, Ben.); the second variety is to be found in the Bombay presidency, called in Bombay *green Bombay plantain*, owing to the green colour of the rind of the ripe fruit; the third variety, named *deshee kola*, Ben.; *dasee keyla*, Hin. (common country plantain), is found in many parts of India—all over Bengal, N.-W. Provinces, Oudh and the Punjab, particularly. This last-named plant is also called *kanch kola* in Bengal, owing to the extensive use of the unripe fruit in cookery. In Bengal *kanch kola* is never allowed to ripen, because the fruit is insipid, wanting in the grateful aroma, and the middle part of the fruit is seedy, which render it very inferior to other plantains cultivated in Bengal; but in other provinces in India, being the only plantain which can be grown and fruited in hottest and driest places, it is grown extensively by the natives and others, and the fruit allowed to ripen, the fruit being considered as one of the indispensable, digestive, if nothing more, fruits of the fruit-garden.

Musa troglodytarum.—This plant supplies the variety found in Bombay, there called *red Bombay plantain*, *lal Bombaya kola*, Hin.; *lal Bombaya kola*, Ben. so named from the red skin of the ripe fruit. The ripe pulp of this plantain has

* Over a large plantation under average conditions, 40 nuts per tree per annum, we suspect, is nearest the mark.—ED.

gamboge yellow colour, wanting in the grateful aroma found in the *chinee champa*, *champa*, and *mortoman* plantains, is also less sweet than any of these. This I say after eating extensively all of these. In Bombay the red plantain fruit is sold from a quarter anna to one anna for each fruit, according to size and quality of the fruit.

USES.

The plantain plant has many uses. Having intimate knowledge of this plant by extensive use, trials and observations, I am prepared to subjoin a description of them which will be serviceable to persons acquainted with the industrial value of plantain in all its bearings.

A.—FRUIT.

It is highly nutritious and consumed in India (Bengal in particular) in two states—(1) *unripe* and (2) *ripe*.

(1) Unripe Fruit.—The consumption of unripe plantain fruit is exclusively confined to the natives of Bengal whether located in Bengal or elsewhere where the fruit is available. In other parts of India, I have nowhere observed unripe plantain fruit used in cookery by any other than the Bengalee people. In Bengal the unripe fruit is cooked in various ways as described below.

(*a*) *Kolá bhája*, Ben.—The fruit is first cleaned of the thick skin by means of a knife, cut into round or oval (according to the shape of the fruit) slices about ¼ inch thick, washed with water, mixed with turmeric, chillies, or red pepper, ground in water, salt, and fried in mustard oil or *ghee*. It is eaten with boiled rice.

(*b*) *Kolár bhortá*, Ben.—The fruit is cleared of the skin, washed and boiled in the same vessel in which rice is boiled, and always with the latter. Since rice occupies a longer time in being cooked, and the plantain fruit less, the latter is taken out some minutes before, is then washed, a little mustard oil, salt, and sometimes black round pepper or chillies added; and served. This is always eaten with boiled rice.

(*c*) *Kolár chorchori*, Ben.—The plantain fruit (skin cleared), brinjal, *doomoor*, Ben., fruit of *Ficus glomorata goolur*, Hin., and potatoes, are cut into slices of any desired shape and size, washed in water, and kept in a suitable vessel till wanted for cooking. This finished, a brass, iron, or earthen *korai* Ben., *karhai* Hin. (pan) is placed on a *choolo* Ben.: *choolha* Hin. (oven) in which mustard oil or ghee is put and heated to the boiling point. On ascertaining this, turmeric, chillies or black round pepper, and fennel, ground in water on the stone slab called *sheel* Ben., *sil* Hin., are, more or less, according to taste, fried in the oil (mustard or any other) or *ghee* (only when intended for rich people) in the *korai*, well mixed with the fried spices; and salt and a little water is added. The *korai* is then covered over with a *thal* Ben., *tharya* Hin. (brass plate), to allow the ingredients to digest on a brisk fire for about 15 minutes. The brass plate is then taken out, the contents of the pan examined, and if found sufficiently cooked, the water, if any, is evaporated, and the *chorchori* served out. Most people like fishes to be added, for whom fried fishes of any kind, large or small, mixed or unmixed, and of any species, according to taste, are put on the top of the fruit and vegetables, a sprinkling of water given, the pan covered again, and 10 minutes more allowed for the fish to imbibe and acquire the flavour of the soluble ingredients of the *chorchori*. The pan is then uncovered, and the contents served out. The latter form of cookery is termed *manchere chorchori*. *Chorchori* is generally eaten with boiled rice and *kolái* or *mash kolái er dál* Ben., *mash* Hin. (*Phaseolus radiatus*); is also sometimes eaten with *chapatis*, Hin. (*gellate*, French) made of wheaten flour.

The Bengalee word *chorchori*, is used to denote the kind of cookery made in the manner described above. It is derived from the Bengalee word *chorchor* (cracking), on account of the sound produced in the pan in the process of cooking. It always retains its name with the prefix of the name of the predominating fruit or vegetable used. For instance, when the predominating vegetable is brinjal, it is called *begoon-er-chorchori*; if potatoe, *áloo-er-chorchori*; and so on. But when fish is added, whatever the predominating vegetables or fruit composition of this kind of cookery may be, the name of the fish will always precede the word *chorchori*; thus we have *bhetki—*, *tangra—*, *koi—*, *boley—*, *ilesh—*, *rooe—*, *or chingri—*, *mach-er-chorchori*. From what I have said it will be seen that the word *chorchori*, like *dal*, is the generic name given, in Bengal, to dishes having various kinds of compositions, but cooked in one particular way as described above. Uncooked pulse is also called *dal*, provided the pulse is split or broken.

The dishes described in the foregoing headings *a* and *b* are also generic terms *Bhája* means fried, and *bhortá* that which after boiling is mashed; so that anything eatable, such as all kinds of fishes, vegetables, flesh, fruit, etc., might be fried or mashed, and in Bengal termed *bhaja* or *bhortá*.

(2.) *Ripe fruit*.—This is eaten raw and singly as many other fruits; such as ripe mangoes (*mangifera Indica*), *leechees* (*nephelium litchi*), pears (*pyrus communis*), &c.; but like ripe mangoe, it is also eaten peeled, in milk, sugar, and boiled rice. This composition tastes very nice, provided the plantain fruit is of good variety, satiating the consumer fully well. The ingenious Bengalee also cooks ripe plantain fruit. Here is the process:—

(*a*) *Kolár borá*, Ben.—A number of thoroughly ripe, but not rotted, plantain fruits are taken, the rind removed, mashed and thoroughly mixed with fine wheaten flour (*moida*, Ben., *maida*, Hin.), a sufficient quantity of sugar, little pounded cardamom (mixed or omitted, according to taste), kneaded with milk and little water, and formed into small lumps of any desired shape; and fried in ghee. This tastes excellent and is highly nutritious.

B.—UNDEVELOPED FRUIT SPIKE.

a.—*Mochar ghonto*, Ben.—This dish is made from the lower part of the fruit-bearing spike containing a large number of undeveloped fruits. This part of the spike is cut out at the time the fruits of the upper portion are developing and the lower portion does not appear to develope more fruits, but must remain in embryo. It is called *mocha* in Bengal, and has feeding value in it; both for man and cattle. First of all, the fruits are taken out of the spike, cut into small bits, washed and boiled for about 20 minutes. The boiled fruit is then taken out of the vessel, water thrown away, and squeezed to separate more water. It is then kept in a *thál* brass plate). This finished, a brass vessel is next placed on the oven in which a composition of ground fennel, black-pepper, cardamoms, cinnamon bark, and water are put and boiled. After the boiling is over, the fruit, unshelled grain, steeped over-night, sliced potato and brinjal, salt, cow's milk, and little sugar, added; and the vessel covered over. The composition is allowed to boil and digest for 10 minutes. This finished, the vessel is uncovered and a *baghár*, also denominated *shántlano*, Ben. (a process which consists of a brass or iron spoon in which ghee or oil is put, and a few cloves, black round pepper, cinnamon bark, cardamom, or any other spices or condiments or both have attained brown colour, then the whole is thrown into the cookery) given. The dish is now ready to be served out. Always eaten with boiled rice.

C.—STEM.

When the fruit-spike of plantain has matured its fruits, it is removed from the stem, and with it the plant also; because plantain never bears fruit twice—hence it is useless to allow it stand. When the plant is denuded of the outer layers or sheaths, such being the construction of this succulent plant, the inner stem, which ends in the fruit spike, is extracted. This stem, which is dull white in colour, and of glassy lustre and smoothness in the exterior, is a food-article in Bengal, and there denominated *thor*. The cooking process of *thor* is described below.

(*a*) *Thor-er-dálná*, Ben.—*Thor* is cut in small bits, washed, and salted. It is then boiled in water, taken out, cooked with the same ingredients as for *mochar ghonto*, with this difference that *ghonto* has no water or gravy in it, whereas *dálná* has. The cooking process does not differ. Always eaten with boiled rice.

(*b*) *Thor-er-chorchori*, Ben.—As in the preceding, *thor* is boiled; and cooked in the same way as *kolá-er-chorchori*—vegetables and fish added, according to taste. Eaten with boiled rice or with *chappatis*.

D.—MISCELLANEOUS OR OTHER USES OF VARIOUS PARTS OF THE PLANTAIN PLANT.

(*a*) *Fruit rind*.—This is greedily eaten by all manner of live-stock. Administered with straw, oil-cake and other ingredients made into *jábná* Ben., *sáni*, Hin. (mixed meat), ripe plantain fruit-rind is valuable food, being both palatable and nutritious.

(*b*) *Leaves*.—These serve as plates and dishes in the home of every Hindu—Bengalee, rich are poor, especially the latter, and on all festive occasions. The leaves also find other uses packing articles by the native shop-keepers, for bedding

o

and covering of *dálees* of fruits, vegetables, and flowers for maintaining natural freshness by not undergoing dryage, thereby retaining original flavour and appearance, and for covering of cigars smoked by the natives of Orissa, especially by the *Oorya beras* in Calcutta. The dry ribs of leaves are twisted and formed into balls of strings used by the native shop-keepers and *málees* (native gardeners) for tying bundles of articles sold, and the sticks of *dálees* (a kind of shallow basket), also for tying balls of earth attached to plants intended for carriage and transplantation to near or distant places.

(*c*) *Stem sheaths.*—Lately discovery has been made by paper manufacturers, naturalists and chemists, that excellent paper-pulp can be made from the stem-sheathes. Owing, however, to the large percentage of water, this paper material can only be made available to commerce and manufacture where plantain is extensively cultivated.

(*d*) *Root-bulb.*—I have ascertained it to contain starch, useful for technical purposes; experiments to be yet made, will determine its intrinsic value, and whether it will pay the cultivator and manufacturer.

Recapitulation of the foregoing.—The principal part of the plantain plant is its fruit, a food article of the first order; the other parts are of secondary industrial value. As a whole, the plantain undoubtedly is one of the most useful, industrial and decorative plants in the whole range of the vegetable kingdom. O. L. Bryce.

—*Indian Agriculturist.*

THE COFFEE AND SUGAR PRODUCING COUNTRIES.

MADAGASCAR.

Madagascar is the largest, finest and most fertile island opposite the southeast cost of Africa, separated from the mainland by the Mozambique Channel, and measuring 228,343 square miles. It has a population of 2,500,000 souls. This island not only produces the sugar cane to perfection, but abounds in nearly every other tropical product that can be grown on African soil; the main island is as fertile. The cane, coffee, cotton, wine, silk, hemp, gums, etc., all flourish in this privileged region. Nor is Madagascar deficient in iron, copper, silver, salt and precious stones. The amount of sugar produced at Ste. Marie and on the coast opposite it is estimated at 40,000 tons. The French have their hands too full at present in Algeria and Tunis to give serious attention to remoter regions, although they are operating around their new colony, Cochin China, and try to expand in that direction. Their campaign in Northern Africa will soon absorb all their attention, a circumstance which the British may avail themselves of to gain a firm foothold in Madagascar, and eventually may even annex it outright. Should this ever occur, and it may take place sooner than is at present apparent, the island would become without a doubt one of the finest minor English possessions on the globe, admirably situated, also from a strategical point of view, for it would command the entire East Coast, the entrance to the Red Sea, and the route from the Cape to Australia. Sugar and coffee, would be grown there in abundance, there being no lack of labour, for if the natives declined to work in the cane fields, coolies would be procured from India, the same as they have been imported into Mauritius by the hundred thousand. Although the French might not like such an additional British acquisition in Southern Africa, all other nations would hail the conquest with joy, for it would stimulate trade, and benefit the world at large.—*Rio News.*

PLANTING ENTERPRISE IN THE WEST INDIES.

(*From Paper by Mr. D. Morris.*)

One of the most simple, but by no means the least profitable, of our West Indian industries is that of coco-nuts, which, to distinguish from cacao, cocos, and coca, are generally known in commerce as "koker-nuts." The finest nuts in the West Indies, and probably in the world, are grown on the coast of Central America; and British Honduras, in this respect, should become one of the largest and most prosperous producers of coco-nuts. Wherever there is a low, rich coast-line, not too much exposed to hurricanes or strong winds, and where there are regular and cheap shipping facilities, coco-nuts offer very advantageous means for supplementing the resources of the planter; and I know of no country where such high prices, and where such a regular demand exists for green nuts as the West Indies. Latterly as much as £6 per thousand were paid in British Honduras for coco-nuts, and very few could be had at that price. The general price for coco-nuts in the West Indies varies from 50s to 80s per thousand; at present they are about 70s.

It has often occurred to me that if, in the palmy days of sugar-planting in the West Indies, an effort has been made to cover the apparently barren coast lands with groves of coco-nuts, the abandoned estates, now so desolate, would have been mines of wealth to their proprietors, richer and more permanent than anything derived from sugar.

A coco-nut plantation in the West Indies, well established and in full bearing (say at the end of eight years) with sixty trees to the acre, may be safely assumed to be of the annual value of £10 per acre. The expenses of maintaining a coco-nut plantation, when once established, is practically nothing; hence the thousands of acres of land bordering the sea-coast of our West India possessions are capable of immense development.

The largest export trade in coco-nuts is probably from Jamaica, where in 1880 over six million nuts, of the value of £20,500, were shipped, chiefly to the United States and Europe. Next to Jamaica comes Trinidad, with exports of over four million nuts, of the value of £14,000. British Guiana exported in 1879 a little over a million coco-nuts, but it is probable that this number has been greatly exceeded. It is remarkable that localities possessing such wonderful facilities for the cultivation of coco-nuts as the Windward and Leeward Islands should, up to the present time, do little beyond supplying their own wants. Dominica, with its unrivalled lands for the cultivation of this valuable palm, does not export a single nut. Barbados is in a worse position, for she has to import coco-nuts for her own use. Whether this is due to want of cultivation, or to the unsuitability of the soil and climate to the growth of the plant, is not known. I believe the coco-nut palm at Barbados is affected by an insect pest; but if this is the only deterrent to the cultivation of so useful and valuable a plant, I believe it might be overcome.

The manufacture of "copra," the kernel of the coco-nut dried and cured, has not been taken up in the West Indies; nor has the manufacture of coco-nut oil or coconut fibre been established. These industries are chiefly confined to the Pacific Islands, to the Seychelles, to Ceylon, and to countries remote from good markets, for fresh nuts, and where the value of the nuts is below 40s per thousand. Owing to the lower value of coco-nuts in Ceylon, coco-nut oil can be actually manufactured there and shipped and sold in the West Indies at a lower rate than we can make it ourselves. If, by making the nuts into copra, the West Indian planter obtains only some 40s per thousand for them, and if, by making them into oil, he only just clears his expenses, it is manifestly to his interest to dispose of the nuts in the green state, and especially at present prices of 70s per thousand. For the American market the nuts must have the outer husks removed; and latterly it is found more convenient and economical to ship the nuts in a similar state to the English market. In the latter case, the nuts are packed in gunny bags, and forwarded as merchandise instead of as "dunnage."

In the Bahamas, "the Madeira of the United States," the cultivation of tropical fruits, especially pine-apples, bananas, oranges, and coco-nuts, has assumed considerable importance. Under the fostering care of a former governor—now Sir Wm. Robinson, K.C.M.G.—and a system of local boards of agriculture, tobacco, onions, tomatoes, and numerous other small industries, have also been started, which must eventually, in the aggregate, add greatly to the prosperity of these islands. The pine-apple trade of the Bahamas, chiefly confined to New Providence, is carried on both with England and the United States, a large proportion of which is in canned goods. The coco-nut plantations are confined chiefly to Inagua and islands to the south, whence the nuts are conveniently and easily shipped. At the Turks and Caicos Island in the neighbourhood, now under the Government of Jamaica, a very praiseworthy and energetic effort is being made by Mr. Llewelyn, the Commissioner, to cultivate oranges, pineapples, and fibre-plants, which, so far, promises to be well seconded and supported by the inhabitants.

The fruit trade of Jamaica has now become an established industry, which is rapidly being taken up by both European and negro settlers. Nearly the whole of the fruit is shipped to the United States, to the ports of New York, Philadelphia, and Baltimore. Some of the trade is, however, in course of being diverted to New Orleans, which is only within three days of Jamaica, and in close communication with all large centres of industries in the Western States. The fruit trade of Jamaica, inasmuch as it fosters and strengthens other and more permanent industries, is deserving of every encouragement; and it is no doubt with this view the Government has promoted facilities for the employment of contract steamers between Jamaica and the United States, so as to find a ready and expeditious market for the produce. As shown when discussing the prospects of cacao cultivation in Jamaica, the profits arising from the sales of bananas, for instance, enable planters to establish the land in cacao, and similarly the same facilities are offered for the cultivation of Liberian coffee, spices, india-rubber, and numerous other plants which would otherwise be beyond the reach of persons possessing small means. The present position of the fruit trade in Jamaica will appear from the following table of exports for the year 1882:—

Fruit.	Quantity.	Value.
		£
Bananas	887,370 bunches	88,737
Oranges	35,456,978	33,684
Coco-nuts	2,763,655	10,225
Lime-juice ...	78,820 gals.	3,941
Pine-apples ...	8,856 doz.	1,111
Limes...	890 bls.	348
Mangoes	150,671	146
Tamarinds... ...	7,696 lb.	96
Plantain	20,412	57
Shaddocks ...	36 bls.	14
Total ...	—	138,359

The great increase in the value of this trade during the last ten years may be gathered from the fact that in 1873 the export value of fruit shipped from Jamaica was only 8,750*l*. That it will still continue to increase, and that, ultimately, numerous other industries will be promoted by it, is proved by the fact that greater attention is continually being paid to *it*; and by the increased demand which is arising in the United States and the Dominion of Canada for tropical fruit. These countries possess a prosperous population, nearly double of that of the United Kingdom, and fruit of all kinds forms an important element in their daily food.

For men with only moderate capital, I know of no industry so promising as this cultivation of fruit, either for its own sake or for the purpose of ultimately establishing other and more permanent cultivations.

The cultivation of spices, such as nutmegs, cinnamon, cloves, black pepper, and vanilla, has also been taken up, not only in Jamaica, but also in Trinidad, Grenada, and St. Vincent. Nutmegs especially do well at Grenada; and with regard to other spices, if they are so successfully and so energetically carried on throughout the West Indies as in the islands above mentioned, we shall have them known in the future, not as the sugar islands, but as the spice islands of the West

With regard to the yield from nutmeg trees in Jamaica, trees at six years old give a return of about 1,500 to 2,000 nutmegs per annum. With trees, say, 30 feet apart, and allowing one-third to be male or barren trees, this would give a return of 1,500 × 30=45,000 nutmegs per acre. Taking an average of ninty nutmegs to the pound, the return in cash value would be 500 pounds of nutmegs at, say, 2*s*. per pound, equal to 50*l*. per acre.

In the Botanic Gardens, Trinidad, the yield per tree net in the market has been over twenty pounds at ninety to the pound this would be 1,800 nutmegs) with an average price of 2*s*. 2*d*. per pound during the year. The value here, per acre, is at the rate of 60*l*. per annum.

In both the above instances, it is only fair to mention that the calculations have been based on a comparatively small number of trees. The average yield over a large area of, say, 40, 50, or 100 acres would be correspondingly lower, but even under any circumstances it is evident that where suitable and favourable circumstances exist, as I believe they do in the West Indies, a nutmeg plantation is likely to be a very successful and remunerative undertaking.

The cardamom, a valuable East Indian spice, has lately been introduced to the West Indies with satisfactory results. It is adapted for cultivation in moist, shady situations, at elevations ranging from 200 to 3,500 feet. The plants have much of the appearance of the "wild ginger" of the West Indies, and require little cultivation beyond keeping the ground clear of rank-growing weeds. The return per acre is estimated, at the end of three years, at about 170 pounds of cardamoms, worth 3*s*. to 4*s*. per pound.

Tobacco, rubber-yielding plants, and numerous medicinal plants are also being introduced and cultivated in the West Indies with marked success. With the valuable aid and by the instrumentality of the Royal Gardens at Kew, the Botanical establishments in the West Indies, and through them the planters in these possessions, are being continually supplied with economic plants of great value, and by these means new industries are being founded, which in course of time should have most beneficial influences upon the commercial prosperity of these islands.

So far, tea has not been tried on a commercial scale in the West Indies. I have some five acres of tea under my acre, which, being some seven or eight years old, indicate that the climate of Jamaica is admirably suited to the growth of the plant. I estimate that with indentured coolie labour and an experienced tea-planter from Ceylon or India, tea might be grown in the West Indies and placed in the market at a cost not exceeding 7½*d*. or 8*d*. per pound. At the present time very inferior China tea is sold in the West Indies at 4*s*. 6*d*. per pound. Hence there is here a very good opening for a tea industry—if only to supply local demands. I am glad to say that an attempt is likely to be made to grow tea in Jamaica, under very favourable circumstances; and as the parish of Portland, with its warm moist climate and splendid rich valleys, approaches so nearly the conditions which obtain in the best tea districts of India, the undertaking promises every hope of success.

Among the newer industries of Jamaica, I may mention that of cinchona, or the quinine-yielding trees of commerce.

For the first seeds of cinchona, Jamaica is indebted to the Home Government, who, at the recommendation of Sir J. D. Hooker, Director of the Royal Gardens, Kew, sent liberal supplies of seeds of three species direct from Peru and Guayaquil. The industry owes its initiation, on a commercial scale, to Sir John Peter Grant, who established an experimental Government plantation on the Blue Mountains in 1869

The fact is, that for the successful and remunerative culture of cinchona plants in a new country such a peculiar combination of elevation, soil, and climate is requisite that there are comparatively few areas wherein all these can possibly exist. Hence we find that very few tropical countries can successfully enter upon the industry, and of these, so far as my experience goes, only two or three possess in so eminent a degree all the favourable conditions enjoyed by Jamaica

As confirming this view by independent testimony, I may mention that a Ceylon proprietor and planter, with some twelve years' experience in the cultivation of coffee and cinchona, after carefully inspecting the Jamaica Government plantations, refers to the growth and characteristics of the trees as follows:—"I am perfectly convinced that were the bark of two equal-sized cinchona trees, one Ceylon, the other Jamaica, weighed, the Jamaica tree would outweigh the Ceylon tree considerably; this is particularly noticeable in young trees. The bark itself has a brighter and more taking colour, looks richer in quinine, and altogether healthier. It is generally (copiously) covered with lichen, and the growth of this I believe to have an effect similar to mossing in developing the alkaloids. The ready way in which the self-sown seedlings grow, and the number of them, surpass anything I have seen in Ceylon, and prove that the cinchona tree has found a most suitable home and congenial climate on the Blue Mountains of Jamaica. The land is self-drained, yet canker in the root, which destroys such a large proportion of Ceylon seedlings, is hardly felt, and would not probably be known were the land drained. The only difficulty I can foresee is labour; if this were removed (as it easily might be, by importing coolies) I believe Jamaica would produce more valuable cinchona bark for the acreage than any country in the world."

At the small but beautiful island of Montserrat, in the Leeward Islands, which for a long time was in a languishing condition, new life and energy has been infused by the successful issue of an industry which a few years ago was confined to the desultory and spasmodic efforts of a few negroes. I refer to the lime-juice plantations and manufactory so ably and systematically established at Montserrat by the Messrs. Sturge. And I would here add, that the example of the Messrs. Sturge, not only in selecting and systemising the cultivation of a minor West Indian product, but in conferring great benefits upon the locality generally, deserves the warmest commendation.—*Colonies and India.*

INDIAN CINCHONA SOILS.

In my article on the above, published in the *Field* of January 13 last, I promised to endeavour to obtain some information respecting the yield of valuable alkaloids from the bark of trees grown on the experimental plots.

I am pleased to say that, through the courtesy of Mr. W. R. Robertson, of Saidapet, the necessary analyses have been placed at my service, together with some interesting particulars as to the age of the trees, elevation, aspect, and average rainfall, which latter information has been furnished through the local Conservators of Forests for the respective districts in which the two plantations are situated.

It will be remembered that eight samples of soil, each representing a separate experimental plot of cinchona, were submitted to me for analysis, and that of these, two (plots 6 and 7) were from the Government cinchona plantations at Dodabetta, and the remaining six from Neddivattam.

SOILS FROM DODABETTA PLANTATION.

No.	Character of Soil.	Elevation.	Aspect	Average rainfall.
Plot 6.	Poor, gravelly.	7·500	N.W.	51·70 in. average
Plot 7.	Rich surface.	7·200	N.W.	for past 5 years.

Extract from the analyses of samples of bark collected by Mr. R. Cross in 1880:—

No.	When Planted.	Quinine per cent.	Cinchonidine per cent.	Cinchonine per cent.	Quinidine per cent.	Amorphous alkaloid per cent.	Description.
Plot 6.	1864	3·49	1·22	2·18	1·25	1·12	Natural Crown bark.
Plot 7.	1865	4·43	1·35	2·15	1·20	0·95	Natural Crown bark.

Now, No. 6 sample was described by the senders as being a poor gravelly soil, and intended for comparison with No. 7, which is a rich surface soil, and upon reference to my analysis it will be observed that the former contains nearly 15 per cent of quartz, and is evidently a generally poor soil, whereas No. 7 is a dark surface mould, particularly rich in the important elements of plant life. It is, therefore, remarkable that the bark from the trees grown on No. 6 plot should be so rich not only in quinine, but in the other alkaloids.

Thus, in the former soil we have 3·49 per cent of quinine, and the total alkaloids amounting to 9·26, while in the latter 4·43 quinine and 10·08 of total alkaloids. Indeed, the 1 per cent. more quinine in the bark from the rich soil of No. 7 is the only practical difference, for the figures for the other alkaloids are so similar in each analysis that they might very well be assumed to be the results of duplicate analyses of the same bark, rather than the figures for different samples produced from essentially different kinds of soil.

It would be unwise to attempt to draw any general conclusion from single analyses such as these; but so far it would appear that the climate and situation are so favourable to the growth of *C. officinalis (v. condaminea)* for medicinal purposes, that valuable bark, rich in quinine, may be produced even from trees grown on a poor gravelly soil such as No. 6.

20

SOILS FROM NEDDIVATTAM GOVERNMENT CINCHONA PLANTATION.

Samples.	Elevation.	Average rainfall for past five years.	Aspect.	When planted.	Result of analyses of bark. Quinine per cent.	Cinchonidine per cent.	Cinchonine per cent.	Quinidine per cent.	Amorphous alkaloid per cent.	Remarks on bark analysed.
1	about 6,929 feet	92·41 inches	N	1870	2·04	0·16	1·86	0·37	·40	C. officinalis.
2			N	1869	5·80	0·13	0·14	—	·24	C. officinalis (angustifolia var.) succirubra, not analysed.
3			N	1862	0·83	0·97	2·30	—	·70	C. succirubra.
4			NW	1869	0·85	1·71	0·90	—	·40	Magnifolia officinalis & succirubra not analysed.
5			N	1866	1·25	1·52	4·14	—	·76	C. succirubra.
8			N	1870	5·55	0·07	0·24	—	·40	C. calisaya.

These analyses, which bear no date, are very different, and present greater variations than the two we have just considered. The name of the chemist who made them is also not given, so that some of the differences in the results of these bark as compared with the two from Dodabetta, may be due to a different process of analysis. Be this as it may, it is, however, apparent that No. 2 and No. 8 stand out as very rich in quinine, and with but little of the other alkaloids. In the former C. officinalis (variety angustifolia) has produced the bark, and in the latter C. calisaya.

In No. 1 the results are disappointing, there being only 2·04 of quinine, while the cinchonine amounts to 1·86 per cent, the proportions of cinchonidine and quinidine being very small.

In No. 3, in which the bark is from C. succirubra, the yield of quinine is only ·83 per cent., and the cinchonine as much as 2·30, the trees being twenty-one years of age up to date, have possibly rather passed their prime for medicinal purposes, or are not suitable to the locality.

No. 4, where the aspect is N.W., all the others being direct N., we notice a poor yield of quinine; but then the variety of magnifolia is more beautiful as a tree, than its bark is useful as a drug. None of the officinalis or succirubra growing on this plot appear to have been analysed.

In the next plot, No. 5, however, C. succirubra, planted in 1866, has been barked with a good result as regards the total alkaloids, which amount to as much as 7·67 per cent., of which 1·25 consists of quinine, and 1·52 of cinchonidine, with 4·14 of cinchonine.

No doubt this will prove a useful bark at the elevation, and it is certainly puzzling why the results in the case of No. 3, where succirubra was also being grown, were not equally satisfactory, both the soils being rich in nitrogen and carbon derived from vegetable organic matter.

In conclusion I would point out that so far as these analyses indicate, it would appear that at Dodabetta, with an average rainfall of 51 in., and an elevation of 7·500 and 7·200, the yield of total alkaloids and certain experimental plots has been decidedly greater than at Neddivattam, where the rainfall is 92·41 in., and the elevation under 7000 ft. At the same time we have instances in the latter (plots 2 and 8), when the yield of quinine has been higher, namely, 5·80 per cent, and 5·55 respectively.

With the arrival of the newly-appointed Government Quinologist in Madras, it may be hoped that we shall be furnished with some interesting analyses of further samples of bark from these experimental plots.—JOHN HUGHES, F.C.S., 79, Mark-lane, London.—*Field.*

CEARA RUBBER IN CEYLON.

The following reports on the cultivation of Rubber trees in a lowcountry plantation, written at considerable intervals of time, will be of interest to others engaged in experiments and we shall be glad to have the result of their observations also. Latterly there has been a despondent feeling prevalent as to the success of the Ceara rubber as an investment in Ceylon. The very fact that the trees run up so rapidly from seed is offered as an argument against expecting the sap to be worth much for rubber purposes, and the planters who have been longest engaged in the experiment are credited with the largest amount of scepticism, alleging that the time taken to collect are appreciable quantity, puts the industry outside of the 'paying and practical.' The sap it is said is too thin and watery to coagulate and form useful balls for industrial purposes, and this is due to the too rapid growth of the trees. Such are the latest current rumours, and they seem to be borne out by the following reports from a reliable source :—

Ceara' Rubber on a Lowcountry Plantation.

(*First Report.*)

I have been experimenting with the harvesting of Ceará rubber. It is possible that the plan sketched by Dr. Trimen, of letting the sap run down the stem and stripping the film of rubber, when it dried, might be made to act, in the case of tolerably mature trees, but I have found it utterly impracticable with those I have to deal with. At whatever height the incision is made, the stream of sap reaches the ground, and no sufficient accumulation of solid matter remains to be stripped at any stage of drying. Again, I find the branches more productive of sap than the stem, and with the present plan of operations that I have arrived at the produce is easier saved, and kept quite free from foreign substances. After trying a great many things with very little satisfaction to myself, or in any degree, advancing the object in view, while passing many possible systems in review, my eye lighted on a small sheet of tea lead, in which I had received a packet of the cheering leaf. "This is the very thing," I said, and I at once cut it into pieces, five inches by three. At one end I made two holes through which I passed eighteen inches of Madeira vine, and the apparatus was complete. Each of the pieces of lead is tied firmly to a branch, and the lower portion turned up, so as to form a kind of cup. Two cuts are then made in the bark, in the form of a V, the point at which they meet being as near as possible vertical to the centre of the cup and the cuts should not extend beyond the perpendicular of its borders. To tie each receptacle in position and make the incisions, will take about one minute, and they may be shifted every quarter of an hour, so that 15 is about the number that one man can work and in going over them the second, and each subsequent, time, they can be emptied into a cup or basin, and that again into a dinner plate or small tin tray, placed on a level, and exposed to the sun, so that the whole day's work may harden into one cake. All this is no doubt crude enough, and is likely enough to be superseded by some more efficient plan before there is much of this work done in the colony, but in the meantime it may save some trouble to such as have trees big enough to stand bleeding. I send a small sample collected in testing the apparatus, but, as the trees are only 14 months old, I only propose to bleed two or three pretty freely, with the view of ascertaining if early tapping is injurious to the health of the plant, and if the yield will be worth the labour of collecting it. So far I can offer no opinion on either of those points, but hope to be able to do so at no distant day. Till that day, however, arrives, and turn the results out satisfactory, I will not extend the cultivation here.

The sample first gathered was pronounced poor and rather dirty, being mixed with a good deal of foreing substauces.

(*Second Report.*)

I did not expect a very favourable report on the sample of rubber I sent in : it was collected from trees probably too young to be tapped, and was the result of experimental trials made at intervals during many months. I believe that besides the true rubber there is in the sap of *Manihot Glaziovii*, another gum of a different character, that will have to be eliminated to get the pure rubber. Fortunately the separationis not a difficult matter ; if the sap be received into a vessel of water the rubber settles and the gum remains suspended ; if left to dry on the stem the rubber strips off and leaves the gum attached to the surface where it remains a black line. Every Ceará rubber tree has its own character as to quantity and quality of sap from a given perforation, and some are mere cumberers of the ground.

A second sample sent was pronounced much better and good offers were made :—the best offer was 2s 6d per lb. for equally clean but less moist rubber (the sample had too much water) if from 5 to 10 cwt. could be given to ship to the Continent of Europe.

(*Third Report.*)

The Ceará rubber is now again in full growth and the sap so thin, that half a gallon would hardly yield an ounce of rubber ; it is now becoming pretty clear that tapping should not be done when the growth is vigorous : the dead season is probably the proper time for operating. Another trouble is, that the quantity and quality of sap yielded by different trees is very unequal : some well-grown trees yield nothing ; others give a scanty yield, of a substance that dries black, and is more gum than rubber. Finally, I have not yet discovered any plan, by which sufficient produce can be collected to pay the necessary labour. I find, however, that a series of small punctures made with the point of a penknife is much more effective than gashes, and perhaps the best means of getting the sap is in small tin vessels stuck to the stem with cobbler's wax, or well cleaned coconut shells might do. It appears pretty clear that unless a cooly collect half a pound daily it will not pay at, say, R1·75. The two coolies will cost 75 cents, then there is rent, value of the land occupied, the cost of cultivation and its share of the cost of an establishment, and all the other odds and ends, that go to cost of production. It may be that there are more rapid methods of taking the rubber than any I have tried, it may be that as the trees get older the sap may be more abundant and more dense, but hitherto I do not see my way. In former times, I have more than once tried the banyan for rubber, but never succeeded in finding any ; but I have now made out how to get it more copiously than from the Ceará, and I really believe of better quality, but my experiments are only in their infancy, and I cannot say much about the result till they are more advanced.

Flying Fox.—A correspondent of the *Town and Country* says that he has discovered a sure preventative for the depredations of the flying fox. His plan is as follows:—"Just take a light wattle stick or bamboo; fix a little paint brush to the upper end in a transverse direction; then have a pot of coal tar. Dip a little of it and then touch the leaves here and there about the tree where the animals are likely to settle. The tar will not hurt the tree. If some pyroligneous acid be added to the tar it will be all the more effective on account of the stronger smell." The tar and acid must be heated considerably to cause them to combine. As this plan has the merit of cheapness and simplicity, we shall be glad to hear that many of our readers have tried it next season.—*Planter and Farmer.*

THE PARAGUAY TEA TREE.

The superintendent of gardens and grounds attached to the United States Department of Agriculture mentions in his last report that the department has recently had numerous inquiries regarding the feasibility of growing in the United States a plant similar to the *Ilex paraguayensis*, or Paraguay tea tree, from which the leaves are stripped and used in infusion as an article of food under the name of *maté*, and gives the following description of the cultivation of the tree, and the method employed in the preparation of this article. In rich soils the tree will attain a height of from seventy to ninety feet; it is said to be confined to mountain slopes, never appearing on table lands nor the broad plains which skirt the river bed, while it is plentiful in all the moist valleys that branch out of the extensive chain of mountains that divide the waters of the Parana and Paraguay rivers. For the preparation of *maté* proper, the leaves are dried, or roasted in cast-iron pans, set in brickwork and heated by fires underneath; when the leaves are sufficiently heated, they are pounded in stamping mills worked by water or steam power until reduced to powder, and then packed in bags by means of presses. There are three qualities or sorts of yerba known in the South American markets. The best is said to be prepared from the young leaves when they are about half expanded from the bud, called *caa-cuys*; the second consists of the full-grown leaves, carefully picked and separated from twigs, and frequently the midrib and veins of the leaves are removed; this is called *caa-mira*; the third is the *caa-guaza* or *Yerva de Palos*, made from older leaves, carelessly broken up with the small branches and leaf-stalks, all of which undergo the roasting and pounding process together. The leaves are also collected and dried in a similar manner to that adopted in the preparation of Chinese tea. This called *maté* in leaf, and is prepared for use by infusion, and taken with milk and sugar in the same way as ordinary tea. *Maté* in powder is also prepared by infusion, by putting into a small vessel about an ounce of the powder, and pouring boiling water over it; as the fine does not fall to the bottom, but remains suspended in the water, the *maté* is taken by means of a sucker, that is, a tube terminating in a small hollow ball pierced with very fine holes. *Maté* contains theine, the same active principle as tea and coffee, but is not possessed of their volatile and empyreumatic oils; it contains less essential oil, more resin than coffee, but less than is found in tea. Chemical analyses show that it contains nearly double the quantity of theine that the same weight of grains of coffee contains, and about the same quantity as tea leaves. The Brazilians recommended *maté* as a nourishing, warm, aromatic, stimulating, and very cheap beverage, its extreme cheapness being a guarantee of its genuineness as it is not worth adulterating.—*Society of Arts Journal.*

INDIA :—CROP AND WEATHER REPORT.

FOR THE WEEK ENDING THE 17TH JULY 1883.

GENERAL REMARKS.—Heavy rain fell during the past week along the Western Ghats from Travancore as far north as Baroda and Surat. At Baroda the river overflowed its banks, stopping communication and damaging property. A break is much wanted in Surat and neighbourhood. In Sind prospects are improving with the rise of the river. Seasonable weather prevails over the Carnatic, but in parts of Mysore and of the Southern Mahratta Country more rain is needed. General, and in most places sufficient, rain has fallen throughout the Berars, the Central India States,' and Rajputana. The tanks in Marwar continue empty and water is scarce, but the recent rain has much improved prospects. The rainfall has been generally less in Assam and Burma, and slightly increased in Bengal compared with the previous week. More rain is, however, required in some districts of Bengal for the rice crop.

MADRAS.—General prospects fair.

MYSORE AND COORG.—Good rain in Simoga and Kadwi districts; light rain in other districts; standing crops in good condition; prospects favourable; no material change in prices.

BURMESE FRUITS.—Every steamer from Moulmain and the south now brings large consignments of dorians to Rangoon. This fruit, the rind of which has a most overpowering and peculiar smell, is in high favour with the Burmese and with many Europeans. Every year special steamers are sent from Rangoon to Mandalay with shipments for the use of the king and the palace, and as they have often already undergone a sea voyage from Moulmain or Tavoy, the condition of the bulk when they arrive at Mandalay after a further four days' voyage may be imagined. But the palace people get about 2 per cent of the cargo good, and they and the villages on the river bank have at any rate the benefit of the smell of the remainder. Another fruit or seed with a still more noxious odour than the dorian finds great favor with the Burmese, who eat it with their *nappi* and curries. It is called *tanienthee*, and like the dorian is just coming into season. The effects of *tanienthee* eating may be experienced by going within a few feet of any one who has been indulging in it. Its odour is as impossible to conceal as the fumes of liquor on the toper after a night's debauch I never heard how, ever of its having any bad effect on the Burmese, who consider it an excellent tonic, digestive and appetiser. I have met with some old stagers amongst Europeans who can stand this fruit too, but their numbers are insignificant compared to the European lovers of dorian. The mangosteen, too, is brought here in largequantities from Moulmain and the Straits. I never heard of any one who did not appreciate this cooling and delicious fruit. We have a few trees in some of the gardens here, but they do not thrive well. In Moulmain the Chinese gardeners grow large quantities, and the fruit is so plentiful here at times, that the price is seldom over R2 per hundred in the season from July to September. Good dorians, be it remembered, sell here at a rupee to R1-8 each! In the Burmese times no subject was allowed to own a dorian tree, which was as strict a Government monopoly as the teak tree, is in our own time. Possibly to this fact may be attributed the small number of fruitbearing dorian trees there are in Rangoon. In the southern districts which have been under British rule so much longer, they are plentiful enough and can be bought at from R8 to R10 per hundred in the gardens, although the price rises considerably when steamers are about leaving for Rangoon.—*Friend of India* Rangoon *Cor.*

IRRIGATION.—The extent to which irrigation has been carried throughout all the cultivated region of the Madras Presidency is truely extraordinary. An imperfect record of the number of tanks in fourteen districts shows them to amount to 43,000 in repair and 10,000 out of repair, or 53,000 in all. It would be a moderate estimate of the length of embankment for each to fix it at half a mile; and the number of masonry works in sluices of irrigation, waste weirs, &c., would probably be not overrated at six. These data, only assumed to give some definite idea of the extent of the system, would give close upon 30,000 miles of embankment, sufficient to put a girdle round the globe not less than 6 feet thick, and 300,000 separate masonry works. The whole of this gigantic machinery of irrigation is of purely native origin, and it is a fact that not one new tank has ever been made by us; and the concurrent testimony of those best informed upon the subject shows that a great many fine works of the kind have been allowed to fall into utter disrepair and uselessness. The revenue dependent on existing works is roughly estimated at 150 lakhs.

MARKET RATES FOR OLD AND NEW PRODUCTS.

(From LEWIS & PEAT's London Price Current, July 5th, 1883.)

IMPORTED FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.

JOURNALISTIC ENTERPRIZE.

Some years ago the enterprize of the *Ceylon Observer* attracted general attention from the fact of its having Special Correspondents at the same time visiting and reporting on tea in Assam and the region between British and Chinese Territory on the North-East of India; on Liberian coffee in its habitat on the West coast of Africa; and on the coffee-planting enterprize in Brazil.

Our programme for the rest of the present year or rather for the next twelve months is perhaps equally interesting, enterprizing and extensive. Mr. T. C. Owen, an experienced Ceylon planter, is sending us Special Letters on the Tea and Cinchona Districts of Northern India which he is now visiting. Mr. A. Scott-Blacklaw is to write on the present aspect of the Coffee-planting Enterprize in Brazil, to which country he has just returned; and another practical planter promises special information in respect of a trip through the States of Central America. Mr. H. Cottam is describing the hard work of pioneering in the Malayan Peninsula; Mr. A. J. Stephens keeps us specially posted in respect of planting affairs and progress in Fiji; Mr. H. Poett does the same service for us in the Northern Territory of Australia; Mr. von Donop's Reports will give the most reliable and practical information for North Borneo (or New Ceylon); while a few months hence we expect to have a series of Special Letters on China, Japan and California, as far as possible bearing on the agricultural enterprize—tea, vine and fruit culture—in those regions. From a Ceylon planter who lately left our shores, as well as from the graphic pen of "G. P. T.," we expect, erelong, to learn the latest and most correct news in regard to the present position of the Java Cinchona as well as Coffee and Tea enterprize; so that with Mr. D. Morris's promise to keep his old freinds in the East abreast of planting progress in the West Indies and adjacent tropical belt:—our programme in respect of information on sub-tropical Agriculture must be confessed to be as extensive as it is unique, and we trust the result will prove intructive and profitable to our readers. We may add that we have already in hand a very interesting report on New Zealand as a field for Ceylon planters by one of our shrewdest, cleverest writers who promises to follow it up by a similar communication on the Western States of America which he visited on the way home. In exchange for the *Tropical Agriculturist* we now receive the reports of nearly every Director of Botanic Gardens in the world, as also all tropical planting journals and the leading British and American Agricultural papers and periodicals—so that there is little chance of anything of importance affecting their interests being missed by the readers of the *Tropical Agriculturist* and *Ceylon Observer*. Our readers will excuse this, perhaps, rather egotistical statement, but it is well that they should be brought into our confidence sometimes in regard to arrangements made for their benefit.

NOTES ON THE STRAITS SETTLEMENTS:—BY H. COTTAM.

Letter No. 7.

ALL ABOUT INDIARUBBER—GUTTA PERCHA GUTTA SUNDEK, AND GUTTA TABAN—CEARA RUBBER (MANIHOT GLAZIOVII)—PARA, OR HEVEA BRAZILIENSIS—INDIGENOUS RUBBER TREES IN PERAK—CAOUTCHOUC PLANTS AND CAOUTCHOUC COLLECTING—LISTS OF VARIETIES—SPECIMENS REQUIRED FOR THE CALCUTTA INTERNATIONAL EXHIBITION TO TAKE PLACE IN DECEMBER NEXT.

Perak, 27th June 1883.

The Malay Peninsula having been as celebrated for its rubber as its tin mines it is matter for surprise that the

trees have not been better cared for and the cultivation extended. It is even difficult to gather information with regard to the varieties of gutta trees, the only person except the Resident who pretends to know any about the subject is a Mr. Wray, and he after promising to give me any information *he might possess* refused to do so, next morning, on the ground that he also *might* at some future time wish to make a report for himself. However, without even a (Wray) of light on rubbers the writer's powers of observation are sufficiently elastic to stretch to the length of a short article on so useful a product. And should Mr. Wray give to the world the benefit of his valuable discoveries at some future time, there is no doubt they will be all the more appreciated by having been bottled up for a quarter of a century.

Within three days of my arrival in Perak, when visiting Kwala Kangsa for the purpose of reporting my arrival to Her Majesty's Resident, I knew that rubbers had been introduced, had grown to perfection, and seed had been gathered from bearing trees and forwarded to Dr. Trimen of Peradeniya, Ceylon, and I see by the last report made by Dr. Trimen that the first lot of seed did not germinate, and that the second lot of seed did germinate and produced healthy seedlings.

Last Christmas I was ordered into Kwala Kangsa to collect plants and pack two boxes for Madras; these were Para or *Hevea Braziliensis* one box of about two dozen, and Gutta Sundek the other, the lattar a hardy indigenous variety. On this occasion, the day before Christmas day of last year, Sir Hugh Low took me round his private experimental gardens at the back of the Residency and pointed out to me several kinds of valuable rubbers and guttas including the famous Hevea in bearing., One thing is very certain—that both Pará or Hevea and the Ceara or *Manihot Glaziovi* require hot moist situations for during my stay on the mountain garden at Gapis, we found both hang fire at an elevation of 3,500 feet above sea level and Ceará would grow better at Cecilia estate, our middle garden, than on the ridges, but did best of all at Catherine garden near the resthouse on Lady Weld's road; here we had trees of Ceara 12 and 11 feet high and bearing seed; the Resident tapped one of them and found the milk flow very feely but being in a hurry we did not wait to see what quantity could be taken from one tree. Mr. Wray with all his vainglory of a secret knowledge of Gutta had not a single healthy specimen to show on the Larut garden near Thaipeng: not that I think they would grow there if planted, for the soil is miserably bad and the garden on Maxwell's hill possesses a western aspect, old Sol turns up about 9 o'clock, over the ridge at the back of the clearing, and before we have time to say "good morning; "Tabbai Tuan, how are you, old fellow?" down comes the rain three inches at a plunge: the result is ye natives take a mean advantage of the anger of the elements, sneak off to their respective shanties, and next day come crawling to work an hour after time—except contractors, whose time is their own, and they please themselves as to the number of hours to work. However, Chinese, Malays and Tamils are all alike in making a clean bolt to their lines when the rain comes. There is still a large quantity of Gutta to be found all over the Malay peninsula; and in Perak, I have noticed very large trees that had been bled and roots of gutta trees cut through in roadmaking with their milk trickling down the cutting or embankment, but being very large trees it is difficult to obtain the leaves, flowers, or seeds to send to experts for particulars, and as mentioned before, the Resident is the only person likely to know what they are. Dr. Trimen in speaking of "Gutah taban putih" says:—"Mr. Low has since expressed some doubt as to this source. They are, however, clearly from a species of Dichopsis (or Bassia?). To judge from the leaf-specimens of Guttah taban putih afterwards sent by Mr. Low, this can scarcely be separable from D. Gutta; the leaves are somewhat broader, and their primary veins more prominent than in that species. Mr. Low writes with them: 'This is the most common of the species of Gutta Percha, but I have never been able to find it in flower; it is a very large tree.'" There still remains the best sort "Gutta taban merah" of these gutta trees to be collected and Mr. Low is energetically endeavouring to secure the seed of this also. Gutta Merah in Malay means red gum or red rubber our Gutta Sundek you will see by Dr. Trimen's report are flourishing at Henaratgoda gardens and 3 feet 9 inches high.

A long correspondence on the rubbers and guttas of the Straits Settlements appeared in the report on the progress and condition of the Royal Gardens at Kew during the year 1881, and an extract taken from it will perhaps be acceptable to your readers interested in new tropical products:—"The Gutta-percha yielded by this species is known in the Straits Settlements as Gutta-Taban. Two varieties are distinguished, Gutta-taban Puteh (white) and Gutta-taban Merah (red). The trees producing the former is said by Dr. Dennys only to differ from the latter" in the fact that its flowers are white instead of red. Gutta-taban, of whichever variety, produces the standard gutta-percha of commerce, and is therefore of most importance." All accounts agree in the general features of the localities in which Gutta-percha producing trees are found to thrive. Mr. Low describes them as growing in the forests on the side of every hill and mountain in Perak; adding, that they do not flourish in the plains.

Mr. Murton states that the tree producing Gutta Taban is most abundant on Gunongs Meeru and Sayong, and Bujong Malacca. A few large trees still exist on Gunong Bubo and the Thaipeng range, while small plants from 1 to 8 feet are abundant on the granite formations in Perak up to 3,500 feet elevation. (The Malay meaning of Gunong Bubois:—Gunong, a mountain, and Bubo or boobu its formation. I have asked several times of old Malay colonists the meaning of the latter word, and some say it means a stamp or impression, others that the coast fishermen give it that name; however, it is a large mountain 5,620 feet about sea-level, and on its summit possesses a peculiar sugarloaf cone rising to a sharp peak and presents a very picturesque appearance from the deck of a vessel crossing over from Penang to Perak. Our mountain Garden at Gapis 3,500 feet is hidden by Gunong Bubo from sea view. The Resident was anxious to cut a road to the top of it, but lately altered his mind regarding the formation of a sanatorium and cinchona garden up there and sent the writer to cut a road to Gunong Hejou instead a large mountain facing Gonong Bubo 4,400 feet only lately I accompanied the Assistant Resident and the Superintendent of P. W. D. to the very top of the peak, breakfasting in the jungle en route and we collected some rare ferns, orchids, pitcher plants, anectacalus, begonias and other plants much in demand by new arrivals in Perak. To return to the subject, In Selangor, Captain Douglas described the trees as growing to a large size on the slopes of low hills in dense primitive forests; they prefer a rich yellowish loamy strong soil, and aspect appers to be of little or no consequence. The young trees require shade and good drainage, the one being afforded by the tree from which they spring, and the other by the sloping nature of the ground in which they grow.

"It does not appear that the juice is collected at any special period. Mr. Low states, however, that there is a very marked difference in the yield of the wet and dry seasons; at the former period an average tree will yield some five catties (a catty = $1\frac{1}{3}$ lb.) while in the dry season it will yield one. Considerable difficulty, by the way, it appears to exist in ascertaining the actual yield per tree, and the difficulty will, owing to native habits of exaggeration, continue until some trustworthy European himself watches the operation. Mr. Murton states that a native gutta percha merchant mentioned 40 catties as the yield of a single tree, while he himself from other information, puts down the yield at from 5 to 15 catties per tree, and never exceeding 20. [Say 27 lb.—not that bad.—H. C.] worth about $20 or £40 per tree, at 3s. per lb. in London. In view of the enormous number of trees which must have been destroyed, if even 10 catties be taken as an average, I should be inclined to accept the higher estimate. In order to procure the juice, the Taban tree is felled and the bark is then ringed in spaces a foot wide and about 15 to 18 inches apart. The upper end of the tree is usually cut off, as this is said to cause it to bleed more freely. Buckets made of wood, coconut shells, or leaves stitched together are used to collect the juice, which is then poured into a hollow bamboo. Thus far the process for all varieties is the same; but in Perak while the Taban merah is simply boiled until it solidifies, the Taban puteh is boiled with water, salt, and Samak bark, the ingredients named being, it is alleged, necessary to cause solidification. In Selangor, where possibly the second variety is not found, the juice is said to be poured into an iron pan over a very slow fire until it assumes the consitency of a very stiff paste when it is moulded into convenient shapes for transport. The destruction of trees involved in this process is so enormous that it seems impossible for the supply to long continue. It is computed that over 7,000 trees were cut down during 1877 in the neighbourhood of Klang, while 4,000 must have perished near Selangore in a single month to furnish the 270 piculs (a picul=$133\frac{1}{3}$lbs.) returned as exported. The estimated annual export from the Straits Settlements and the Peninsula was given as 10 millions of lb. in 1875, which at the high average of 15 lb. to a single tree, would give 600,000 trees. The demand seems always to exceed the supply. The principal adulterant made use of seems to be gutta jelutong. Singapore and Penang are the chief collecting depots for gutta percha, and a failure in supply might seriously injure trade of either port."

Fancy more than half-a-million of trees destroyed worth perhaps two millions of pounds when a moderate supply might be obtained by periodically tapping or shaving the bark. One consolation remains—that millions fo acres suitable to the growth of gutta trees are going begging in the Peninsula, and if Government liked to plant extensively there is nothing to prevent them doing so without further loss of time and thereby keep up the supply of an article becoming more in demand daily. Planters in Ceylon who are early in the field with rubber culture will doubtless be rewarded by high prices for their produce should the supply fall much below the demand in Europe and America.

To resume the interesting subject of Guttas in the Malay Peninsula a few more extracts will be necessary from the report on Kew Gardens, the Director of which, the leading botanist of England takes so lively an interest, any information regarding new varieties will surely interest your readers who are devoting heart and soul to make their plantations pay:—

"Gutta Sundek.—Although I have constantly urged my correspondents in the Malay Peninsula to send me specimens of the now well known tree producing this kind of gutta, no material for its adequate botanical determination has hitherto reached Kew. Dr. Beauvisage, of Paris, obtained fruiting specimens from Mr. Low, British Resident at Perak, and has identified the species. (Contributions á létude des origines bontaniques de la gutta-percha; these pour le doctorat en médicine) with payend (Kefatephorus) Léeru, Hassk. Mr. C. B. Clarke having, however, examined similar specimens from Perak (communicated by Mr. Cantley, Superintendent of the Botanic Garden, Singapore) while elaborating the Sapotaceæ for the Flora of British India, is of opinion that the identification of Beauvisage is erroneous, and that "without fuller material, this tree cannot be safely referred to any genus." If does not, however, seem to belong to Isonandra or Dichopsis. Dr. Trimen, Director of the Royal Botanic Gardens, Peradenaya, states in his report for 1880: "I have during the year, through the kind exertions of Mr. Low, our Resident at Perak, received a consignment of germinating seeds of the second best variety of that country. This is called 'Gutah Sundek,' and Mr. Low informs me that it forms a very large tree 120 feet high, but quick growing. From specimens of the foliage and fruit sent with the seeds it would appear (so far as can be identified without flowers) to be a species of Payena. This is a valuable gift, as 'the Gatah trees in Perak sufficiently large to produce the gum are now very rare, and very great difficulty arises in procuring seeds or specimens.' The young plants are growing vigorously in Peradeniya and Henratgoda." It is as well to mention here that Mr. Low Her Majesty's Resident of Perak, whose name has been so often quoted as a contributor of seeds and plants of different gutta trees, and whose opinion on subjects connected with the same in the Straits Settlements and Borneo has not been forgotten by Her Majesty the Queen for his long and useful services, numbering thirty-four years in the Straits, out of which he told me himself he had only taken about 14 months' leave to England and still works hard in shaping the wilderness of Perak into a flourishing place, paid off the Perak war debt, and commenced a railway, encouraged the mining enterprise—introduced at any cost all tropical plants for trial in the country and is still contemplating vast and costly improvements in the shape of new roads, townships, public buildings, sanatoriums and hill gardens. You will be glad to hear that the Queen has been pleased to knight this veteran civil servant of the Straits. Our Resident is now Sir Hugh Low, K. C. M. G.

One more extract on Gutta Sundek and I will never trouble you with such a sticky subject again as long as we both live:—"With regard to Gutta Sundek or Putch Suudek, Dr. Dennys's report merely contains the following remarks :—It is stated by Captain Murray to be identical with Gutta Taban. Mr. Murton, however, describes it as the product of a tree differing from Dichopsis Gutta in having leaves 'much shorter and broader' more ovate in general outline, and the pilose hairs on the under surfice not so fulvous as in that species. Captain Murray's remark, however, points to the that: commercially Gutta Sundek and Gutta Taban are deemed much the same, the former being only an inferior variety." It is evident from the facts stated above, that the running out of existing natural sources of gutta percha is an event within measurable distance. The preservation of the supply is peculiarly a case for Government and not for individual enterprise. I reproduce here the concluding passages of the convincing report of Dr. Dennys, in the hope that before it may be too late the policy suggested may seriously engage the attention of the Governments of some of our Eastern possessions:—"Comparatively scanty as are the details as yet to hand regarding both gutta percha and caoutchouc, two facts may be considered ascertained: (1) That the demand is increasing and is likely to increase for some time to come and (2) that the supply threatens to become exhausted within a very short period.

"As regards Singapore, there is ample evidence that both Ficus elastica and Dichopsis gutta at one time abounded on the island, and that their disappearance is entirely owing to the want of foresight of those who reaped the first harvest of their yield. In view therefore of the very large amount of suitable unoccupied ground as Government disposal, and which is not likely to be wanted for building or other planting puposes, I would respectfully suggest that measures be taken to ascertain whether an appreciable increase to the future revenue of the colony might not be ensured by selecting and planting suitable localities.

"It may be difficult for the Colonial Government to exercise a direct influence in favour of care and prudence on the part of the native administrations, but much might be done to encourage enterprise in the formation of new Gutta plantations. It may also be worth while to ascertain whether the appointment of European Conservators under the control of the residents, would not achieve the end of preserving a most valuable monopoly to the different Governments, as it may be assumed that the expenses thus incurred would be amply justified by the Commercial results both to Singapore and Penang as depots, as well as to the original collectors and vendors of such important articles of trade. It is not impossible also that fresh discoveries might be made if not of new trees yielding similar products, of sub-varieties which might furnish a commercially valuable substitute while it is more than probable that vast areas of virgin growth might be discovered in the interior portions of the Peninsula by an explorer under Government auspices." The principal obstacles in the way of individual enterprise lie in the time necessary to mature the tree, said to be about 15 or perhaps 20 years at least, and the difficulty of obtaining seeds, saplings, or cuttings wherewith to commence plantations. These can only be met by the Cordial Co-operation of the residents and native authorities, the latter especially needing to be convinced that by aiding the movement they will not be depriving themselves of a valuable monopoly. As regards the former it is probable that but very few Europeans would embark capital which would not yield an out-turn for 15 or 20 years, which I am informed on botanical authority is the average time required before a tree is ready for tapping; many trees indeed are reputed to be 30 years old when tapped, and it would therefore seem that the Government alone could afford to undertake the establishment of plantations.

"At present we are not without data as to probable expense but, as the trees are essentially jungle trees, and equire no care when once fairly started, this may be aken as very low. Assuming each picul of 133⅓ lbs of the best qualities to represent the yield of 10 trees, and to be worth $45,—10,000 trees would give a gross return of $45,000. The available Crown lands in Singapore could probably grow 100,000 trees at the lowest estimate giving $450,000 in the gross out-turn, though this estimate must be mere guesswork until a proper survey be made. But assuming that the annual income of the colony could be increased by $200,000, or less than half the sum named, the matter seems worth attention; while there is reason to believe that even if the yield from the native states continued at its present figure the additional supply would soon find a market without materially lowering the price." Hear, hear, let the Straits Government have foresters the same as Ceylon though yours were only appointed when nearly all the Ebony and Satinwood had been murdered and shipped to Europe. With the Straits Settlements it is not too late to save the gutta percha and rubbers until then."

The Calcutta International Exhibition Committee having invited the Perak Government to contribute samples at the coming fair at the City of Palaces, the Resident has called upon his officials in various departments to prepare samples in time for shipment to Calcutta. Amongst other local industries such as paddy and rice, sugar, tobacco, rattan, mats and agricultural instruments, our principal Show from Perak will be specimens of tin in its various stages of preparation for export, these Mr. William Scott the inspector of tin mines in Larut will no doubt do justice to, for I know he has stored already an interesting collection. Next comes gutta-parcha and rubbers. With samples of parchment coffee, clean coffee and perhaps a sample of Liberian coffee to be contributed by the superintendents of the Government experimental gardens at Gapis and Larut, also samples of tea (two samples from each garden). Captain Schutze has been asked to contribute, and no doubt he will do so with samples of machine-cured coffee. H. C.

LONDON CHARGES ON TEA: HOW HOW "THE GILT IS TAKEN OFF THE GINGERBREAD."

We have before us Account Sales of 3,374 lb. Ceylon tea ranging from 1s 4½d per lb. for pekoe down to 6d for dust. The gross proceeds amounted to £276 3s an average of over one shilling per lb. This is not bad as times go, but what do our readers think os "charges" aggregating £49 11s 4d, or within a few shillings of £50, on £276, not very far short of 20 per cent on the amount realized at public sale! The net proceeds are thus reduced to £226 8s 8d, or about 10d per lb. and from this will have to be deducted cost of cultivation and manufacture, of packing into leaded chests, of cart and railway freight to Colombo (much heavier than in the case of coffee, in consequence of the greater bulk), shipping, export duty and port dues, and local agency charges. When all such deductions are made, it is evident that the net profits to the owner of the tea estate will be reduced to microscopic dimensions. The duty of exercising all possible economy in regard to such local charges as are under the control of the owners or superintendents of tea estates is obvious, and probably cart and railway charges may be ultimately lowered. But, whatever else is done, it is quite clear that a combined and strenuous effort must be made to get London charges reduced, especially the exorbitant item termed "London Dock Charges." In the case under review, that item constitutes considerably more than one-third of the whole amount of charges, and appreciably exceeds the cost of freight of the tea from Colombo to London. The steamer freight of 128 half-chests of tea was £16; the London Dock charges are put at £18 3s 5d or £2 3s 5d in excess of freight. And what adds insult to injury in this matter is the fact, that the owner of the tea has this extortionate charge to pay mainly for a process which does his produce the greatest possible amount of injury; that of turning out the tea on cold, damp and probably dirty floors. The truth is that tea is traditionally fair game for harpies from those who infest the London Docks and the Custom House, to the middlemen and finally the grocers, who look on 6d per lb., as the very minimum of *their* profits, another 6d going to the Imperial Government in the shape of duty. But all else is over-shadowed by the atrocious imposition of "London Dock Charges," for we feel perfectly certain that in the vast majority of "breaks" of tea, half-a-dozen packages, selected with discrimination, would give a fair average for the whole. But even if, for duty purposes, every single package has to be emptied out and repacked, we fail to see how, such a sum as £18 3s 5d can be necessary for 128 halfchests, an average charge of very nearly 3s for each half-chest! We do not forget that some portion of the charge constitutes the rent due to the Dock Companies, but even so the exaction is exorbitant and to the grower of the produce ruinous,—for he actually pays for injury done to the contents of his packages. The other London charges which seem susceptible of reduction, are thus stated in the case in question:—

Brokerage, 1 per cent	... ...	£2 15s 3d
Sale charges	.. ..	1 5s 0d
Together...	...	£4 0s 3d

When breaks are large, we should think a consolidated charge of 1 per cent on the gross proceeds, ought to be sufficient for brokerage and sale charges. Dock charges, brokerage and sale charges aggregate £22 3s 8d in the case we are noticing, and we should be glad if other receipients of Account Sales, would compare notes with us in regard to these particular charges, which in this special case are not far short of one half of the whole charges against the Invoice: £22 3s 8d against a total of £49 14s 4d. The balance of £27 10s 8d is made up of items against which, we suppose reasonable complaint cannot be made, unless £16 freight for 128 half-chests is rather high. The items apart from London Dock charges, brokerage and sale charges, are:—

	£.	s.	d.
Sea Insurance, £285 at 25s and duty	3	12	0
Freight 350 at 50s per 50 feet	16	0	0
Fire insurance	0	10	0
Interest on charges	0	10	7
Commission and guarantee ...	6	18	1
Total ...	£27	10	8

The local agents to whom the London charges were referred, stated in reply:—"The position of tea as regards London charges and trade allowances, is most unsatisfactory, but there is no means of avoiding the items you call attention to and unless shippers in India and China unite to demand an alteration, we fear matters will go on as at present. The high dock charges are perhaps in part due to the very objectionable practice ot bulking India and Ceylon teas in London."

THE PLANTING DISTRICT OF MONARAGALA, CEYLON.

At Bibile, a tavalam road from Alutnuwara crosses the Badulla-Batticaloa cart road and proceeds along beneath the Madulsima range, in the direction of Monaragala and, as my friend and companion's route lay homeward, there we parted company. Thus my course was with Madulsima on my right, the low-country and some grass-covered round-topped hills upon my left. The distant ranges were bluer than I ever remember seeing them; can this be the reason why Nilgala a rocky hill in this neighbourhood is so called? For the first time in my whole route were paddyfields met with being cultivated during the south-west monsoon, it having hitherto been in continuation of a rainless country during these months, except, when watered by an occasional thunder storm.

There was little along this road that was interesting; the continual chena broken by paddyfields with patana-like hills around, and as I progressed the Madulsima range after being skirted was left in the distance. A very uninviting resthouse at Madegama was passed unentered, said to be 12 miles from Bibile though it appeared to me far less. From this point the road hitherto in good order, began to show less signs of care and attention, and I think I may say everything assumed the same appearance. In places I had to dismount to lead my horse under over-hanging thorns. At noon I found I was passing the Monaragala hill which suddenly became conspicuous on the left, with its forest and clearings, and along ravines large masses of white rock piled upon each other and spotted over every clearing.

After reaching Nakal the road turned more towards the range and at Mupane almost touched it, which must be over 30 miles from Bibile. Much cannot be said of this rising village except, that it has the reputation of being very unhealthy, and that owing to the enterprize of the residents, fresh meat is procurable twice a week and beer and brandy and other drinks to the heart's content. My route, however, lay along a number of buffalo tracks to the foot of the hills, after which I finally reached "Sirigalla" estate up a zig-zag path, through some very fine forest passing on my way to Monaragala pansala.

After a week in Government resthouses, it was quite a luxury to find myself again among the comforts and cleanliness of a European's household. The systematic order contrasted with the continual solicitation required for the hundred and one wants of we dependent whites upon the aid of others. I was 1,500 feet above the sea amongst very promising Liberian coffee and cocoa, from the verandah spread out a panorama before me of the whole eastern feature of the Uva chain. At my left, enveloped in clouds was Nakwana in the far, far distance. Nearer lay the Wellaway Peak and above it Duffus very conspicuous, and the Haputale hills. The locality of the Ella Pass was just distinguishable, then Namunakuli, and Passara right in front and to the right Madulsima and Hewa Eliya, with a more rugged and bold skyline. Pricking up nearer, were the Monaragala Pansala, Peak and the forestclad hill lying to the south of the range. There I had a good day's rest, tended my tick-bites which were beginning to look serious, the penalty of a low-country trip.

Next day I had an opportunity of seeing something of the district, so we clambered to the top of the ridge above "Normandy." I was struck with the total abscence of all kinds of palms. There were rocks and precipices, but neither kitools nor dotalas, rattan canes were met with up on the highest point of the range. Most of the forest trees of the coffee districts were to be seen, keena and cattabodde very prevalent, with lofty nuga trees the higher branches of which, were out of the range of small-shot. Ubberiya, dawata, wal buruta, millila and many other of our forest trees were frequent and of all districts I have visited I never remember before observing such a uniformity of soil. The land throughout is covered with boulders, in many places heaped upon each other so that a subterranean passage is sometimes the easier one to choose. These rocks are highly felspathic, and felspar is every where met with in many stages of disintegration, from pure white to a crumbling into mould. An analysis of some of the most marked kinds would be very interesting and would denote what are the valuable properties the land possesses. The soil resulting from the decay of these rocks should surely be good and lasting. It is usually a brownish red in colour varying in places to a chocolate, in others, somewhat lighter in colour but usually, it is deep and good with no great difference below in character; thus of great depth and even quality. The higher blocks did not always appear to have the depth of soil possessed by those at lower altitudes, at least it was not so evenly deep, yet most of it was good land. The chief object of all proprieters should be to plant their blocks up with that product which is most suited to the soil and climate and in doing this I fear *Coffea arabica* must not be in all cases strictly adhered to. I saw good coffee bearing heavily and well and no very great display of leaf-disease, yet enough to encourage the wish that other economic plants might be tried instead. Cardamoms were growing well, with every promise of proving a paying investment and their extension should be encouraged. I thought they did better above 2,000 feet, rather than below.

Cocoa, however, upon the lower blocks was certainly the most promising cultivation. Where sheltered and the soil deep and moist I saw growths I have never seen excelled elsewhere. The pods, notwithstanding a month's drought were full and large, the stems smooth, healthy and robust. Upon ridges they were not equally fine and I think there should be belts of shelter and shade trees, so as to have as much of a clearing as possible lying beneath their protection There was no indication of really injurious winds, those experienced being more dry and somewhat hot and for these nothing could be better protection to the cocoa, than ridge-belts of well foliaged trees. During the north-east monsoon the wind is strong, yet from what I saw I think there is none likely to materially harm most cultivations and certainly not cocoa, with ordinary provision. Cinchona too, had been planted, it was most of it too youngto form any certain opinion of its success. I spent some days upon the hill and met with great hospitality from the residents who I may say number six, far more than I expected to meet in so out-of-the-way a district.

The one great want at present is an outlet. There are six Europeans working away upon an isolated hill. having their communications with other disticts cut off with all the many difficulties of pioneers to contend with. Labour precarious, supplies not absolately certain, fever not unfrequent. Time was, when all these difficulties might have been called fate (kismit) but surely they are now surmountable. The present outlet is by Passara, right across the course of the streams and finally up a very steep and consequently never-in order bridle-road. It is now generally considered that the most satisfactory point to reach is Yalkumbura upon the Batticaloa-Badulla cart road, to which a tavalam road could be taken from the hill in about the same distance as Passera without any abrupt rise or fall and without crossing so many and in wet weather dangerous rivers,—indeed I believe there will be none or at most only one. Much of the existing tavalam road to Madagama could be utilized. The chief aim, however, should be to have a well-traced, and afterwards well maintained outlet, so that the subject may be settled, once and for all. The question at present is whether this should be done by the estate proprietors or by Government? It is an absolute necessity, not only for the district, but to induce a Government official other than an assistant to come this way occasionally, and so see things himself.—W. F. L.

Blue-gum Culture, on the Nilgiris.—Now the monsoon is fairly on us. the planting of this highly useful tree is being carried on most extensively, and prices for plants range from R3 to Rupees per 1,000. We would advise our friends engaged in this enterprise to use plants in baskets if at all procurable. The Blue Gum planted under ordinary circumstances is very capricious as regards growth when first planted; therefore every precaution should be taken by planters, several plots which have come under our notice having been planted up not less than four times.—*South of India Observer.*

The Life of Trees.—The ordinary life of unprotected timber structures is not more than twelve or fifteen years. Timber exposed to moisture in the presence of air, especialyl if in a warm place, or to alternate wetting and drying, will decay rapidly. Sap and moisture retained in timber, by painting or closing in the sticks before they are seasoned through, will cause decay of a very insidious kind, as it works in the interior, leaving an apparently sound exterior or skin, which is the layer that had an opportunity to season. Paint on unseasoned timber is, therefore, more hurtful than serviceable. Large sticks of timber dry so slowly that, before they are seasoned throughtout. decay may begin; and hence pieces of small scantling are preferable to large ones. Dampness and a lack of ventilation combined will hasten decay. The best seasoned timber will not withstand the effects of exposure to the weather for much over twenty-five years.—*Lumber World.*

The Indigo Crop does not promise well this season. The *Indigo Planters' Gazette* says:—"The saying that a good mango season means a bad indigo one. has been strikingly verified this year in Purneah. One mishap seems to have followed another. No rain during the preparations, May drought, heavy rain in the middle of June, and early floodings from most of the rivers. What little plant there was has been considerably damaged, and the produce up to the first week of July has been wretched in the extreme. Most of the indigo concerns have had to drop down to few vats only, while others have literally had to close manufacturing altogether, so as to allow backward plant and khoonties to grow. Since the heavy June rain the weather has been very hot and close; indeed, a little rain now would be highly advantageous to the indigo on the high lands. What with the backward crop, bad produce, and the inability of planters taking advantage of the prevailing fine weather to push on *mahai*, proprietors scarcely hope to realize half of the out-turn first estimated for."

Cinchona Plantations in Bengal.—The result of planting operations in the Government cinchona plantations in Bengal during 1882-83 shows a total of 50,000 trees less than in the returns of 1881-82, which is attributed to the uprooting of a large number of hybrid varieties, and about 100,000 red bark trees. The total number of cinchona trees of all sorts at the close of the year was 4,711,168, and the crop was the largest yet harvested. amounting to 390,980 pounds of dry bark. The whole of the produce was made over to the factory, except about 41,800 pounds of bark which, at the request of the Secretary of State, was sent to London to be there converted into various forms of febrifuge, and returned to this country for trial by the Medical Department. The revenue derived from the sale of febrifuge, seed, plants, and bark amounted to R1,52,807, leaving a profit of R66,284, which is equal to a dividend of 6½ per cent on the capital. The cost of an equal quantity of quinine at R96 per pound would have been R4,01,328, whereas the febrifuge used cost R68,988, leaving a saving to the Government and the public of R3,32,340.—*Pioneer.*

Sugar from Melons.—Southern farmers do not seem to know that a beautiful and excellent article of sugar can be made from water melons. Press the juice out of the melons, boil it down and treat in about same manner, as when making sugar from maple sap. The sugar will be found clear and sweet, and entirely free from the sharp or caustic taste which is usually found in the best sorghum sugar, being as pleasantly sweet as the water melon itself. A gallon or gallon or barrel of the juice will make as much sugar as the same quantity of maple sap. More gallons of juice and pounds of sugar can be made from the melons grown from an acre of land than from beets or sorghum grown on the same space of ground: and then, as every farmer knows, it is so much more pleasant to raise, gather and handle melons than beets, which must be dug from the earth and washed. Farmers of Arkansas can make experiments on a small scale at a slight cost, to test the maoter to their own satisfaction, and we think they will not only be plaesed with the result, but they yet bacome one of our reliable staple productions.—*Hot Springs Sentinel-Star.*

Correspondence.

To the Editor of the Ceylon Observer,

TASAR (SILKWORM) CULTIVATION.

19th July 1883.

DEAR SIR,—In Major Coussmaker's Report on his experiments in 1881, there are one or two points which call for the attention of all interested in the cultivation of the wild silk-producers. The experimental clearing established at Poona (the expenses of which are defrayed by the Indian Government) consists of a plantation of *Lagerstrœmia Indica*. The plants are grown at the distance of one foot apart in the rows, seven feet between each row, and the shrubs are kept topped at the height of four feet. All branches are removed with the pruning-knife as fast as they are bared of leaf by the worms, and in this way a constant supply of succulent foliage is produced.

Major Coussmaker states that in the Ahmednagar Collectorate the natives habitually cut back their trees very hard, two-thirds of the trees being pollarded each year, and that this system of cultivation is "most favourable to the Tasar worm, for the constant lopping of the trees and burning of the branches and leaves harass the squirrels, birds, lizards and wasps, while the fresh shoots which spring from the mutilated trees afford the best food possible for the worms." There can be no doubt that the natural foes of the worms are in this way put to a great deal of inconvenience, and that the constant attention rendered necessary by the process of regularly pruning the shrubs, which Major Coussmaker recommends, makes the destruction of lizards and other enemies a rather easy matter, but I cannot concur in the opinion expressed as regards the suitability of the tender foliage as food for the worms.

In the cultivation of the mulberry-feeding worm, *Bombyx mori*, neglect to supply mature leaf has largely tended to increase the debility which either too great kindness, or too little care, has engendered; and it seems reasonable to suppose that the wild worms, which in their natural state never devour the young leaves unless driven to do so by a scarcity of food, should become speedily debilitated when fed on immature leaf. In attempts made to rear the *Atlas*, *Mylitta* and other larvæ indoors on branches, the stems of which are plunged in water, it is invariably found that the foliage becomes, sooner or later, distasteful to the worms, and although the strongest of them may escape disease and spin good cocoons, the majority are more or less affected by the excessive moisture in the leaf. The same deterioration is produced by severe or frequent pruning.

Major Coussmaker attributes his want of complete success to the existence of some climatic influence that he was unable to contend with, or to the worms having been attacked by small spiders, mosquitoes, or other minute enemies. It is quite possible that many of the worms were killed by insects, but detection in cases of this kind should not be difficult, and I think it almost certain that it was the want of properly matured leaf that caused his losses, since he himself admits that some of the worms commenced spinning before they were full-grown.

M. Wailly, in one of his reports on silk-producing worms reared in London, mentions an instance in which a number of *Selene* and *Luna* larvæ which were fed upon a nut tree, that had been tapped and heavily pruned, died one after other, although other worms from the same broods of eggs reared on other trees growing close by, but unpruned, spun very fine cocoons.

It is of the utmost importance that the cocoons produced, whether of Tasar or other wild species, should be as free as possible of the cement which the worm naturally secretes. Mr. Thomas Wardle, in his recently published handbook of "The Wild Silks of India," states that Major Coussmaker has succeeded in obtaining perfectly white silk by causing the Tasar worm to void all its cement before allowing it to spin its cocoon, but particulars of the method are not given. Inasmuch as the quality and quantity of the cement in the wild cocoons depends largely on the health of the worm, it would seem that in the production of Tasar silk by Major Coussmaker's method a decrease in the amount of the cement must be accompanied by a corresponding loss of vitality in the worm. And this is a very serious consideration, because it raises a barrier in the way of progress towards the domestication of the insect, for it would, of course, be useless to attempt to utilize for breeding purposes, cocoons spun by worms whose constitutions had been impaired in this way. Any naturalist, I suppose who has studied this subject, will admit that the silkworm when it is prevented, by any cause, from commencing to spin its cocoon at the appointed time, is more or less injured by the delay; and there is also a considerable loss of silk to be taken into account. It is only by rearing one brood after another and by feeding each successive generation on the same kind of plant that any real progress can be made. The moths of this species do not readily pair in confinement, at first, and it would add considerably to the cost of production if the sericulturist were compelled to rely on any of the wild insects he might procure in the jungles for renewing his stock.

It is in another direction that we must look to effect an improvement—from the manufacturer's point of view—in Tasar silk. What is required is that the food-plant should be of such a nature that the worms reared on it would secrete as little as possible of the cement, which at present so greatly depreciates the value of the cocoon; the plant should also be one on which the worms are easily reared. If these conditions are fulfilled, one of the greatest difficulties in the way of Tasar cultivation will have been removed. There are probably many indigenous trees which might be utilized with this object, but prolonged experiments will be necessary to enable us to ascertain the most suitable, and in this investigation the chemical analysis of various kinds of foliage might be of great service. In judging of the effect of the food on the silk, it is important to bear in mind that temperature and other surrounding circumstances exert some influence on the colour and texture, and it is not safe to infer from the appearance, size and weight of a few individual cocoons that the food-plant on which they were produced is beneficial or otherwise. The Tasar worm is extremely polyphagous, as much, perhaps, in the Ceylon hills as in the low-country; and it is impossible for worms proceeding from such a parent stock to produce cocoons of uniform character until they have been reared through several generations on one species of food-plant. In a former letter on this subject I mentioned, I think, that the Tasar worm was found in the hillcountry feeding on the loquat and the Avocado pear trees. I have not had sufficient time to ascertain whether either of these would be of use in the direction indicated, but experiments might easily be made with them. The sapu is another tree from which good results might be expected, but as I have not yet heard of a single instance of the Tasar being found in a wild state on this tree in Ceylon, it is drobable that a good deal of patience should be required in inducing the worm to adopt it. Whatever trees are selected, it is essential that they should be perfectly healthy: no foliage that has been 'forced' by heavy pruning, by manuring, or by irrigation, can be good food for the worms, and trees that are shaded or deprived in any way of their proper quantity of sunlight are equally objectionable.

I have mentioned the sapu as being probably one of the trees best suited to our purpose. In "Silk in India," compiled by Mr. J. Geoghegan, I find the following note on the silk of *Antherea Assama*—(a closely allied species if not a variety merely of *A. paphia*):—"Champa: the silk produced from the worm feeding on this plant (*michelia*) gives the finest and whitest silk." There is another tree which may probably be made use of, since it is commonly met with in the jungle over 4,000 feet elevation. It is the tree the leaf of which so closely resembles the tea leaf that coolies are hardly able to distinguish them. It is probably *Eurya serrata*. The Atlas worm feeds on this tree in India, and there should be no difficulty in getting the Tasar worm to feed on it also. In Dimbula worms of Atlas, Selene and Mylitta have been reared on the Avocado pear and on loquat, and in their wild state these three species may be found on the so-called "patana oak," the *kahata*.

There are other species of wild silk-producers, the cultivation of which might give even better results than the Tasar, but the acclimatization of these is a matter of time, and the commercial value of their silks has yet to be ascertained.—Yours faithfully,

PERCY N. BRAINE.

THE COFFEE PLANTING ENTERPRIZE IN CEYLON: ITS DRAWBACKS AT PRESENT.

July 24th, 1883.

DEAR SIR,—The purport of my last letter was an endeavour to shew wherein our mis-directed remedical measures for H. V. had failed, and that the further blunder of indiscriminate cessation of cultivation was hardly surpassed by the next move, when cinchona planting received exclusive attention, even to the extent of being put alongside the already heavily handicapped coffee tree, and yet we are surprized at the falling-off of its productive power! Such treatment I hold, even in the palmy days and under the most favorable circumstances of immunity from pests, suitable seasons, and young trees, could have but ended disastrously. Verily it is a matter of surprize that coffee has life left in it to tell its woeful tale.

Exhaustion, unsuitability of soil and altitude, are elements in the combination, the noticing of which I approach with less trepidation that I should have a few years since when coffee was our only resource, for no one cared to believe that either of these contingencies were applicable to his estate. Here, too, the "fungus" was made the scape-goat! It goes without saying, however, that had the possibility of such been sooner recognized, attention would have been turned to substitutes before they were so rudely forced upon us.

You will remember the howl of indignation that burst on Sir Hercules Robinson * when he ventured to insinuate, in a memorable dispatch, that coffee might not prove a permanent industry in Ceylon. I doubt not, but that he was led to this rational conclusion in reflecting on the habits of fruit-bearing trees in more temperate climes, for do not they all require frequent renewing, and replacement when at length the artificial methods adopted in forcing crops impair their vitality! Might we not have read a lesson from nature itself? Are not all fruits and other trees sooner or later replaced when they are left to nature's laws? In short, is it not a recognition of this law which renders rotation of crops imperative if they are to be remunerative? Why therefore should coffee alone have been exempt in any respect from a law so universal? I say that an earlier recognition of such a possibility would have saved much anxiety and a great deal of money. But because such is undoubtedly the case and because the all-pervading fungus latterly swept away the small and fitful profit margins, is that any good reason why every estate and every district should be deemed worthless as coffee producers? Where exhaustion arises from age or where estates in coffee never could have been profitable there may yet be a bright future in store for them, for I agree with Mr. Bosanquet when he says there is not an acre of opened land that may not by dint of patient and intelligent energy, be turned to advantage in some product.

Exhaustion through the wash of years, I look upon as irremediable, and I think it may not be out of place here to sound a note of warning to those who meditate the substitution of tea for coffee: where nothing but subsoil remains disappointment only can result, more especially so where the "lay" is steep and the land cannot be worked up. The existence of such places is no reason why the whole industry should be branded. The fungus but accelerated by a few years only the end of such; on comparatively young estates and with rational treatment, good crops may yet be counted on.

It would not be difficult to name many old estates which for as many years have given annual returns of from 30 to 40 per cent. on the original cost and opening out of the land; where can we find another agricultural industry that has better earned for the soil the short rest that substitution of another product entails; or for that matter the more lengthened one of utter abandonment, or any industry that less merits the indiscriminate declamation of croakers? *Grub* comes next in my list, and although a more tangible pest than our "bogy" fungus, the means of ridding ourselves of its ravages must be similar to those I suggest for the more subtle enemy. Few planters believe in the formidable proportions which these insects have reached. A tree is seen almost leafless, and it is at once concluded that *H. V.* is the cause thereof. Of recent years there has been so little disturbance of the soil that their increased numbers have not attracted attention. I have frequently been assured by neighbours that they had no grub, but on careful search being made there they were in large numbers. I am strongly of opinion that the ravages of these insects have more to do with the falling-off in the bearing power of our coffee trees in the younger districts of Dimbula, Dikoya and Maskeliya, than all the elements in the combination put together.

The instinct and voracity of these creatures are marvellous, for they will destroy and greedily devour almost any vegetable or animal substance they fall in with, and they have a wonderful faculty for selecting first, as food, that which is most palatable to them. Coffee rootlets seem to be their special weakness; but even the bitter rootlet of cinchona, in the absence of the former, is not despised by them, nor is that of grass and almost every description of weed. I am told that they will not attack the roots of tea bushes, but of this I am very sceptical, and, were I planting it where I knew they existed, I should adopt every possible means of reducing their numbers.

In dealing with this pest, we have not been content with a patient and persistent course of ameliorating measures. The well-known applications of lime and salt as insect destroyers have been scouted because forsooth some pseudo experimentalist gave forth that he had seen the insects living thrivingly in these. If they are effective in other countries, when all the conditions are observed in rendering them so, why should they not be so here?

* Was it not in a speech of Sir Wm. Gregory?—ED.

With grub, as with leaf-disease, only some drastic application for their utter extirpation once and for ever was considered worthy of a fair trial. Similarly as with the fungus, I contend that we have unwittingly fostered the insect by a system of applying manure which obtained some ten years since, and also by the nature of the fertilizers themselves. The soil on being slackened up immediately round the stem of the tree was scraped away by hand in order that as few roots as possible might be disturbed, and coconut poonac and castor cake were spread in the hollow thus made and covered up with earth, thereby forming a soft mound into which the beetle, with no difficulty, burrowed for the depositing of its eggs. Here were all the conditions essential to grub life. The soil was undisturbed by coolies working amongst the coffee; incubation went on apace; sufficient sunheat reaching the spot through the centre of the tree, which is always kept handled out. The grubs, on reaching that stage, found they were indeed in a bed of roses: turn where they would coconut and castor cake were in abundance; not only that, but a mass of tender rootlets were ready for their operations. Small chance of a single egg or larva perishing here, and little wonder that the tree rapidly shed its leaves; but a short space of time was necessary to deprive it of every feeding rootlet. Ever since there was a coffee estate there has been grub, but not to the extent we have it now, and if we are to reduce their numbers we shall only succeed by rendering their conditions of existence hard. This can be accomplished by applications of fertilizers obnoxious to the insect, dug broadcast into the soil. In spreading the manure over a larger area we not only induce a larger root surface, but we reduce the chances of every rootlet being reached and make grub life harder.

From constant communication with the Entomologist for the Royal Agricultural Society of England, and through experiments carefully conducted here, I have come to the conclusion that rape cake, in which mustard seed forms a considerable proportion, is a remedy as well as a valuable manure, for I have found it is the only substance of the kind that they cannot exist on. Castor and coconut cake they seem thoroughly to enjoy.

Miss Ormerod found that forty-eight hours' confinement in rape cake kept moist was sufficient to kill wire-worm outright. This ought to be encouragement to those who are continually looking for specifics to give rape cake a fair trial. In case of disappointment, however, I should advise those who purpose experimenting to be careful that they procure the cake I mention, as I understand pure rape is shipped from many parts of India, into the composition of which no mustard seed enters. Manures in the manufacture of which sulphuric acid is used, such as dissolved bones and superphosphate of lime, are also very offensive to grub.

The only antidote with which I am acquainted and which at the same time is innocuous to the roots of plants, is powdered mustard, but my experiments with it scarcely warrant me in stating that the quantity used, to be effective, would be practicable, owing to its cost. Later on I shall be glad to communicate the result of my experience.

I may mention that on my attention being directed to the use of mustard seed by hop farmers in some parts of England, as a remedy for wire-worm, I procured a few bushels, which have had the most satisfactory results in expelling the insect from the soil on which it was sown broadcast and mulched in green before it reproduced seed.

Again I have occupied more of your space than I had intended; however, I promise you that my next will be more brief as well as the final one.

DIOGENES.

THE TEA PLANT AND ITS CEYLON ALLIES.

Ambagamuwa, 29th July 1883.

DEAR SIR,—I enclose 3 packets marked A, B, and T. T contains tea leaves, Assam hybrid. What are the leaves in A and B? They are from a plant I have noticed in a tea clearing and also growing wild in the jungles about here. Is this an indigenous tea, or what? The flush of the latter has a reddish tinge,—Yours,

PLANTER.

[The leaves in A and B are those of a species of *Eurya*, a genus of plants closely allied to the tea plant, and one of which is the niya-dessa of the Sinhalese. These plants spring up in all the tea estates in the higher districts, and are called wild tea plants. Ask your correspondent to send a specimen in flower or fruit.—W. F.]

CARDAMOM POOCHIES: INFORMATION WANTED.

Yatiyantota, 1st August 1883.

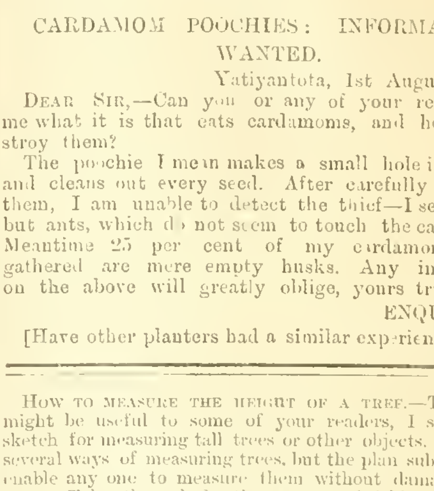
DEAR SIR,—Can you or any of your readers tell me what it is that eats cardamoms, and how to destroy them?

The poochie I mean makes a small hole in the pod and cleans out every seed. After carefully watching them, I am unable to detect the thief—I see nothing but ants, which do not seem to touch the cardamoms. Meantime 25 per cent of my cardamoms when gathered are mere empty husks. Any information on the above will greatly oblige, yours truly,

ENQUIRER.

[Have other planters had a similar experience?—ED.]

HOW TO MEASURE THE HEIGHT OF A TREE.—Thinking it might be useful to some of your readers, I send you a sketch for measuring tall trees or other objects. There are several ways of measuring trees, but the plan submitted will enable any one to measure them without damage to the trees. Take three laths, the same as bricklayers use for tiling and nail them in the shape of the framing; B B must be of equal length; B and *a* being placed on the ground,



the eye must follow up the longer lath (*d*, *d*, *d*) until it is in a line with *c*, the top of the tree or object you wish to measure. The frame must be placed as level, with the bottom of the tree as possible. Should the ground be very uneven you must give and take accordingly. You will see that *a* to *c* is the same length as *c* to *c*, and thus the height of the tree is obtained.—E. COVENEY, in *Journal of Horticulture.*

SULPHURIC ACID *VS.* CARBOLIC ACID FOR DESTROYING WEEDS.

By an inadvertence I am made in answers to correspondents, page 330, to recommend carbolic acid for destroying weeds. I have never done so, but did some time ago call attention to the value of sulphuric acid for that purpose. As some confusion appears to exist in the minds of many gardeners concerning the two acids, it may be well to explain what they are, and something of the uses to which they are applied. Carbolic acid is a substance resembling creosote, and is obtained by the distillation of coal tar. I have used it quite recently mixed with oil as a disinfectant with much success among animals, but have never known it to be regarded as useful for the wholesale destruction of weeds. Sulphuric acid or oil of vitriol, on the contrary, is a wellknown destroyer both of vegetable and animal life. It is obtained by an elaborate process from sulphur and nitrate of soda, which is fully explained in Brande's "Dictionary of Science," where, too, in a lengthy account of its various properties, it is stated that "its affinity for water is such that it rapidly absorbs it from the atmosphere, and when mixed with water much heat is evolved. It acts energetically upon animal and vegetable substances, generally charring them, and often, as in the case of sugar, with singular rapidity." I may add that when using it for destroying weeds, I have noticed that the heat imparted by the acid to water is so great, that it may instantly be felt outside a waterpot after the half pint of acid is poured into a gallon of water.

EDWARD LUCKHURST.

LIME LEAVES AS FOOD.

TO THE EDITOR OF THE JOURNAL OF FORESTRY.

SIR,—It is perhaps not generally known that the young leaves of the Lime have a pleasant, sweet, mucilaginous taste if eaten raw or boiled as a vegetable, or used for salad. I and my family have used them for years.

Often, when weary and hungry after some hours' toil surveying, I have refreshed myself by eating the young leaves of the Lime. Before garden produce becomes plentiful, this palatable substitute might, if known be more beneficially used.—J. CHARLES KING.

FOREST TREE PRUNING.

SIR,—Might I presume to ask Mr. M'Corquodale, Scone, through the medium of your Journal, whether, in his excellent paper on Pruning, read at the last annual meeting of the Scottish Arboricultural Society, he is correctly reported where it is stated, with reference to the point at which branches should be foreshortened—'These should always be cut at a lateral small branch or twig of an *upright* growth.'

My reason for asking is that my experience leads me to practice rather the opposite to what he is reported to recommend. I agree with him as to the point at which the cutting should take place, viz., at a small branch or twig, but, in place of one of an *upright* growth, I would, if possible, select one inclined rather in an opposite direction. A branch or twig of an upright growth will, sooner or later, assume the force of a competing leader, and attract much of the sap which should find its way up the main stem. In my opinion, all branches of an upright growth should be speedily checked in the manner described, as also all others of a straggling habit. With the exception of the remark to which I have referred, I am glad to know that my opinions in this important branch of forestry altogether coincide with those of such an authority as Mr. M'Corquodale. FORESTER.

VEGETABLE PRODUCTS AT KIUNGCHOU.

A recent report from Kiungchou states that the quality of sugar produced is slightly below that of Swatow, but somewhat better than the Formosan article. The export of brown sugar always exceeds that of white, the reason apparently being that the former is better suited for manufacturing purposes, while the latter goes to Canton and elsewhere for use in sweetmeats and sugared fruits. Two varieties of the cane are cultivated—the "water cane" and

22

the "bamboo cane"—the juicy stalk of the former of which is is much eaten by the natives in summer, while the latter furnishes the sugar of commerce. The method of propagation is extremely simple. In the first month of the year the tops of the best stalks in a field of sugar-cane are lopped off and stuck in rows as progenitors of the next year's crop, into ground which has been carefully prepared and well manured for the purpose. Towards the end of the year, when the harvest is gathered, the roots are left in the ground to produce the crop of the following year. The same course is repeated in the third year, after which the ground is used for less exhausting crops for at least four seasons before being again planted with sugar-cane. The second year's harvest generally turns out the best, as the third is expected to be the worst. The process of crushing the cane is laborious and wasteful; in drying it the molasses are not separated from the sugar, and clog up the machinery so badly in Hongkong that recent experiments with the Hainan article gave a result of only 58 per cent. Ground nuts (Arachis hypogæa) are the farmer's second most valuable crop, and the annual outturn of cake and oil has been estimated, on competent authority, to about 500,000 piculs, of which 64,164 piculs were exported last year through the foreign customs. The seed is sown in February or March, and when the crop ripens (about December) women and children may be seen everywhere in the fields busily engaged in taking out the nuts, which are taken at once to the factory in the farmer's homestead, where they are dried on a kiln furnace, steamed, and after much labour reduced to oil and cake. Another very large item of export from Hainan is Betel-nut, but somehow foreign steamers are not much employed in its conveyance. The two districts of this island most noted for their Betel-nut groves are Aichou and Ling-shin, the fruit from the latter of which is considered the best. The trees are planted some 15 feet apart, and bear fruit from the ages of ten to ninety years. Their most prolific period is between their fifteenth and thirtieth year, when one tree will produce 700 or 800 nuts, valued at about 40 cents. Large herds of cattle are allowed to roam at will through the plantations, and their manure serves to fertilise the soil from which the trees derive their substance. The groves are said to be the seat of pestilential malaria, especially at the season when the trees are in flower. In preparation for the market the nut is made to assume a variety of forms to suit the fastidious tastes of the Chinese customers, which are different in almost every province.—*Gardeners' Chronicle.*

THE FAUNA AND FLORA OF THE KEELING ISLANDS, INDIAN OCEAN.

I have only recently been able to obtain my copy of Mr. Wallace's "Island Life," in which I find an estimate of the fauna and flora of the Keeling Atoll in the South Indian Ocean. I had the fortune to visit that outlying spot in the year 1879, and made a collection both of its plants and of its animal life. With the exception of my birds and a few of the insects, my collections were destroyed by sea water, so that it is now impossible for me to give a definite list, but I may note that rats were in such numbers as to have become almost a plague. A goodly herd of introduced *Rusas*, a cross between the Sumatran (*C. equinus*) and Javan (*C. Hippelaphus*) species, were in excellent condition, and were living wild on Direction Island, where also pigs were living, in the same state. Among birds,, the *Gallus bangkiva* (introduced) was in considerable numbers; I saw also the nest of the *Ploceus hypoxanthus*, which comes, not every year, but very often to breed there, but the progeny seems either to die or to return to Java (?). I did not see the snipe, but of the *Rallus philippinus* I got several specimens. Egrets, blue and white, abounded and rested on the high trees on some of the islands. Lizard of several species are now found on most of the islands in large numbers. Of insects the number of species is very considerable. Coleoptera were represented by *Melolonthidæ*, *Cetoniidæ*, *Carabidæ*, *Elateridæ*, *Chrysomelidæ*, but as I have not my journals of that date by me, I cannot recall other families nor state the number of genera represented. Of Hemiptera I caught a good many species, mostly of small size. Many species of ants were observed. Neuroptera are represented, unfortunately, by the *termite*, introduced some years ago in furniture, it is said, but it occurs now on every islet of the group in myriads.

I am told that during the cyclone of a few years ago, the whole surface of the sea was covered with the mangled bodies of dragon-flies for miles out to sea, but that since then very few have been seen. Of Lepidoptera I caught many species both diurnal and nocturnal, some very handsome, of which I sent a small collection to London in 1879. The Atlas Moth is rather common. Orthoptera were represented by the ubiquitous cockroach, and a few *Acridiidæ*.

Mr. Ross told me that on several occasions the large fruit bat, called the flying fox, has reached the islands, and once a pair arrived together, but died, from exhaustion apparently, soon after arrival. Under favourable circumstances, as in the case of an unusually strong pair, these may yet become inhabitants of the islets.

There are, I believe, considerable additions to the flora since Mr. Drawin's visit. It is only within recent years that the islands have become so greatly covered with cocoanut plants. Their original vegetation consisted principally of "iron wood" (sideroxylon?) and other trees, and of low shrubs. There were nearly all burned out by accidental fires, one of of which burned for three months.—HENRY O. FORBES.—Fatunaba, Timor Dilly, January 21.—*Nature.*

DEAD BRANCHES DETRIMENTAL.

I have been asked whether the statement lately going the rounds of the American papers that "a dead branch on a tree makes almost as great a strain on the main plant for moisture as does a living one" is accurate or not. The statement is coupled with another referring to its practical application in tree culture, the conclusion being that every dead branch "should be at once cut away." Briefly it might be answered that the first statement is true in the main, and that, without any doubt at all, the conclusion is a wise one, and ought to be followed in practice. To explain this matter will take considerably more space, and in order to understand it we must go to vegetable physiology and inquire into the nature of the evaporation of water from plants. It was long supposed to be a physiological process, and was considered to be entirely different from ordinary physical evaporation. As long as this view was held the process was called transpiration, to distinguish it from the physical process. The breathing pores, the stomata, which occur in the epidermis of all leaves in great numbers, were supposed to be organs of transpiration, which was considered to be one of the most important functions of the leaf.

Within a few years, however, our knowledge of these matters has been greatly increased, and we now know that the escape of water from the leaf does not differ in any way from the evaporation of water from any other moist surface. A leaf is a mass of cells, every one of which is gorged with watery matter, which in a dry atmosphere, as a matter of course, tends to escape. The epidermis, composed of dryish impervious cells, which entirely surrounds the watery cells of the leaf, would prevent almost completely the evaporation of water from the latter were it not for the breathing pores before mentioned. These pores are for permitting the free ingress and egress of gases, particularly oxygen, carbonic acid, and probably, also ammonia. Now, when the pores are open for their legitimate purpose it happens that more or less water escapes if the air is dry. If the air happens to be very moist the loss of water through the breathing pores is very little, or even none at all.

We may put it in this way: The leaf loses water simply because it is a watery structure; its epidermis is designed to prevent this loss, and the breathing pores with their power of opening and closing are for the same purpose. A leaf instead of being an organ of evaporation is actually a structure in which evaporation is quite successfully checked. Careful experiments made under my supervision in the Iowa Agricultural College in 1880 by Miss Ida Twitchell, a graduate student, demonstrated that the evaporation from a moist piece of dead wood was exactly like that from a living leaf. Now, when a dead branch is long enough to keep contintually moist in the interior it will in dry air constantly lose water by evaporation from its surface. This water so lost is taken from the tree, and must have been supplied directly or indirectly by the living portions. Moreover, it must be remembered that a living branch is well protected against loss of water through evaporation by the epidermis which covers all its surface when young, or the impervious corky bark which is always found on it when older. When a branch dies, these protecting devices soon fall into decay, and the water, so carefully guarded by the living parts of the plant, is wasted by evaporation.—PROF. C. E. BESSEY (in the *New York Tribune*).—*Journal of Horticulture.*

CULTIVATION OF THE ARTICHOKE.

(*Cynara Scolymus L. Compositæ DC.*)

This vegetable is a hardy perennial, a native of Barbary and South of Europe. It appears to have been esteemed as a vegetable from very early times, as Pliny speaks of it as having been cultivated by the Romans. The culinary part is contained in the immature flower heads. The broad fleshy flower receptacle, termed the bottom, and the thick base of the horny involucral scales are the parts eaten. It succeeds with little care and trouble, and is often met with in the gardens of Europeans, but seldom in those of natives.

On the plains the flower heads begin to appear in March, but are most plentiful in April, and continue in season until the middle or end of May. The plants are raised from seed or by suckers. The former should be sown broadcast in beds, from the beginning of August to the end of September. The seedlings are very hardy, and seldom suffer from damp; the seeds should, therefore, be sown as soon as an opportunity occurs after the beginning of August. When they have made four or five leaves they are fit for transplanting to where they are intended to be grown. They love a deep and rich soil, and when preparing the ground for their reception it should be trenched 2 feet deep and liberally manured. When time and labour does not allow of such an effective preparation of the ground, holes 2 feet broad and 2 feet deep should be dug, and the soil thrown back liberally mixed with old manure. The plants should be transplanted at 2½ feet apart, in rows 4 feet asunder. They should be watered regularly, and the soil between the plants occasionally stirred with a fork. When raised by suckers the strongest should be separated from the old plants in September, and at once transplanted at the same distances apart as given for seedlings. They should be annually transplanted in a fresh plot of ground. If this is not done the flower heads decrease in size, and by the third season are all but worthless. It is a good plan to raise one-half of a plot from seeds and the other by suckers. The latter should be annually thrown away after the flower heads are past use, and the former preserved for the production of suckers for the following season. Suckers flower sooner, and the advantage gained is a crop of flower heads a fortnight or three weeks earlier than when seedlings only are used. This vegetable does not degenerate if seed is saved from flowers produced by the leading shoots of the plants raised from seed. A few of the largest flowers should, therefore, be annually reserved for this purpose.

On the hills the plantation need only be renewed every three or four years. When a stock has once been secured from seed, this should be done every third or fourth year by suckers, and the same plan followed as described for the plains. When the plants have to be raised from seeds, these latter should be sown in March or April, and transplanted as soon as they have made four or five leaves. At elevations below 5,000 feet suckers should be transplanted in September, but above that elevation, and especially if on a northern aspect, it should be done in March or April. At elevations above 6,000 feet, the stools should be protected from frost by a covering of stable litter or half-decayed leaves. In spring, when all danger from frost is past, the covering material should be removed, and a quantity of old manure forked in between the plants. During the operation uncover the stools and remove all the suckers except two or three of the strongest. At lower elevations manuring and removing suckers should be done in autumn; in spring and during their progress all that requires to be done is weeding and occasional stirring of the soil.—W. G.—*Indian Forester.*

TEA, SILK, AND CINCHONA FARMING IN NEW ZEALAND.

TO THE EDITOR OF "THE COLONIES AND INDIA."

SIR,—I have much pleasure in communicating some extracts from the letter of an Indian chinchona planter sent me by last mail from New Zealand. This gentleman has gained his experience at Coorg in Southern India, both among the hills, where the rainfall is 300 inches per annum, and in the bamboo district, where the more moderate quantity is 80 inches; and his carefully-formed opinion is that in the North Island of New Zealand is to be found plenty of land suitable, as regards climate and soil, for the remunerative cultivation of all three products forming the heading of this letter. He says: "I have been in charge until a recent date of the largest chinchona nurseries in Coorg, but was obliged to leave India on account of the health of my wife and family. I have no desire to return to India, as I think there is a great future in store for the North Island in tropical and semi-tropical agriculture, if the Government will encourage the necessary experiments, in granting land for nurseries, and in supplying labour; the products could soon be made to attract capital, and would soon bring a large extent of country into profitable use. . . . Some notes on plants and seedlings may not be out of place here. In May 1882 an acre of land having been cleared of timber, a large thatched shed was erected in which 5 lbs. of *succirubra* seed were sown, producing 200,000 seedlings in August fit for transplanting outside, and valued at 8 rs. per 1,000. About 15,000 of the finest were pricked out and sold afterwards for 20 rs. per 1,000. When the seed sheds were empty the nursery was extended and other sheds erected, under which 13 lbs. of *succirubra* were scattered, yielding 400,000 seedlings. In January last 300,000 of these were transplanted and 100,000 sold at 8 rs. per 1,000, those transplanted being from 4 to 6 inches in height, and will be worth 25 rs. per 1,000 in June next (the present month).

I have built two propagating houses with forcing flues, and in these scattered some of the finer seeds from trees yielding a larger percentage of quinine. One pound of *calisaya* seed produced 150,000 seedlings which sold for 50 rs per 1,000 when 2 inches high. I also raised in the house, from 1 oz. of the celebrated *Java ledgeriana*, about 15,000 seedlings which brought 4 annas a plant. This seed came from trees yielding from 6 to 9 per cent. of quinine. During the present year I have cleared other four acres of land, built extensive seed sheds, and planted four varieties of chinchona—namely, *calisaya*, 2 lb.; *condaminea*, 1 lb.; *robusta*, 4 oz.; and *officinales*, 2 lb.; most of which germinated in fifteen days. It is worthy of note that tea and silk could be grown under the same management and conditions in the north of New Zealand, and those three products should prove a very valuable investment.

These quotations may be deserving of some attention as emanating from a skilled Indian planter of ten years' experience, and as confirming the widely-spread belief that northern New Zealand is well suited for the cultivation of several tropical and semitropical products, if only the Government will judiciously loosen for a time the colonial purse strings. That the apparently uncongenial task of subsidising such industries must be faced sooner or later there need be little doubt, as the capital of Europe, so much of which New Zealand has already absorbed, can scarcely be expected to flow always in one direction. Considering that this is the fourth year of recent endeavours to obtain official aid and sympathy for the promotion of tea and silk farming without satisfaction, many people at Home, as well as on the spot, are beginning to doubt the sincerity of the many favourable protestation on the subject which have issued from the Executive at Wellington. The opinion has been expressed in numerous instances on both sides of the equator that these industries, with a little Government assistance at first in money or in kind, may be profitably conducted, and be rendered a source of great wealth to the Colony. It is everywhere known that Government aid has been given or offered to the promoters of the wollen, chemical, metal, sugar and other useful and important trades; people are not ignorant of the fact that distillers were, under a former Administration, bonused to commence the manufacture of whisky and afterwards premiumed to give it up,—these and other merits and eccentricities of the Executive are perfectly well known; it is therefore surprising that much astonishment should now continually be expressed that the advocates of the specially useful, valuable and nondeleterious industries of combined tea growing and silk preparation should alone be left out in the cold with nothing offered but the taunt of being enthusiasts to warm them.

Under such circumstances it is both refreshing and encouraging to find that the Colonists of the Thames Valley, who some time ago commenced silk culture, have issued their first annual report, in which it is mentioned that about 1,000 mulberry trees of the *morus alba* kind have been planted at their little experimental farm at Parawai. Experimental gardens of this kind will undoubtedly help on the enterprise by drawing attention to and keeping the public eye upon it, and the shareholders deserve the thanks of the community for the pecuniary sacrifice they are making meanwhile; but the efforts of the "Thames Sericultural Association" ought to embrace tea and chinchona culture, and be largely supplemented by Government aid if a rapid and enduring success is aimed at.

No less gratifying is it to learn that the progress made by Mr. G. B. Federli, the Government sericulturist at Christchurch, Canterbury, last season, has prompted the issue of an interesting little manual on silkworm rearing for the instruction of the Colonists. Nevertheless something more is needed. By all means let the Government pecuniarily encourage local silk associations and colonial nurserymen to cultivate the best varieties of the mulberry in quantity; let them, if preferred, through their own official machinery, establish nurseries for the supply of the various silkworm-feeding shrubs and breeds of silk-producing moths, as well as tea and chinchona plants and seed; or, what would probably prove ultimately of most value to the Colony and to chasericulture, let the Executive subsidise the proposed "New Zealand Chasericultural Company" as a great national teaching establishment, to become a grand focus for instruction and practical work, rather than fritter away the funds of the Colony here and there in paltry 50*l*. bonuses as proposed by the Commissioners of 1871 and 1880.

I remain, Sir,
Your obedient servant,

Overdale, Dunblane, Perthshire: WILLIAM COCHRAN.
June 7, 1883.

SCIENCE IN CULTIVATION.

Among the numerous remedial measures to which the "seven lean years" have given rise, as partial or entire specifics for the evils of hard times, none commends itself more forcibly to us than that which enforces a thorough knowledge of the nature and treatment of the soil, the composition of the plants we cultivate, the sources whence the ingredients of such composition are derived, the deficiency of our own particular soil for the requirements of any crop and the remedy.

Quite recently Professor Jamieson expressed his conviction at a public meeting that three-fourths of cultivators were ignorant of these things, and it is the aim of the Sussex Association for the Improvement of Agriculture by science to enlighten; and it has proved to demonstration that as soil differs greatly even upon the same formation, so must its treatment differ according to its requirements in order to cultivate it profitably. It has done much more than this, for it has shown that land declared to be so poor that a decided loss attended its culture under the old hit-or-miss system, could by careful scientific treatment not only be made to pay all expenses but to yield a fair profit, or, to put it more forcibly, that profitable cultivation is possible on the poorest and foulest land, and that unprofitable cultivation is the fault of the cultivator and not of the land. In selecting land for trial poor land was taken in preference to rich, in order that the work might be thorough and its result really useful. Careful and full diaries have been kept of the work done at each station in different parts of the county, and they are printed fully in the annual report, together with clear statements of every detail of the crops, soil, and manure.

Nitrogen and phosphorus are found to be two great wants in Sussex soils. In supplying these wants artificially the effect of phosphates proved to be more lasting than was supposed, beneficial effects being clearly visible the second year. Important as this fact is generally it is doubtless so to members of the Association, who, under the advice of professor Jamieson, and by the light of his teaching, have applied to the land 3 cwt. of finely ground coprolites and 3 cwt. Steamed of bone flour per acre. This dressing is a heavy one, recommended for a poor soil at the outset, and will be reduced subsequently to about 2 cwt. of each sort of manure. The action of cropolites alone, even when reduced to dust, is not sufficiently quick; mixed with the bone flour it answers admirably. Steamed bone flour contains 55 to 70 per cent. of phosphate, and is therefore superior to natural bone, which contains only 50 to 55 per cent. of phosphate, and cannot be ground so finely as the steamed bone. This is worth remembering.

It may be fairly asked, Of what use are the Sussex experiments to cultivators in other parts of the country? And as fairly and usefully it may be answered that the results obtained are in many instances so clear and unmistakeable, and of such great practical value, that not only are they of general importance as an incentive to the formation of, other county associations, but also to persons individually as showing them that such knowledge well applied is profitable. It also shows them how to help themselves in a comparatively inexpensive manner by ascertaining the deficiencies of their soil and supplying them, and it is hoped the lesson indicated will not be lost or overlooked by cultivators generally.

Having learnt that the essential elements of plants are pottash, nitrogen, lime, magnesia, sulphur, iron, and phosphorus, every cultivator in the garden and on the farm can follow the advice given by Professor Jamieson—namely, "chocure a small quantity of each kind of manure and apply it thus: To one patch of land no manure whatever; to another patch of land all the essential elements; and to six others all the essential elements excepting one, and that excepted one being a different element in each case." Properly there ought to be seven such partially manured plots, but of the seven essential elements iron is required only in traces, and soils always contain more than enough. This is what he calls making the soil analyse itself. It cleanly does so sufficiently well for all practical purposes, and two or three years' careful trials, or even those of a single favourable season, give a certainty of aim and purpose to our work such as nothing else can do.

Although great prominence has been given to the relative value of manures, yet no essential detail of culture has been overlooked. The trial land was well drained first of all, and then thoroughly worked to get a good seed bed. This pary drainage is rim of at least equal importance with the correct application of manure, for without it our efforts will prove comparatively futile. Last summer I saw a large field of wheat stunted in growth and of that sickly yellow hue which shows unmistakeably that "something is wrong below." What was it? no manure? No, that could not be the cause, for an exceptionally heavy dressing of forty-five cartloads of farmyard manure per acre had been given it. How were the drains acting? The land, a close tenacious soil, was undrained! Cold, sodden, inert, how could the wheat grow in it? It did grow, but how slow and feeble was that growth in comparison to what it might have been had the land been drained. Let not the teaching of this experience be overlooked. It is of importance to gardeners as well as farmers. Land must be drained or it cannot be fertile. Far better to incur the loss of a little nitrogen by overdrainage, even though it were double the quantity shown by the Rothamsted experiments, than to have none at all. The land referred to forms part of a large estate, and is in the hands of a cultivator who is perfectly alive to the importance of drains, but he cannot get them. It is, however, reasonable to suppose, that as the primary importance of drainage becomes fully recognized it will receive due and just attention as a necessary prelude to the economical application of manures in gardens, orchards, fields, and parks.—EDWARD LUCKHURST.—*Journal of Horticulture.*

REVIEW OF BOOK.

(*Artificial Manures*: GEORGES VILLE. London: Longmau & Co.)

This, the second edition of a work famous in France and America, but less known in this country, is a series of lectures delivered at Vincennes some years ago by M. Georges Ville, and embodies the results of that gentleman's experiments at the place named. The work is characteristically French—that is to say, unbounded enthusiasm appears on every page. It has been said that nothing worth having can be gained without enthusiasm. This may be so far true, but when it acts like a runaway horse it is apt to take its victims too far, and this, especially in experimental science, has serious drawbacks. Possibly our prejudices may influence us, but an idea has taken possession of us that the pre-eminently English quality of the power to plod, plod on over mountains of difficulty, no matter how steep the path, and over quagmires, however treacherous, is less apt to mislead either the plodder or his disciples. M. Ville thinks that though artificial manures are more extensively used in England, Frenchmen are better acquainted with their action. Taking Ville himself as an authority on the state of knowledge among French cultivators of the soil, we think our countrymen will stand a comparison with favourable results. Indeed, one cannot unbiassedly read through the enormous amount of collected information of experiments in scientific agriculture by Messrs. Lawes and Gilbert alone, to say nothing of other earnest workers, without feeling that it is indeed the English who know far most on the very subject Ville imagines us to be not well informed; and we may add that the knowledge gained on our side the Channel is of a real, solid, if of a somewhat doubting kind, and not a will-o'-the-wisp born of enthusiasm, which, we may say frankly, is very characteristic of the book before us.

M. Ville is the friend of the farmer. This is apparent in the very preface. There is a table inserted there to show that farmers pay 12s per cwt. for manure, the materials of which cost no more than 6s 5½d., and which farmers might have for 7s 2d if they would form themselves into co-operative Societies or mutual supply Associations. Manufacturers will thank neither M. Ville nor us for the idea, but it is certainly a good one, and well worth considering.

The author (against the world) is fully convinced of the power of certain plants—the Sugarcane and members of the Leguminosæ for instance—to assimilate the free nitrogen of the air. This is proved by *logic* instead of by scientific tests. We are shown that certain crops contain much more nitrogen than is applied to them; that the nitric acid and ammonia supplied from the air cannot account for more than a fraction of the increase, and are asked to consider this as proof that the increase has been assimilated from the air in the form of free nitrogen. This is enthusiasm and not science. We can discover nothing to show that M. Ville has considered it necessary to ascertain whether the nitrogen always present in the organic remains of every soil has suffered diminution. Had this been done we imagine that even M. Ville himself would have doubted.

Our author is not, it appears from the following, quite sure of his own assertion. He proposes that £100,000, internationally collected, should be offered as a prize for a method of converting the free nitrogen of the air into an assimilable compound, and offers to head the list with £40. Very good. But if peas, beans, clover, lucerne, &c., already do so, and for nothing—nay, give us the richest of foods besides, the problem has been solved! Why then the £100,000? Ammonia sulphate at 1d per lb., we are told, means cheap bread and cheap meat; but if clover and beans assimilate free nitrogen, why not cheap meat now? If such feeding secures manure rich in nitrogen and the clover remains furnish more, why not cheap bread now? These questions M. Ville would have some difficulty in answering.

It is when theories are left behind for what actual experiments have proved that the teachings of Ville become of value as the common property of mankind. Experimenting at Vincennes with chemical manures, it was found that a liberal application of mineral manures on a soil unusually deficient in the mineral food of plants, without nitrogenous manures gave 18 bushels per acre. With no manure at all the yield was only 12. When nitrogenous manure alone was given, 22 bushels was the result; but when the two were combined, 50½ bushels was the amount of grain per acre. This experiment is illustrated with a diagram which shows at a glance even more decidedly than figures do the difference between the samples.

In another experiment at Champagne 32 tons of manure gave 14 bushels, but what Ville calls normal manure gave 36. On a sandy soil, which without manure at all gave only 2¾ bushels, and with 16 tons of farmyard manure 8¾, chemical manure gave 31 bushels per acre. An instance is given when in Italy on poor land a large quantity of manure gave from 9 to 11 bushels, but Ville's mixture gave from 27½ to 33 bushels per acre. Almost all of these experiments have been made on land of a poor description; but, unfortunately, most of the land in England, as well as in France, appears to be in this condition. On richer soils equally striking results need not be looked for, but, taking the land as a whole, there is reason in the assertion that the proper use of chemical manures would render England and France independent of America. Startling though such an assertion may appear, it is less so when we consider that millions of acres are idle, or afford a scanty pasturage only, and yet are capable of raising good crops by the aid of manure, and that more than one-half our land yields only half what it might, and even the best seldom a full crop.

Tables are profusely given shewing that perfect manure must contain nitrogen, phosphoric acid, potash and lime, and when any of these are left out the crop suffers. Not only wheat, but all other farm and many garden crops have been experimented on, and the same tale is told by all. It is shown, however, that the Legumines are not benefited by manurial applications, and sugarcane but slightly so. Chemical manures raised the latter crop from 24 cwts. to 23 tons!

We are tempted to linger over the work, and to quote largely. As the work has been put into an English dress our duty to our readers is done by indicating the nature of the book, by warning them against some theories in it not sufficiently supported by evidence, and to the results of practical experiments. It would be well were all cultivators to procure this work and to study it carefully. It would be better still if it were studied in the light of what has been discovered by others. It is not always necessary to include lime as M. Ville insists, for on thousands of acres lime is already abundant. Moreover, it may be obtained in a cheaper form than the sulphate. Even potash is not always wanted, even though Ville's experiments point that way. Some soils—that of the fertile Carse o' Gowrie, for instance - contain more potash than can possibly be used up in hundreds of years even with the most exhaustive methods of culture. In such cases it would be throwing money away to apply what is there already. Ville's advice to analyse the soil by trying on a small scale how long plants will give a maximum yield with this, that, and the other substance withheld, we can recommend as superior in every way to costly chemical analysis, which may tell what soil contains, but not what it will yield. We may also draw attention to the remarks on the difference between the market value and the cost of stableyard manure, but experience tells us that he is wrong when he tells us that chemical manure *alone* is superior to a mixture of chemical and farmyard manure. Chemical manure, properly used, will undoubtedly do a great deal towards increasing all kinds of crops by supplementing farmyard manure, and, by producing greater quantities of straw and fodder, increase even farmyard manure. Ville considers that a knowledge of the subject and its universal application would save us from forty to eighty millions sterling a year. As a first step towards sharing in the "plunder" we can conscientiously recommend a study of the work in question by every cultivator of the soil.—*Journal of Horticulture.*

TEA AND ITS SUBSTITUTES.

Few articles of commerce and daily use have had more written upon them than tea; and this is not to be wondered at when we remember how widespread is the use of this beverage, and from what a remote period its use has been known. Tea with us is at all times, and by most persons, considered a refreshing beverage, "the cup that cheers but not inebriates" diffusing its fragrance and increasing the pleasures of the social board. On this, the social phase of tea-drinking, Mr. Baildon, in his recently published work on the *Tea Industry of India*, thus quotes from *Food Papers:*—"That all classes of the community in this country have derived much benefit from the presistent use of tea is placed beyond dispute. It has proved, and still proves, a highly-prized boon to millions. The artist at his easel, the author at his desk, the statesman fresh from an exhaustive oration, the actor from the stage after fulfilling an arduous *rôle*, the orator from the platform, the preacher from the pulpit, the toiling mechanic, the wearied labourer, the poor governess, the tired laundress, the humble cottage housewife, the votary of pleasure even on escaping from the scene of revelry, nay, the Queen on her throne, have one and all to acknowledge and express gratitude for the grateful and invigorating infusion."

The Trade Returns inform us that during the year 1881 212,462,577 lb. of tea were brought into this country, 160,225,789 lb. of which were entered for home consumption. The millions of British tea drinkers ought for such a boon to be especially thankful to the original discoverer of the value of tea, which, if we are to trust Chinese legendary history, belongs principally to an Indian prince named Dhauna, who about the year of grace 510 imposed upon himself in his wanderings the rather inconvenient penance of doing without sleep. According to the Chinese narrative this Indian prince got on very well for some years, when all at once he gave up and had forty winks on a mountain-side. Upon awakening he was so grieved to find that he could not go on many years without sleep, that in despair he pulled out his eyelashes and flung them on the ground. Returning again that way at a later period Dhauna found that the offending eyelashes had taken root, and grown into bushes such as he had never before seen. Tasting the leaves, he found they possessed an eye-opening influence, and the fact becoming known to his friends, the Tea-plant was henceforward largely cultivated.

Though tea proper—that is, the infusion of the leaves of Camellia Thea—is the prevailing non-intoxicating drink of England, Russia, and Holland, the Germans, Swedes, and Turks, for the most part drink coffee, while the Spaniards and Italians delight in chocolate. France is also noted for preparing good coffee, but chocolate is also very extensively consumed. In every part of the world plants of some kind indigenous to the soil are used by the natives for making an infusion which is as necessary to them as tea, coffee, or chocolate are to us. Even in England, in the good old times before the introduction of tea, an infusion of the leaves of the common Sage was in general use, and Sage tea is at present still used in some remote parts of the country.

At first sight it would seem that these tea substitutes are unimportant except to a very few inhabitants of the countries where the plants grow, but some are of very great value commercially as articles of sale; such, for instance, as the Paraguay Tea, which we shall notice more fully in its proper place, as we propose to arrange the plants furnishing these tea substitutes according to their natural order, with a few remarks on each. It will be noticed that many of these teas have a medicinal value distinct from that of an agreeable beverage.

1. *Anonaceæ* (Corossal Tea).—Under this name the leaves of Anona muricata are described in the catalogue of the products of the French colonies at the Paris Exhibition, 1876, as being used in French Guiana. The tea is described as an anti-spasmodic.

2. *Cistineæ* (Thé Arabe).—This name seems to be applied to the leaves of Cistus albidus as well as to Globularia Alypum, belonging to the natural order Selagineæ, and to the flowers of Paronychia argentea, which will be noticed in its proper place.

3. *Violariæ* (Mountain Tea, Sauvagesia acceta).—Used in Martinique, and considered a stimulant tonic.

4. *Sterculiaceæ* (Cola acuminata).—A tree of West Tropical Africa, the seeds of which are known as Kola or Goora nuts. The trade in these seeds on the Gambia is thus described in a report by Acting Administrator Berkeley, copied in the *Kew Report* for 1880:—"The trade in Cola nuts is an attractive feature in the commerce of the Gambia. The Cola nut is the produce of the Sierra Leone district, and the trade in it, both at Sierra Leone and the Gambia, is almost entirely in the hands of women, to a large number of whom it affords the means of livelihood, and in many instances the acquisition of considerable wealth. The nut is largely consumed by the natives of the Gambia. It is of a bitter taste, and produces no exhilarating effect, but is said to possess the power of satisfying for a considerable time the cravings of hunger. For this purpose, however, it is much less used than it is as a luxury. The trade in the article is rapidly increasing." In 1860 the imports were about 150,000 lb., while in 1879 they had risen to about 713,000 lb. The trade in these seeds has also spread to Central Africa, and even to the African shores of the Mediterranean. Besides the use of these seeds for staying for a prolonged period the cravings of hunger, and enabling those who use them to endure increased fatigue without loss of power, they are very important for the preparation of a refreshing and invigorating beverage. The Cola nut has recently attracted a good deal of attention in this country, one of the newest revelations in connection with it being the property it is said to have of curing drunkenness. A single nut is ground up and made into a kind of paste with water, and swallowed, and half-an-hour afterwards no sign of intoxication remains.

5. *Rutaceæ* (New Holland Tea, Correa alba).—A compact much branched shrub, 3 to 4 feet high, native of Victoria Tasmania, and South Australia. The leaves of this, and perhaps of other species, are used for tea in Australia.

6. *Ilicineæ* (South Sea Tea, Ilex vomitoria).—A handsome North American shrub, extending along the sea-coast from Carolina to Florida. The use of this plant is thus described:—"The leaves are used by the Indians to make the black drink so much in use amongst them, not only as a medicine, but as a drink of etiquette in their councils when matters of consequence are to be transacted. At a certain time in the year the Indians come down in droves from a distance of some hundred miles to the coast for the leaves of the tree, which is not known to grow at any considerable distance from the sea-shore. They make a fire on the ground, and, putting a great kettle of water on it, they throw in a large quantity of these leaves, and seating themselves round the fire, from a bowl that holds about a pint they begin drinking large draughts, which in a very short time occasions them to vomit easily and freely; thus they continue drinking and vomiting for the space of two or three days, until they have sufficiently cleansed themselves, and then, every one taking a bundle of the branches, to carry away with him, they all return to their habitations."

7. *Paraguay Tea* (the leaves and twigs of Ilex paraguayensis).—A large bush, or small tree, native of Paraguay. The tea is made both from wild and cultivated plants, and various qualities are produced, according to the localities where it is grown or prepared; that of Paraguay is said to be the most bitter and aromatic of all, and consequently the most esteemed. The mode of gathe ing and drying the leaves is different from that practised in India and China with ordinary tea. A kind of expedition is formed consisting of from forty to fifty persons, mounted on mules, and having with them a reserve stock of mules and bullocks. On reaching a locality where the trees are abundant, ofen 200 miles or more from the place of starting, a small space of ground is cleared, and the soil beaten down with heavy mallets until it is quite hard and level. At the four corners of this space sticks or posts are driven into the ground, and upon these a sort of net, made of strips of hide, is stretched; beneath this a fire is lighted, and the boughs of the plant, with the leaves upon them as they are brought from the forest, are placed on the net, where they are thoroughly dried—in fact almost scorched, but not actually burnt. These scorched leaves and the small twigs are then reduced to a fine powder in a rude wooden mill, after which they are weighed and put up into packages for export. Half a bullock's hide is used to form a kind of sack to hold the tea, being first sewn up at the sides. The tea is then rammed in until the sack is quite full, the mouth is sewn up, and the package, which usually weighs from 200 lb. to 250 lb. is left to dry in the sun for a few days, during which time it becomes as hard as a stone. The tea is sometimes packed in the skins of other animals, and for retail purposes is put up into small paper packets, or bags. While the bulk of Paraguay tea consists of powdered leaves and twigs, some of the kinds are composed solely of the roasted unbroken leaves. Enormous quantities of this tea are consumed in South America, 27,000,000 lb. being used in the Argentine Republic in one year. In the rural districts, as well as in the smaller towns, "yerba," as it is called, is considered a regular form of diet, and not, like tea in England, a mere beverage. One form of drinking "yerba" is to mix sugar with the decoction until a thick syrup is produced; the usual way, however, is to place a small quantity of the tea in a cup, pour hot water upon it, and when it cools to suck the infusion through a tube called a "bombilla." The effect of this tea upon the system is similar to that of Chinese tea, though the flavour, which is bitter and herby, is not agreeable to the English palate.

8. *Winterberry*, or Appalachian Tea (Prinos glaber).—A bushy evergreen shrub with smooth leaves, native of Canada

9. *Rhamnaceæ* (New Jersey Tea, Ceanothus americana).—A shrub found in dry woods from Canada to Florida. An infusion of the leaves is said to resemble ordinary tea both in colour and taste. In has been strongly recommended by many persons in the United States. One writer says:—"The tea prepared from this shrub, drawn as common tea, is certainly a good substitute for indifferent black tea. Properly dried and prepared it is aromatic and not unpleasant." To make tea from this shrub it is recommended that the leaves should be carefully dried in the shade.

10. *Arabian Tea, or Khât* (Catha edulis).—This is a shrubby plant extensively cultivated in the interior of Arabia, mostly in gardens along with Coffee. To prepare the tea for trade purposes amongst themselves, the Arabs gather the twigs with the leaves attached and carefully dry them. They are made up into closely-pressed bundles of different sizes, the quality being known by the form and size of the bundles. The best are about a foot or 15 inches long and 3 inches wide. About forty slender twigs compose these bundles, and these are sent into Aden from the place of cultivation in the interior of Arabia to the extent of about 330 camel-loads a year. The use of this tea in Arabia is said to antedate that of coffee, which was early known in that country. Besides the use of the leaves in the preparation of a beverage, the Arabs also chew them both in the fresh and dried states, the effect of which is to increase the flow of hilarity and mirth, and to produce extreme wakefulness and watchfulness, so that a man may fulfil the duties of sentry all night without a feeling of drowsiness. The plant is considered by the Arabs as an antidote to the plague, and they also believe that infection cannot be contracted if a twig is carried about the person.—JOHN R. JACKSON.—*Gardeners' Chronicle.*

THE *American Cultivator* states that "Every spring peach growers select specimen branches from variously situated trees, and these are placed in hothouses and their ends dipped in water that is kept tepid. Then but head are forced until an expert can tell, with the aid of microscope, precisely what the nature of the coming crop will be. From these and other recognized indications it is thought that the yield this year will be of average bulk and of the finest flavour." This "finest flavour" prognostic as determined by the microscope, we think rather clever.—*Horticulture and Cottage Gardener.*

CEDAR-WOOD AND CIGAR-BOXES.—In a report from Bremen-Bremerhaven, under the head of "Wood," it is stated that the traffic in Cedar-wood (Cedrela odorata), for manufacturing cigar-boxes, was languid all the year through, and manufacturers only bought sufficient to supply their customers, being apprehensive of the introduction of the tobacco monopoly. This apprehension, combined with the increased imports of the wood from Cuba, caused the prices to decline to such an extent that they became lower than they had been for thirteen previous years. In September, however, the market improved, and higher prices were accorded. The imports of this wool in the year 1881 were 5,750 blocks less than in the year 1880.—*Gardeners' Chronicle.*

KHAKI (COTTON) CLOTH.—In connection with the subject of our late article about khaki clothing, made from natural-coloured cotton grown in various parts of India, it may interest some of our readers to know that this same cotton has recently been discovered in Arakan. Mr. Hildebrand, Deputy Commissioner of the Arakhan Hill Tracts, came upon a quantity of it, which had been brought to a small exhibition of produce, held annually in the Hill Tracts. Samples of cloth made from this cotton stand any amount of washing without fading, and are not affected by perspiration. The Local Government, with a view to stimulate and encourage the cultivation of this cotton in the Hill Tracts, has offered prizes for the best and largest samples from this year's sowings.—*Englishman.*

NEW TANNING MATERIALS.—At the Exhibition of Brazilian Products lately inaugurated at Berlin, form the subject of an elaborate report by a jury of experts, including the well-known German tanners, M. M. Eberz and W. Kampffmeyer, jun. The tabulated results show the percentage of moisture in each material in an air-dried state; the total percentages of tannin, and of substances other than tannin, but soluble in water, contained in each material after drying at 100 degs. C. (212 degs. Fahr.), being respectively the sums of the percentages obtained by extracting such material (after drying) first with cold and then with boiling water; the tannin and other percentages, colour of the liquors, and colouring properties on hide, of the said cold and hot extracts; the perchloride of iron reactions furnished by the same; and lastly, the probable value of the material for purposes of export to Germany, in view of ruling prices and prospects of supply. The report is too bulky for reproduction even by the trade journals interested, but the *Tanner and Currier's Journal* of May 1 extracts notes on twenty-four Brazilian tanstuffs, most of which are unknown, even by name, in the Old World.—*B. M. Gazette.*

CINCHONA BARK HARVESTING.—Haputale, July 29th.—The following extract from a letter of a planter in this district, who, from his lengthened experience and ability, is well able to speak with authority, is of great interest, particularly with regard to what he tells us of the poor results in renewed bark obtained from very old succirubra trees as compared with officinalis:—"As regards disease in the pith of cinchonas, I am constantly finding it in the finest of my hybrids; trees that look perfectly healthy are infected with this discoloration, well developed, too, of a dark brown colour. On examining a dead tree the other day, I found canker at the collar, but the pith of the branches showed no discoloration. By the way, I found a young officinalis tree covered with what looked like white bugs. The stem and the branches were simply covered with this bug, like scales. I have found by experience that condaminea officinalis, 12 years old, renews better than succirubra of the same age. I give you the figures:—145 succirubra trees gave in August, 1882, 1,602lb. original wet bark, and 135 of the same trees yielded 1.046lb. of renewed wet bark in March 1883, or 65 per cent, on original harvest; whilst 123 officinalis trees in August, 1882, gave 444lb. of original wet bark, the same trees yielded in March, 1883, 367lb. of renewed wet bark, or 82 per cent, on original harvest. Ten of the succirubra trees were not shaved at all as they had renewed very slightly. I prefer the term original bark to natural bark, as all barks are natural, whether renewed or otherwise. To show that young succirubra renews well, I send the following:—5,400 trees succirubra planted in December, 1878, gave in July, 1882, 847lb. of original wet bark. In February, 1883, 1,519 lb. of renewed wet bark were harvested from the same trees—an increase of nearly 100 per cent.—"Times of Ceylon."

HOW PLANTS GROW.—In the practical view of the subject the nutrition of plants is a matter of the greatest importance. It underlies the whole business of plant production for economic purposes, and illustrates the near relation of the chemist to the manufacturer. Here is a grave question: How do plants obtain their carbon? When the water and gases have been expelled from a plant by heat what remains consists of carbon to the amount of about 50 per cent. It follows that the living plant does a large trade in the article, and a hasty explanation might be found in the assertion that plants obtain their carbon from the soil. But Dr. Masters does not favour this view. He says, "This large amount of carbon has to be taken up in the form of carbonic acid by the leaves. It is a moot point whether any carbon is taken up by the roots, but, if any, it is only a small proportion. In any given volume or quantity of air the proportion of carbon is very minute, so that the leaves must be very active in securing and utilising all that comes within their reach." That plants obtain carbon by the aid of their leaves almost exclusively is one of the first propositions of Liebig in his "Chemistry of Agriculture," and it is made evident by experiments in manuring that to supply carbon directly to the roots of plants is a waste of power. Having this knowledge, we turn the functions of the leaf and consider once again the uses of air and light to plants. It is by the agency of the green colouring matter, when exposed to the action of light, that the leaf is enabled to decompose the carbonic acid of the atmosphere, retaining the carbon in aid of its own structure and liberating the oxygen for the advantage of animal life. And of necessity we must inquire into the nature of the chlorophyll, for it is compounded for the most part of carbon, with small proportions that of oxygen, hydrogen, and nitrogen. It is by the agency of chlorophyll that glucose and starch are formed, and light is absolutely essential to the process. The case of parasitic plants illustrates in a curious manner the uses of chlorophyll. The broom rapes and dodders are destitute of chlorophyll, and yet they cannot live without it. How then do they overcome or evade the impossibility? They attach themselves to other plants and rob them of the elaborated secretions that their chlorophyll has contributed to produce, just as a man without an income may contrive to live by thieving. But the mistletoe presents a curious case, for it has its share of chlorophyll and yet disdains to dig for its bread by putting its roots in the earth. The case of the mistletoe is full of suggestion to the man whose business it is to make plants grow, for the chemistry of this parasite explains its predaceous character. An apple tree can obtain from the soil only so much potash and phosphoric acid, and a mistltoe probably could do no more if similarly circumstanced. But then "so much" will not satisfy the parasite; it requires twice as much potash and five times as much phosphoric acid in proportion to bulk as the apple tree. Therefore, instead of beginning with water and clay as the apple tree does, it begins by absorbing elaborated vegetable juices from the tree that fosters it, and always, however slightly and slowly tends to the destruction of that tree.—*Gardeners' Magazine.*

A NEW SUBSTITUTE FOR COFFEE AND COCOA.—The kola nut, which has claimed attention from time to time as a remarkable stimulant, rivalling the celebrated *coca* leaves as a means of sustaining long periods of fast and severe exertion, now comes forward in a new character. Dr. Neish, of Port Royal, Jamaica, reports that the value of these nuts is enhanced by the fact that citrate of caffeine—a medicine now much employed for the relief of sea-sickness, megrim, and other nervous complaints—can be readily obtained from them, for the reason that they actually contain more caffeine than coffee berries. Another advantage is that in the kola nut the caffeine is in the free or uncombined state. These nuts seem therefore likely to take their place in the market as furnishing a nutritive and stimulant beverage. Besides being rich in the active principle of coffee, and containing also a large proportion of theobromine, the active principle of cacao, these nuts, in addition, contain three times the percentage of starch contained in chocolate; and, moreover, they also contain less fat, so that, in addition to stimulant and nutritive properties, there is the probability that a chocolate prepared from them will more readily agree with delicate stomachs. Mr. D. Morris warmly supports Dr. Neish's suggestion as a very appropriate one. Both the cacao and kola belong to the same natural order, *Sterculiaceæ*, and the habits and characteristics of the two trees are very similar. They both effect low warm situations, and, in view of the probable demand for kola nuts, attention might very well be given to their cultivation. The tree is already cultivated to a considerable extent in Jamaica, where it is known under the name of byssi, and its nuts seem likely to become quite a valuable product.—*Colonies and India.*

LONGEVITY OF TREES.—How vast are the periods of lief alloted to the longeval trees may be judged from the following list of ages known to have been reached by patriarchs of the respective kinds:—

Elm	300 years.
Ivy	335 „
Maple	516 „
Larch	576 „
Orange	630 „
Cypress	800 „
Olive	800 „
Walnut	900 „
Oriental Plane	1,000 „
Lime	1,100 „
Spruce	1,200 „
Oak	1,500 „
Cedar	2,000 „
Yew	3,200 „

The way in which the ages of these vegetable Nestors have been ascertained leaves no doubt of their correctness. In some few cases the data have been furnished by historical records, and by tradition; but the botanical archaeologist has a resource independent of either, and, when carefully used, infallible. . . . Of all the forms of nature trees alone disclose their ages candidly and freely. In the stems of trees which have branches and leaves with netted veins—that is to say, in all exogens—the increase takes place by means of an annual deposit of wood, spread in and even layer upon the the surface of the preceding one. In the earlier periods of life, trees increase much faster than when adult—the Oak, for instance, grows most rapidly between the twentieth and thirtieth years, and when old the annual deposits considerably diminish, so that the strata are thinner and the rings proportionately closer. Some trees slacken in rate of growth at a very early period of life: the layers of the Oak become thinner after forty; those of the Elm, after fifty; those of the Yew, after sixty.—LEO. H. GRINDON.—*Journal of Forestry.*

HOT WEATHER BEVERAGE:—It may be useful to some gardeners to know that a pleasant and wholesome beverage for the hot weather can be readily made by mixing a little fine oatmeal in water, adding if desired a little sugar or a lemon. Larger quantities of this can be safely drunk than either of water alone or beer, and in some public establishments around the metropolis where a large number of men are employed a considerable quantity is used.—*Journal of Horticulture.*

DESTROYING GRUBS.—With summer suns the flies come, and after the flies follow caterpillars and grubs on boughs and at the roots. In some districts a friend of the bluebottle provides for its voracious progeny by laying its eggs at the roots of the cabbage tribe. Delicate in its taste it is, for it very much prefers the delicate cauliflowers, and thus they are frequently destroyed. Happily its organ of smell is also delicate, and a weak manuring of cow urine not only starts the plants, but sends the blue-tailed fly searching elsewhere. Applied stronger round the stems, but not in quantities sufficient to reach the roots—it would when strong kill them—it also kills the grubs. Sal ammoniac applied in water first, followed after by lime water, is said also to destroy them utterly. The chemical reaction liberates the ammonia, which poisons the maggots. —N. B.—*Journal of Horticulture.*

A CHEAP FERTILIZER.—The following combination is recommended by the Boston *Journal of Chemistry* as a cheap and reliable substitute for commercial fertilizers, such as superphosphates, &c.: Take one barrel of pure, raw, finely ground bones and one barrel of the best wood ashes; mix them on a floor, and add gradually three pailsful of water, mixing thoroughly with the hoe. Use in small quantities in about the same manner as the superphosphates. If the ashes cannot be procured, dissolve twelve pounds of potash in ten gallons of hot water, and with this solution saturate the bone flour thoroughly; a barrel of dry peat or good loam, without stones, may be added. The mixture should not be sticky, neither too moist nor too dry. In applying it, avoid direct contact with the seed; for instance, when applied in the hill, scatter a little earth over it before dropping the seed. A very early visible effect may not be anticipated; but the good results will manifest themselves as the season advances.—*Southern Planter.*

THE LUCKIMPORE TEA COMPANY OF ASSAM (LIMITED.) —Capital £150,000 in 15,000 shares of £10 each, of which 10,190 shares have been issued; area under cultivation, 921 acres. The directors much regret to have to announce another unfavourable season, resulting in a loss of £1,213 1s. 11d. on the working of the year. The causes which have led to this disappointing result are to be found, firstly, in the large deficiency in crop, viz., 97,116 lbs. under the estimate, combined with an expenditure excessive in proportion to the quantity of tea made, and with an abnormally short crop the general expenditure cannot be reduced in the same ratio; secondly, to the heavy fall in value of Indian teas amounting to an average of from 3d. to 4d. per lb. The last must be left to rectify itself as our teas get more widely known and better appreciated. The Mijica Jan crop was of excellent quality, and realised the high average of 1s. 5¾d. per pound, while the condition of the garden, as shown in Mr. Magor's report, reflects creditably on the careful management of Mr. Swinley. Nothing but the ravages of blight, which reduced the crop to 83,168 lb. against an estimate of 135,200 lb. and an actual outturn in 1880—before blight had attacked the bushes—of 150,700 lb. prevented last season being a successful one. We are glad to be able to report that up to the latest advices very little blight had appeared; so that there is a fair prospect of a good crop, and we have excellent reports on the new season's teas. In this division the estimated local expenditure is put at R34,300, being R9,160 under that of last year. The outturn for both divisions to the 30th ultimo is 56,955 lb. but although this shows unfavourably in comparison with last year, the Company is by no means alone in making a bad start in this respect—the crop over all the province having suffered from the protracted drought in the spring. With favourable weather the decrease ought soon to be made up. The estimates of outturn for 1883 are—

Bihallie Division	... ...	201,600 lb.
Mijica Jan Division	... ...	104,000 lb.

Should, however, blight not appear to any great extent, the crop of Mijica Jan ought to be considerably in excess of the estimate."—*Home and Colonial Mail.*

JAM SALES.—*Truth* says:—Lord Sudeley is building a large jam manufactory on his estate at Toddington, in Gloucestershire. Two years ago he planted there 93,000 gooseberry trees, 167,000 black-currant, 20,000 plum, 3,000 apple, 900 pear, 9,000 damson, 500 cherry, 10 000 red-currant, 25,000 raspberry, and 100 cobnut, and 52 acres were planted with strawberries. At the same time 100 Scotch firs and 10,000 poplars were planted for sheltering purposes. I wish him every success, for most of the jam now sold in shops is horrid trash. It may not be pernicious, but it is as different from the old-fashioned home-made jam as chalk is from cheese." There is a good deal of truth in this remark. There can be little doubt that the Australian jams which are being now imported into India are far purer than the articles manufactured in England.—*Madras Mail.*

THE KEELING ISLANDS.—Some few years ago, a visit was paid to them by a vessel bound from Melbourne to Madras with a freight of horses, and the following information results from that visit. The original settlement of the Keelings was formed under Captain T. C. Ross, four of whose sons are now resident on the islands working the cocoanuts. The Messrs. Ross, sons of Captain Ross by a Malayan wife, have been educated in Scotland, one of them being an M. D, who has taken his degree at a Scotch university. These four gentlemen own the islands, and a cocoanut oil manufacture of considerable importance is carried on by them at the Keelings. There are about eight hundred Malays and natives on the islands in the Messrs. Ross's employ, all engaged in collecting cocoanuts and converting them into oil, which is exported from the Keelings to Batavia, a distance of about 700 miles, in a sailing craft belonging to the Ross's. This vesel after discharge and sale of her oil freight in Java, returns to the Keelings with stores for the settlers. The Ross's live in a stockade on one of the islands, which they are capable of defending on occasion against any rising amongst their Malayan protegés. The four brothers exercise absolute authority in the islands, even to the putting an end with a revolver to the existence of any obstreperous Malay who may take it into his head to run amok. Money is quite unknown to the Messrs. Ross's subjects, who are paid for their labour with the means of existence, necessaries and small luxuries in the shape of baccy, rum, and so on, from the stores in the stockade. The natives give little or no trouble to their employers, and live their isolated island-life contentedly. The chief drawback to existence in the Keelings, however, is want of fresh water; there are no springs, and rain water has to be carefully collected and husbanded. Besides the cocoanut palms which clothe the islands, there are some eight other species of trees; but as mentioned in *Ross's and Imray's Seaman's Guide,* these form a very small part of the verdure of the islands. The craft owned by the Ross's, which transports their, cocoanuts and oil to Java, is sailed under the Dutch ensign; this is done to evade the heavy duties, export and import dues, levied on other than Dutch vessels at ports in the Dutch Indies. But the Ross's consider their settlement to be under the British flag; and by way of check to the designs of any Russian cruisers that may be hovering around the Indian Ocean, the Keeling Islands have recently been added to the Crown colony of Ceylon, and are thereby recognised to the satisfaction of the Ross's, as an integral item in the British dominions The beaches of the islands abound with land-crabs, sea-birds, and turtle. On some of the islands the cocoanut trees grow so densely crowded together that it is a difficult matter to make one's way through their groves."

THE SPRING VALLEY AND OUVAH (CEYLON) COFFEE COMPANIES' REPORTS.

We now give details of these documents. It will be matter of wide-spread regret that even the fine and liberally cultured Uva properties, which form the subject of these reports, and which once gave such splendid returns, have suffered so much from the effect of leaf-disease and adverse seasons, that Spring Valley gave but a trifling profit, while the other group of estates showed a positive loss. The appearance and prospects of the estates had, however, very greatly improved, and much is justifiably hoped from the systematic application of manure by means of wire tramways. We meant to have noticed those tramways and the facilities they afford for conveying fertilizing substances up the steepest inclines and to the most distant portions of the cultivation, in the proper place in our account of a recent visit to Uva and of Spring Valley revisited, after an interval of over forty-two years. We are compelled, now, however, to anticipate and to state that all we saw and heard during our visit was calculated fully to support the statements as to improved appearance and prospects of Spring Valley contained in the report. We should have scarcely imagined, from the appearance of the magnificent expanses of coffee which clothed the sides of Namunakulikanda, with scatterings of fruit still on and blossom bursting in snowy whiteness, that the leaf-fungus had ever been here at its debilitating work. In walking up to the fine cattle establishment on Spring Valley, the younger Mr. Rettie descanted on the beneficial effects of manuring the estate by means of "tramways." Having for the moment forgotten all we had heard of aerial wire tramways, we thought only of narrow gauge railways, and we asked, looking up at the steeps which surrounded us: "what is the gradient you are able to manage?" "Oh! any gradient," was the response, "even one in one." We looked sharply for the usual signs of insanity, but our informant did not seem conscious of having said anything extraordinary, and speedily we came to where, by the motive power of the splendid water-wheel, the wire tramways were at work, carrying baskets of manure not only up to the tops of the hills but beyond them in places hidden from sight, while the emptied baskets came streaming back. We did not ask for details of the cost of the fine and well kept cattle establishment, in which there were some beautiful animals, but the encouraging fact we did learn was that the cost of sending the manure uphill to central positions by means of the tramways was only 9d per ton! That is a fact of great significance not only to those whose surrounding circumstances enable them, like the proprietors of Spring Valley estate, to keep cattle for the sake of the resulting manure, but to those who, although they cannot keep cattle profitably, wish to apply to their plants composts of pulp, ravine stuff and artificial manures. Estate proprietors know that the mere cost of conveying such manure, in small baskets carried generally on the heads of women who think it undignified to hurry themselves, is so high as to be almost prohibitory. This source of expenditure can be most materially diminished by the use of wire tramways, the first cost of which, it will be seen, is not large, while they can be worked by the ordinary water-wheels of estates. The manure used on Spring Valley is compost of cattle during, made as bulky as possible with mana grass, &c., and fortified with phosphatic and ammonical substances in proportions which science and experience have dictated. The effect of such manuring is unmistakable, and now that capital expenditure on Spring Valley estate has ceased, the place being in perfect order and with all appliances except additional wire tramways, we were told that the 20,000 bushels of coffee anticipated as the crop of this season will yield more net profit than 40,000 did in the palmy days of large crops and wonderful dividends. While the wire tramways were carrying up the compost to where it was needed and where it was doing so much to improve wood, leafage and fruit, guinea-grass was flying down from the topmost portions of the cultivated ranges by means of wire shoots. The fields of guinea-grass on the summits of the Namunakuli sub-range, which constitute Spring Valley estate, were conspicuous from their brilliant emerald-green colour, as we descended the mountain passes of Uva to Badulla, the limit between coffee and grass being defined by a line as sharp and straight as the use of a theodolite could make it. What with bundles of guinea-grass coming flying down from distances aloft which reduced the grass-cutters to pigmies, baskets of manure going up, and empty baskets coming down, the air seemed alive with large hawks and mountain eagles. It was an animated and animating sight, and we can honestly bear testimony to the fine condition of this grand property, so well managed by Mr. Rettie and his assistants, and especially testify to the excellent effect of the liberal system of manuring adopted. Here, at any rate, manure does not go merely to provide more food for *Hemileia vastatrix*. It was to us a source of great regret that on this occasion we were unable to accept an invitation—which we were told had held good for ten years (!)—to visit the highlands of Glen Alpin—in its day one of the very finest estates in Ceylon and with the promise now of rejuvenescence by means of Mr. Brown's tramway system and under the careful superintendence of Mr. Lavie. *En route* to Spring Valley we saw evidences of the success of cacao on Rockhill, as noticed in the report. Details, however, we must reserve for the regular account of our journey. But we could not let the reports go forth without adding the impression—altogether favourable—left on our mind by our recent visit to the magnificent estate of Spring Valley, before which, managed and manured as it is, we believe there is still a great future. The same may be said of a large proportion of the coffee estates of Uva, and we are sanguine that Sir Arthur Gordon will not be long ruler of Ceylon when he will feel justified in proposing that the Uva railway extension be completed into Uva, through twenty-five miles of the finest country with the most salubrious climate in the world.

SPRING VALLEY COFFEE COMPANY LIMITED.

(*From the Annual Report*)

Good spring blossoms for crop 1883-84 have been out, and are reported as maturing favourably, and should the autumn blossoms prove equally good, there is every reason to believe that this crop will be a large one, as leaf disease has been less virulent and the weather generally seasonable. Recent reports from Spring Valley indicate a marked improvement in the condition of the property as compared with the two previous seasons, and wherever manure had been applied, the effect was most telling and satisfactory. With reference to this latter point, the Company's Manager assures the Directors that with plenty of manure, such as is now made on the property, there is little to be feared from leaf-disease. That a large and liberal supply of good fertilizer is an essential element in the profitable cultivation of coffee property, no one of extended experience will deny.

It has, however, always been difficult and expensive to deliver bulky manure to steep and distant fields. Hitherto, the chief mode of delivery has been by bullock carts; but these are slow when worked on narrow and steep roads, and their use involves considerable wear and tear of cattle, carts, and roads. The only other available means was by the carriage of the manure in basket on coolies' heads; and both these plans are out of the question when there is any considerable distance to transport the manure.

Shareholders will therefore be glad to learn that this obstacle to manuring operations has to a large extent been overcome on Spring Valley by the suspended wire tramways referred to in last report. These have now been completed and at work for some time, and are pronounced not only a mechanical success, but prove to be highly economical, and might with advantage be extended. Your Directors take this opportunity of specially complimenting both the Manager and the Company's Engineer on the pains taken in their erection.

Cinchona planting has received, and is getting every attention, and many new and improved varieties have been introduced. The great mortality taking place amongst cinchona trees in many parts of the island, has not extended to Spring Valley. The Ouvah district, owing to its free subsoil, is believed to be highly suitable for the growth of this plant. It has been found imprudent to take the bark off very young trees, so that large harvests must not be expected for a year or two. On Oolanakande the coffee tree has almost ceased to bear, the only product that seems capable of being grown profitably to supplant it is cacao. This is getting all due attention, but the number of enemies which attack the young plants are so numerous, that success seems by no means certain.

OUVAH COFFEE COMPANY, LIMITED.

(*From the Annual Report*)

As you were informed in last report, the Directors hoped to have declared a dividend during the past twelve months but thought it prudent to wait until they could form an opinion as to the crop to be secured during season 1882-83. It is feared, however, that on account of the blossom failing to fructify, this crop, which was at first estimated at 5 000 cwt., will not be over 4,000 cwt., and as more than half of this has yet to come forward, the working of that year at a profit greatly depends on the future of the Coffee market. This prospect has therefore been kept in view by the Directors in coming to the above decision.

Leaf disease has been much less virulent, during the past two seasons, than formerly, and strong hopes are entertained that it will soon cease to be a source of trouble. The two last unprecedentedly small crops are said to be mainly, if not entirely, due to unfavourable weather.

The Directors cannot but feel that Shareholders, in common with themselves, will be somewhat disheartened by the results of the working of the last two seasons, but they have much satisfaction in being able to report that prospects for season 1883-84 are excellent, on account of the favourable setting and maturing of good Spring blossoms.

It is impossible, however, as yet to form any definite idea of what the total crop of 1883-84 may be, as the Autumn blossoms have yet to come out: should they prove at all equal to the Spring blossoms, the crop will no doubt be a very satisfactory one, and if the Directors' anticipations in this respect are realized, they would have the pleasure of paying an interim dividend in January next.

During the past adverse seasons, your Directors have not deemed it wise to curtail, in too large a degree, the expenditure on the up-keep and cultivation of the Company's properties, and to their strict adherance to this policy, coupled with a more suitable season and comparitive immunity from leaf disease, are due the good prospects above referred to, and the present favourable condition of the estates.

Particular attention has been given to manuring on all the Company's estates, especially on Rockhill, and also on Ballagalla and Gabbela, where the erection of the Tramway has made liberal manuring not only practicable but easy. The Manager reports that the coffee on the two last named properties is looking as healthy and vigorous as it did in the days before leaf-disease, and this statement is confirmed by the superintendent who had charge of these properties when leaf-disease was unknown. The Manager further states that the excess of crop to be secured from this group of estates during the season of 1883-84, owing to the successful carrying out of these manuring operations, will alone be sufficient to meet the cost of erecting the Tramways.

The capabilities of the Tramway to lay down, at a low cost, large masses of manure in proximity to the fields to be manured, have been so forcibly pointed out by those who have had the working of it, that your Directors resolved on extending the line to the boundary of Glenalpin.

On the 1st June this extension was completed and commenced working. The promptitude and diligence displayed by the Manager and his assistants, and especially by the Company's Engineer in the erection of this is most praiseworthy. It will bring a large area of Glenalpin under a system of manuring similar to that adopted on Ballagalla, etc., and by another short extension of the Tramway not only could all those fine fields of the first named property, which formerly bore such splendid crops, be manured with the greatest facility, but also the adjoining portion of Graham's Land. This last contemplated extension will not, however, be added until further results are shewn.

With reference to cinchona, the Directors are pleased to report that as yet the percentage of deaths of these trees in Ouvah has been small, and it is generally believed that the soil of this district is well adapted for its growth. The Company has now considerably over 1,000,000 growing trees, but no large harvest can be expected from them for a year or two, as the barking of young cinchonas is found to be injudicious.

On Rockhill, for the past three years, attention has been given to the planting of cocoa at wide intervals among coffee. The oldest of these trees have now attained a good height, thereby indicating that the altitude, soil, and climate are favourable for this product. On Glenalpin, Ballagalla and Narangalla considerable areas have been planted with this product, and on the lower fields of the two latter estates its success is almost certain.

WEST INDIAN PLANTATIONS: "THE CONSIGNEE'S LIEN."

In the present state of public business, it is not, perhaps, of much use to urge that the condition of our West Indian Colonies deserves the attention of Parliament. The Legislature cannot find time to deal with more than a few of the domestic questions that stand imperatively in need of settlement, and will not, therefore, be disposed to look into the affairs of these comparatively remote possessions of the British Crown. Yet it is certain that the present circumstances of the Islands are far from satisfactory, and, unless some ameliorative measures be adopted, are likely to become worse instead of better. Some time ago, attention was directed in these columns to the evils resulting from the working of the West India Encumbered Estates Court. This Court, established in 1854, on the model of that which had then been for some years in operation in Ireland, was devised to facilitate the transfer of landed properties to persons who possessed the means of working them. The motive which animated its promoters was no doubt good, but the working of the experiment in the West Indies, as in Ireland, has been anything but beneficial. Its effect has been to transfer the actual and, in many cases also, the nominal, ownership of the soil to British mercantile capitalists, whose only concern is to secure a large return for their investments. There is no difficulty in understanding the process by which this result has been brought about. It is by the recognition of what is known as the "consignee's lien"—that is, a priority over every other creditor to any merchant or consignee who advanced money to the owner of a West India estate, or supplied him on credit with machinery or goods. This peculiar form of hypothec gives to the West India merchants who enjoy it a practical monopoly of the produce of the islands, and has transferred to them the actual possession of a large part of the soil. Embarrassed planters are obliged to come to them for advances, because of the impossibility of offering adequate security to any other class of capitalists. In this way the planter who, through inherited embarrassments or want of capital to work the property that has come into his possession, has had recourse to the merchant capitalist, can scarcely help sinking into the position of a mere resident agent for his consignee. The latter has no other interest in the property than as a source of pecuniary profit. He works it in that way till the land is exhausted, and then he either abandons it or asserts his prior claim as a creditor, and becomes the actual—though still the non-resident—owner.

The evils arising from such a system are obvious. But the actual reasons why during recent years the prosperity of most of our West Indian colonies has either been stationary or has absolutely receded, lie still deeper. The working of the Encumbered Estates Court has, no doubt, served to hasten and intensify their operation; but that Court could not have done much mischief if the position of the proprietary class in the Islands had not been radically unsound at an earlier period. It was the fact that a great many planters were hopelessly embarrassed which led to the establishment of the Court; and the question naturally arises—what was the cause of all this embarrassment? The subject is discussed with much ability and candour in a pamphlet just published by Mr. C. S. Salmon, under the title "Capital and Labour in the West Indies." Mr. Salmon maintains—and he advances a formidable array of argument and evidence in support of his contention—that the root of all the evil is the existence of false relations between the landowners and the labouring class, first created at the time of the emancipation, and since rather intensified than diminished. At the period when the slaves in the West Indies were freed by an Act of the British Parliament, which at the same time compensated the planters for the loss of the human property of which they were deprived, the only labour which was available for the cultivation of the soil was that of the imported Africans; the aboriginal population had been completely extirpated. Under these circumstances, it might have been supposed that the owners of the land would have endeavoured to arrive at a friendly understanding with the emancipated negroes; would have conceded to them the rights and privileges of free men; and would have convinced them that it was their interest, as well as their duty, to assert their place as a section of the community. Unhappily, except in a few instances, nothing of the kind took place. The barrier of dislike and suspicion which the long continuance of the system of slavery had reared between the white men and the blacks was still kept up. The negroes looked upon their former masters as their natural foes, who had perpetrated cruel wrongs upon them in the past, and were not at all inclined to be friendly to them, now that the terrible power of ownership had been taken out of their hands. The attitude of the planters gave too much justification to this feeling. They were, for the most part, firmly convinced that it was impossible to get good work out of the Africans except under the lash; this conviction regulated all their dealings with the emancipated blacks, and has long been elevated into an article of faith with most West Indian proprietors. It is a belief which has no foundation in actual experience. Badly paid, under-fed, looked upon by their employers with dislike and contempt, the West Indian negroes have not proved efficient as free labourers; but it may be asked whether, under like conditions, men of any other race would have done better. They have no incentive to industry. They know that the planters have no care for or interest in their welfare; they are still aliens in a country where they form the largest part of the population, and where a pernicious fiscal system makes them, notwithstanding their extreme poverty, bear the greatest share of the burden of taxation. It would almost seem that the generous principles on which the emancipation was carried out, though offering a noble example of self-sacrifice and abstract justice on the part of the mother country, have had an injurious effect on the subsequent development of the West Indies. The method by which the curse of slavery was banished from the United States, though far more rough at the time, and inflicting great temporary suffering on the slave-holding class, has had happier results so far as the permanent progress and well-being of the country and the population are concerned. The change was there accompanied at the sword's point. The slave-holders receive no compensation. They were left to accommodate themselves to the new order of things as they best could, without aid from anybody, and they have done so. The process of social reconstruction in the Southern States is, of course, far from complete, and it has been attended by some unsatisfactory features. But the States have already, in great measure, recovered from the shock which their prosperity sustained during the war. The cotton and other crops they produce are larger than in the most prosperous days of the slave system; and the negroes show none of that incapacity for work with which their fellows in the West Indies are credited.

The significance of these facts cannot be overlooked. More than half a century has passed since emancipation took effect in the West India Colonies. They are naturally one of the most fruitful and productive regions on earth; they have every advantage afforded by facility of communication and vicinity to great markets. Yet few of them have made any progress during the last fifty years, and some are positively worse off today than they were in 1830. In Antigua the population has declined; the exports have increased since 1850 by about 22½ per cent; but the revenue, and the consequent burden of taxation on the inhabitants, has more than doubled, and a large part of it is raised by duties levied on food imports, which, of course, tell most heavily on the labouring classes. As regards St. Kitts, the statistics are slightly more favourable; for Nevis, Dominica, and several other islands they are less so. Barbadoes, where the African population has generally been well treated, and has consequently been industrious, is prosperous and flourishing. In Jamaica, on the other hand, the relations between the proprietary class and the negroes are well known to have been the reverse of friendly, and there, though during the last ten years there has been a large importation of coolie labour, the increase in the value of exports has been very small, while taxation is heavy and the expenditure large. Speaking generally, the condition of the Islands is not one of progress or prosperity. The estates are falling more and more into the hands of non-resident proprietors, who are absolutely indifferent about the general welfare of the inhabitants, and are favourable to the coolie system because it enables them to work the land cheaply. But this is not the only result which should be aimed at by the Imperial Government. The West India Islands form one of the oldest portions of our Colonial Empire, and it is not for the national credit that they should sink into a condition in which land-owners and labourers alike are alien to the soil, and different to the permanent well-being of the colonies. That, however, is the tendency of the present system, and the ultimate outcome of the substitution of imported East Indian labour for that of the resident population will be serious embarrassment for the Government, and impoverishment for the Islands themselves. How the evil is to be remedied it is not very easy to say ; but, at all events, a case has been made out for Parliamentary inquiry as to whether, by the continuance of the Encumbered Estates Court, the existence of a resident proprietary class should be rendered increasingly difficult.—*Scotsman.*

THE CAUSES OF PLANTING DEPRESSION.

(*Paper read by Hon. J. L. Shand before the Dikoya Planters' Association.*)

Forty years ago, if Ceylon had had a Governor, who, preferring the ease and comforts of the viceregal residency to the inconveniency and difficulties experienced in travelling with the then limited means of locomotion and lacking sympathy with the people he ruled over, was contented to acquire a knowledge of them from a perusal of the memorials and petitions he received, had been asked by the Secretary of State "Who are these coffee planters who are beginning to agitate Ceylon?" the answer might have been "They are a turbulent hill tribe probably of Bohemian or Bulgarian origin constantly on the borders of insurrection but showing vague signs of a crude civilization by a restless hankering after roads, bridges and other visionary impossibilities."

But as time passed on the numbers and strength of this hill tribe increased: they purchased land ; in the face of great difficulties they imported labor and cultivated it ; they opened up large tracts of country; the roads and bridges which had appeared impossibilities were constructed; they provided, in great measure directly by an export duty upon the coffee they grew, the funds for the construction of the Colombo-Kandy Railway, which often being talked about for twenty years was opened in 1867, and which even in these times of depression is a source of net revenue to the colony of £1,000,000 per annum. The product they cultivated soon became and still continues the staple export of the island, and as is shown by the customs returns and land sales in spite of the vicessitudes to which coffee-planting has always been exposed they steadily and rapidly increased the revenue of the island and became a power in the state. Time will not allow me to follow the history of the coffee enterprise in Ceylon: the variations to which it has been subject are fully accorded in "Ferguson's Handbook" and proceed to some extent from the same causes which have brought about our present depression, and whether it is the relation of cause and effect, it is remarkable, how the several periods of planting poverty and prosperity have been attended by similar cycles of apathy and activity on the part of the Government of the island. All previous crises seem to have been brought about by the opening up of land unsuitable for coffee, extravagant outlay, the low price of produce, and the whole withdrawal of due credit; and we may partially attribute our present difficulties to the two first causes. We cannot blame the price of produce, for it has ruled higher for the last ten years than the most sanguine would have dared to predict; nor can we blame the withdrawal of credit, for money is abundant, and it is clearly the failure of our land to produce coffee crops which has caused our financial difficulties, and this present, as I shall show afterwards, a far gloomier but at the same time a far more hopeful side to the picture than any previous crisis, and it is in great measure dependent upon ourselves which side we shall look upon.

About twenty years ago some adventurous men began to take up land in these districts : I say adventurous advisedly, because most of the older and more experienced men shook their heads and said soil and climate rendered these lands unsuitable for coffee culture and black bug would prevail, and though some of the early opened estates in Dimbula had yielded good crops, this opinion seemed justified. Several planters who lived on the confines of what now forms these districts and knew the land preferred seeking investments in the drier Laggala country, and there is a notable instance of an old planter, who persuaded by a younger and more sanguine man to enter into partnership in purchasing a block of land, and who, has been living for many years in comfort on the proceeds of this land, has told me that when he saw his first clearing he expressed the opinion that it might grow potatoes, certainly not coffee; but wonderful results attended the labour of these pioneers : they got crops beyond their most sanguine expectations ; the climate which had been pronounced unsuitable seemed suddenly to change (attributed by many to the felling of forest), and to become all that could be wished for. Incited by the opening of the Kandy-Colombo Railway, by the confidence and credit afforded by merchants and bankers, and by the immense stimulus of 1873, when the price of coffee was nearly doubled, purchasers, flocked eagerly to take up land (in spite of leaf-disease which first appeared in 1869, and which had overspread the country), until £20 per acre for forest, and £100 an acre for coffee land in bearing, became almost standard valuations which were fully justified by the returns coffee land was giving and which would have been borne out if it had fulfilled early promise.

It would be presumptuous for me in these limits to account for the collapse of coffee upon which cynics and philosophers form out weekly columns but I shall touch upon what I consider a few conducive points :—

1st.—The excessive price paid for crown lands enabled Government to bolster up a false revenue and treat as income money realized by the sale of land alienated in perpetuity. If the price of land had never exceeded R10 per acre we might not yet have had a museum or a new lunatic asylum, or several other offices and buildings which might be dispensed with, but the position of both state and individual would have been far healthier.

It was not generally the capitalist who paid R200 per acre for forest, but the man who traded upon credit, and this means not only a direct drainage from the land of both for purchase and payment of future interest money which should have gone to develop it, but also the opening of all land suitable, for no borrower can afford to pay R200 per acre for forest and leave it standing idle.

The price of coffee property is, of course, regulated by the price and quantity of suitable forest land in the market, and the steady drain from the island of money to pay interest on borrowed money has prevented land having justice done to it and has done much to precipitate matters. The high price of land and the injudicious opening occasioned thereby, over-speculation and extravagant expenditure caused by too liberal facilities for obtaining credit, may be classified together, and this extravagance was not confined to the purchase of property but extended to cultivation so much so that for years the cultivator who crammed in most manure, who erected the largest buildings, cut the finest roads, who spent most money, ignoring financial position or results, was accounted the best planter ; but in spite of all the cruel things now said about coffee the men in this and other districts who brought with them money enough to justify of their purchasing property, who neither traded nor lived beyond their means, who have been guided by experience and not negligent of their interests, have as a rule found good investments and are in the position now of being able by the cultivation of other products on land where coffee has ceased to be remunerative to steadily increase the value of their properties.

2nd.—Any careful observer of the weather (and we are fortunate in having in Dikoya one whose observations have been very extensive) inclines to attribute much of the failure of the last five crops to insufficient heat and untimely rains, and there can be no doubt that, just as the climate for some years took a favorable turn and coffee yielded fruit beyond expectation, so we are now suffering from a corresponding period of unfavorable seasons, which, added to the fact that owing to periodical attacks of leaf-disease coffee is more suspectible to the action of the weather than formerly, has compelled many reluctantly to stop the application of manures, of which ver large quantities were for years applied without the rasult of a proportionate increase of crop yield. The monsoon we are now undergoing is such a complete change from the months of cold damp sunless weather which have been familiar to us of late years that we may look for a change which must befor the better.

3rd.—Animal pests have also done much harm, and there are those among us who still say they fear not leaf-disease if they could get rid of grub; but I am still of opinion that much is attributed to grub which is due to the condition of the soil or to its action upon trees the constitution of which is already weakened by leaf-disease. There is another animal pest from which we have suffered a good deal, and which resembles the grub in many ways, but chiefly in attempting to destroy in the dark the tree upon which it feeds. I refer to the croaker or pessimist pest: I prefer the latter name, because my dictionary tells me to croak is to caw like a crow. I have no objection to croaking or cawing, I have every wish that my spade should be called a spade, but I object to being told, especially if I have to pay for this opinion, "This spade is apparently a very good spade, but I tremble to think what might be the consequences to this spade if at some future date in unskilful hands it came in contact with a granitic boulder, and I cannot, therefore, attach a value to it." I object to being told, as I was a short time ago by a Colombo merchant with great influence in London, after having discussed with him, and, as I had hoped, disposed of satisfactorily, the question of yield per acre and quality of tea, that he foresaw difficulties in the way of procuring labour when tea became largely grown in Ceylon. He had seen more of the world than I had, and if he had told me he dreaded the extinction of the tea entereprize in Ceylon by an iceberg which would one day float down the Paumben Channel it might have given me a momentary anxiety, but to tell me, who have been working Tamil coolies for eighteen years and who have seen them in their own homes, and who know that the extra 150,000 or 200,000 coolies we may require when we have a large area of land under tea can easily be procured by those who treat their laborers well and pay them regularly, is to go out of the way to create a phantom.

There is one more animal pest which I may call the *company* pest.

There have been several companies connected with Ceylon, formed perhaps in some cases, as companies are generally said to be, by philanthropists desirous of benefiting their fellow-creatures by affording them opportunities for the profitable investment of capital, in other cases by designing men who would relieve themselves of doubtful responsibilities at the expense of others, and whichever the object of formation there is no doubt the agricultural Companies of Ceylon, have with few exceptious proved a failure. The Company which so prominently bears the name of our island, but which hitherto has attributed its losses to another island, has done much to weaken our credit, and the malignant rony of fate pursues us still, for just as we are on the ipoint of securing confidence and attracting capital to the tea-growing industry in Ceylon this Company publishes a report showing that its yield of tea per acre was less than 140 lb. over their acreage in bearing, and that it has lost £900 on the cultivation of 1,100 acres for the year; but even in this there is comfort, for if the loss is less than £1 per acre on producing 140 lb., it requires only a simple proportion sum: what will the profit be if we can produce 400 lb., which can be done if tea-planting be carried out properly on almost any estate in this district?

4th.—And now I come to the fourth and gravest cause of the barrenness of our land, that is LEAF-DISEASE. Well do I remember when, as one of a sub-committee working up figures for the Matale railway, it was resolved that crop 1872 was so abnormally short and so unlikely to recur again that it would be unwise and unfair to include it in our statistics: *that* crop was, off a very much less area, three times as much as the crop now being shipped. This mysterious disease, which has so far baffled science and practice, still continues to work its insidious way, and though there are still districts, estates and parts of estates where, with favored circumstances of soil, climate and above all things shelter, high cultivation can still be profitably carried out, we must face the fact that there is much land now under coffee cultivation which is not only unremunerative itself but which is absorbing for the cost of its cultivation the money which might be very profitably expended upon crop-yielding coffee: in other words our good coffee is being made to pay for our bad, and the first step towards placing Ceylon upon a sound footing is to rectify this. I do not take the gloomy view. I think there are on most places fields which will go on yielding profitable crops of coffee, and I do not overlook the fact that with the favourable blossoming seasons of 1876-78, *i.e.*, after 6 or 8 years of leaf-disease, many old estates gave bumper crops, and I do not despair of their doing so again, but in nearly all our valleys there is a certain zone in which coffee never has and probably never will be cultivated profitably, and on every estate there is a certain non-yielding acreage which is hampering the better fields to maintain. To plant this non-productive land up with the products adapted to it and to relieve poor productive land of the cost of maintaining it is the thing to consider. The way to increase our yield of coffee is to reduce our acreage of coffee, and in this we have the best chance of mitigating leaf-disease, for we all know estates or fields upon estates which surrounded by forest or isolated from other large areas of coffee do not suffer from leaf-disease so acutely as estates surrounded by coffee.

And here I must say a few words about cinchona, which is being unnecessarily decried. No doubt, a great deal is dying out, but no doubt a great deal of this was hurriedly planted not always from well-selected seed. We know it is a delicate thing, and we are beginning to know that it won't grow everywhere, and he who, instead of going on year after year planting up land suitable and unsuitable, exercises judgment in the selection of land and plants, and goes about the cultivation properly, will reap his reward. The continuous wet of the last two planting seasons has proved fatal to many young plants, and those put out early this year have already caught up many of last year.

And here we must look at both sides of the picture I have referred to. Our crisis is more serious than any other crisis, in that fall in prices and financial difficulty are temporary troubles which time adjusts but the failure of land to produce crops from a disease which we have no prospect of curing is a far graver matter or would be if it were not for altered circumstances. For many years—indeed until lately—it was an accepted theory that it paid the European to cultivate coffee in Ceylon, that anything else would ruin him, and that when his estate ceased to yield coffee profitably it ceased to be of any value. eWe have changed all this: we have proved that tea, cinchona, cocoa, cardamoms, &c. &c. can be profitably cultivated, and some of the most valuable properties in Ceylon at present are properties upon which coffee was exhausted.

I had meant to touch upon all our new products in turn but I have already trespassed too long upon your patience. The question which is of particular interest to this meeting is: will it pay to cultivate tea at this elevation? I am myself satisfied that it will. We have had much scepticism to conquer introducing tea. "Your land is too steep," said one; one; "You will never get sufficient yield," said another "You may get quantity but not flavor," said a third. We have overcome these difficulties, and now scarcity of labor and new and hitherto unknown diseases are suggested. The duty of man is to try and overcome difficulties, not to create them, and with our advantages of labor, transport and climate, not to speak of the minor advantages of water power and many other things, judging from the way tea adapts itself to our circumstances from sea level to the tops of our hills, there is every promise of its proving a remunerative investment if carefully carried out and of Ceylon becoming the greatest tea-exporting country in the world.

I had collected figures as to the yield of tea, cost of production &c. from several estates, which I meant to lay before you today, but as Mr. Armstrong has kindly promised to address our Association upon this subject soon I prefer leaving this subject in his hands, the more so as his practical and lengthened experience of tea-growing at a high elevation stamps him as one of those best able to answer the question. It is in times such as these that we should look for help and sympathy from Government, but, I fear we look in vain. The same fell disease has been at work on native coffee gardens as an European plantations, with even more disastrous results, for a large tract of the most valuable land in Ceylon has been allowed to pass out of cultivation the people having been driven to theft to make a livelihood.

In the Kandian valleys there are thousands of acres of the richest land in Ceylon capable of growing cocoa, cardamoms, tea, all cultivations specially adapted to the native, but what encouragement has been given to, or compulsion put upon, the people to again render their lands profitable to themselves and to the country, and what has been done for the European planter ? Roads have been refused on all sides, and instead of reducing railway rates on manures and produce, which we might look for, the freight upon cinchona bark has been increased, and an export duty in this the time of our greatest need has been placed upon our produce, because we enjoy the same medical advantages which are afforded gratuitously to all other sections of the community. But, as I have pointed out, apathy and activity on the part of Government have periodically succeeded one another, and I think we may look for a reaction.

And now, gentlemen, in conclusion : I have been eighteen years in Ceylon, during which I have shared the ups and downs common to that period, and I never felt more sanguine of being able to retire with a competency when my life's work is over than I do at present.

We have had a hard fight ; many a man has had to succumb to his difficuties after a brave struggle more may have to do so ; but given health and strength there is time for all to rise again, but especially to you young men who are not hampered by previous investment nor handicapped by advancing years does Ceylon offer an opportunity which it has never done before. A hundred pounds does more now than a thousand pounds did eight years ago : you will be able to buy cheap land, you won't be allowed to trade beyond your means, and property has now a permanent value which it never had before. I have put these remarks together not so much to convey instruction as to encourage hope and perhaps discussion. Those who have the opportunity of going about the country, of seeing tea, cocoa, cinchona and other things thriving where coffee had ceased to be remunerative, of seeing lands at Polgahawela and elsewhere, which a few years ago were considered valueless, giving the promise of splendid returns, must agree with me that it is not yet noon in Ceylon, and I am sanguine enough to think that with care and energy on the part of planters and help or sympathy from Government extended to all classes we shall tide over our time of depression and place the island upon a firmer footing than it has over been on before.

Dikoya. J. L. SHAND.

CONSULAR REPORTS : PROSPECTS IN COCOA, COFFEE AND RUBBER, PEARL FISHERIES, &c.

By a recent mail our London correspondent sent us number of interesting extracts from Consular Reports, stating first that in a report by Colonel Mansfield upon matters connected with the trade, etc. of Venezuela the following statements relative to cocoa and coffee cultivation in that country, occur :—

COFFEE AND COCOA IN VENEZUELA.

Cocoa is always a profitable business, and the export of the Tonquin bean has brought a satisfactory profit in the districts of Guayana.

The depreciation of the price of coffee is most serious to a country like Venezuela, which depends almost entirely upon the export of that article ; and no alteration upon this head can be anticipated until the coffee-growers of Brazil have been ruined, and untill railway communication is opened in Venezuela whereby to diminish the cost of delivering the article upon the coast. It is understood that the Brazilian grower already finds himself subjected to considerable straits, and upon this the Venezuelan, perhaps somewhat uncharitably, bases his hope that better days are in store for him at no distant date.

"There is a very valuable report by Mr. J. A. Crome, Commerial Attaché to our Embassy in Paris, touching the use of silos in France. It is too long for insertion here, but you will find it enclosed, as you might probably like to reproduce it in the *Tropical Agriculturist.*"

In Mr. Consul O'Neil's report on Agriculture and Labour in Mozambique, he writes respecting coffee and indiarubber :—

COFFEE AND RUBBER IN EAST INDIA

Coffee.—It is painful to have to repeat here the old tale of failure. Stronger efforts have perhaps been made to establish in this Colony the plantation of coffee than that of any other product. We are told that in the first year of this century, in consequence of recommendations from the Court of Lisbon to encourage this industry, the Colonial Government offered to purchase from all producers the coffee they could not otherwise dispose of—a great boon in those days of dangerous and uncertain communications. And some years afterwards the Government charged itself with the purchase of all the coffee that could be collected. Mozambique coffee had been declared at Lisbon to be of the best quality, even that which grew wild ("todo o cafe do Moçambique era optimo, atè o que nascia espontaneamente"), and His Majesty the King was pleased to receive as an annual present all that was grown in the province, presumably with the intention of extending the taste for it and encouraging its production. But if we are to judge from the following statistics of coffee exported, we must conclude that, notwithstanding all this, its cultivation was never even seriously embarked upon.

Amount exported in—	lb.
1811	352
1812	314
1813	None.
1814	320
1815	208
1817	160
1819	96

"The last present of coffee from Mozambique was received by the King in 1832."

The same recorder tells us that the failure of this industry was due to the indolence and inability of the planters ("nunca progediu esta industria pela inhabilidade e preguiça dos agricultores"). Another cause, probably, lay in the Slave Trade of that day in which all, to a greater or less extent, embarked, and which stifled every legitimate enterprize. It was easier and more profitable to export labourers than to instruct and superintend them in the cultivation of the products of the soil.

Coffee has failed utterly in the adjoining Colony of Natal after the expenditure of many scores of thousands of pounds in efforts to make its cultivation successful. The sudden variations of temperature, the uncertainty of rain fall and liability to droughts, I have heard alleged as the causes that brought about the failure.

These certainly do not exist to the same extent in Mozambique, and I think the profusion with which the tree grows wild, and the quality of the berry from the tree in that state afford fair proof that it may be cultivated here with success. It is still collected by the natives and sold to traders on the coast. The point at which I have seen the largest quantity is at Mwendazi, in Mwemba Bay, to which port it is brought a distance of three and four day's journey from the neighbourhood of the hills Eradi and Mwaja. I have been told that the slopes of these hills are thick with the coffee bush, and that the natives, who pay no attention whatever to its cultivation, shake the berries off the tree at the proper season, collect them, and bring them down to the coast. A few words must now be devoted to these valuable products from the growth of which —with two notable exceptions—the commerce of this province derives, as yet, no benefit. Some of these are indigenous, others have undoubtedly been introduced, but no reliable record remains of the date of their introduction. Although they may seem somewhat out of place under the head of "Agriculture," yet no attempt to describe the agricultural capabilities of the province would be complete without mention of them.

India-Rubber.—The collection of this product is of very recent date ; but it has so rapidly extended that it now forms the largest and most valuable export of the Colony. I regret that the imperfect nature of the returns of the Custom-house of Mozambique do not enable me to show statistically the remarkable development of this industry ; but I believe I am well within the mark when I say that not less than 50,000*l.* worth of india-rubber passed through this Custom-houes within the past twelve months. whereas in 1873 the export was only of the value of 443*l.*

The rapid extension of the rubber industry is due entirely to the natives, and in its working they have been left from the very commencement to follow their own devices. Untaught and clumsy in their method of collection, it is but natural that an enormous number of these valuable trees should have been destroyed by them: In proof of this, I may mention that there comes into the market an inferior quality of rubber extracted from the roots of this tree. When the natives see that no more juice can be drawn from the stem, and believe the tree to be dead, it is their custom to pull up the roots, and by pounding and boiling to extract the last trace of rubber from them. As far as I have been able to discover, the india-rubber exported from the northern portion of this province is drawn from only one species of plant of the genus Landolphia, whereas I believe that a very little research will show that two, if not three, species exist in the same locality. Five years ogo I was employed upon a mission by Sir John Kirk, on the continent of Zanzibar, one of the objects of which was the collection of specimens of this plant from which the rubber of Zanzibar commerce was drawn. I was then so fortunate as to light upon two new species of this plant, called by the natives Mbungu and Mtolia. These were sent to the Royal Gardens at Kew, but I do not know under what names they bave been classified. One of these, the Mbungu, is to be found upon the mainland of Mozambique. I have met with this species upon several parts of the coast, but nowhere do the natives appear to be aware of its value. Growing upon more humid soil than the species from which the rubber of Mazambique is extracted, it yields a more watery juice, which the native has not yet discovered a method of congealing. Asking them if they never attempted to collect it, they have replied, "It is impossible, it is too watery, we can only use it for making bird traps." Smeared over and about the traps it adheres to the feathers of the birds, and retarding their flight makes them easy captives. There is also another species upon the coast land of Mozambique, called by the natives "Rava," utilized for the extraction of rubber, and bearing a like watery juice. The milk of both these may be congealed by the application of the juice of the lime, as is done, I believe, in the collection of a similar species of rubber in Madagascar. The market value of the rubber drawn from these plants yielding a watery juice will I think, always be less than that which is wound off by hand; for in congealing it carries with it a certain amount of water, and it loses weight for some months after collection. But this collection is easier, and in the untouched forests that exist of these distinct species of the rubber plant, I think I may venture to say, there lies an additional source of wealth to the province.

There is a communication by our Political Resident in Persia, and here are some papers having reference to the Pearl Fishery in the Persian Gulf which have a bearing perhaps on the kindred industry in Ceylon :—

The Agent at Lingah to Lieutenant-Colonel Ross.

November 1st, 1882.

I beg to report that on the 23rd October small fishing-boats went to sea to fish in a western direction from the place where the native craft lie at anchor at Lingah, in 5 fathoms water, and being about ¾ of a mile from the shore. The boats began to fish, when the fishing-line got entangled at something under the sea. The boatmen dived to get the thing out. When they reached the sea-bottom they found it covered with shells ('Ziunee" and "Mahar"*). They then commenced to dive for the shells. Up to the presen some twenty boats, of large and small size, have been engaged daily in fishing at the pearl bank. They have now taken out some 50 maunds of shells, at 9 lb. each maund. They principally take out the zinnee shell, as the mahar shell is small in quantity. Daily they get pearls to the value of about 200 krans. They sell the zinee shell at 2¼ krans per maund of 9 lb. Owing to cold weather, they cannot dive for the shells more than four hours every day.

*"Zinni" is a mussel-shell larger than "mahar," and is ovally elongated; its inside is lined with a thick ename of a pearly lustre, for which it is in great demand for various oranamental purposes. It yields smaller and lighter pearls of inferior quality, which are liable to deteriorate by change of colour.

"Mahar" is description of pearl-shell much smaller than "zinni," and is more or less round: the enamel is not so thick, and is a more reddish tint than that of "zinni," but it yields pearls of large size and best quality.—A. R. H.

A second bank of pearl shells has also been discovered to the east of the place of Lingah shipping, extending to Kong. This bank possesses more mahar shells, and the people dive for them at this bank. I beg to send by post some specimens of shells, viz., two zinnee shells, and two mahar shells from Kong. True purport, (Signed) A. R. HAKEEM.

No. 10.

(*Mr. Thomson to Earl Granville.—Received February 2nd*, 1883.)

Tehran, December 11th, 1882.

My Lord,—With reference to my despatch of the 27th ultimo, I have the honour to forward herewith copy of a further report which has been addressed to the political resident in the Persian Gulf, by the residency agent at Lingah, announcing the discovery of another pearl bank to the west of the ports of Charak and Tavaneh. I have, &c. (Signed)

RONALD F. THOMSON.

The Agent at Lingah to Lieutenant-Colonel Ross.

November 16th 1882.

I beg to report, for your information, that on the 11th instant I received information that to the west of the Ports of Charak and Tavaneh, at a place called Mowiah, where the people of Charak and Tavaneh always fish the "matool fish," a pearl bank was discovered, during September and October 1882. The divers came to know about it at the close of the diving season. About 40 "baggarhs" belonging to the people of the Islands of Kais and Hindrabee, and Shaikh Shaab, went to the above spot, and dived there. In a short time they got pearls valuing about 15,000 krans. As the cold increased, they closed their operations. They dive there in depths varying from 2 to 5 fathoms. The pearl shells are principally the "Arabee Mahar" shells. True purport,

(Signed) A. R. HAKEEM.

THE "CORNER" IN RUBBER.

The annual product of crude rubber amounts to many millions of dollars, and in its manufacture in this country alone from $30,000,000 to $40,000,000 are invested. Yet within three months, by shrewd and audacious and skillful manipulations, a single individual has "cornered" this commodity, forced up the price from 95 cents to $1·20 per pound, and kept it at the latter point for several months, notwithstanding that the nominal price of crude rubber is from 60 to 65 cents a pound. The man who did all this was one J. C. Gonçalves Vianna, barão de Gondoriz. He has before shown his ability as a remarkably bold and successful speculator. Once a promising clerk in the rubber exporting house of Victor Rodrigues d'Oliveira, of Pará, Brazil, he was in 1877 admitted to partnership, and soon became the controlling spirit of the firm His first great achievement was executed in 1879, when by skilful scheming he forced the price of rubber up from 40 cents to $1 per pound, and made for himself a fortune of several hundred thousand dollars. In 1881 he attempted a similar experiment, but this time met with less success. Treacherous contracts made by his junior partner with New York merchants involved him in great difficulties, and long negotiations, after he saw that he must fall, resulted in his paying $52,000 in cash to two of the manufacturers whom he had treated most shabbily. Failing in this attempt, he next, in July, 1882, bent his energies to organize a gigantic syndicate to control the rubber market of the world. At that time the ruling price of Pará rubber was 90 to 95 cents per pound, to which price it had been elevated by purely natural causes. Backed with heavy capital, he set at work buying the new crop as fast as it arrived at the exporting markets of Brazil. For months he seemed to be completely successful. The price of rubber went up, up, up. Manufacturers were astonished at the audacity of one man attempting to monopolize the market, and at first abstained from purchasing at the extreme price he named. But afterwards, being forced to purchase against contracts that they had already entered into for manufactured goods, they accepted his terms, and sparingly, it is true, bought to protect those goods. Fortunately for the manufacturers, the early part of the season of 1882 had produced about 40 per cent. more manufactured goods than usual, and as the end of the season drew near it was seen that the supply of goods was far in excess of the demand. The price of the raw material had been forced by the baron to a dangerous height, and for manufacturers to continue business meant for them to accumulate goods which had an unprecedented cost and they could see no market in which to dispose of them. Therefore, they felt obliged to protect themselves, and many of them agreed at meetings held about the middle of October last to close their factories until the trade should warrant their paying the extreme prices which the baron demanded. Baffled by this unexpected flank movement, the baron attempted to unload hisenormous stock, but without success. Again finding himself blocked, and that the rubber which his friends had on hand was costing him by shrinkage in weight and interest from $60,000 to $70,000 per month to carry, he could see no way out of the snarl in which he had involved himself and his friend, and it would seem that he has ceased to pass sleepless nights over the situation, and has concluded to let the other fellows walk the floor.

The American manufacturers still preserve their apathy and will continue to close down, it is said, until the middle of May. Their increased capacity for manufacturing goods enables them to make their full supply in less than one half the time that they required a year ago, and the jobbers of this country are also wide awake to the situation, and can see that in the next few months there must be a shrinkage in the value of crude rubber on hand of possibly $2 ,000,000. They therefore refuse to buy any goods, as they do not need them before next July or August to distribute to their trade.—*Boston Globe.*

CONSULAR REPORTS.—JAVA.

(From the *L. & C. Express.*)

The following paragraphs are from the report by Consul Cameron on the Trade, Commerce, and General Matters relating to the Island of Java for the year 1882:—

EXPORTS.

Sugar.—The total production of this year is slightly in excess of that of 1881, the crop at the eastward of the island being estimated at about 10 per cent larger, whilst those of western and central Java are about equal to the harvests of the proceeding season. Transactions in the 1882 crop commenced considerably earlier in the season than has been the case for some years past, the first business being put through in December, 1881, at fl.15 per picul for No. 14, which quotation was maintained throughout the year, little or no variation in prices being experienced. Considerable interest has been taken in the invention of a Mr. Bal, consisting of a patent stove for the dying of the "ampas" or cane refuse, by which treatment the substance is immediatloly rendered useful as fuel: a matter of great importance in most mills, where formerly the "ampas" took two or three days to dry in the sun. The cost of the stove is moderate, and it is reported that a considerable number have been ordered for use during next season. The total production for the year is estimated at about 4,500,000 piculs, as compared with 4,100,000 piculs in 1881, and 3,294,500 piculs in 1880.

Coffee.—On the whole the out-turn of year's crop has been satisfactory, the production of private gardens being soomewhat in excess of that of last year, whilst from the Government plantations 17,255 piculs more have been obtained than in 1881, viz., 1,024,868 piculs, as against 1,007,613 piculs in that year. Numerous fresh concessions of land at eth eastward of the islands have been granted, and their cultivation with coffee has been immediately undertaken both by private individuals and companies. Owing to the opening of the Preanger and Kediri railways transport has been much facilitated, and the complaints as to accumilation of Government stocks in the interior, which were so rife during last year, have not been heard. Little or nothing has been heard of the leaf-disease this year, and it is now considered probable that the exceptional prevalence of the disease during 1880 was alone due to the unusual wetness of the east monsoon of that year. Special attention is now being paid in Java to all new machinery tending to decrease the hand labour required in preparing and sorting coffee, and considerable supplies of the latest patents have been imported here, both from Ceylon and Europe.

Rice.—The crop of this staple has been satisfactory throughout the island; at the eastward the floods above referred to effected considerable damage in certain districts, but the yield in those residencies that did not suffer seems to have been ample to supply all wants, and imports of foreign rice were not above the average of past years. The Bantam crop exceeded expectations and in all parts of west and central Java the production was fair.

Tobacco.—In many parts of the island, especially to the eastward, the culture of this article, which in former years was a fruitful source of wealth both to Europeans and natives, has become almost a thing of the past, and even in central and southern Java, where several planters have presevered in the cultivation, the results are such as to warrant but little hope of of industry being continued.

Tea.—Planters have paid unceasing attention to the improvement of their gardens, and with few exceptions have quickly adopted all improvements in machinery proved to be successful in British India and elsewhere. The yield of Java gardens (nearly entirely confined to the westward portion of the island) is rapidly increasing, and every care is being taken to introduce the best description of plants, the preference being still given to the Assem Hybrid.

Cinchona.—Private exports, althoughly considerably larger during 1882 than in the preceding year, only amount to 181,354 Amsterdam pounds, but as numerous cinchona gardens commenced some five or six years ago must shortly begin to yield, this article may shortly be expected to take a prominent position in the list of exports from Java.

Black Pepper.—The "Lampong" corp of 1882, which constitutes the bulk if not the whole of so-called Batavia pepper, has been unusually large, being estimated at about 53,000 piculs, as against an average of 23,000 to 25,000 piculs for the last two years. The crop commencesnto arrive at Batavia during August, and the final sendigs will not be received until well into March, 1883. It is anticipated that after so large a crop the yield of 1883 will be considerably less and probably not above the average already noted.

Kapock.—The exports of this article have increased both to Australia and Europe. The chief consumers are mattress and furniture makers, and from all reports kapok seems to form an excellent substitute for horsehair in most departments of the above indurstries.

GOVERNMENT CINCHONA PLANTATION.

The Government cinchona crop is steadily increasing year by year, as the plantations are enlarged. This year's crop to Dec. 31 amounted to 230,000 Amsterdam lb., as against 165,000 Amsterdam lb. in 1881, and 100,000 Amsterdam lb. in 1880; but this figure does not represent the whole crop, the remainder of which will be gathered during the commencement of 1883. Experiments were made during the year with a view to ascertaining what percentage of alkaloid was contained in the bark of young *Ledgeriana* trees, grown from the seed of the parents tree, from which it would appear that bark of four years old, when bearing the crue type of the mother stem, contains from 9 to 11·75per tent. quinine, or fully more than the older parent trees.

COFFEE IN NATAL.—The Natal agents of the *Tropical Agriculturist* report under date 11th July;—"Splendid season for coffee with us. Pity not a larger cultivation. A good deal to be learnt here yet. Some few who have stuck to 'their last' make it pay; but others lost heavily."

THE "TROPICAL AGRICULTURIST."

We have pleasure in acknowledging the receipt of the first number of vol. III., being the number for July this year, of this most valuable journal, which every planter in the Straits would do well to have on his table, full as egg is of meat as every number of it is of invaluable practical information upon all matters connected with planting in the East and West Indies, the Americas, the Australias, and the South Sea Islands. It is published, monthly, at the *Colombo Observer* Offices, Ceylon, and the annual subscription is only £1 or R12. The present number contains 79 two-column closely printed pages; and some idea of the nature of its contents and their varied and interesting character may be obtained if we summarise a few of the subjects dealt with. There are then several editorials on cinchona and cardamom cultivation in India, Ceylon and Java; on the labour question in Fiji and Mauritius; on Madagascar plants; on clean weeding; on coffee and its insect enemies. There is a large amount of correspondence regarding Tea-planting in all its aspects; silk culture in Ceylon; planting experiences in Fiji, Chili, California, Jamaica; how to collect Rubber; seasons; manuring; weeds, &c., &c. Then numerous extracts are given from the local publications regarding planting in Brazil, West Indies, Eastern Arabia, India, Java, Queensland, the Northern Territory, &c. There is nothing regarding the Straits, Sumatra, or Borneo, but no doubt the Planters of the Malay Archipelago will erelong, when they have had more time and experience, be moved to exchange views with their brother planters elsewhere, and they could not have a better medium for doing so than this excellent magazine.—*Straits Times.*

"TEA-BULKING."

The report of the East and West India Dock Company just issued speaks of a new system of "tea-bulking" which has been invented by one of the company's staff, by which it is hoped that a much larger share of the tea imported into London may be attracted to their warehouses in Fenchurch-street and Crutched Friars. So much is mysterious in connection with the tea trade that this incidental allusion to one more mystery will hardly perhaps awaken a passing curiosity in the generality of the public, who as a rule do not not know at all what "tea-bulking" may be, and will hardly feel it a very hopeful subject of enquiry. Yet it is a matter not altogether without its interest for most of us, as will be readily apparent when it is stated that this "bulking" is simply turning the tea out of the chests or boxes in a heap, partly for the purpose of mixing thoroughly, so as to ensure perfect uniformity of quality throughout a "break," and partly for the purpose of "taring" the receptacles in which the tea arrives. Ordinarily the contents are turned out upon the warehouse floor, well mixed up with wooden shovels, and then returned to the chests, into which—*incredibile dictu*—the warehousemen get, and tread down the tea with their boots; and it has been noted by some who ought to know a good deal about these matters, as a very remarkable illustration of the great care with which the proceeding is carried out by this company, that the men are not permitted to do this treading with their dirty boots entirely unguarded, but are compelled to put a cloth over the tea before stepping upon it. It is more than hinted that in some establishments this little precaution is neglected. The great objection however to the ordinary mode of "bulking" is that the tea being turned out in a heap in the warehouses in which it is practically exposed to the open air, is very liable to lose much of its freshness and aroma, and indeed, the whole process of exposure, shovelling and refilling is calculated to deteriorate its quality. The secretary of the company, the warehouse superintendent (Mr. Adams) and one of the engineers, have, therefore, been turning their attention to this matter, and they contrived a machine which seems to do all the work very efficiently and to avoid all the objections. Instead of being turned out in a heap upon the floor and shovelled about in the open air, the tea is tipped out of the chests or boxes into a revolving drum capable of holding, if completely filled, about 100 chests. Some 50 chests are poured into this, and then the machine is shut up close and set revolving by hydraulic motive power. Inside the drum is a system of iron rods so arranged as to toss the tea about well, and three or four revolutions are sufficient to thoroughly "bulk" the contents. When this has been accomplished, the mixture is poured out again into the chests that have the mean time been "tared" and placed in nposition on a scale which constitutes an adjunct to the machine. The tea, however, will not fill into the chests in so close and compact a body as before it was turned out, and treading or something equivalent to it must still be done. For this a very ingenious provision is made. A flat, iron "presser" may be brought down upon the tea, fitting into the receptacle, and thrusting its contents down gently and evenly, while upon the sides of the chest the machine brings to bear four iron beaters, which, by an ingenious method of rapidly turning on and cutting off hydraulic power, are made alternately to fly out and fall back to the sides of the chests with a succession of thumps that shake down the tea into a close, compact mass. These beaters have already been in use for some time past in the company's coffee warehouses in the docks, and their application to this "bulking" machine appears to render it a very complete and satisfactory operator, though what may be thought of it by the wielders of the wooden shovel, and the wearers of the hob-nailed boots, whose services will, we suppose, be materially curtailed, is a different question.—*Globe* July 12th.

NOTES ON STRAITS SETTLEMENTS: LETTER NO. 8.

By J. H. COTTAM.

MANNERS AND CUSTOMS OF THE MALAYS OF PERAK—COSTUMES OF MALE AND FEMALE—SARONG AND KRIS—HABIT OF SMOKING CIGARETTES FROM MORNING TILL NIGHT—THEIR LEGENDS—THE TABOOED MONKEYS—A BOLTING ELEPHANT—THE MALAY HOUSE—CULTIVATIONS IN MALAY GARDENS—THE RAJA'S FALSE SET OF TEETH—THE STORY OF FAIR HELEN IN THE "LADY'S MAGAZINE"—FEATURES OF THE WOMEN OF PERAK—FILING AND BLACKENING THEIR TEETH—SNUFF—RUNNING AMOK A RARE OCCURRENCE—MR. AND MRS. BOKKAR AND LITTLE GIRL "TEE"—RELATIONS LOAFING—THE MOTHER-IN-LAW BIRD: A GOOD STORY—MALAYS AS ROAD MAKERS AND BUILDING CONTRACTORS—BASKET MAKING—FISHING—SONGS AT NIGHT—SLAVERY ABOLISHED AT THE END OF THE CURRENT YEAR.

Taking the Malays all round they are not a bad people: on the contrary a new arrival is very much astonished to find them so gentle and respectful to Europeans, and well behaved to each other in their daily avocations. It is true most of them, if not all, carry a "parang" or knife of some sort, but not to cut people's throats with, only to cut their way through jungles and defend themselves against wild beasts. During the past year not a single instance of a Malay drawing his knife on a fellow-creature has even been heard of by me in Perak. The kris is only worn by chiefs and well-to-do Malays by permission of the Perak Government, so when your Young Ceylonese correspondent whoever he was stated they were "an ugly people, drawing their kris upon you on the slightest provocation," he, your Young Ceylonese correspondent from Perak, told "*a cram.*" They certainly don't like being trifled with or illused in any way, and are naturally reserved, though as before-stated very polite and respectful.

Both Chinese and Klings often forget to salaam a European before stating their business, but the Malay never forgets himself and will always say "Tablai tuan" (their term of respect equivalent to your "salaam durai"). If they are told to call next day, they ask the time they are to come, and on being informed are very punctual, "Apa mow orang?" (What do you want, my man?) is generally answered by "blimya"—*advances* on the work in progress or about to be commenced. In making a contract the Malay always wants to think over the matter with the aid of his tobacco and betel-box: he will never begin a thing in a hurry, and when he engages men to help him with the contract they must all form a council over their cigarettes, the old ones being addicted to snuff!

As they go to bed late, very often through yarning and singing it is difficult to get them up early in the morning, but as few work on wages for their employers the loss is their own. They certainly do very little work in wet weather, although highly paid, and hence scarcely clear more than enough to live upon. The Malays are not very clean in their habits, and are not hard on soap and water: in fact the writer has not seen Malays bathing yet during the past 8 or 9 months in Perak. Of course we presume they do bathe, and hope they do, yet their skins tell the sad story of the great unwashed: they scratch themselves into ugly sores, brought on partly by mosquito bites, partly from constantly living on salt provisions, and partly from their dislike of soap and water. Then if we enter a kampong (village) the smells are overpowering, caused by the lazy practice of pouring all their dirty slops through the floor made with slabs of bark or strips of palm stem and a small opening left between each slab or strip to allow males and females to spit their betel juice and empty their rice water—beastly idea, but too true. The customs of males and females are very much alike: the women cook their husbands, rice, whilst he earn the dollars to pay for it with strong smelling curries when they can afford to buy them. Their dress is much the same: a yellow and red sarong or comboy. Teeth filed and blackened, the man wearing a little cap or topi; if dressed for a holiday he sports black shoes and red sash with a piece of red or yellow silk round a white felt crown of a hat, or say a hat without a brim. The sarong and kris may be as costly as a Malay gentleman or chief may wish it to be, with a different style of cap worn on one side of the head, the cigarette always in the mouth and in course of preparation, mild tobacco rolled in dried plantain leaves and skins of corncobs &c. This vile habit of smoking from morn till night must tell on the Malay constitution and cause degeneration of at one time a fine race of people: the men as a rule look emaciated and prematurely old, and exceedingly short in stature, hair cut short, and wearing little or no ornaments. They have like all other nations extraordinary stories handed down from their forefathers. There is a legend of the tabooed monkeys tabooed from going from the left bank of the Perak river to the right bank on pain of death and they hold to this fact to the present day that no monkey wild or tame ever lived to be old on the right bank of the Perak river. The mother-in-law bird story is tremendously fine:—It appears that a Malay had taken a great dislike to his mother-in-law, and, tired of her stopping in his house, one day hit upon a plan to abolish his mother-in-law. The wife was sent off on some long errand and told not to return for some days; the poor old woman was then drugged with opium and sent into a sound sleep, and then the dreadful Malay commenced operations, first, by selecting a gigantic tree close to the family mansion, and, as his mother-in-law slept in fancied security, he plied his axe to the tree, until, after half a day's hard labour completed his diabolical task, crash went the tree and crash went the house containing the mother-in-law, who never lived to tell the tale. The wily Malay thought no witness near at hand, and was about to return to his young wife when he was suddenly converted into a large ugly bird, and from that day to this may be constantly heard in the dense forests of Perak repeating the noise imitating the dreadful deed committed by him when in man's estate.—The traveller's steps are arrested almost daily on jungle journies by the extraordinary noise over his head "chop-chop-chop-chop! chop, chop, chop, chop,—ah-ha-ah-ha-ah-ha-aha-aha-aha." It needs little description or explanation that the above noise of the bird is a repetition of the tragic story. The strokes of the axe until the tree fell on the mother-in-law and the diabolical laughter of the bloodthirsty son-in-law after the perpetration of the murder. There is no mistake about the resemblance of the bird's noise tallying with the Malay legend, and moreover, should a European lose his path in the jungle, the same noise of loud laughter overhead sounds uncommonly like mockery and to say the least of it would not tend to sooth one's nerves under the circumstances. The bird is known I believe to ornithologists as a species of hornbill with black and white plumage and enormous double bill and in size about as big as a goose. When flocking in numbers the noise of their flapping wings approaching unseen is like the arrival of a paddle-steamboat; they fly very high and rest themselves on the tallest trees in the forest very seldom appearing in the open.

The Malays are not communicative about their private affairs: an instance of this was proved to me lately by our krani (clerk) who had been in the habit of riding one of our elephants and sending rice to his wife and family living in a distant kampong (village). Having occasion myself to travel in the same direction *via* the Kwala Kangsa high road, and mounted on the same elephant with a portmanteau, containing a change of clothes, all was going smoothly until suddenly off went the elephant at a tangent, bolting up a lane through dense bamboo and plantain trees, dorians, coconut and other vegetation that proved it to lead to some village. The mahout could not catch up for the beast was galloping until we came to a stand-still at a wooden fence of a paddy field, when the Marhout then mounted again and turned his head back to the high road, and afterwards the brute got very sulky and like his companion sister who smothered me with dirty water on a previous journey, he drew up the contents of every little pool in the road and perhaps to cool himself from the sun's fierce heat at mid-day spurted his dirty water all over poor me. I therefore, decided once for ever that elephant travelling like many other things in this world was more pain than pleasure. Poor fellow, when I left Kwala Kangsa and Gapis side of the Perak, he was laid up with a snake bite and was disabled from carrying rice and other stores up to the Mountain Garden. There are no elephants connected with the Laroot Garden on Maxwell's Hill now under my charge, and really I am better without one, for they spoil all our hill paths.

The Malay house is built without a nail, every part tied with rattan cane and raised on piles, thatched with attaps and the dividings or partitions of the same material; they can build a good shanty for from $20 to $30 or say R60. As for the cultivations round their houses, in the kampongs (villages) plants are thick like in a village hamlet among your Sinhalese; things come up more by good luck than good management, and like your Ceylon fruit trees and coconut palms thrive best within sound of the human voice.

The Malay does not indulge his table for agri-horticultural pursuits: in fact a few ragged plantain trees, a cluster of areka or betel-nut palms, dorian, jak and mangosteens with a few beds of sweet potatoes under their shade, and a patch of sugarcane about makes up the sum total of a swell Malay garden. The higher class of Malay cultivates coffee and other useful products on a small scale, and I had to send one dozen picked Ledger plants in baskets to some big chief near Kwala Kangsar. My knowledge of native ranks here is as mixed up as it was with regard to your Kandian chiefs; a case of which is the Duke of Wellington and which is his horse—"You pays your money, my little dear, and takes your choice." However, an amusing story is related of one big Malay chief in Perak: he applied to Government for a set of teeth, and after several interviews the request was sanctioned and the teeth were duly ordered, but previously to issuing the order a mould of wax or something of that sort was inserted into the old gentleman's mouth, and sad to relate, he went to sleep and swallowed the mould! Presuming that the experiment was tried with a second mould, and that the former was duly digested, the false teeth arrived and were presented to His Excellency; the question then arose to what department were these teeth to be charged? They could not very well be put down to salaries of officials, nor to public works department, so after much perplexity in the Perak "Kachcheri" the chief's false teeth were put down to the experimental Mountain Gardens!

Anyone interested in the manners and customs of ye natives of the Malay Peninsula, and especially Perak (pronounced Pera meaning silver) should read a novel called *Fair Helen.* A few straggling chapters met my eye in the *Lady's Magazine* brought up here by the doctor's wife on a visit with her family. The story is highly sensational and well written. The belle of the station being kidnapped by "Murad" a Malay chief whose women drug her for the purpose of transforming her into a pucka Malay a woman with sarong instead of petticoats and her beautiful white pearly teeth filed and blackened to be in the Malay fashion with nose ring and ear ornaments and silver wire in mingled with the following tresses of beautiful hair! The young lady's admirer, a captain at the station, is also kidnapped by Inchee Muda who sets her mind on marrying him right off, but to this he won't agree. In the *story of Fair Helen*, some other well-drawn characters appear, a doctor and, a clergyman: the latter falls into captivity but soon gets free as the Malays arrive at the conclusion that he is as mad as any two hatters on account of rushing frantically after weeds hanging from trees and growing wild on the ground, the former orchids, and the latter ferns.

As for the Malay women of Perak, they are a very ordinary lot, and any admirer of the fair sex must not look for female beauty in Perak; filing the teeth and blackening them for instance is simply abominable, and yet they say animals have white teeth and as they have no wish to resemble animals accordingly disfigure their principal feature. For the ordinary Malay woman is a helpless, sulky-looking creature with a stumpy figure, and as a sailor would say all stern, and they waddle along in a lazy listless manner as though they had no other idea in their heads but eating curry and rice and going to sleep. The old gentlemen amongst the Malays indulge in the old-fashioned habit of taking a pinch of snuff to clear their brains, when asked their opinion on a knotty subject, and like the great Bunssby in replying to Captain Cuttle will decide an argument by the profound remark:—"That the bearings of that there observation lies in the applications of it."

We used to hear a lot about Malays running amok: this is quite untrue, for it is a very rare occurrence indeed, on the contrary we do hear of Europeans "running amok" occasionally, especially when the grub is badly cooked or the boy runs off with the spoons. I only wish other natives we know of were as quiet as the Malays are in Perak.

Of course you will say they received a severe lesson after the murder of poor Mr. Birch, but then they were solely under the influence of their chiefs and intruments for good or evil in their hands. The Malays are not grasping or avaricious but hospitable when it is in their power to be so. An instance came under my notice on the Gapis mountain garden our "tindal" or as you would call the same functionary on a coffee estate in Ceylon "conductor" continually received his own and his wife's poor relations and fed them for weeks, even overdrawing his wages to keep up their entertainment without complaining. He is not a handsome man, having a great red patch on the side of his face, like a daub of vermilion paint, the result of some skin disease, but he has been twice married, his first wife died, and his second a widow was rescued from a log of wood after floating at the mercy of the winds and waves for 18 hours, she still looks cold and moist looking from the effects of the long immersion, and the pale faced little girl Tee jumps about in fine weather and helps her mother to get up a fire for making Mr. Bokkar's curry. They are a good couple, and like each other, the little girl being a great pet with everybody. His father lived with them and contributed to the mess by earning a few dollars by basket making; they all belong to Penang island. Malays as roadmakers are slow and sure and do their work fairly well. Most of my time has been spent in tracing and superintending bridle paths and branch roads, draining, &c. The rate of pay will form the subject of a letter in this series. As building contractors, they strictly adhere to the terms of their agreement and have no desire to try and cheat, the only difficulty being to get them to make a start.

Many natives must of necessity gain a living by fishing both in the rivers of Perak and in the open sea, for salt fish seems to be their principal food with rice and vegetables and such fruit as may happen to be in season. At present the fish are diseased according to reports, there are worms in the fish; a similar complaint existed in Ceylon.

Up the Perak and Plus rivers they spear the fish from the bows of their canoes and this amusement was one of the entertainments got up for Governor Weld and staff, loud laughter greeting the fall of the Tuan Bessar or Governor on taking a header out of the boat and when Mr. Maxwell (then Assistant Resident of Perak) speared a fish and lost it again much to the delight of the natives. I remember reading an account of the Governor's tour and journey to Kinta in your paper, and kept a copy of it; the Malays on that occasion gave His Excellency Governor Weld a very hearty reception, and seventy elephants were placed at his disposal for transport of provisions. Their songs on moonlight nights often strike me as very pleasant compared to the singing of other natives of savage countries. One would think the voices were those of women instead of men and reminded me of your Sinhalese village girls singing as they weed their paddy fields. Paddy cultivation is extensively carried on in parts of Perak bordering the large rivers, and brings in some revenue to the Perak Government I believe, as also do the sugar gardens, cultivated by Chinese, opium, tobacco, cocoanuts, vegetables, and grass. There is a field open still for enterprising natives to cultivate guinea grass for the increasing number of Chinese ponies used for gharries plying between Matang and Thaipeng and Kwala Kangsa.

A proclamation was issued by Government during the current year, that after December next all slaves are to be liberated in the state of Perak; the Government arrange for compensation to Malay owners of slaves, but as far as can be ascertained the slaves themselves hardly know the value of their liberty, and some have said they prefered remaining with their old masters for the rest of their days. Good slave owners no doubt would treat their slaves better than if they were free labourers, similar to the cotton planters of the Southern States of America, they treated their slaves as members of their families and doubtless many of the negroes scarcely appreciated the change; however, time will show, the Malays may learn the value of time and money by and by, and after tasting some of the fruits of civilization and comforts of dress and clean houses may mingle more freely with Europeans as the Chinese do. Their religion is chiefly Muhammadan and their language easy to learn and rather a pretty lingo.

This letter is long enough without dwelling on the peculiarities of the language spoken by the Malays of Perak, and the same will make an interesting subject for a future letter. Meanwhile the writer hopes the above outline of the true character of the "orang utan" (wild man) of Perak will remove that phantom dread of the Malay which lives in the minds of people who have not had the pleasure of his acquaintance. H. C.

THE CEYLON TEA-PLANTING INDUSTRY may date a new period in its existence from the Colombo Agri-Horticultural Show of 1883. Nothing could bring home better to the officials, the visitors and the Colombo residents, the great strides which have been made in "tea" during the past few years in this Colony, than the fine series of exhibits brought under their notice during the past few days; and the question being now settled as to Ceylon planters being able to supply the finest teas required by the home trade and to work the enterprize at a handsome profit, we feel sure the necessary capital for its extension will henceforward, month by month, be more freely made available. After all, tea is by far the most important product which the planters of Ceylon can take up. It is peculiarly *the staple* drink of the mother country and by a long way the favourite among her many daughters, especially in Australasia, where year by year, population and wealth are advancing at such rapid bounds. It is impossible in the face of steadily increasing exports and weekly sales in Mincing Lane, each more favourable than the preceding, for Ceylon teas, that London magnates, who have been exceeding hard in their criticisms of Ceylon and its planting industry for some time back, can resist the evidence of the rapid approach of better times and of the fact that if they want to recover the whole or part of the money sunk here, no better means than to invest in tea can at present be suggested to them. It requires no suggestion on our part however. The solid facts are quickly enough making themselves patent to hard-headed men of business. London brokers' reports are proving a better advertizement for the colony than even the *Tropical Agriculturist* in respect of our tea industry at least. Men in the trade write out: "Your new season's teas have arrived in splendid order; flavour all that could be desired"—when the fact is that these teas are those dispatched at the end of our season, and that the fine flavour and good order are mainly to be attributed to the unequalled facilities in Ceylon for careful manufacture, fresh packing in hermetically sealed packages and speedy dispatch. Perhaps there may also be something due to caiful picking at the end of our season so as to secure fine teas to meet the London demand. The day is fast approaching when from a long series of plantations and even tea districts in Ceylon, the packages of tea—month by month—will be placed from the tea-house on the railway trucks and from them probably transferred, at the Colombo wharf jetties, on board the steamers which will in four weeks' time, or less, land them at the London docks. If so much has been achieved since 1878; how much more will the next five years bring forth?

The fact is that Ceylon merchants and planters, as a body, attach far less importance to the local tea industry than do the tea merchants and planters of other lands! Men in the China tea trade, calling here on their way eastwards, look very grave when they learn what we have done and are doing. Tea planting visitors from India speak in high terms of our teas, our climate, labour, roads and prospects. If tea-planting does not pay in Ceylon, it ought to be "ruin" for the investers in tea in Northern or Southern India, seems to be a not unfair inference from the opinion of many of our experienced visitors.

We have learned within the last few days that a tea expert who has been closely watching Ceylon teas at the London sales for some time back, has arrived at the conclusion that they can be generally divided into two distinct classes:—one to all intents and purposes being of the same quality and characteristics as average Assam, and is therefore classed as such; while the other is peculiar to Ceylon, and although not established in favour as yet, is nevertheless in his opinion, likely to secure a special position with correspondingly good prices. This expert without knowing anything of Ceylon or the situation of its plantations, gives marks illustrative of his classification, and nearly all of the so-call d "Assam" teas come from the lower Ceylon estates, while the teas peculiar in flavour and classification are those produced at the higher altitudes. There is however, the utmost encouragement for one and all, and it is interesting to know that the same Agency Firm which has been chiefly instrumental in proving the success of tea in the Kalutara district within reach of the seabreeze, is about to plant this favorite product in Udapussellawa up to 6,000 or 6,500 feet above sea-level with full confidence in a satisfactory result.

COMPARATIVE POSITION OF THE VARIOUS TEAS OF THE WORLD

From Mr. Moody, of the firm of Messrs. James Henty & Co., of Melbourne, we have received the following paper:—

SEASON 1883-84.

MELBOURNE, 20th July, 1883.

The Calcutta Tea Syndicate,

in conjunction with the Government of India, will carry on their operations during Season 1883-84, but necessarily on a smaller scale.

The favour with which Indian Teas have been received, and the enormous increase in the consumption, have been most gratifying to the concerned, and they hope the trade will be firmly established, to the mutual benefit of the colonies and India.

All Teas passing through the hands of the Syndicate are carefully selected and examined prior to shipment from India. Further, on arrival in Melbourne the bulk of the Teas have been submitted to inspection and chemical analysis, and the result announced on the catalogues in clear and unmistakable language. This has been the course prsued for the last three years, and at heavy expense. Indian Teas have passed this severe test with flying colours, and there is no case on record of adulterated Tea. It is submitted that no Teas from any other part of the world have passed such an examination and chemical analysis.

The crops of Indian Tea during the past 11 years have been as follows:—

	lb.
1872	17,900,000
1873	19,750,000
1874	23,300,000
1875	26,100,000
1876	29,400,000
1877	35,800,000
1878	35,000,000
1879	40,000,000
1880	46,500,000
1881	48,300,000
1882	57,899,751

India, with her Tea gardens at altitudes of from 400 to 7,000 feet above the sea level, her climate and rich soil, possesses advantages unequalled in the world. Her Teas are prepared under the immediate supervision of Europeans, and with the help of tho finest machinery procurable, many of the Indian Tea-growths are as much in repute as some of the far-famed vintages of the Continent. London deliveries of Indian Tea have been for the years, say—

1879-80	36,312,000
1880-81	49,458,000
1881-82	47,141,000
1882-83	56,000,000 (estimated)

showing an enormous increase in the trade of Indian Teas, estimated by some to exceed 12,000,000 lb. weight for the last year.

During the last twelv months the imports of Indian Tea into Melbourne equal, say—

1st July 1882 to 30th June	1883	...	2,251,702
,, 1881 ,,	1882	...	979,520
,, 1880 ,,	1881	...	671,000

This speaks volumes for the increase of the trade, for, with exception of 220,000 lb. weight exported, all the Tea has been sold, and there is no stock now in first hands.

Messrs. Cosmo Newbery & Dunn, who have analyzed over 800 samples of teas, have kindly furnished the following report, which is published in full and gives most invaluable and interesting information:—

INDUSTRIAL AND TECHNOLOGICAL MUSEUM,

LABORATORY, 22nd June, 1882.

The following results show the highest percentage of Extract we have so far obtained during our series of examinations to date:—

Locality.	*Percentage of Mineral Ash.*	*Percentage of Extract.*	*Percentage of Soluble Salts.*
CEYLON	4·16	53·18	2·58
INDIA	4·82	52·85	3·01
CHINA (Hankow) ...	5·82	52·80	3·26
,, (Foo-Chow)...	6·30	46·71	3·27
JAPAN	5·75	49 90	3·28
JAVA	5·28	45·82	3·19

The samples of Indian and Ceylon Teas were obtained from the Melbourne International Exhibition of 1880-81; the small percentage of Ash and Soluble Salts is probably owing to the rapid growth of the Tea plant, and also the carefulness bestowed during the process of manufacture. The three last samples are the best that could be obtained, but we do not consider them as representatives of the "Finest Teas" that their respective localities are capable of producing. The results of our examinations lead us to expect that each country is capable of producing a Tea which contains the same percentage of Extract

J. COSMO NEWBERY.
FREDERICK DUNN.

These teas may be classed as the highest standards (so far obtained) of excellence from the analyst's point of view, which is also confirmed from a Tea Taster's standpoint by the aroma and liquor of the teas analyzed. This result tends to show that many countries can grow the finest description of tea.

To the consumer the question of the greatest importanc is, How near do the teas of commerce go to the above standards? As far as Melbourne is concerned, the question is easily answered by the following tables, prepared from numerous analyses made by Messrs. Cosmo Newbery & Dunn:—

SEASON, 1882-3.	*Percentage of Mineral Ash.*	*Percentage of Extract.*	*Percentage of Soluble Salts.*
Average of 12,000 half-chests of Indian Teas	5·46	47·04	3·27
Average of 13,299 half-chests of 1st crop Foo-Chow Congous	5·48	31·58	3·45
Average of 10,299 half-chests of 2nd crop Foo-Chow Congous	5·66	30·94	2·87
Average of 10 samples 3,000 half-chests of Moning Congous	5·53	37·51	2·80
Average of 4 samples 118 packages of Japan Teas ...	5·16	36·32	3·27
Average of 7 samples of Java Teas	5·28	41·53	3·20

The Japan and Java teas, though sold in the market, are rather too small in quantity to give a fair average for this class of commercial teas.

It is claimed for India, and confirmed by the foregoing analyses, that her commercial teas rank far higher than those of any other producing country in the world, and are nearest to the highest standard of excellence as determined by one of the most exact sciences (chemistry) that civilized nations possess.

Professor Hassall writes: "Tea owes its properties mainly to tannin, theine, and the volatile oil. The first gives it astringency, the second stimulates both the vascular and nervous systems, while the third acts not only as a stimulant but imparts the aroma, which is so characteristic of good tea, and which is grateful to many. Tea exerts its power chiefly on the nervous system. It excites the activity of the brain, and stimulates the flow of thought."

Professor Johnson writes:—"Tea exhilarates without sensibly intoxicating. It excites to increased activity, and produces wakefulness. It soothes, on the contrary, and stills the vascular system, hence its use in inflammatory diseases and as a cure of headache."

From the above it will be seen that, as far as proportion of extract is concerned, no tea analyzed by Messrs. Newbery and Dunn of Melbourne, or, we feel perfectly confident in saying, by any other chemist in the world, has excelled a specimen of Ceylon tea sent to the Melbourne International Exhibition of 1880-81. The tea in question was prepared by Mr. James Taylor of Loolcondura estate, Hewaheta, and we recollect that Mr. Dunn was, in view of the large result in extract, puzzled to account for the low percentage of mineral ash and soluble salts. In consultation with the chemist, and Messrs. Moody and Sibthorp, we were inclined to trace the low proportion of mineral ash to the comparative youth of the Ceylon bushes. About 5 per cent of mineral ash is the received standard for pure teas. When the percentage appreciably exceeds 6 per cent, the presence of foreign matter is certain. The low percentage of mineral ash in the Ceylon teas, shewed that they were absolutely pure. The small quantity of soluble salts we were inclined to attribute to under-fermentation; but it will be observed that so good a judge as Mr. Moody attributes the low proportions of both mineral ash and soluble salts to the rapid growth of the plant in our forcing climate and also to care in preparation. It will be observed that the standard specimen of Indian tea, while coming within ·23 per cent of the Ceylon tea in extract, exceeded it in proportions of mineral ash and soluble salts, and that in these respects (ash and soluble salts) both Ceylon and Indian teas shewed results lower than did the standard China, Japan and Java teas. In looking at the results given by the China and Japan teas, our readers will keep in view the fact, that the specimens analyzed were the *very choicest* that could be procured, and that compared with the bulk of the stuff imported from China (especially from Foo Chow) such teas are "few and far between." Even in the choice specimen of Fow Chow tea, it is a suspicious circumstance that the mineral ash should be so high as 6·30 per cent. While the Hankow tea ranks close to the products of Ceylon and India in extract, it will be seen that the very best Foo Chow gave only 46·71. Japan was better with 49·50 of extract, but Java gave a result in this direction which we certainly never could have anticipated: only 45·82 of extract, or lower even than Foo Chow, and 7·36 below Ceylon. We could understand the rich volcanic soil of Java giving a peculiar and not over-pleasant flavour to tea, but we should have expected it to produce a larger instead of a lesser amount of extract. The secret may, possibly, lie in the larger proportion of iron in the soils of India and Ceylon. It is possible, however, that, as so little Java tea now goes to Melbourne, the specimen analyzed by Messrs. Newbery and Dunn was not the very best which Java could produce. The general result of the scientific work of Messrs. Newbery and Dunn is that each of the great tea countries is *capable* of producing a tea "with the same proportion of extract";—meaning, no doubt, a proportion between 52 and 53 per cent. But capacity and achieved results on a large scale are different things, as is shown by the extent to which the bulk of the teas of commerce, in the case of China, fell below the standard of choice specimens. Against *averages* of 47·04 of extract in the case of Indian teas, and 41·53 in those from Java (the manufacture being in both cases conducted under the oversight of Europeans), we get for China averages so low as as 30·94, 34·58, and as the highest 37·51. The lowest is over 16 per cent and the highest 9·47 below the Indian average; while the average of the three China bulks of tea is 34·51, or 12½ per cent below the Indian commercial average. The Japan teas are better by nearly 2 per cent than the general average of the Chinae teas. It must, finally be remembered, that the China teas of which the general averages are given, were teas of fair ordinary quality, and that from the comparisons are entirely excluded the large amount of inferior and adulterated teas which are forced through the Melbourne customhouse by the influence of interested brokers, who, buying them at 3d or 4d per pound, we may take it for granted, mix them with superior teas, especially Indian, for which they pay three or four times the price. The great point for the consumer to keep in view is, that, in paying a good price for Indian, Ceylon, or Java tea, not only is he certain of obtaining an article with the maximum of extract, combined with fineness of flavour, but that he has also the moral certainty that the tea is really and wholly tea: absolutely pure and unadulterated. The reason why more Ceylon tea has not gone to Australia, and why the fine Indian teas sell in the Melbourne market at such inadequate prices, is that the colonists have been so long accustomed to "cheap and nasty" teas from Foo Chow Foo and other ports in China that they grudge giving a good price for a good article. Nevertheless, the good article is making headway against taste prejudice and very strong interested opposition. The imports of Indian tea had gone up from 671,000 lb. in the Exhibition year, when the attack on the China monopoly was first made in force, to over 2¼ millions of pounds in 1882-83. Of all this tea only 220,000 lb. have been exported, and there was no stock in first hands. Indian tea, therefore, which now constitutes one-third of the tea consumption of England, is already up to one-tenth of that of Australia and the process will be onwards, there and in America.

THROUGH THE TEA DISTRICTS OF NORTH INDIA: No II.

(*By a Ceylon Planter.*)

Tejpore, Assam.

From Dhubri onwards up the river the country maintains the same character as below until the neighbourhood of Gowhatty is reached: long stretches of grass land, liable to floods, and at certain times forming the bed of the river when it changes its channel, a by no means uncommon occurrence. All this country is very wild and abounds with game of all kinds; rhinoceros, elephants, buffalo, tiger, &c., are said to be very plentiful. Immediately opposite Dhubri lie the Garrow hills, where Sanderson's elephant-catching establishment is, and it is from here that the Government supply of these animals is maintained. At Dhubri several passengers who had come up direct from Calcutta joined the steamer, having been kept waiting for two days at the former place in consequence of the slowness of the steamer, which was several days late. At Gowhatty, which by the way is an exceedingly pretty but very hot and unhealthy place, the first tea gardens in Assam are to be seen, and they are not very good it must be admitted. As the steamer stopped here some time to deliver machinery, I had an opportunity of visiting gardens in the neighbourhood, of which I availed myself. Much of the tea land in this district is "teelah," on slopes which in Assam are considered steep. In Ceylon we should look on it as gently undulating merely, we have nothing similar to the flats in Assam a little higher on the river. The slopes are entirely undrained, and in consequence are seamed by wash, as might be expected; terracing does not appear to have been at all largely practised. In Cachar it was thought for many years that tea would not grow on the flats, and gardens were mostly formed on "teelah" land. Terracing on such land has been largely gone in for of late years, but the Ceylon system of draining does not seem to have found favor. The difficulties in the way of following our system of cultivation are not obvious till one realizes the peculiarities of the Indian climate, and the style of work which it necessitates. The tea gardens in Assam are all in a normal condition of weeds which would not be tolerated in Ceylon for a day. Much of the land that is opened is grass jungle, full of a flowering grass very similar to our "iluok": to eradicate this in such a forcing climate would be exceedingly difficult and expensive, if not impracticable. Again in these latitudes there is a period of dry cold weather, a mild form of winter in fact, during which the growth of all vegetation is more or less arrested, and when the ground becomes thoroughly hard and caked, and impenetrable to the early rains of the spring. This condition of the soil necessitates deep holing, and in some large concerns the experiment of regular systematic ploughing is being tried. This disturbance of the soil makes it very desirable that the land be flat, or, if on a slope, that some form of terracing be accomplished, whilst it would seriously affect the stability of catch-water drains cut across the hill side. It is quite obvious to any-one who sees the country for himself that the system of hoeing the soil and so keeping the weeds from choking out the cultivated plant is the only practicable form of cultivation. On flat land this system presents no difficulty whatever; on slopes some form of terracing is necessary to prevent serious loss of soil, and the expense of this is a great drawback, and is one chief reason of the present universal planting of flat land only, to the exclusion of anything approaching to a steep face. It is difficult to believe that the hoeing of the soil does much positive good, as some planters here affirm: it seems more probable that the benefit is mostly of a negative kind, the obviating of the caking effect of the cold season on the surface. The depth hoed is generally from 9 inches to a foot, and this portion of the soil being constantly disturbed (it is turned over every 3 or 4 weeks during the rains) cannot afford much nourishment to the roots. On the other hand, nothing in the shape of weeds is removed from the land, and the soil receives a constant supply of rotten vegetable matter grown on its surface, and which must fertilize the undisturbed soil in which the plant feeds. The suitability of this system to the circumstances under which tea is grown in Assam is no argument in favour of its adoption in Ceylon, and most planters with whom I discussed the matter wished that it were practicable for them to keep their land clean without disturbance of the soil, as we do. It is also no small consideration that the cost of these constant hoeings is treble at least the cost of weeding clean land in spite of the length of time in the cold weather when the growth of weeds and teas is alike at a standstill. It would appear probable that at one time the whole of Assam, from the spurs of the Himalaya on the north to the Naga and other hills on the south, was a vast inland sea. The soil is mostly a stiff loam, very rich and fertile for 10 feet, more or less, and below this a very deep and impenetrable stratum of sand and waterworn gravel. From the foot of the hills extensive banks of almost absolutely flat land extend towards the river, and between these banks lie stretches of swampy grass land liable to inundation, and which the natives cultivate with paddy. This is the character of the land higher up the river, the neighbourhood of Gowhatty being more hilly, and probably an older geological formation. Towards Tejpore the tea gardens improve greatly in appearance and yield, and are formed solely on flat land. These banks of land are generally intersected by numerous deep gullies, which carry off the drainage water, and which are always allowed to remain in jungle, as they are liable to be flooded. In many cases the land is so flat that it is very difficult to cut outlet drains, and sometimes these have to be made ten or more feet deep to carry the water off into the nearest natural ravine. There is a most remarkable absence of stones and rocks all over the country, stone masonry and metalled roads are therefore almost unknown, at least I came across none. The roads are, on the whole, very good, and much better than one is led to expect. They are, of course, very much cut up during the rains, and very muddy, being made of earth only with no foundation, but the horses which are never shod are accustomed to them, and riding is very quiet and easy. From all accounts Assam in the cold weather must be a very pleasant place: the fishing and shooting are both good then, and there is little work to be done on the gardens but pruning, so that planters have abundance of leisure. In fact, whatever subject you discuss except tea, reference is always made to the cold weather. It is then that vegetables grow and flowers bloom, lawn-tennis courts and polo-grounds then become playable, fishes allow themselves to be caught, and game gives opportunities for shooting it. During the manufacturing season, planters have to work very hard in a very trying climate, and they seem to fully appreciate the period of comparative leisure which comes with the cold weather.

Tea planters in Assam are now making the same mistake which many of us in Ceylon have had cause to repent of so bitterly: they are trusting to one product, and one only. The gardens consist of stretches of tea uninterrupted by anything but patches of jungle; no such things as boundaries marked by other products are known, a feature which has always been common on coffee estates in Ceylon. Ceará rubber is having a trial in one or two places, but on an absurdly small scale, and what I saw had not had a fair trial, but had suffered greatly from neglect. Government have made a large plantation of the indigenous so-called "Pará" rubber, which promises fairly well. A lakh and-a-half of rupees are said to have been spent on it, but there is very little to show for the money. This rubber tree is the *Ficus Indicus* [*elastica* ?—Ed. C. O.] of which there are many specimens in Ceylon, but it is not apparently a very paying species to cultivate. Cardamoms have been tried in one or two places on a very small scale, and appear to have grown and fruited in a most promising way, but the cultivation has been abandoned from lack of labour to pay the necessary attention to them. Cocoa has not yet been tried, but might be worthy of attention. It is doubtful whether it would stand the cold weather, probably not, but an experiment on a small scale would be interesting. Liberian and Arabian coffee are now being tried on a large scale in the Nowgong district, and are most promising in growth and appearance: they compare favourably with anything in Ceylon, no signs of leaf-disease have been detected and there is every appearance of a heavy crop. There is a very curious indigenous wild coffee in the jungles here, which is very common. It does not seem to fruit much, and I was unable to procure specimens of the bean. Aloes appear to grow very freely everywhere here, but no attention has been paid to their cultivation.

The general appearance of tea gardens in Assam compares unfavourably with the neatly kept estates in Ceylon. As has been said before, the ground is very dirty and the surface covered with clods of earth, and half rotten weeds, whilst there is generally a quantity of ilook growing up in spite of constant hoeings, especially near the stems of the bushes where the hoes do not touch it. Another peculiar feature is the way in which the hoers invariably cut up the paths about the garden, leaving six inches or so in the centre to walk on, a style of work which does not improve the appearance of the place. The buildings also are a great contrast to what we are accustomed to, being generally "kutcha," that is with walls of bamboo or other perishable material, the roofs being supported by wooden posts. Earthquakes, which are very frequent in Assam, make it unsafe to erect masses of heavy masonry, and though some factories have brick walls and piers very lightly built and supporting a light iron roof, most of them are of more perishable material. One very great advantage afforded by the flatness of the land is the facility with which buildings can be erected, and the abundance of suitable sites afforded. In a hilly country where it is seldom possible to put up a building without expensive cutting and levelling, it is necessary to economize space to the utmost, here the large extent of the buildings and the amount of unplanted ground, useful for many purposes about them is remarkable. In most cases the factories have been put up for hand work, with long rows of firing stoves and ample accommodation for rolling and sifting. The recent introduction of machinery for these purposes and the large economy of space effected by it renders the buildings as a rule unnecessarily large for the work now done in them. This is, however, a fault on the right side, want of space being a great drawback in tea manufacture. Prohibition of smoking, the exclusion of dogs and babies, general neatness and tidiness in fact, is a characteristic of all well regulated factories in Ceylon, but it is far from being so in Assam. No actual harm is done by a manager entering the factory with a pipe or cigar in his mouth, but the example is bad to the coolies, and is liable to lead to breaches of the strict rules of cleanliness which should be enforced. The sight of children, whose bodies have probably been abundantly anointed with oil, allowed to roll about in close proximity to and even over the tea, is not edifying, but all these, with the irruption of dogs and other unauthorized animals, are the usual occurrences in Assam tea factories. Neatness and tidiness in field work seem difficult to attain under the circumstances, and it strikes a visitor that the absence of these qualities outside leads to inattention to them where they are most necessary and where there is nothing to prevent their enforcement.

In all these matters, coolies and their overseers take their cue from the European manager, and if he is strict in all that relates to cleanliness and tidiness they will follow his example, but any laxity in the matter is sure to be taken the fullest advantage of. We have, of course, much to learn in tea planting, but in this one respect at any rate India tea planters may learn a lesson from their brethren in Ceylon, and if they appreciate the necessity for the greatest strictness in matters of cleanliness in the tea factories there will be a distinct gain. T. C. OWEN.

THE BRITISH NORTH BORNEO CO.

We have received from Mr. W. D. Gibbon the full report of the first half-yearly meeting of this Company, held in London on 27th June. In our issue of 21st July we quoted from the London *Times* a summary of the report and proceeding, so shall now give such patrs of local interest as were therein omitted. Regarding labour the following extract from Mr. Von Donop's report was read:—"It is perhaps rather hard to blame the natives of this country for not taking agerly to work seeing they have hitherto never been forced to earn their livelihood, except in a very eay manner, such as collecting the produce of the jungle and fishing, but I fancy the day will come when they will have either to cultivate land themselves or assist others in doing so. Though I am of opinion the present existing races of North Borneo will not be found suitable for a planter's requirements, nevertheless, I think they may be found useful in other ways. Before this country was ceded to the B. N. B. Company it was in a very unsettled state, and any man who was thought to be rich was instantly murdered and his possessions divided; but now matters are altogether altered, and we may expect to see the natives of Borneo (with education and other benefits) not only holding positions of trust and importance in the Company's service, but also settling down and giving their attention to agriculture.—In fact occupying the same position as the Singalese do in Ceylon." Then regarding the deaths which have occurred among the Company's officers the Chairman said:—"The Company has within the last few months lost three of the most efficient of their staff, two by misadventure and one by sickness. Of the first, Mr. Witti, a very energetic and zealous explorer, in one of his expeditions in a country not previously known, met with a party of natives believed to have crossed from the other side of the Dutch boundary, and was killed, with several of his native attendants and guides. Mr. Hatton, a promising young officer engaged as a mineralogist, met with his death from an accident: his own gun going off while threading his way through the jungle when out elephant hunting. Mr. Collinson, an energetic and capable Commissioner of Works, was most unexpectedly carried off by sickness while on leave at Hong Kong." We also quote the following passages:—"In proof of what I have just said as to the profits yielded by sugar plantations in Colonies less favourably circumstanced than North Borneo, let me cite one or two instances, and first as to sugar-planting in Madagascar. A very interesting and trustworthy account from a Special Correspondent of the *Times*, under the heading of the 'Resources of Madagascar—a new Field for Enterprise,' appeared in that journal some two months ago (April 2nd, 1883). In this long and detailed account of the trade resources of Madagascar in connection with the British Consular Reports the writer observes:—'It is upon sugar that those who believe in a great commercial future for Madagascar pin their faith, and not upon the rich mines which are supposed to be hidden in the interior of the great African Island.' And he proceeds:—'As regards the profitable production of sugar the experimental stage has already been passed. Four years ago the first real attempt at establishing a sugar plantation in the neighbourhood of Tamatava was tried, and already dividends of 15 to 20 per cent. on the capital invested are being realised. Next year one estate, which is becoming the property of a Joint Stock Company, promises to pay 30 per cent., and the limit of remuneration has by no means been reached.' Many other details are given of the same nature, all tending to show the enormous profits that may be realised from sugar plantations in Madagascar, notwithstanding 'a few obsolete and impracticable Hova laws.' If this be true of Madagascar, where,—besides Hova laws, frequent tornadoes, and now French invasion,—there are many difficulties to be encountered in the purchase of lands, &c., what may we not hope for North Borneo, to which Australian Sugar Planters are turning their attention, and investing largely in land declared by them to be all that they can wish? So also, if we take the reports of the Sugar Estate Companies from the Mauritius. It appears that 'of the 20 old sugar estate Companies in Mauritius there are six which paid 10 per cent. dividend on the last occasion and one 18 per cent., one 15, one 14 and one 6 per cent. dividend.' So of Tobacco, for which soil and climate in our Territory are believed by experienced planters and experts from Sumatra admirably adapted. Planters from Deli in that island, who have exhausted the most available land there, have already begun operations in our Territory as offering better conditions." In the discussion which followed the chairman's address Mr. Hildyard said:—"I should like to make one short remark. I took this from a trade paper: 'It is generally accepted that the sago palm grows on the island of Borneo; it grows there in very large numbers almost everywhere, and Borneo furnishes by far the largest quota of all the sago exported. In the interior of Borneo, along the river courses, the natives make rafts of the palm trunks, and float them down to the trading settlements, where the pith is taken out, tied up in bundles, covered with palm leaves, and shipped to Singapore or places where sago is manufactured. The Borneo sago palm is counted the most remunerative as to quality and quantity.' I wish to know whether the Company could not arrange to grow sago." To this the chairman replied:—"In reference to one or two questions that have been put I would say, in reply to the first gentleman who spoke, there is a charge of six per cent. on all calls in arrears, and that no shares have been issued since the 31st December. In reference to the question as to the raising of additional capital, the Directors see no reason to doubt that they have quite sufficient capital, in view of all the inflow of capital now going on from the outside, to work Borneo as rapidly as circumstances will permit; and having that outer source of the inflow of capital we do not require to raise more. Of course we shall be glad to see the work more freely supported, and I have not the slightest doubt that when all this information is fully digested and understood there will be a greater desire to invest in our shares, seeing that progress has been so rapid and that there is every prospect of its continuing. With regard to the question of the cultivation of sago, this plant is indigenous no doubt, and its cultivation is very profitable; but it takes 7 or 8 years to work it, and that is too long for the Company to wait. They have had their attention drawn to it, and some private speculators will go in for it very largely. Although it does yield a large profit, as I have said, it does not yield it for 7 or 8 years."

INDIAN TEA AND WEATHER REPORT.

(*From Balmer, Lawrie & Co.*)

Calcutta, 4th August 1883.

Our last report was dated 21st July. The weather throughout the manufacturing districts has been more favourable of late, but most gardens have a long way to pull up before they reach last year's outturn, not to speak of their estimates; unless the weather during the next 3 months is more than usually favourable, it is not likely that the total crop will exceed last year, even taking into consideration the new extensions coming into bearing.

ASSAM.—Dibrughar.—The latest advices by letter bring new of continued improvement in the weather over this district, although more rain would be an advantage, to make up for the previous very hot and dry days. Flushes are coming out fast on most gardens, but the general state of backwardness still prevails, and it is clear that many estates will not make their estimates. Jeypore.—There has been lately a heavy fall of rain which was much required as the ground was very dry in spite of the thunderstorm reported in our last; flushes are now coming out better, and the river is rising. Sibsagar.—The weather has been extremely hot over this district which has made the leaf dry and the flushes thin; lately some heavy rains with cold winds have done but little good, and the nights have been rather too cold for leaf. Jorehat.—The weather here has not been unfavourable for tea although very changeable; most gardens are however going steadily behind last year's corresponding outturn; it is estimated that gardens are about 15 per cent. behind. The rainfall since our last, has been about 12·6 inches, most of it falling at night; much hotter weather is wanted to be certain of regular flushes. Telegraphic advices report perfect weather for manufacture. Lakhimpore.—The reports are not so satisfactory from this district as last fortnight. The thermometer has been high and the sun extremely hot; there is little moisture in the soil, and rain has fallen so slightly as to be of hardly any good, the river is lower than is usual at this season, leaf is scarce, and green fly is showing again and tending to stunt the flushes; the extremes of heat and changes in the temperature, have effected the leaf. Mungledie.—More rain is wanted in this part as only a few showers have been falling locally and nearly all the gardens are much behind last year, and it seems unlikely that this year's estimates will be made, red spider is troubling some gardens again for the third time this season.

CACHAR.—Many gardens are still suffering very much from blight and some are nearly shut up altogether with it. The weather has been on the whole favourable with hot sun and rain, and a few gardens are doing well that have escaped blight and red spider; the majority, however, are very much behind last year's outturn, and estimates cannot be realised.

SOUTH WEST SYLHET.—The weather since the last report has been on the whole favourable, although more rain would have been desirable; the rainfall at present is about 9 inches less than last year up to the same date. A peculiarity of this season so far as it has gone, has been the unequal distribution of sun and rain, continued wet weather at one time and continued dry at another.

DARJEELING.—Close and damp weather prevails here which is good for the bushes but unhealthy for the coolies; consecutive days of drizzle, mist and clouds, broken only rarely by a few hours morning sun; transplanting has been successfully carried on on some estates.

KUMAON.—There has been little change here since our last, except perhaps rather more rain has fallen, and the sun has shewn itself less.

KANGRA VALLEY.—Plenty of rain seems to favour this part although the fall is about 1·1" behind last year; there has been a good deal of sunshine which has brought out some fine flushes; the thermometer in the shade has ranged from 88° in the valley to 83° in the upper gardens.

CHITTAGONG.—Throughout July the weather had not been favourable; cold south easterly winds and want of sunshine being complained of; the rainfall is about 21·41 inches

TEA ON FLAT AND HILLY LAND.

(To the Editor, Tropical Agriculturist.)

1. Lansdowne Place, Cheltenham, July 27th, 1883.

DEAR SIR,—The June number of your paper just to hand under "Tea Culture in Darjeeling, Sylhet and Ceylon" contains errors in regard to my garden of Adam Vila which you will doubtless be glad to correct in the next number.

The Tea estate of the Adam Tila Association has 200 acres of tea, of which 89 acres are in full bearing and which gave last year 885 maunds of tea, which I believe to be the season's maximum, in fact the maximum outturn ever turned out over as much as 89 acres. Of the 89 acres, 54 acres are flat and 35 acres are hilly: the former reported to be the finest piece of tea in existence, and the 35 hilly is very second rate. I have not kept details of outturn on flat and telah separately, but my experience over 8 years leads me to estimate the outturn over the 35 acres at a maximum of 5 maunds per acre or 400 lb. On this basis the flats of 54 acres gave a total of 710 maunds or just 13 maunds or 1,040 lb. per acre. I may mention that in one plucking during last season one portion of the flat gave 6 maunds of leaf per acre $=1\frac{1}{2}$ maunds or 120 lb. tea. Then as to expenditure I mentioned that we estimated in 1883 to lay down our tea in Calcutta auctions inclusive of sale charges in Calcutta at 5-8 per lb., on which we of course hope to make reduction as a larger area comes into bearing. As to labour, Sylhet is doubtless amongst the most favoured in India, probably second only to Darjeeling, Terai and Dooars. I am not absolutely certain that $5\frac{1}{2}$ annas is the estimate at which the Calcutta firm set the cost of their tea landed in Calcutta. I am inclined to think it is possibly even lower. If you will insert what I have above noted in connection with what you said in the June number you will do good to me individually and the Tea Industry generally.—Yours faithfully,

HENRY A. BROWN CONSTABLE,
NOT CONSTABLE BROWN.

[Our information was obtained from an Indian tea planter and the question started was the cost of draining and bringing the flat land into cultivation. The return of tea mentioned is firstrate, but information as to the cost per acre from first to last would be useful. In Ceylon we find that tea does well on very steep featured lands.—ED.]

AUSTRALIA: THE NORTHERN TERRITORY

We are sending a first-class collection of minerals to the Calcutta Exhibition, including specimens of golden quartz, argentiferous galena, and other silver ores, and magnificent samples of stream and lode tin,

25

I am sorry to say that our private plantations will not be represented, though Mr. Holtz, of the Government Gardens, is sending a collection of vegetable oils, cotton, tapioca, indigo, and other tropical products which will be sufficient to show that such can be produced in the Territory. Considering that Mr. Holtz has but the crudest methods of extracting the oils—obtained from teil seed and peanuts—and for the manufacture of the indigo, his exhibits reflect great credit upon him. The most absurd collection sent is a variety of woods, highly polished, and made to look as if we had some of the finest timber in the world. These specimens have been got from the immediate neighbourhood of Palmerston, and I believe that a similar lot could not be got again in twelve months' time. Any one who has travelled the Territory knows that it is about the worst timber-producing country on the coast of Australia, and it is, I think, not right to send a few picked specimens of ornamental and other woods to an Exhibition without giving an account of their scarcity, knowing well that if any one interested in timber was to pay us a visit with the view of opening up a trade that we could not load a vessel up in twelve months. I do not think it is an exaggeration to say that there are more valuable woods in five square miles of a southern timber scrub than in the Northern Territory altogether. True, we have plenty of gnarled and knotted mangrove and if lumberers want it we could well spare it.—*South Australian Register.*

BRAZIL: THE EMANCIPATION LAW.

It is now nearly twelve years since the adoption of the emancipation law of 1871, a period which ought to determine both the efficiency of its provisions for the extinction of slavery in Brazil and the sincerity of its promoters who saw advantages in it far greater than those which any other scheme could offer. In the absence of trustworthy statistics it is impossible to determine, however, just what these results have been. In some provinces the returns are more or less defective, and in three—Parahyba, Sao Paulo and Matto Grosso—the movements of the slave population are wholly lacking. So far as they have been obtained, however, these statistics warrant two conclusions: (1) the law has failed to secure the results anticipated, and (2) there is really very little popular sympathy with its aims and operations. The first of these conclusions is warranted by the fact that with an expenditure of over ten thousand contos during the nine years since the close of matriculation in 1873, including the personal contributions of the slaves themselves, only 12,898 slaves have been liberated through the operations of the fund created by that law. This in an average of only 1,433 per annum in a slave population of over a million and a half when the law went into effect. The second conclusion is warranted by the causes producing the first, by the absence of statistical returns, and by the general apathy and indifference regarding the subject, except when opposition is aroused by some exceptional advance on the part of the few abolitionists of the country.

Imperfect as they are, the statistics on this question give cause for serious dissatisfaction. The emancipation of slavery in this country is not a question to be trifled with, not only as a matter of internal economy, but also as a matter of international honor.

The existence of slavery is clearly the cause of many, very many of the ills which afflict the country, and is still not only a source of serious danger but is an obstacle to all real advancement. The present situation of Brazil is such that every delay in achieving the emancipation of slavery and its substitution by free, voluntary labor, is not only dangerous but is positively suicidal. An increasing public expenditure and public indebtedness, coupled with diminishing industries and business activity is not an economic combination upon which a people should look with complacency. The sooner, therefore, the prime and greatest cause of this state of affairs is removed, the sooner will the country be able to meet its difficulties with chances for overcoming them. To continue this cause, on the contrary, is to court inevitable disaster.

In its international relations, also, the settlement of this question is no less important and urgent. It must be remembered that the status of slavery is no longer an open question in the general opinion of the world. Slavery is simply a crime, and has been so stamped over and over again. Like many of the other crimes which are now forbidden by the statutes of civilized nations, it has cost years of constant efforts and education to crush out the selfish personal interest and advantages through which it had been sustained, and to transform it into an offence against society. This great revolution which has had the whole civilized world for its theatre and a century for its period, has made the traffic of slaves a crime against civilization to be put down as piracy, and it has also made the holding of slaves a crime against humanity, to be tolerated only because its violent suppression would require an armed interference in the domestic affairs of friendly nations. Slavery does not exist here and in Cuba because of any recognized right, but simply because the world chooses to tolerate it for the time being, while pacific measures are employed to secure its extinction. What these measures have been in Brazil is known to not a few, and more than one foreign power has been led to believe that the emancipation law of 1871 was an honest effort to redeem many a promise made, and to meet the desire of civilized society that the great evil of slavery should speedily be extinguished throughout this empire. At the time and since this law was adopted every effort has been made abroad to create the impression that Brazilian slavery is to be rapidly abolished, and that no efforts are to be spared to secure that result. In justice to the expectations thus aroused and in keeping with the promises thus formally and tacitly made some better and more effective measure of emancipation should be at once adopted.

Referring to the statistics contained in the latest official reports, covering the period from the adoption of the emancipation law down to the close of last year, we find that only 12,898 slaves have been liberated through the operations of the fund, while the number liberated by voluntary gift was 65.056. The total expenditure on the part of the state for the liberation of these 12,898 slaves, including the expenses of collection and administration and the private contributions of the slaves, was 10,476,102$220 making an average cost of 812$ for each liberation.

According to the official returns the slave population of the whole empire on the 30th June, 1882, was 1,346,648, showing a total diminution of only 194,148 since the matriculation of 1871-73. This gives an average annual decrease in population from all causes of only 22,188, or, a little over $1\frac{1}{2}$ per cent. This result must certainly be erroneous, or else it proves that the slave population of the empire is being illegally increased. The returns account for 87.005 of this total decrease, leaving a balance of 107,143 to be accounted for by death. As this is equivalent to an average mortality of only a little over *eight per thousand per annum*, it is evident that there is something very wrong with the returns, or something criminally wrong in practice.

One of the most common and most emphasized arguments against the abolition of slavery is that they are improvident and will not work except under compulsion. And yet, according to these official returns, compiled by the very men who hold these opinions, the 12,898 slaves liberated by the emancipation fund contributed to that fund from their own private savings the sum of 695,551$332, or an average of nearly 54$ apiece. This certainly is not a proof of improvidence! If these poor wretches have managed to gather together a sum like this from their earnings from overwork, from the stray pennies now and then thrown to them, or from whatever other source, then certainly something better may be expected from them after emancipation. If to these be added the unrecorded hundreds who have actually earned and purchased their own freedom, and in some cases that of wife and children, we have a record which affords an unanswerable proof that the freedman does work and save. Everyone is familiar with instances of this character, and also with others where the negro has secured an education and has made his way through life shoulder to shoulder with men of the more favored race. This charging a down-trodden, untried race with idleness and improvidence—faults far too common among the whites, be it said—is simply gratuitous injustice.—*Rio News.*

"FRESH FIELDS AND PASTURES NEW": NEW ZEALAND.

(By a Ceylon Planter.)

I promised you a letter from New Zealand, and am somewhat late in fulfilling that promise. Behind time as I am I would even put off yet, so disinclined am I to write, but the promise must be fulfilled, and the task completed in some way.

In regard to New Zealand as a suitable place for the Ceylon planter to go to, there are differences of opinion. Men of considerable local experience have views so opposed to each other on this question, that it is somewhat hard to know which to accept as valuable. When seeking information I tried as far as lay in my power to give a fair idea of what a Ceylon planter was like, his habits and style of life; and there seemed to be a consensus of opinion that he would have very much to unlearn, and a good deal to learn, ere he approached the standard of the true type of colonist.

In a new country, agricultural or pastoral farming must of necessity take the first rank, and it is the free grants of land, with the smiling homestead, and the future of peace and plenty we hear of, which fills the heart of the hard-tried planter with envy, and creates the desire to rise and possess such a land. Now, whether this farming El Dorado was a vision or a reality was made a subject of enquiry by me, and that diversity of opinion which was so puzzling and so prominent in almost all things relating to New Zealand came out here in its strongest form. The simple question was—Does farming pay? I cannot do better than give you one or two answers I got to this enquiry. A gentleman for thirty years a colonist, and many of them as a farmer, said to me: "I never made money by farming: where I did score was in the rise in the price of land." He held that to have even a fair chance of getting along meant some practical knowledge of the industry; without this a man was at a great disadvantage: almost certain to come to grief. He had, as a further article of belief, that the man who followed the plough *anywhere* never did make more than a living. Another farmer told me that twenty-five years ago he took to farming, did not then know one end of a plough from another but had been so successful, that all his sons are now following the same profession, and if he had fifteen other sons he would put them to it.

Another hard-headed Scot said to me in his mother tongue: "Twa things are wanted to mak farmin pay: 1st a guid heid, 2nd a thousand or twa"—adding, that with whatever sum a man might start farming, he would find, ere he had gone far, that he would have been all the better of "a thusand mair"! These are but samples of the opinions I got from practical men in regard to agriculture as a profession.

If on this important point, the probable financial success of farming, I found such opposite views, there was no hesitancy among any of the questioned, of a man, when he did come to New Zealand to settle, not being in a hurry to begin. A year's looking about, if you have money to invest, would not be too long, and when you do buy, buy good land, was the advice of all. Those who had only a few hundred pounds of course were different: the sooner *they* tackled to work the better, and they were not to be particular in regard to the kind of start they made. To make a start was with them the one thing needful: they could as well acquire the local knowledge valuable to know while in employment as when idle.

For a man to make anything like a fair start in farming the capital required was more than I had expected would have been needful in a new colony. As far as I could gather, something like £3,000 was the sum wanted, and all the better of "a thusand mair." Still, starts could be made on very much less, as there were all kinds of land and mortgage companies about, with property to sell and money to advance. By means of these companies a man with £1,000 could buy a farm worth three times that: but whether a man were wise to do so, would be for him to consider. The interest charged on loans of this kind was from 7 per cent to 8 per cent according to circumstances. I was assured that the profits on farming would average 15 per cent. nett, so that to go into the hands of a mortgage company was not an unsafe thing: indeed people with *nothing* had sometimes induced the managers of the companies to advance money towards a purchase, and in time cleared their feet. That however was very exceptional, and the sum of £500 was fixed as about as low a sum as a man could with any pretence to prudence and future success enter a farm with.

That my readers may experience some of that mental confusion which resulted from my numerous inquiries I may say that the gentleman who named 15 per cent nett to me as the average profit on farming operations introduced me to the gentleman who had been thirty years out, and who had *never made money by farming*, stating, at the time when he gave me the letter of introduction, that I might depend upon his friend giving me nothing but sound advice, as he was a man of great experience in the colony! I am enclosing an estimate of working a farm which speaks for itself. I am indebted to Mr. Carswell, of Messrs. Carswell, White & Co., Invercargill, for it, a gentleman who showed me much kindness and who was very patient in answering my enquiries. Mr. Carswell is a man of high standing and experience in Southland, and if any Ceylon men think of trying New Zealand as a "pasture new," they could not do better than consult him, and he will be glad to give all information as to land and its belongings. In my run through New Zealand I went in at the Bluff, and left at Auckland, and consequently saw something of the Middle and North Island, but more of Southland than elsewhere. Mr. Carswell's estimate refers to land farmed in Southland, and, from what I saw of it, it is a wonderfully productive part of the country. The colonists there are quite a sight, so robust are they, and the climate is not by any means unsuited for Ceylon people. While there I met two men who had been in Ceylon for several years, and who spoke highly of the climate of Southland.

In New Zealand it is well to see a place for yourself There is so much petty jealousy and parochial littleness about, that you cannot get anything like an unbiassed opinion in regard to the merits of any province or place. Each man extols his own, and depreciates everywhere else. Canterbury scorns Dunedin, while Dunedin pohpoohs Canterbury and regards Southland with contempt. I collected the hard things some Dunedinites had regaled me with respecting Southland, and they amounted to this:—"Southland! ugh! who would ever think of going there? It can't grow anything: it's a place where it rains seven days every week, and in bad weather eight; the outskirts of the universe, made of the leavings of creation; a God-forsaken part of the world, to be avoided, if by any means possible." I found it, the portions I went through, bathed in sunshine, studded over with homesteads, inhabited by a hospitable people, fruitful exceedingly, and a land of much beauty. I had a most enjoyable day in the Wyndham-Fortrose district through the kindness of a farmer there, who was good enough to show us about, and as we had heard so much of the poverty of Southland, he gave us a striking refutation on the spot. Going into the garden of his beautiful homestead near Fortrose, he seized a "potato-shaw" that was growing, gave it a vigorous tug, and pulled the potatoes up. One of the tubers unearthed in this rude way weighed *two pounds all but three ounces.* "We can't grow anything in Southland," said our hospitable friend as he handed the enormous potato for inspection: "oh no," adding—"but you might take it back with you to your hotel, stick it up in the public room, label it 'potato which should have grown in Dunedin, but realy grew in Southland.'"

Farming in New Zealand is not the severe drudgery it was in the old-country. The want of cheap labour has forced the colonists to employ labour-saving machines: and besides this everything can be done by contract, as cheaply, I was assured, if not cheaper, than by days' wages. I visited a fine property, some 700 acres and learnt there, that there was only one team of working horses on the place, all the work was given out to contractors. Of course a man who goes in for Government land, either on immediate or deferred payment system, is not as a rule in a position to take advantage of this, but must reclaim his wilderness with the sweat of his face. It did not seem to me, however, that the colonists worked very hard: but I may be doing them an injustice. Certainly I had my view on this matter confirmed by an American "drummer," who was travelling for a Chicago firm of agricultural implement makers, and who told me that the farmers of New Zealand should take a run through the Eastern States to see how farmers can work. "We don't come here to make slaves of ourselves," was the answer I got from several when I spoke of the easy-going way of things. Nevertheless, if the work be less severe than usually obtains among the farming class, they are always at it, a dull constant round, husband and wife alike with their noses at the grindstone. And the worst of it is that in time they don't see any further than their noses. Speaking one day to a well-to-do farmer of the possibility of one's feeling the want of congenial society in the rural districts, I got for an answer: "What has a farmer or his wife to do with society? He has his farm to attend to; she has her house, her baking, cooking, washing and dairy—there is no time for society." Put in this plain way, it was startling and came like "a bolt from the blue." Good land for farming, that at least which is near to railways, is as a rule in private hands, and can be bought unimproved at from £1 10s to £2 10s an acre. Government land of any value has been taken up long ago, except such as lies far away from means of transport. I am sending you by this post a copy of the *Crown Lands Guide,* which contains much information in regard to Government lands, and the terms on which grants are made. Ceylon men who think of trying farming in New Zealand should consist in my opinion only of those who know something about it, and whose wives are capable of helping. About openings independent of agriculture, I was told that if a man had "his head properly screwed on," was steady, could afford to wait till he had got a footing, he might do well. All agreed, however, in pitying the new chum during the first year of his residence. Besides the struggle to get anything suitable to do, colonial ways are so different, that the new arrival is apt to lose heart. If this applies to those from home, how much more therefore to those from Ceylon. Self-help is the rule, and to enjoy life in New Zealand one's wants have to be reduced to the fewest, and one must be able to do everything for oneself. This state of things presses very hard upon the ladies, for domestic servants are difficult to get, and often not worth much when they have been got. "You have got to serve *them*," said a lady to me while speaking on this subject; "so, without talking of the high wages they demand, I would far rather do the household work myself than be bothered with them." So they toil and moil, doing their own cooking, their own washing, their own everything; and the true colonist wonders what there is to grumble about, being to the manner born. It may be that residence in the East has made me regard labour with a less favourable eye than I should do, but I did think that many ladies in the middle class in New Zealand, if not drudges—were very near it. I got into conversation with a lady in the railway one day. She told me she had been many years out, and she said: "It is no place this for the middle class. It suits working folks. If I had known what hardships were before me I never should have come." With the freedom of colonial life—Jack there is not only as good as his master, but better. A man sitting opposite, miner by profession, struck in with: "If I had known what kind of place New Zealand was, I would have been fifteen years sooner." Both I am convinced gave a true report of the land and its suitability for the classes to which they belonged. This drudgery of the wives and daughters will mend in time—is mending now, but it is a thing which Ceylon planters who think of going to New Zealand with their wives and families have to consider. I may read somewhat comic in the land of dhobies, and the handy Ramasami, of the work ladies have to do when they elect to make a new country their home; but that is only in the reading, the reality is stern and serious enough, there being very little romance bending over a washing tub, or cooking meals at a hot fire.

Schools are good as a rule, and are provided by Government. Wherever the settler is, there you find the schoolmaster and the three "Rs" being taught. Those, however, who desire better education for their families, drift into the towns if they can manage it, or if not employ a governess.

Living is cheap, and clothing not much different from what it is at home. To give an idea of the price of provisions I copied from a New Zealand paper the following retail rates:—Fresh butter 1s. to 1s. 3d. per lb., cheese 10d. to 1s., eggs 1s. 6d. per doz., bacon 8d. to 10d. per lb., ham 1s. per lb., fowls 3s. to 4s. per pair, ducks 4s. do., flour 100 lb. 13s, Oatmeal 100 lb. 18s, milk 4d. per quart, bread 5d. to 6d. per 4lb loaf, beef 2d. to 6d. per lb., mutton 2d. to 5d. per lb.

Houserents are very high, but the building societies there give every inducement for people to become their own landlords, and almost everyone has a home of his own.

The working man gets high wages; the capitalist gets good interest; the middle class man is however not well paid: the remuneration offered being as a rule not better than obtains at home. It is a paradise to the capitalist and working man, but not so to the middle class. In the meantime he is not wanted except to a very limited extent. The result of my observations and enquiries in regard to New Zealand as a home for the Ceylon planter is this—he is better in Ceylon if he can knock along in any kind of a fair way; if however, he is so situated that he can get but a bare subsistence; then, he could yet that in New Zealand, and carry on the struggle for existence with more likelihood of a successful issue than he can in the tropics.

J. L. D.

ESTIMATE OF COSTS CONNECTED WITH IMPROVING AGRICULTURAL LAND IN SOUTHLAND.

	£	s	d
Land purchased from the Crown say a block of 1,380 acres at 40s per acre... ...	£2,760	0	0
Fencing boundaries of same allowing for neighbor's share, 6 miles at £50	300	0	0
Four miles subdivision fencing at £50 per mile...	200	0	0
Buildings. House say £350, stables and granary £200, other buildings £150	700	0	0
Clearing and preparing land for the plough 3s 6d per acre...	207	0	0
Breaking up—charge to permanent improvement, 8s 6d per acre	586	10	0
Total first cost...	1,753	10	0
Sowing turnips on first furrow for sheep-feed, 2 times harrowing 1s 8d. Sowing turnips 6d. Rolling 1s = 3s 2d per acre	253	0	0
Average value of turnip crop on first furrow say 12s 6d per acre...	862	1	3
Profit on turnip crop...	609	1	3
Second ploughing in July and August for wheat 7s. Harrowing 3 times, 2s 6d. Seed $1\frac{1}{2}$ bushels 6d. Sowing 1s. Rolling 1s ...		17	6
Harvesting by contract, and reaping, binding, stooking and stacking		13	6
Cost per acre producing crop in stack		31	0

At 31s per acre in stack the following yield would be:—

25 bushels.	30 bushels.	40 bushels
1s 3d	1-$0\frac{1}{2}$d	$9\frac{1}{2}$

	£	s	d
To this add cost of threshing $3\frac{1}{2}$d and cost of cartage and railage to market, say Port of Bluff 5d = ...			$8\frac{1}{2}$
To average of 30 bushels at 1s 9d cost to produce at port...	2	12	6
Average cost of landing in London 2s 3d ...	3	7	6
30 bushels at 40s per qr. in London ...	6	0	0
	7	10	0
Profit 30s per acre = £2,070 to this add profit on turnips... ... £609 1 3			
2,679 1 3			

I believe the average yield of wheat in Southland county will exceed 30 bushels per acre. 1881's statistics, which is the first season of county statistics, give an average of $36\frac{3}{4}$ bushels, while the average price of N. Z. wheat in London during the last 5 years will be about 45s. Taking these figures as a guide the return would be much larger.

Oats are a cereal which thrive exceedingly well in Southland in nearly every part of it, and under certain circumstances it may be grown with profit, equal to average crops of wheat; although low in price at present, I do not advise their being disregarded. From 60 to 100 bushels being grown in many instances per acre reckoned at 2s as an average at port give £6 to £10 per acre; on his choice of a crop the farmer must use his own judgment to suit the land, prospect of market which is ever varying, and his style of farming. As a grazier the writer has found it profitable to consume a quantity of oats on the farm for winter or spring, good for stock in shape of chaff and hay.

At this stage the land may either be cropped with oats or with turnips or sown down with artificial grasses with a sprinkling of rape or turnip. This latter brings the land to the resting stage, and to do this the following expense will be incurred:—

Ploughing 6s 6d, harrowing 2s 6d, sowing 6d, rolling 1s ... 10s 6d

Seeds.	20 lb. per reygrass	.. 4s 6d	...	
	5 „ clovers	... 4s 6d	...	
	4 „ timothy	... 1s 9d	...	
	1 „ parsley	... 9d	...	
	turnips or rape	6d	...	12s
				£1 2s 6d

If the object is to put the land into wheat-bearing condition as quickly as possible this will perhaps be best done by sowing a crop of red clover only and either cutting or feeding it off as the cultivation of this crop seems to leave in the soil the elements necessary to the production of wheat. Where close to a market, grass cropping with potatoes will have the same effect, and occasionally the crop is most profitable. Whichever method is adopted this would be called the resting or preparatory stage during which the land would be grazed, or otherwise prepared, from 2 to 3 years at the option of the farmer, when the land may be again put in wheat as under:—

Ploughing 7s, harrowing 2s 6d, seed 6s, sowing 1s, rolling 1s		17s 6d
The yield from land in this state may be fairly reckoned at 35 bushels per acre; the writer has often known 45 to 50.		
Harvesting and stacking ...		14s
		31s 6d
Cost of producing in stack say ...		11s
„ of freight &c. as already given ...		8s 2d
„ to London „ „ „ ...		2s 3d
		3s 10½d
35 bushels at 3s 10½d =	£6 15s 7½d	
4¾ quarter at 40s =	9s 10d	
Profit per acre =	£2 11s 4½d	

Thereafter the land may be followed with a green crop and fed off with sheep to be followed by a grain crop and sown down with grass at the option of the farmer.

I think the foregoing results are easily obtained in the hands of a practical farmer and will be found rather under the mark. From grasses well laid down on carefully farmed land good results may be obtained by running a good flock of crossbred longwool sheep, and for this purpose a regular system must be followed at the farm of having so much in crop of various kinds each year, say one-third, and so much in grass or greenfood, say two-thirds, to be fed with sheep. For this purpose on a farm of this size the paddocks would require to be about 150 acres, having say two paddocks in grain crop each year, and one paddock in turnip for winter feed, the remainder of the farm six paddocks in grass or greenfood 900 acres. These 900 acres with 150 acres turnips should keep 3,000 sheep all the year round with a return as follows:—

300 sheep mixed sexes average clip wool 9 lb. per sheep at an average price of 10s	£1,125 0s 0d
Increase of lambs from 2,000 breeding ewes	
for sale cull ewes say 600 at 8s ...	£240 0s 0d
„ „ „ lambs 1,000 at 6s ...	£300 0s 0d
leaving 4000 of the natural per centage as an allowance to keep up the death rate of the flock	
	£1,665 0s 0d
less ⅛ per sheep working expenses ...	£ 187 10s 0d
	£1,477 10s 0d
Profit on 300 acres grain on the average per acre from improved land of £1 19 4½ ...	£ 590 12s 6d
giving	£2,068 2s 6d

as a rental or return of interest. A practical farmer will have various methods or minor details of his profession by which to add to the profit of the farm, such as feeding off his refuse grain by a herd of well-bred swine, running a few young growing cattle or horses to top any rank grasses that get away from his sheep; grass seeds of various kinds are also a fruitful source of income. The above is calculated on the main staples of wool and wheat or oats as what may be relied on with almost certainty. One advantage we have in Southland is that we can almost to a certainty depend on our root crops, in most instances without any application of artificial manures or special labor farther than broadcast sowing on prepared soil, this giving us the means of quickly restoring and reinvigorating the land which has been somewhat exhausted by taking a grain crop and also of keeping our sheep stock and clip of wool in a healthy condition during the winter season. Labor has hitherto been a great cause of anxiety to the N. Z. agriculturist, but recent years have made such strides in labor, saving machines such as double and treble furrow ploughs, reapers and binders, steam thrashers and steam rolling stock, that that obstacle had been very much overcome, and the figures I have quoted for labor are not likely to be exceeded, as they are a good deal above the current rates now. Land carriage has also been very much facilitated of recent years by our railway system, the extension of which will no doubt keep pace with settlement, for which there is yet so much room. As our land becomes occupied by a good class of farmers our railway tariff will not only be reduced but it will pay to interweave the country with branch lines, for which the level features of the district are so well adapted. There is little doubt now the refrigerating process—which is successfully established—applied to our beef and mutton and dairy produce is going to assist us greatly in obtaining better returns from our soil than we have hitherto realized, and there can be no doubt that a line of steamers calling regularly at the various ports along our coasts thence to Great Britain fitted up with the means of landing our produce fresh to the markets of the home country, will give, combined with an influx of good settlers, such an impetus to our production and wealth as to exceed the most sanguine expectations.

THE DARJILING CINCHONA PLANTATION.

Dr. King's report for 1882-83 (given on page 763) like all previous documents of the same kind from his pen, contains much that is generally interesting, besides embodying facts which are calculated to be specially useful to those engaged in the cultivation of the fever plants. The total of trees standing in the plantations was 1,711 168, a decrease of about 50,000 compared with the previous year. But this is due to the deliberate policy pursued of as speedily as possible superseding the inferior species or varieties by those proved to be superior as quinine-yielders. Accordingly 20,000 hybrids and 43,667 calisayas of poor quality were uprooted. The same process was followed in regard to 160,085 succirubra trees, which were *replaced*—for the soil allows of successive crops—by good hybrids and yellow barks. The hybrids uprooted were such as gave an analysis of only 0·97 of quinine, 1·94 cinchonidine, and 0·80 of cinchonine alkaloid. It was right that such trees should not be allowed to cumber the ground, when seven other varieties of hybrids were available which gave results varying from 1·48 per cent of quinine up to an analysis thus represented:—

Crystallized sulphate of quinine	6·12
„ „ cinchonidine...	2·46
Cinchonine alkaloid	0·55
Total... ...	9·13

As this is quite equal to the outturn of some of the very best ledgerianas, No. 7 hybrid ought certainly to be propagated largely, especially if, as is probable, it is of a more robust habit than the ledgerianas. We were about to say that there would be a run on Mr. Gammie for seed of No. 7, but for the doubt that gentleman entertains if the seed of hybrids will give plants true to type. When we visited the gardens in 1876, the hybrid then provisionally known as *ignota* was being propagated from cuttings, and it is probable that such is the system still pursued, for we notice that in the nurseries there were of "stock plants" 10,000 of hybrids against 3,000 calisayas. With regard to both, propagation from seed is much the easier and quicker mode, and we should think that at a year or eighteen months old the seedlings would develop appearances which would enable a planter to select the best kinds. Next in quality to the extraordinarily fine No. 7 are Nos. 8 and 1, the only objection to them being the proportion of cinchonidine. We give the results of analyses of these two:—

	No. 8.	No. 1.
Crystallized sulphate of quinine	3.69	2.87
" " of cinchonidine	3.33	2.94
Cinchona alkaloid	0.57	0.72
Total... ...	7.59	6.53

All three are well worthy of attention, as they may grow and produce robust stems and large quantities of bark, in soils and climates where the king of all cinchonas may refuse to flourish. The grand superiority of the ledgerianas consists not only in the fact of the superior richness of the thick bark in quinine, but in the additional facts that scarcely a trace of the inferior alkaloids or of obstinate colouring matter or tannin is present to trouble the chemist. Of hybrids, it will be seen, there are now 504,578 planted out in the Sikkim Gardens, besides the 10,000 stock plants already noticed, and 40,000 seedlings or cuttings. It will, therefore, be seen that Mr. Gammie has laboured well and successfully to propagate the superior hybrid which reached the Sikkim gardens originally from Ceylon, thus supplying the hiatus created by the almost total failure of officinalis, of which only 25,000 plants remain. The original cinchona reserves in the Mounghoo and Sitting divisions having now been filled up, a trans-Teesta plantation has been opened to receive the best kinds of *ledgerianas* and *hybrids*. Of calisaya no fewer than 662,998 have been already planted out, while 211,220 seedlings or rooted cuttings were ready for the new plantation in Runjung. Mr. Gammie is, therefore, within easy distance of the round million of yellow barks, most of which are good ledgerianas. In favour of these, if they flourish equally well, we should say that the red barks would be gradually uprooted, but for the important and, in view of some recent opinions, cheering fact recorded in regard to succirubra trees subjugated to Mr. Moens' shaving process. It is unfortunate that nothing is said as to whether the shaved trees were covered or left bare, but we should think the latter, in view of previous experience of the ravages of ants on trees subjected to McIvor's stripping and mossing processes. But the great fact is the improved quality of the renewed bark. It was slow to renew, but when it had done so, the renewed bark yielded on analysis:—

Crystallized sulphate of quinine	3.70
" " of cinchonidine ...	4.88
Cinchonine alkaloid	1.81
Total... ...	10.39

This is a splendid result, even allowing for the large proportion of the inferior alkaloids, and supports Dr. King's statement that "there can be no doubt that, in countries where red bark trees are perfectly at home and their continuance in good health and vigour for a long series of years can be absolutely counted on, this shaving process must be a very excellent one." Of course it cannot but be anticipated, from all analogies of natural laws, that the lives of the trees must be appreciably shortened by the periodical decortications, but they seem likely, in good positions, to last long enough to render them sources of good profit. The plantations in Northern as well as Southern India have advantages of soil, deep and porous, such as few parts of Ceylon can equal; but even in the Sikkim plantations a proportion of red barks seems to be subject to the "dying out" process, for we read that no less than 182,720 lb. of the bark harvested last year was obtained "from trees that had *begun to show signs of maturity*," and which were, therefore uprooted. As the very oldest succirubra trees in the Darjiling plantations are not more than a score of years planted out, it is not probable that any have reached or approached the period of *natural* maturity. We have read of trees on the Andes which are believed to have existed for centuries. The total crop of bark for the year reached 396,980 lb., the largest return, since the first harvest of 2,400 lb. was made in 1869-70. From 1875-76 the figure has always been above 200,000 lb. and for the past six years the average has considerably exceeded 300,000 lb. The total from the commencement has been no less than $2\frac{1}{2}$ millions of pounds, the vast bulk of which has been converted into febrifuge by a rough-and-ready process conducted on the plantation. Improvements have gradually been made, and this year, besides a better return being obtained from better bark, 300 lb. of "crystalline febrifuge" has been turned out. As the general order of Government says, the simple process pursued is acknowledged to be a wasteful one, as the whole of the alkaloids cannot be extracted from the bark. A more costly process, Dr. King acknowledges, might be more successful in the direction of exhausting the bark, but it is quite a question if the cost per lb., only R8 8 annas this year, could possibly be so low. The bulky raw material, calculating its cost to Government and not the net results it might fetch in the market, was in the past year only 2 annas and 10 pies per lb. The quantity of febrifuge made from the commencement is 56,512 lb. It is calculated that the saving to Government by the substitution of cheap febrifuge for costly quinine (which averaged R96 per lb. in 1882-83) has been $23\frac{1}{4}$ lakhs of rupees, or more than twice the total cost of the plantations. The returns in the past season alone were equal to a dividend of 6 per cent on expenditure. The question, however, still remains, whether febrifuges more acceptable to both the faculty and their patients could not be as cheaply obtained by sending the bark to quinologists in London, who should simply be paid for their services as chemists, while the resulting alkaloids were sent to India for use. It is to solve this question that the Secretary of State has requested and obtained 27,000 lb. of yellow bark and 14,000 lb. of red bark. The result will soon be known and the final decision arrived at, whether the febrifuge manufacture on the spot is to be continued, by means of such simple appliances as boilers and casks, and such chemical agents as muriatic and sulphuric acids, and soda, returning a febrifuge of mixed alkaloids costing only 13s per lb, even with the acknowledged loss of about 2 per cent of the total alkaloids in the bark; or whether the bark is to be sent to experienced chemists in London who can practically exhaust the bark of every particle of quinine, quinidine, cinchonidine and cinchonine, in their separate or mixed forms, as may be deemed desirable. We notice that the cost even of Mr. Gammie's crystalline febrifuge (which is probably free from the nauseating effects of the other) is only R12, 13 annas, 2.47 pies (say 20s) per lb., which is very different to 10s per *ounce* for quinine. As the better and more easily worked yellow barks are substituted for the red, the resulting alkaloids will probably be more in proportion and the cost less to Government, so that we should not be surprised to find the decision is in favour of the local manufacture, or that a compromise is made, by which Government will get what they want of pure quinine manufactured from the best ledgeriana bark in England; mixed alkaloid febrifuge being obtained from the red barks so long as they escape uprooting by not "showing signs of maturity." Curiously enough the Indian febrifuge does not seem, as yet, to have been indented for in quantity by any Colonial Government, except that of Mauritius. That Government took 150 lb. last year, and 30 lb. were previously supplied to the Straits Settlements. All the rest was used by the Indian Medical Departments, with the exception of 19,631 lb. sold to the public and 105 lb. given as samples. It seems curious that the cheap Indian febrifuge should not have received a trial in the hospitals, dispensaries and jails of Ceylon. It was at one time anticipated that the febrifuge would be purchased in quantity for the purpose of being sent to London to be separated and refined; but this result does not seem to have been realized, and notwithstanding its alleged nauseating properties, when taken in considerable doses, the Indian febrifuge seems to have established its character as a valuable though cheap therapeutic. It will be seen that all attempts to acclimatize the Carthagena barks in Northern India had hitherto failed, and that the plants from which *cuprea* bark is obtained had not been established. The Indian Government, it will be also seen, distributes what it can spare of ledgeriana seed, not only amongst Indian planters but to applicants in Ceylon. This is a contrast to the Dutch policy in Java. Mr. Gammie, as cultivator and febrifuge manufacturer, deserves all the credit Dr. King gives him, and Dr. King himself well merits the testimony borne to his good work by the Government of Bengal, thus :—

The thanks of the Lieutenant-Governor are again due to Dr. King, whose management of his department leaves nothing to be desired. Dr. King has reported very favourably of the services of Mr. Gammie, and the Lieutenant-Governor entirely concurs in the praise accorded to him. The other assistants of the Department are also well spoken of.

We hope to see Dr. King's name included in the next creation of Companions of the Indian Empire, an honour already so well bestowed on Dr. Bidie of Madras, who was lately amongst us.

To us in Ceylon, such reports as that now under notice have been and are of great value, as giving us the results of carefully conducted and honestly recorded experiments.

CINCHONA:

ANNUAL REPORT ON THE GOVERNMENT CINCHONA PLANTATION IN BENGAL FOR THE YEAR 1882-83.

Tho planting operations of the year leave the grand total of Cinchona trees on the Government estate on 31st March at 4,711,168 of all sorts. This shows a diminution of about 50,000 on the returns of the former year, the decrease being consequent on the uprootal of 20,000 *hybrids* and 43,697 *Calisayas*, which, on analysis, were shown to have bark of rather poor quality. The removal of these inferior trees is in conformity with the policy which has been followed for some years of raising the standard of the produce of these estates by cultivating only the finest kinds of quinine-yielders. In conformity with the same policy, 160,985 red bark trees, which had to be uprooted in the ordinary rotation followed on the plantation, were replaced, not by red barks, but by yellow barks and *hybrids*. Ground was towards the end of the year, broken at Runjung in the new Cinchona reserve across the Teesta. A European assistant has been located there, and preliminary measures have been taken for planting out there, during the year now entered on, a number of the best kinds of *Ledgeriana* and *hybrid Cinchonas*. This new clearing has been connected with Callimpong by a bridle road. It will be under the general supervision of Mr. Gammie, who will visit it as often as may be necessary. In my last report I explained that among our *hybrid* Cinchona trees there are distinguishable several distinct forms, and I gave the results of the analysis of four of these. During the year I had analyses made of the bark of other four of these forms. For convenience of reference I give the whole of these analyses in the following table :—

Analyses of samples of hybrid bark from Mungpoo.

	No. 1.	No. 2.	No. 3.	No. 4.
Crystallised sulphate of quinine...	2·57	1·48	1·88	0·97
Do do of cinchonidine	2·94	2·85	2·93	1·94
Do do of quinidine ...	traces.	traces.	traces.	traces.
Cinchonine (alkaloid)	0·72	0·57	0·52	0·80
	No. 5.	No. 6.	No. 7.	No. 8.
Crystallised sulphate of quinine ..	2·12	2·04	6·12	3·99
Do do of cinchonidine	2·84	2·26	2·46	3·33
Do do of quinidine ...	traces.	traces.	traces.	traces.
Cinchonine (alkaloid)	0·33	0·68	0·55	0·57

In this table Nos. 1 to 4 are the analyses which I published last year. Nos. 5 to 8 are those which are now published for the first time. Hybrid No. 4, as the analyses made last year showed, is very poor in quinine, and it was the trees of this sort which, as above stated, were uprooted during the year. The total number of cinchona trees of all sorts standing in the plantation at the end of the year is shown in the following table :—

	Red. (C. Succirubra).	Yellow. (C. Ledgeriana).	Hybrid unnamed variety.	Other kinds.
Mungpoo Division ..	2,581,000	644,218	250,500	30,592
Sittong do ...	1,132,200	18,780	53,878	...
Total ..	3,713,200	662,998	304,378	30,592
Grand total of all kinds on both plantations ... Mungpoo ...			...	3,506,310
Sittong ...			...	1,204,858
Total			...	4,711,168

2. *Details of the year's crop.*—The crop for the year is the largest that has yet been harvested on these plantations. It amounted to 396.980 pounds of dry bark, of which 38,880 pounds were collected on the young plantation at Sittong, and the rest on the old plantation. Of the total crop, 372,610 pounds were *Succirubra*, 22,120 pounds were *Calisaya* and *Ledgeriana*, and 2,250 pounds were hybrid bark. As usual, the crop was harvested by two methods—182,720 pounds having been got by uprooting trees that had begun to show signs of maturity, while the remaining 214,260 pounds were got by thinning the plantation at spots where the trees had begun to crowd each other. The bulk of the crop was made over to the factory for conversion into cinchona febrifuge; but 27,800 pounds of yellow bark and 14,000 pounds of red bark were (at his own request) sent home to the Secretary of State, by whom the consignment has not yet been accounted for. It is, I understand, intended that these 41,800 pounds shall be converted in London into various forms of cinchona febrifuge, and that these shall be sent to this country for trial by the Medical Department. The result, financial and other, of this experiment will probably be given in next year's report. Including the crop of last year, the total outturn from these plantations since their beginning now stands (as may be seen by the annexed table) at considerably over two-and-a-half million pounds of dry bark.

3. *Expenditure of the year.*—The budget allotment for the year was R82,225 : but of this only R80,739-6-2 were spent, there being thus a saving of R1,485-9-10. Of this expenditure the sum of R17,548-3-9 was incurred on the newly opened plantation at Runjung, and on the young plantation at Sittong, which is not yet in full bearing. This amount is therefore a charge against capital or block. The remaining expenditure was incurred on the old plantation. It is therefore chargeable as working expenses, and is to be put against the year's crop.

In return for the outlay on the old plantation, there was received a crop of 358,100 pounds of bark, the cost price of which is therefore 2 annas 9·88 pies per pound. But besides these 358,100 pounds of bark yielded by the old plantation, there were collected from the thinnings of the young plantation at Sittong 38,880 pounds; and for convenience of account the Sittong bark has been taken over at the same price as the produce of the old plantation, the value of this Sittong bark being credited to the Sittong Plantation which, from its commencement, has had separate accounts. The whole of the bark has, in accordance with the usual custom, been made over to the factory at cost price, and further particulars about it will be found in the Quinologist's report.

4. *Carthagena Bark.*—I regret to have to record the continued failure of *Carthagena* bark, only three plants being alive at the end of the year. Nothing could well have been more disappointing than has been the attempt to introduce this bark. The plants received from Kew at first grew vigorously, and it appeared as if the species would be easy of cultivation. Gradually, however, all the plants sickened. Every care was taken of them by Mr. Gammie; individual plants were tried at various elevations, and with various exposures, but the results have been uniformly disappointing.

5. *Cuprea Bark.*—Some years ago a quinine-yielding bark, under the name of *Cuprea*, began to be poured into the London market from the northern parts of South America. The supplies of this have steadily increased, until now *Cuprea* forms a very large proportion indeed of the total quantity of quinine bark imported into Europe. At first the botanical origin of *Cuprea* was unknown; but it has now been ascertained to be the produce of a species of *Remija*, a genus botanically allied to cinchona. *Remija* is said to be less particular than cinchona as to soil and climate, and it is not unlikely that it may be possible to cultivate it in this country. I have therefore been anxiously trying for some time to get seed of *Remija*. I regret, however, to say that from the only packet which I have been able to secure, only a single seedling has resulted. Further efforts shall however, be made to secure seed, and I hope before long to have a patch of *Remija* trees added to the plantation.

6. *Distribution of plants and seeds.*—In accordance with the wishes of Government, and with former practice, the whole crop of seed of *Cinchona Ledgeriana* (after supplying our own wants) was distributed gratuitously amongst applicants. This plantation being the only source of supply in this country of *Ledgeriana* seed, I have reason to believe that the boon of free distribution of it has been much appreciated by planters all over India, as well as in Ceylon. The sum of R996 received during the year from the sale of seedlings and of *Succirubra* seed was paid into the treasury.

7. *Land rent.*—The rents and grazing dues received from tenants on the reserve amounted to R1,824-4, which sum was paid into the treasury, but it is not taken credit for amongst the plantation receipts.

8. *Estimated crop of* 1883-84.—About 350,000 pounds of dry bark will probably be required for the factory during the year, and I propose, as usual, to regulate the bark taken by the factory demand.

9. I have now obtained an analysis of the bark renewed on *Succirubra* trees that had had their original bark removed by Mr. Moens' shaving process. The bark renewed rather slowly, but the analysis shows that it is very rich both in quinine and cinchonidine; and there can be no doubt that, in countries where red bark trees are perfectly at home and where there countinuance in good health and vigour for a long series of years can be absolutely counted on, this shaving process must be a very excellent one.

10. The fuel plantation which was begun during the previous year has been extended during the past year, and now extends to nearly 180 acres. I have great hope that it will prove a thorough success.

11. Mr. Gammie was in charge of the plantation during the year, and conducted his work with his usual assiduity and energy. Mr. Pantling, the senior assistant, also did excellent work, and during Mr. Gammie's absence on three months' privilege leave, he officiated for Mr. Gammie. The junior assistants, Messrs. Crofton, Parkes, and Kennedy, also worked well.

George King, M. B., *Surgeon-Major*,
Superintendent, Royal Botanic Garden, Calcutta.

QUINOLOGIST'S REPORT FOR 1882-83.

The factory continues to be located at Mungpoo, and it has been worked during the year under the supervision of Mr. Gammie, his son Mr. George Gammie being in immediate charge. The percentage of febrifuge extracted from the bark used in manufacture was 2·73. This is a better result than was obtained last year, and the improvement is mainly due to the larger percentage of good bark used during the year. The net result of the manufacture for the year was an outturn of 10,363¼ pounds of ordinary and 300 pounds of crystalline febrifuge.

[Then follow details of expenditure and results.]

3. The cost price of febrifuge necessarily fluctuates from pear to year, but it has in no former year been so low as R8-8. This good result is of course chiefly due to the larger percentage extracted from the bark used in manufacture.

4. The issues of febrifuge fell below those of 1881-82, but are a little in advance of those for 1880-81. The falling off last year was, however, confined to the demand for the Government Medical Depots of Calcutta and Madras, the issues to the public having been 120 pounds below of those of 1881-82.

5. The stock of febrifuge on hand at the end of the year was 2,962¼ pounds. This, although considerably in excess of the stock in hand at the end of the previous year (which was only 1,500¼ pounds), is not at all too high for safety, being equal only to about four months' consumption.

6. The value of the stock at the end of the year is R7,058-8-4 in excess of the figure at which it stood at its beginning.

8. From this statement it appears that the year's working resulted in a profit of R66,284-9-5, which is equal to a dividend of six and a half per cent. on the capital—a result which I trust may be considered satisfactory. Quinine ruled through the year at an average of about ten shillings ounce in London, which, calculating exchange at 1s 8d. pa rupee, is equal to R96 per pound in India. The quantity of febrifuge supplied to Government departments during the year was 4,180½ pounds, and the cost was R68,988-8. An equal quantity of quinine, at R96 per pound, would have cost R401,328. The saving to the State effected by substituting febrifuge of Government manufacture for English made quinine was therefore R332,340. If this be added to similar savings from the substitution in former years, the total saving to State in the matter of quinine amounts to above R2,325,000. And as the total cost of these plantation has been only R1,000,000, the result, I think, may be considered satisfactory. Only a very small quantity of bark was sold during the year: the profit is therefore derived solely from the sale of febrifuge.

9. Much attention has been given during the year both by Mr. Gammie and myself to the improvement of the process of manufacture; and, as I have already stated, a better result has been obtained during the past than during any previous year. There is no doubt that by the adoption of a different and more costly process of manufacture a still larger percentage of febrifuge might be obtained; but that the febrifuge so obtained would cost less per pound is another question. With a raw material which is cheap, bulky, and practically unlimited in supply, processes of manufacture which involve expensive carriage and apparatus are of doubtful advantage. The whole matter of manufacture is receiving most earnest attention; but the subject is not at present in a state in which it can be advantageously reported upon.

10. Mr. Gammie's continued good services again demand my warmest acknowledgment. Mr. Gammie, junior, has also worked steadily and well, as has Babu Gopal Chundra Dutta, the head of the office and sale department.

George King, M. B., *Surgeon-Major*,
Superintendent, Royal Botanic Garden, Calcutta,
and Offg. Govt. Quinologist.

Silkworm Culture.—Mr. P. N. Braine, a gentleman who has directed a good deal attention to this subject, has just presented to the Colombo Museum his collection of silk-producing moths carefully arranged. The collection ought to be of practical value to all who contemplate trying a new and promising industry from time to time. We have a letter from Mr. Braine on Tusser silk moths which will appear shortly. We trust, during Sir Arthur Gordon's time, to see careful experiments made in introducing this industry among the Sinhalese people—an industry that ought to suit their tastes and resources admirably. What has become of Father Palla's collection now that he has returned to Europe, can any one tell us?

SLAVERY IN BRAZIL.

(FROM A CORRESPONDENT AT JUNDIAHY, SAO PAULO, TO THE LONDON TIMES, JULY 27TH.)

Brazil is the last remaining civilized land where slavery exists, and not only this, it owns more slaves than any other civilized land ever had that freed its slaves by peaceable measures (the serfs of Russia are not here included). Slavery has existed in Brazil since the first colonization of South America by the Portuguese in 1531, the first slaves being the aboriginal races found peaceably living on this wonderful continent. These however proved to be too physically weak and indolent a race to bear the iron yoke of oppression, so for them were substituted the stronger but more unfortunate African, the Caboclo or aboriginal becoming thenceforth incorporated with the dominant Portuguese colonist.

From very early days a regular trade in slaves was carried on between Africa and Brazil down to the year 1830, when the Brazilian Government declared it to be piratical. That it was not thoroughly stopped for many years afterwards is well known; it fact it was still going on clandestinely in 1854, so that even today, more than 50 years after the Governmental declaration, there are to be found here and there African-born slaves. It may be easily understood why the abandonment of the trafficking in slaves was but gradual, because with a cargo so lucrative the slave-dealer could afford to risk the loss of his ship and human freight and be incarcerated in a fortress for a few years, seeing that a successful trip would make him a wealthy man.

Since the year 1830 many and various endeavours have been made to do away with the system, but it was not until the 28th of September 1871, that the first note of total abolition was sounded by the passing of the now famous law declaring all children born of slave mothers after that date to be considered free-born, with the only condition that the child should serve the mother's owner as an apprentice until 21 years of age, after which he would be absolutely free.

More than 11 years have rolled away since the promulgation of this law, and still things seem very much as they were. The slaves, perhaps, are treated more humanely; the young negroes, however, running their term of apprenticeship of 21 years, in little seem to differ from their fathers and mothers, being equally uninstructed in anything but rude labour; they cringe and crawl to their temporary owners just as the unfortunate out-and-out slave does, who has no bright light of coming freedom to stimulate him to the end of his time of bondage, and who has no rays of sweet expectation to gild his dark life.

At the same time as the passing of the law giving freedom from birth to all children born of slave mothers, and as part of the same measure, was created an annual emancipation fund, to be formed of certain imposts for the freeing of the slave fathers and mothers of the free-born child, or for giving freedom to all slaves who would never be able to purchase that blessing. Since the date of this law the following results have been obtained:—first, there are about 150,000 free-born children serving their apprenticeship; secondly, 11,000 slaves have been freed by the emancipation fund. This latter cannot be considered as a very satisfactory state of things as the result of 11 years, but it is in part explained by the fact that some politicians have gone so far as to apply part of the money towards the education of the young negroes serving their apprenticeship, instead of using it for giving freedom to so many slaves. Much diversity of opinion exists as to the wisdom of this application of the funds voted by the Chambers. The chief difficulty, however, seems to be that it is contrary to the express spirit and disposition of the law of 1871; therefore it cannot but frighten thoughtful men to see a Ministerial interpretation of a law at variance with its evident meaning. In other respects, if the money were properly used for educational purposes (a thing most difficult to do), then not much objection could be raised.

Although the official emancipation of 11,000 in eleven years cannot be considered as satisfactory, that representing only about one per cent. of the slave population, to this number must be added the manumissions by private individuals—a noble practice which has become the fashionable way of showing any extraordinary rejoicing, at which time one or more slaves are freed. Many owners at their death leave freedom as a legacy to some of their slaves; and lastly, many truly generous people free theirs from motives of pure charity. The number of private manumissions amounts to about 30,000 for the past eleven years, making, with the official, 40,000 in all, or less than four per cent. of the whole slave population. From this it is evident that, even were the unfortunate slaves to have abnormally long lives, the present rate of freeing would allow some hundreds of thousands to reach very advanced ages and still die in bondage.

After the Birth Emancipation Law had been in force a few years the planters of the Southern Provinces, finding that the Northern men were sending their slaves down south to be sold, commenced to talk of provincial duties on all slaves taken for sale from one province to another. After being rejected in the provincial assemblies for a year or two the law passed creating prohibitive taxes of £150 to £200 on inter-provincial slave bargaining, which has been the means of virtually stopping the trade. The Northern Provinces, however, managed to get rid of so large a proportion that now there is but one-third of the total number of slaves in the Northern Provinces, whereas in former days things were the reverse, the South having but few.

Among the classes of slaves in Brazil the lives of some are so different from those of others that the case of one class cannot be taken to represent the state of the whole. The highest-class slaves are the maids, pages, or valets, whose sole work is to attend on the master or mistress to whom they have been dedicated at birth, the custom in many planters' families being to give to each of their children the soundest and best looking slave child nearest in age and of the same sex. These little slave maids or valets have to do all the labour and bidding of all sorts of their young owners, acting as shadows when so required, and as substances when occasion demands. These children, the one free, the other bond, grow up together, often weaving cords of love and affection, so that whatever may be the lot of the other slaves these remain with their first owners and are never sent away to work in the plantations or elsewhere, except in case of very bad behaviour. The next in favour are the artisans, the bricklayers, carpenters, and smiths, who are often hired out, and who are well treated in consideration of the great revenues they bring to their owners; in fact, many a hired slave of this class earns for his master from five to ten shillings a day. Then come the house slaves, the coachmen, the cooks, and the washerwomen; following these are the town slaves who are hired out to work at any labour, the owner receiving so much per head per day. Last of all come the plantation slaves, who often in appearance look little human, and seem very Calibans in many, many cases. These sad ones are they who earn all the wealth of the land; these are they who rise before the sun, and after asking in forced formality the blessing of Christ from their master or overseer, are led off in herds to toil till dark, their food being taken to them in carts, and doled out as to a herd of creatures more swine-like than human; these are they who do all the hard work of the plantation, the life-sapping toil, leaving that which is easy to the colonist or free labourer. No one who has only seen the city slaves can form an idea of a herd of slaves being led off to their works nor can tell the sensation of meeting a half-hundred human beings homewards turning after a hard day in the sun, each carrying wood to serve for the food-cooking, each on meeting you folding his hands and abjectly begging your blessing in Christ's name. On they come, one straggling behind the other, the young and still strong in front, the old and feeble and the women, with their little ones bound to their waists, toiling far behind.

A good defence of slavery cannot be given, for by it a way is left open for the almost unrestrained exercise of the passions of the owner; but, as in all systems where men govern, in some cases the governed are much better treated than in others, according to the temperament of the Governor, so in Brazil are there many hundreds of humane masters whose bondage is more suave than the vaunted freedom of many a farm labourer or toiler in the mines of Europe. These are the masters who will be the heralds of the day of emancipation, seeing that they, wishing in their hearts for the freedom of the slaves, are only awaiting some reasonable means to bring it about, being men of like minds to those who in 1871 passed the law of freedom from birth.

The total abolition of slavery in Brazil cannot be accomplished without bringing with it most serious consequences to the financial prosperity of the country; hence the wild abolitionist who shouts for emancipation without showing the way or aiding in anything, rather obstructing by his noisiness, will never attain to the end he pretends to long for. This assertion will doubtless rouse much opposition, but it will remain unanswerable so long as the abolitionist lives on the fruit gained by the sweat of present or former slaves' brows, or on the gains accumulated by the sale of his own slaves, or on the proceeds of similar sales by his father or his grandfathers.

Slavery, unfortunately for the Brazilians, is wedded to their lives and customs, so that when abolition is talked of then must the whole body of the nation be prepared to bear part of the burden, and not thrust it on to the few owners of slaves, who may have bought them from the abolitionist himself, his father, or his grandfathers. This is a point the enthusiast or the youthful emancipator fails to see; he only sees the consummated facts of the abolition of slavery by the English in one case, and the confiscation for political purposes of the slave property of the Southerners by the men of the Northern part of the United States in 1863.

Before entering, therefore, into the question as to how Brazil is to bring about the emancipation of her slaves, it will be well to examine the plans adopted by other nations, ever bearing in remembrance the fact that whereas the sons of European nations had other homes to retreat to, or send their families to, and be supported by, when they found insupportable the trials and troubles generated by the bulk of the society in which they lived being suddenly equipped with freedom, a power it knew not before, and was as equally unfitted to use, the Brazilians, on the contrary, after emancipation will have to remain—men, women, and children—to bear the brunt, a fact in itself enough to place the question for Brazil on quite another footing. So important, indeed, is this point, that all considerations of emancipation must gyrate about it as one of the great centre thoughts.

The English, after many years of debating, emancipated their slaves by the most simple method, that of paying their owners the value of them. This for rich England was possible, seeing that the proportion of slaves to free persons of the Empire was not very great—the number of slaves being probably under 800,000, which would be about one slave to every 40 free English-speaking persons, a proportion so comparatively small that the burden on the nation could hardly be considered heavy; on the other hand, Brazil has today upwards of 1,100,000 slaves and a free population of about 9,000,000, which is in proportion of one slave to less than nine persons, and which would, even if emancipation were possible by payment, be an enormous burden in itself, apart from other considerations to be made further on.

The places principally affected by the English emancipation were Jamaica, Barbados, and other West Indian possessions. As to Jamaica, its history is well known, being on of gradual decline in prosperity from the date of the promulgation of emancipation for 15 or 20 years, since when it has recovered its former prosperity. The chief decline was between 1834 and 1844, a period of ten years immediately after the emancipation, during which time the trade of the island fell off more than 50 per cent. The Barbados and the other islands did not suffer so seriously, owing to being very much smaller, and having less unoccupied land for negroes to squat upon; to which must be added the foresight of some of the masters, who had all the bananas and other fruit trees cut down, so that the emancipated slaves were from the very day of their freedom obliged to work to live, the masters possessing the money and still retaining the land. If this destroying of fruit trees and roots was impossible in the Island of Jamaica, how much less possible would it be in the Empire of Brazil, with its thousands upon thousands of unexplored miles abounding in game, rich in soil, full of edible roots and fruits, watered by magnificent rivers abounding in fish, a hiding ground where nations could hide and could thrive unseen.

The next emancipation to be considered is that of the United States in 1863. This, however, cannot be received as having been dictated by humanitarian feelings or principles, it being simply a confiscation of slave property by the Northern party for purely political advantages during the civil struggle, to see whether things should remain as defined at the time of the secession of the States from England or if a new mode of Government should be inaugurated. The old style fell before the rushing flood of democracy, and the world is now asked to admire the beneficent effects of the confiscation in 1863; but before the stupendous growth of the present apparent prosperity of the States began to appear there were dark days of weeping, and sorrow, and desolation, when the lands formerly tilled by the slaves rolled back into the forest and jungle, when the unfortunate ex-master had to sit almost starving on the burnt threshold of his but lately flourishing homestead. This interregnum of darkness, this starving of former proprietors, forgotten by the ingoing thousands from over-crowded Europe, is now all transformed, and the land is brighter than ever it was; but there is a bitterness in the mouth after telling of the confiscation, after telling of the widows' tears, and the slow starving of the orphan for ten long years. Blot out the memory of this interregnum, speak of the States with slaves before 1861, and span over to 1871, then can the States be held up to the Brazilians as a model to encourage them to make one fell swoop on to the system of slavery; but, so long as memory serves her end, so long will the case of emancipation in the Southern States of North America be a warning to Brazil to be prudent and cautious. The States, with all their rich soil and their thousand mines, could never have paid in cash for the redemption of their slaves as the English did without having created a burden heavier than their war debt; hence they chose the shortest way, which was to throw the burden on to the weaker and oblige him to bear it. In this they were right, before the law that right is might and might is right, but in no other form.

All this, however, teaches nothing to the Brazilian who is striving to find an equitable way in this sad problem. He wishes to avoid bloodshed, he wishes to avoid unfairness, and he shrinks from the terrible ten years of national bankruptcy and anarchy. As beforesaid, the wealth-winning force of the nation is the slave population, seeing that thus far the cities and towns have absorbed four-fifths of the colonists who have sought these shores, these immigrants naturally preferring an easy city life with some few diversions to the comparatively hard life in the coffee and sugar plantations.

Now, to find a substitute for this slave labour without annihilating for a time the export trade of the Empire is a mighty problem, and unfortunately neither of the cases of emancipation cited can help Brazil in the least degree, seeing that she, although territorially and minerally rich, is really financially poor, hence could not dream of paying down cash for 1,100,000 slaves, each worth about £70, taking one with another; and, again, before withdrawing this wealth winning labour from her plantations, colonists and free labourers would have to come in, and before these can become thoroughly accustomed to all the work of the plantations it will be necessary to add very largely to the machinery and appliances to do work now done by the slaves, but which free labourers would not undertake, being unaccustomed to work as the slaves do in the hot terreiros, or coffee-drying grounds. This, therefore, means an expenditure of capital which is not within the reach of the majority of the planters, especially at this present time of low prices and uncertainty.

Brazil, again, having coffee for her chief product, is unfavourably placed with the English West Indies, where sugar was chiefly grown, or with the Southern United States, whose chief product was cotton. Coffee is an evergreen shrub, which requires careful attention for five years before bearing fruit, and which, if abandoned for an equal time, dies out; whereas cotton and sugar alike produce in one year after planting, hence, if abandoned for any number of years, would yield a return to the planter after one year's tilling of the soil. This, therefore, makes it more imperative that before abolishing slavery free labour shall be at hand to replace the slaves of Brazil, for of these latter not one-third will work after emancipation, and this third will not do more than two-thirds of what it now does. To estimate the number of free labourers required it is necessary to find out how many emancipated slaves would consent to work. At present about 500,000 slaves are engaged on the coffee plantations, of whom, (more than probably) only 150,000 would work after being liberated, if freedom were granted unconditionally; and as the real working value of these would only be two-thirds of what it now is, this number can only be valued at 100,000 out of the 500,000 now working, leaving 400,000 to be found among the incoming colonists or among the city labourers. The present rate of colonization in Brazil does not exceed 15,000 a year of which number only about one-quarter goes to the great agriculture, the others preferring to gain independent livings on railways, at small trades, or in the producing of the smaller necessaries of life, which shows that to supply the want of 400,000 in the great and only agriculture that maintains the exchequer of the nation less than 4,000 a year arrive. The difference between 4,000 and the needed 400,000 is so stupendous that it is evident that, unless some system be adopted to oblige the negroes to work after they are free, this great and fair land will become desolate and bankrupt.

The law of 1871 as it now stands, is in a very fair way of accomplishing emancipation without its being necessary to advance any aggressive measures connected with general abolition, for, taking the life of a slave to be less than 40 years, and remembering that already the youngest born slave child is over twelve years old, the greatest length of time that could elapse before the last slave was free (leaving out the comparatively insignificant number of manumissions) would be only 28 years—that is, in the year 1910; but the law of 1871, although simple in its action up to the present time, will soon begin to have serious complications, seeing that at 13 years of age many women marry here, and this especially among the negroes. The relations, therefore, of the child of a free-born child to the master of its grandmother will make matters rather difficult, so that in order to avoid these and other complications of the same order, and to satisfy the noisy clamour of the so-called city emancipators, the owners will find that instead of the year 1910 the year 1890 will be much more near the date when all will be free. As this consummation cannot be brought about without money to aid in the promotion of colonization and the introduction of new appliances and machinery, it becomes clear that those who have commercial and other relations with Brazil cannot engage in a nobler task, and at the same time one which will more enrich the whole civilized world, than in the making of the emancipation of Brazilian slaves possible without an ensuing ten years of darkness and ruin.

The question of the emancipation of 1,100,000 slaves is one that might well occupy the many great minds now lying idly by in Europe. What a glorious prize to strive after, the finding of a way to accelerate the freedom of a million human beings without having an interregnum of anarchy, bloodshed, and misery between the freeing and the perfect establishment of free labour! He, however, who undertakes this herculean task must not forget that in trying to obtain freedom for slaves he must secure the honour and lives of the thousands of delicate women and children who would find it hard to be thrown into a flood of a million emancipated creatures, many of whom, like Caliban, are calling out for freedom, and who, like him, look at freedom as free licence to all passions.

If the anti-slavery people of England have any real weight in society—if they really wish for the end of all slavery—then can they help the Brazilians in this the last great emancipation of slaves. It has been demonstrated that without the aid of a very large sum of money the Brazilians cannot hope to bring about a satisfactory emancipation. Now, the raising of this money in the empire being out of the question, it would have to be done by a loan, which would require more than an ordinary single-handed effort on the part of the Brazilian Government. The anti-slavery people, therefore, can do good service here, bearing in mind—first, that the total value of the Brazilian slaves is about £77,000,000 sterling; secondly, that before the abolition of slave-labour the plantations must be placed in such a condition that free labourers or colonists may work them, which means a very considerable outlay of money in laying down tramways for the moving, apparatus for the lifting, and obtaining some method of artificial drying for the coffee.

Were the Brazilian Government at the present time to attempt to raise a loan sufficient for immediate emancipation—say, £77,000,000—of course, it would fail; but, even were it possible, it would not be advisable, as a sudden emancipation is only another way of defining national bankruptcy. In order, therefore, that the national exchequer may still be replenished during the transformation of the slave labour into the free, some method whereby the Government will become the owner of the slaves is necessary, something similar to the following:—

The Government to attempt to raise a loan of, say, £33.000,000 and apply the same in advancing £30 a slave to the owners as purchase-money, granting, however, to the owner, as further indemnity, the right of using the slaves without any payment in the form of hire for four or five years, after which the slave to be considered as free, but as still owing the Government £30, which sum he would have to earn and repay to the Government in a time, say, not exceeding two years, by still working for his former owner, who would be responsible to the Government for the repayment of the loan made by it on behalf of the slave. By some such means a fixed time would be marked for abolition; the slaves also, being the property of the Government, would be well treated by their hirers, and newly-freed ones themselves would gradually learn the use of freedom and moderation—things they have not the most rudimentary notions of now. Doubtless there are faults in this plan, but, in the shadowing forth of a possible means for accomplishing so vast a scheme, the details which would enter into it when being shaped for action cannot, of course, be foreseen.

That the nations of the world ought not to stand idly by to see this struggle on the part of Brazil is evident, from the loss which must result if unconditional emancipation come about before the nation is prepared with free labour, seeing that the value of the coffee trees of Brazil alone is about £36,000,000, which would be all lost to the world were there no provision made for the keeping up of the plantations after emancipation, as a five years' neglect is sufficient to kill a plantation.

In the coffee cultivation there are employed about 500,000 slaves, who at this work are worth at least £120 a head, or a total of £60,000,000, which, added to the value of the trees, makes the enormous sum of £96,000,000, without taking into account the value of the land, machinery, &c. Again, if the Brazilian people were only to suffer the loss of one-half their annual revenue, as Jamaica did during the ten years succeeding the emancipation of 1834, this on coffee alone would amount to £4,500,000 a year—a sum of such respectable dimensions that it can but call the most serious attention of all who have philanthropic, general, or real interest in this great land.

Should the Brazilian Government undertake some scheme of emancipation by part payment of the value of the slaves, it could hardly be considered unreasonable were it to try to raise the money in England, seeing that the English are interested in this country to the very great extent of many millions sterling, a great part of which money might possibly be lost were further aid refused; at the least, this capital would receive no interest for a number of years.

Here is work, therefore, real and material, for the anti-slavery people and their friends, the enthusiastic shouters for emancipation, to do before they can lay claim to any higher title than obstructionists rather than helpers, for be it borne in mind that the Europeans or Americans who, through the fortune of birth, were not born slave-holders, do not of necessity absorb all the human kindness there is in man towards slaves, neither are their hearts of softer material; otherwise we should be spared the pangs of knowing that there are some Englishmen, Frenchmen and Americans slave owners in Brazil at this present time. That which is born in the bone can be expected to come out in the flesh, so a man whose earliest days, whose whole moral education is associated with the holding of slaves, must be judged from a stand point removed from passion, he being in the case of the man who knew not the law, therefore he could not sin.

One word in conclusion about immigrants. Up to this present time a steady current of immigration has been prevented chiefly by these causes. One was the most unfortunate circumstance of the Government having, at its first essay at colonization, intrusted the care of the immigrants to men without any administrative capacity, whose only object in undertaking the work seems to have been their own enrichment by various means. This sad lesson Brazil has taken sorely to heart, so that now everything is being done to give true and real help to immigrants. Secondly the large landed proprietors, little dreaming of impending emancipation, steadily refused to sell one inch of land, thus obliging the immigrants to settle on the poor lands of the Government or else find a residence so far from the markets that their labour was to no purpose. This also is altered now, not by common law, but by the stronger law of necessity, the owners beginning at last to find out that if they wish to draw any revenue from their estates they must encourage settling on their lands either by giving or selling them. A third cause is that ambitious and bellicose statesmen of Europe have ever set their faces against and used their power directly or indirectly to prevent emigration, as tending to reduce the number of pawns on the European chessboard. A fourth obstruction to immigration is due to ignorance in Europe as to the climate and other characteristics of Brazil, which has always been considered as an intensely hot place, quite unfit for the bulk of Europeans to live in. This is explicable by the fact that the towns which have the greatest number of foreigners in them and which are best known to travellers who "do Brazil" and write about it too, but who rarely go more than 50 miles inland, are Pará, Pernambuco, Bahia, Rio de Janeiro, and Santos, all of which places are very hot, intensely so in summer: whereas a few miles from the coast, in the highlands, especially in the southern half of the Empire, the climate is similar to that of southern Europe, the nights are always cool and refreshing, and in winter occasional frosts appear. As an instance of the difference of climate in two places, take the city of São Paulo, which is about 45 miles from the city of Santos, where the heat is at times from 100 deg. to 108 deg. Fahrenheit in the shade; whereas in São Paulo pears, apples, and all European fruits can be grown, it being only moderately warm, and situated on a tableland 2,400 feet above the sea. The same difference of climate and physical conditions exists between the city of Petropolis and Rio de Janeiro, from which latter it is not 40 miles distant. As another proof of the mildness of the climate, it may be mentioned that the whole of the maintenance of the permanent ways of the railways in South Brazil is done by Portuguese, Germans, Italians, and Lombardians, who never fail through the heat of the sun. If, therefore, these men can toil without any shade and can with-stand the glare of the refracted rays of the ballast of the railroad, how certain is it that they or any other Europeans could work pleasantly in the shady groves of the coffee plantations.

A glance, also, at the physical geography of the country is sufficient to prove the fact that there is a great diversity of climate. Parallel with the ocean is a narrow belt of low land, 10 to 20 miles wide, generally mangrove swamps, with here and there a hillock a hundred or two hundred feet in height peeping out of the morass. Beyond this, in the province of Rio de Janeiro and northward, rise the Organ Mountains, which are backed by the Serra da Mantiqueira, and from Rio southwards, past Santos, down towards Rio Grande, runs the formidable Serra do Mar. How boldly and grandly these mountains rise is known to all who have passed down the coast on board ship. These splendid ridges appear Dover's cliffs a hundred times magnified, and instead of Albion's white walls rise ramparts of primeval forest, one mass of rolling green from their bases to their summits. Overcoming these mountains, either starting from Rio de Janeiro, by the winding Dom Pedro II. Railway, with its score of tunnels, or 200 miles farther south, from Santos, by the shorter but equally grand mountain line of the São Paulo Railway, by which incoming freight, human or material, is dragged up the mountain side by wire ropes for five miles, rising in this distance 2,500ft., the rolling tableland is reached, gradually sloping down to the head waters of the mighty Rivers Paraná and La Plata. Here it is that the colonist is asked to come and live, and not in the frizzling heat of the towns on the sea-shore.

Reputation is a great thing, so the northern parts of the United States being better and more generally known than the others, all have become credited with being mild and temperate in climate, from Maine down to Florida, or from Pennsylvania to Lower California. Brazil, however, being but little known, and this little being chiefly confined to her hottest parts, is, in like manner, credited with having a climate like that of the Guinea coast, whereas between Pará and Rio Grande, a distance of 2,400 miles, the diversity of climate is very great, only slightly inferior to that of the States, and the interior being cut up by several ridges of very high hills, almost any climate may be found by going up or down these so-called hills.

As a nation, though, Brazil is sick, and needs all the gentle care her friends can give her. That she will recover no one doubts, that she will rise still more vigorous than she now is is certain, if she can but get help, moral and material, to beat down the monster anarchy which will clutch her by the throat if her emancipation of slavery be not very thoughtfully and prudently carried out.

SLAVERY IN BRAZIL: THE COMING CRISIS.

From the *Rio News*, a paper which is honestly and ably conducted by an American gentleman, we have frequently quoted articles on slavery in the great South American Empire, advocating immediate abolition, and pointing to the case of the United States as a warning and an example. "Be just and fear not," is the principle of the policy advocated, the danger of a catastrophe involving anarchy and ruin lying not in immediate action but in undue delay. The writer forcibly used the argument that slave fathers and mothers are not likely to endure bondage patiently, when they see their children attaining freedom under the law of manumission passed in 1871, and which provided that all children born to slaves after that date should be free under certain conditions of apprenticeship, such as were not found to work well in the West Indian Colonies of Britain. The abolitionist views of the *Rio News* were controverted by an English resident in Brazil, who conjured up many lions in the path, and we believe we are not wrong in attributing to the same gentleman the authorship of the very elaborate paper on the whole history, condition and prospects of the slavery question in Brazil, which we quote from the London *Times* of July 27th. No one could more forcibly depict the inquity of the whole system, from the original operations of the man-stealing traffic to the deliberate policy of keeping the slaves in such abject ignorance, that they always ask for Christ's blessing at the hands of those who have made property of and are making profit by their flesh and blood. It is no new thing in the history of the slavery controversy, that the brutalizing effects of the system on the slaves should be pleaded as an argument against emancipation until, at some indefinite time, the wretched bondsmen are fitted for freedom. The writer in the *Times* foresees and dreads the dangerous crisis which is rapidly approaching, and he predicts that slavery, instead of existing up to the time fixed by law, 1910, will come to an end even before the close of this century, of which only seventeen years have now to run. But the tone adopted is most extraordinary. Instead of recognizing that righteous law of retribution which ever follows high-handed iniquity, and which appeared in the shape of temporary ruin in the West Indies and civil strife and bloodshed like water in the United States; instead of warning the slaveholders that their only hope of escaping like consequences lies in making the fullest atonement for their own sins and those of their fathers, by restoring to the slaves that freedom which no human being had the right to deprive them of; instead of telling the slaveholders that they must face the consequences of wrong in the process of righting it; the writer directs his shafts against the advocates of freedom, and tells them that they must assume the responsibility of any disastrous consequences, and that they are morally bound to provide the sum of about seventy-seven millions sterling required to pay the slaveholders for the value of property to which they never had any moral right! The plea, as addressed to the friends of freedom, is outrageously preposterous: as much so as if it ran:—"Don't deprive the poor thief of the goods which he has stolen, or which his ancestors stole and left to him, until you have paid him their full value in the shape of compensation." There is force in the plea, however, when addressed to such Englishmen (and we fear they are more numerous than, for the credit of our country, we could wish) who have traded with money in Brazil and whose security consists largely of slaves,—the lands on which the slaves labour being worthless without them, or their equivalent in free labour. In the ranks of commerce and finance are found too many whose only maxim is "Make money"—"honestly, if you can," being left out. It was the interest of such men—citizens of the Northern States—in Southern slavery which really made the "peculiar institution" die so hard,—being extinguished, finally, only in the best blood of the nation, which was poured out like water. Our mention of free labour reminds us of the fact, that the writer in *The Times* fails not only to rest the responsibility of whatever consequences accrue on those who refuse to do justice to their slaves, and not on those who demand that justice in the name of humanity and in the name of that Saviour of humanity (which name the poor slaves are taught to use so parrot-like), but that, as was to be expected from slaveholders, they are rendering the cultivation of their estates by free labour impossible, from their tyrannical and cruel treatment of the free immigrants who have consented to work on plantations. In the Province of Ceará, where public opinion has led to a good deal of manumission, there was a case recently before the courts, instituted on behalf of some free labourers, who when they were able to escape from the plantation on which they really had been held in bondage, appeared as almost skeletons from starvation and covered only with filthy rags. It is only dire necessity that would lead any freeman to adopt plantation work, while slavery exists; but many of the slaveholders, by their conduct, are doing their best to render the substitution of free for slave labour impossible. There are good and wise and benevolent men even amongst the slaveholders, and for the sake of such men, as well as for the sake of the slaves and even for the sake of the cruel and bad slaveholders, we could wish that the transition period in Brazil might be peaceably passed over, without involving bloodshed or ruin. But we must face the facts as they stand,

and the desperate nature of the case is shown by the cry of the writer in *The Times* :—" Anarchy, ruin and bloodshed are certain to accompany the process of slave emanicipation, unless the English philanthropists who plead for freedom will provide a loan of little short of eighty millions sterling to compensate the slaveholders for the loss of their property" : property which was never rightly theirs. The natural reply is : "You have made your bed, and on it you must lie." The difficulties which have to be faced are certainly most serious, and we confess that we see little prospect of a catastrophe being long averted. "Am I my brother's keeper?" was never a morally right question, and it is now less defensible than ever. Because Britain amongst other nations of the world, has not insisted on the abolition of slavery in Brazil (we did much and were hated in proportion), this colony has added to her other causes of depression low prices for coffee produced by over-production in Brazil ; a result which would have been impossible but for the existence of over a million slaves, one-half or more of whom are predial. If the coffee enterprize in Ceylon, recovers from the depression which has overtaken it, owing to natural or providential causes, it will still have to contend with the slave-grown coffee of Brazil, so long as slavery in that country is allowed to exist. We, in Ceylon, are, therefore, deeply and specially interested in this question of Brazilian slave emancipation which the writer in *The Times* clearly expects will be precipitated by the action of abolitionists in the Empire and beyond its bounds. The writer in *The Times*, it will be seen, values the coffee trees of Brazil at £36,000,000, without counting land, buildings, or machinery, all of which would be lost to the world, by five years' neglect of the coffee estates, which would be fatal to them. But the value of the coffee property is far exceeded by the money value of £120 a head put on the 500,000 slaves engaged in its cultivation, the total being £96,000,000, without counting land, machinery, etc. Taking into account the enormous tracts of land appropriated by slaveholders for coffee cultivation, the property at stake cannot be much less valu ine than £200,000,000. No wonder, therefore, if the slaveholders, educated as they have been, cling to slavery and do their best to defeat or delay the operation of the emancipation law. The worst and most dangerous element in the case of Brazil, however, lies in the treatment of free immigrants. Not only is the public sentiment of the slaveholding interest hostile to them, unless they consent to work and be treated as slaves, but the laws of the Empire (which do not recognize religious liberty) seem as if they had been framed to impede a process on which not only the progress but the very existence of the country depends. It is very true that the Emperor, personally, is a man of liberal views and a friend of freedom. But he is largely in the hands of his "constitutional advisers," and but few of these have the courage to fully admit the gravity of the position and to take the only measures which can avert anarchy and ruin. It will be seen that the writer in *The Times* talks of "the shady groves" of the coffee estates, in which men from temperate climes could easily work. About this we are doubtful, and we suspect that, if the plantations of Brazil are to be kept up, it must be through the agency of Chinese or Indian coolies. But the Government of India would demand conditions which the slaveholders of Brazil would never consent to, or at least never fulfil. If, on the other hand, the laws of Brazil were altered, so as to give full civil and religious liberty to all immigrants, it is quite true that in the vast territory of the South American Empire,—on its mountains as over its plains and by the sides of its great rivers,—there is every possible variety of soil and climate, for immigrants to resort to and settle on. We cannot doubt that there is a great future for Brazil, but it will only come when the curse of slavery has been ousted from the land. One of the natural consequences of the system is just what the writer in *The Times* predicts : if the slaves obtain their freedom, not more than 100,000 out of the 500,000 employed on coffee plantations will continue to labour on them. Slavery not only makes labour hateful to the slaves but degrades honest toil in the eyes of freemen. It is not probable that the desire of the writer will be gratified by a sufficient contingent of freemen being ready to take the place of slaves who will interpret freedom to mean abstention from work. The Brazilian slaveholders ought to learn the lesson which so-called "confiscation" of their slave property has taught the planters of the Southern States of America. By offering their former slaves proper inducements, in wages and treatment, the planters have obtained labour better and more profitable than in the days of the "peculiar institution," and the Southern States are now rapidly advancing. But we suspect the Brazil slaveholders, generally of Portuguese descent, are too proud to learn and practice such a lesson, and therefore, we fear that "dark days of weeping, and sorrow, and desolation," such as the slaveholders of the Southern States had to pass through, before they learned the needed lesson, are in store for Brazil,—the only great nation of the world in which slavery is still rampant.

Coffee in Java.—The *Java Bode* states that the yield of coffee this year in the Padang Highlands promises to be so unusually abundant that unless timely measures are taken to facilitate its conveyance to the coast it will become impossible to find room for the crop in the Government storehouses there.

Borelli Tea Company (Limited.)—Capital, £1,20,000 in 12,000 shares of £10 each, of which 7,817 shares have been issued; area under cultivation, 810 acres. The total crop of tea packed has been 496,930 lbs.—representing an increase of 26,930 lbs. over the estimated out-turn, and 39,255 lbs. over that of the preceding season. Owing to the heavy fall in the value of Indian teas, the average price realised for the crop has been only 1s 1·17d., against 1s. 4¾d. for that of 1881 ; but the low cost at which it has been produced—viz., 9·92 per lb.—to a great extent counterbalances the fall in price, and admits of a profit which, if not quite equal to that of last year. may be considered fairly satisfactory in the present condition of the tea market. The accounts show a profit of £5,782 14s. 11d., which, added to the balance at credit of revenue account, admits of the payment of a second dividend of 4 per cent.—making 8 per cent. for the year, free of income tax—and leaves a balance of £3,925 7s. 3d. to be carried forward. During the past cold season an extension of about 44 acres has been made to the cultivation, and as this has been planted out with seed of the best description it should prove a valuable addition to the Company's estates. Mr. Lumsden, whose management continues to give satisfaction to the Board, reports the estates to be in thorough cultivation. He estimates the crop of the current year at 436,000 lb, which he hopes to lay down here at a cost not exceeding 10d. per lb., including all home charges, and the cost of the above extensions. The out-turn for the present season, as advised to 31st May, viz., 15,737 lb. shows a decrease of 11,719 lb. from that of the preceding year, but this being entirely due to the protracted drought experienced in the early part of the year, need cause no uneasiness to the shareholders. A copious fall of rain has since taken place, and the directors have no doubt the decrease will soon be made up. At the request of the superintendent, a large size Kinmond's dryer has been sent out, which will prove a valuable help in the further reduction of expenditure. We congratulate the shareholders on the results of the year. In face of low prices a profit of 3¼d. per lb. of tea has been realised by careful attention to economy in working.—*Home and Colonial Mail.*

Correspondence.

To the Editor of the Ceylon Observer,

PLANTING MATTERS IN MYSORE.

July 26th, 1883.

DEAR SIR,—Owing to its being a stern necessity to grow coffee under shade, and owing to a superabundance of wood being allowed on the trees, the returns are notso good as they seem. This is caused bythe lower branches doing nothing owing to their "light being hid under a bushel" (of crop) while the top branches have all the fun to themselves. Now you may ask why it is a stern necessity to grow under shade? I can read you a sad story as to that as soon as I can get access to past records of coffee planting in Munzerabad. Leaf-disease lets you down so quietly that you have actually got to the foot of the precipice without realizing it. But here the borer severed the tree forthwith, and down!—crash!—went the whole district. Some limped off thoroughly scared; a very few plucky planters held on and tried other coffee and other products; and really Ceylon can't be compared to what one can see here. There is no great bumper to demoralize dories and coolies; no temporary wealth to attract all England's younger sons and Scotia's plodding energy; but a good margin over outlay and upkeep. It was found that the terrible *borer* liked a nice dry place for its reproductive operations and hatching its eggs. Open clearings and open handling suited it *down to the ground*, and the borer thus had fine scope for pushing its family in the world. Shade and thick coffee thus became necessary. There is another thing that makes up in a degree for want of severity in leaf-disease. That is "stink rot." Now that's not a pretty name, but it gives you a good idea of its nature. I have seen something similar in unpruned and neglected coffee in Ceylon. The top of the tree gets blacks, the wood as well as the leaves being affected, and a thin film can be taken off branches and leaves like a fine cuticle. This has been subjected to the microscope by a gentleman who is well-known here on account of his scientific researches into the ailments of coffee, and its requirements in the way of food. He says this blight is a fungus; and he gave me the technical jawbreaker, but I have failed in retaining it. The decayed foliage has a nice (?) smell of mushrooms, rather far gone. The blight I believe to result from insufficient evaporation in the wet season. Drainage would modify it. ABERDONENSIS.

THE PLANTING ENTERPRISE AND COFFEE CULTIVATION.

4th August, 1883.

DEAR SIR,—In continuing the subjects of my letter of 24th ult., I ought to mention that in using the word "remedy" with reference to rape-cake, etc., I do so in the sense only in which it is applicable to agricultural pests; for experience both at home and here teaches that a pest once fully established, it becomes impossible to utterly extirpate it. Hence there is no remedy in the strict sense of the word. These pests remain always in a more or less virulent form as conditions favouring them are present or absent, or to the extent to which remedial measures have been attended to or neglected.

I am satisfied that coconut poonac and castorcake are the fertilizers in which grubs mostly flourish, and that caustic lime properly and seasonably applied, rape-cake in which mustard forms a proportion, manures in the manufacture of which sulphuric acid is used, and all the alkaline manures are most efficient grub deterrents.

With regard to mustard seed sown broadcast under the coffee and mulched in green before it reproduces seed, I fear that, my experiments extend over too short a time to justify me in giving out that I have fallen on an effective remedy, but I can safely say that the insect is anything but happy in close proximity to growing mustard. On the space first experimented on, and at the time the seed was sown, grubs existed in large numbers when the green mustard was dug in, about three weeks afterwards, very few were to be seen, and now, two months after, they have disappeared entirely! Whether they have gone down out of reach of the decaying pungent plant and will return in course of time, remains to be seen.

The pest is assuming such serious proportions and the remedy offers so many advantages, besides that described, that I cannot do better than quote from the letter of the friend in London who procured the mustard seed for me:—"On purchasing the mustard seed and refuse for you, Colman referred me to several farmers that he was in the habit of selling it to from whom I made enquiry concerning the uses it was put to. I find it is used to rid the soil of grubs and wireworm, preparatory to certain crops; the green stalks clear the ground for three years, and it is considered that a green manuring in this way is equal to ten tons of cattle manure per acre. A quarter bushel of seed will suffice to sow an acre, it is allowed to grow about a foot high and then harrowed, or ploughed in at first, and before the stuff decays in the soil, it may tend to give the tree a yellow appearance, but will afterwards shew its good effects. You fear weeds getting into your place, there is no danger of this, mustard comes up so quickly. Mustard seed is cheap about 14s sterling per bushel, I think, so that the experiment is within the reach of all whose estates are not too steep." The remaining element, the noticeing of which I have at last arrived at, is one that I can perhaps write about with less confidence than those I have already had in hand, for I have neither kept temperature registering instruments or a raingauge. I cannot help thinking, however, that too much weight has been attached to abnormal seasons, although I must confess to some misgivings in offering an opinion not exactly in accord with such an authority as Mr. Giles Walker, his deductions being the result of many years' careful observation and comparison, while mine are merely the result of a littse exercise of memory. I am one of those who think there has been but little abnormality in the seasons for the past three years at all events, with the exception perhaps that less rain has fallen in the autumn months than formerly.

The last blossoming season in particular was very marked in the *apparent* ill-luck we had in rain coming on the top of every blossom we had, culminating in heavy and lengthening showers at the critical stage, but I hold strongly to the opinion that but for these selfsame showers the trees had not strength to force out a blossom. On the 17th of March on many estates in this vicinity a blossom was in full bloom, and a fine spike quite visible for three weeks the weather was of the most perfect description, very hot and dry without a single shower during which the spike referred to never budged; then came light showers in the afternoon, which soon forced it out. The rains continuing every evening and the blossom having failed, of course the unfortunate weather got the credit of having done the damage. I feel sure from the appearance which that spike presented after three weeks of hot dry weather that it would have been here still had it not got moisture to force it out. But sir, even if I am mistaken here, what, I ask would our trees have been like today, if the weather had been to our ordering with the result of even 3 cwt an acre "set" all round; would the crops ever have ripened up and if not could we have blamed abnormal weather? I think not. From the causes already noticed the trees are in such a sickly and weakened condition that the slightest change in weather visibly affects them; hence undue stress is laid on it. Planters of over ten years' standing will remember how little it disturbed us when heavy rain fell on our blossoms!! Eliminate the other factors enumerated, as forming the combination I have been referring to, and less will be heard about abnormal seasons and the "bogy fungus."

I may be told that, but for the latter, most estates would still have been remunerative, my combination notwithstanding, and there may be some truth in the remark. But, even if that were so, it is no sufficient reason why we should follow the advice of croakers or slide along unintelligibly waiting for something to turn up. Let us rather follow the tactics of the good soldier who, finding that his direct attacks on the enemy's position but end in disaster to himself, searches out other means of overcoming him; such as bribing his allies, and taking advantage of weak points in his armour. Suppose we deprive *our* insidious enemy of his numerous allies, the most prominent of which I have tried to describe (perhaps somewhat confusedly), we then draw his fangs and render his attacks innoxuous. In short, we must adopt an improved method of cultivation to that which has been general for the past six years, and coffee will, for a long time to come, hold its own against any of the other products. That does not mean, however, that it will prove sufficient to raise the present race of involved nominal proprietors out of their difficulties, nor am I aware that I have at any time indicated that my solution comprised that. Most of us know what a few years of good crops and high prices can do. I doubt not that a large proportion could pull through, given three consecutive years of 5 cwts. an acre with coffee at 100/, the former being within reach of many, and the latter on the cards.

DIOGENES.

TEA IN THE LOWCOUNTRY ON SOIL LONG UNDER CULTIVATION.

4th August 1883.

DEAR SIR,—It may interest you and your readers to know that the tea reported in your last sale list as C M (in diamond), 12 half-chests pekoe, 1s 5d, was the *bulk tea* from a small field of about 5 acres in the lowcountry and not 50 feet above sea-level. The tea is planted on old land that had been 15 years in cultivation, and as it took 2½ months to get in the 12 half-chests referred to, so the price must be considered very good.

Had the parcel been a larger one it would doubtless have given a higher price per lb.—Yours truly,

A NAYIKIG.

S. P.—The tea is in its fourth year now and is giving nearly 400 lb. per acre at present.—N. A.

[The information is interesting, notwithstanding the barbarous signature and the absence of the name of the locality. Why should there be any secret made about so successful an experiment?—ED.]

COFFEE LEAF-DISEASE EXPERIMENTS.

Dimbula, August 4th, 1883.

DEAR SIR,—During the past six months I have been trying my hand on the everlasting leaf-disease; all the remedies I have applied tended to purify the tainted sap which I *believed* to be the cause of the malady and of which I am now all but certain, but as the cause is of not much importance providing the remedies put crop on the trees, and of this there can be no doubt, as I am going to show, and to come as near to the truth as possible, I have weighed one ounce of parchment coffee and find it contains 80 beans or 40 berries. I counted 440 berries on one of my trees which would be very nearly at the rate of 10 cwt to the acre, but the trees are still throwing out healthy blossom and berry, so that I can't say what the ultimate turnout will be, but it looks very much like 12 cwt an acre and possibly more and reminds me of the ton an acre I had on Mahatenne estate some thirty years ago whereas on other trees in the same field there is scarcely a bean to be seen.

When the remedies have had full time to act and the trees time to bear, I will let you know the final result.—Yours faithfully,

J. HAWKE.

SALES OF TEA AND AVERAGE PRICES.

14th August 1883.

DEAR SIR,—With reference to the para. under "Notes and Comments" in your issue of 13th instant, regarding average prices realized at recent sales of Ceylon teas I would point out that in giving prominence to the Windsor Forest break you are doing injustice to other estates which in the same sale have done better. I may mention the following averages to prove my assertion:—

Sembawatte	...	118 chests	1s 8d.
Mariawatte	...	...84 ,,	1s 6¾d.
Blackwater	...	...35 ,,	1s 6¾d.
Windsor Forest	...	252 ,,	1s 6¼d.

I agree with you that the price realized for Windsor Forest reflects great credit on the superintendent, and it therefore follows that the better prices realized by the other estates reflects still greater credit on the superintendents in charge of them. This is not the first occasion, and I hope it won't be the last on which Sembawatte has topped the list of averages realized for both Indian and Ceylon teas, and I consider the superintendent is entitled to rank first in your editorial commendation until such time as he is also overtopped, and may that time come to pass very soon is the desire of, yours faithfully,

HONOR TO WHOM HONOR IS DUE.

I again agree with you, that the Windsor Forest 252 chests is a large break, but probably is not the produce of one estate or the manufacture of one month as in the case of the two first-mentioned estates.—

P. Q. M. F.

[We especially mentioned that it was according to "quantity" we gave Windsor Forest the palm: for instance if any part of the "break" is taken, we might put Windsor Forest with 86 chests for an average over 2s.—ED.]

OVER-PLUCKING OF TEA BUSHES.

Colombo, 15th August 1883.

DEAR SIR.—There seems lately to have been a growing impression that the system of weekly plucking and taking off very young shoots is being carried to an extreme point on many tea estates in Ceylon now, the proprietors and superintendents looking only to getting a large yield of fine tea at present, to the damage and, perhaps, ruin of the trees in some cases, in a year or two.

I have met several of our leading tea men lately, and without exception they all condemned the hard style of plucking that has been recently practised on many estates, more especially the *picking the laterals round the bushes down almost to the ground*, which they said will inevitably ruin the trees.

Lately a Calcutta "tea man" visited Ceylon (I was told), for the express purpose of advancing on and investing in Ceylon tea; but, on seeing the tea plucked in the style referred to in the first and onyl estate he visited, he simply looked aghast, murmured something to the effect that it was "a good estate ruined by close plucking," and took ship to Calcutta again; condemning our, to us, promising industry as a complete failure, and being a man of influence and money, doubtless directly and indirectly, prevented a certain amount of money being embarked in Ceylon tea.

The foregoing has induced me to pen this letter, and its object is to solicit through your columns the opinion and advice of our experienced Indian and Ceylon tea planters, of whom there are not a few in the island now, and who as "fathers of the tea enterprize" (in the growing success of which they all naturally take much pride) will, I have no doubt, freely discuss a question of such grave importance as this one, as on it in a great measure depends the permanency and future success of this our most promising industry.—Yours faithfully,

IGNORANCE.

[The alleged conduct of the Calcutta man seems idiotic: to run away because he saw one estate over-plucked. The estate could not be ruined by such a mistake, the effects of which can always be remedied by judicious pruning. But there is doubtless danger of picking too closely, not merely because the owner or proprietor of an estate may be desirous of obtaining and showing large returns, but because it is so difficult to restrain the coolies. The one great principle is never to pluck leaf from the end of a sprig which has not attained a length of six inches at least: eight inches being a still better minimum to be insisted on.—ED.]

GRUB ON COFFEE ESTATES AND WEEDS.

DEAR SIR,—Would "Diogenes" be surprized to hear, that weeds are a perfect cure for grub? A few years ago, the upper part of Maria estate (Lindula) was very bad with grub; the proprietor allowed it to get weedy so that the grub should have something to feed on, and not eat the roots of the coffee, and the cure was perfect. Then why waste money in buying mustard seed? In India, they have found that smut is worse in wheat growing close around the wild mustard. If we are not allowed to *cultivate* the green crop for the coffee that nature provides, then Indian corn is the next best we can grow, provided they are buried before the pods form, but the whiteweed kept in bounds is undoubtedly the best.

In former years, if one looked at the back of a healthy coffee leaf, he could see with the naked eye, the tiny mouths along the midrib, wide open, sucking in the humus arising from the weeds; look at a leaf now, and all that can be seen are a few knots and the humus was kept up in dry weather by the fall of dew at night. We know that the brighter and clearer the night, the greater is the fall of dew, and the following are what dew clings to most of all;—threads of the gossamer, swansdown, raw silk, unwrought cotton, flax, wool, grass, hair, *low plants and vegetables living or dead*, glass, and animal substances. The substances that show a marked ineptitude to receive dew are rocks, *bare earth*, large masses of water and metals in certain order. Baron Liebig told us what the whiteweed is, and he told us to grow an intermediate crop. He could not tell us to grow weeds, for the simple reason that he was a botanist. In botany, there is no such thing as a weed: every plant has its name, but a plant out of place is a weed, therefore if the whiteweed is in its place in the coffee and kept in order, it is not a weed but ageratum, and no doubt, the intermediate crop Baron Liebig intended, and it must be remembered that the first coffee planters in Ceylon were experienced coffee planters brought from the West Indies, and had they been taught to keep the estates thoroughly clean in the West Indies they could have done so in Ceylon quite as easily as has been done of late years.—Yours truly,

G. F. HALLILEY.

THE LONDON CHARGES ON TEA.

Lindula, 18th August 1883.

DEAR SIR,—In your paper of the 7th inst. I notice you bring to public notice the exorbitant "London dock charges" on tea, and it seems to me some mistake has been made in charging nearly 3s on each half-chest of about 42 lb. weight.

It's likely the account was not credited with the large discount allowed by the dock company. I presume the different dock companies' charges and discounts are about the same, and I enclose for your information table of the rates, charges, etc., made by the London and St. Katherine Docks Company, and discount allowed, which please publish if you think of any service.—Yours faithfully,

WM. JORDAN.

PER PACKAGE WEIGHING GROSS.

TEA.	160 lb. to 199 lb. s. d.	130 lb. to 159 lb. s. d.	80 lb. to 129 lb. s. d.	60 lb. to 79 lb. s. d.	45 lb. to 59 lb. s. d.	35 lb. to 44 lb. s. d.	17 lb. to 34 lb. s. d.	Not exceeding 16 lb. s. d.
Landing and Housing Rate, comprising: landing, wharfage, housing, separating into chops, weighing, furnishing landing weights, examining and turning out and in for damage, mending, laying down for private inspection, lotting, nailing down, placing in delivery pile, and *delivery by land*	3 6	2 7	2 1	1 9½	1 7	1 3	0 9½	0 5
Management, Rate comprising the same operatios as the landingn and housing rate, also laying down for public sale, attendance whilst on show, extra warehouse room, and any other operations consequent thereon and *delivery by land*	4 4	3 3	2 7	2 1	1 9½	1 4	0 10½	0 6
Additional if shipped	0 5	0 4	0 3	0 2	0 1½	0 1¼	0 1	0 0½

Bulking and taring	2 10	2 4	1 11	1 5	1 5	0 11	0 11	0 9

Discount 35 per cent.

"DEAD AND DYING COFFEE" IN BRAZIL is thus noticed in the *Rio News*:—The Emperor and Empress left for Campos on the morning of the 22nd inst. to attend to the formal inauguration of public electric illumination in that city. His Majesty will find abundant objects of interest on the journey—the sterile lowlands between Nitherohy and the mountains, the numerous dead and dying coffee orchards about Cantagallo, the absence of thorough cultivation down the picturesque valley of the Parahyba, and the decayed cultivation of coffee about S. Fidelis.

EXPORTATION OF GROUND NUTS.—The trade in ground nuts this season between Madras and Pondicherry with Europe has been very large, and it is calculated that five hundred thousand bags must have been shipped up to the end of last month, and that at least two hundred thousand bags more will go forward before the trade for the season closes. The yield of nuts near Pondicherry has been very large. The Marseilles and Genoa firms send extensive orders for the seed to Madras and Pondicherry, and ground nut oil in large parcels is also shipped annually from Pondicherry. Ground nuts do not want any care to grow them—they thrive in sandy soil and the demand has been such that the ryots in the South Arcot district have given increased attention to the growth of the nut, the trade in which has never been so large as it has been during during the past two or three years. Different descriptions of oils are manufactured from the nuts sent to Europe.—*Madras Standard.*

STREET PLANTING IN CALCUTTA.

The following extract from a letter of Mr. C. B. Clarke may interest some readers of the *Gardeners' Chronicle*:—"I give you a list of the trees planted in the street on the east side of Tank Square, Calcutta (there are more than a hundred species of trees and large shrubs around the tank):—

Michelia champaca	Anthocephalus Cadamba
*Calophyllum Inophyllum	*Mimusops Elengi
*Pterospermum acerifolium	Millingtonia hortensis
*Melia Azadirachta	*Tectona grandis
Cedrela Toona	Grevillea robusta
*Cassia Siamea	*Ficus benghalensis
*Poinciana regia	*Ficus religiosa
*Albizzia odoratissima	Causarina equisetifolia
*Lagerstrœmia Flos-Reginæ	

With the exception of the Poinciana, Grevillea, and Casuarina, these are all Indian trees; and all those marked with a * are in flower at the time of writing."

Some idea of the aspect these trees present when in flower may be obtained in the "North" Gallery, Royal Gardens, Kew, where paintings of nearly every one will be found.

Respecting the temperature Mr. Clarke writes:—"Our shade thermometer rose to 98 ° to 102 ° daily by April 7, and has been somewhat higher ever since. It is said to be the hottest season since 1869. The nights are just so hot that at 4 a.m. the perspiration streams over your ribs." W. B. H.—*Gardeners' Chronicle.*

COTTON SEED OIL.

It is not many years since that cotton-seed was almost a waste product, now it is largely used for the expression of oil, as will be seen from the following notes from a report on the industries of the State of Georgia. Year by year the great commercial value of cotton-seed has been gradually developed. A great authority has stated that if Cotton could be grown in the Northern States, it would be grown if only for the value of the seed alone. It yields an oil which is widely used as a substitute for lard, and is largely sold for exportation to France and Italy for the adulteration of olive-oil, while the cake finds a ready sale at home and abroad as food for cattle and as a fertiliser. For every bale of Cotton grown there is half a ton of seed, and if the crop of the present season yields but 6,500,000 bales, of which there can be no reasonable doubt, there will be 3,250,000 tons of cotton-seed. The oil-mills pay 12 dols. a ton for seed delivered at a railroad station or a river landing. Planters ordinarily put aside from 40 to 50 per cent. of the seed for planting; this would leave 1,630,000 tons as the marketable crop of the year, but as many planters live far away from railroad stations or navigable rivers, and the transportation facilities of the South are limited, 12 dols. per ton to them would leave no profit, and the seed is therefore used as a fertiliser, so that the actual quantity placed on sale may be put down at less than 500,000 tons. It is estimated that a ton of seed yields from 28 to 32 gallons of crude oil, worth 45 cents a gallon; 750lb. of oilcake, worth from 22 dols. to 24 dols. a ton, and about 20lb. of lint-cotton, worth 6 cents per pound. The hulls furnish more than sufficient fuel for the mills. The demand for the oil and the cake has grown enormously during the past few years. Until recently the demand was almost entirely from Europe, but during the past year the New England States alone took 15,000 tons of cotton-seed meal (the oil-cake ground), and the lard-packers of the West are now largely using the refined oil, which is worth about 60 cents per gallon, to mix with lard, which sells for 12 cents per pound or 90 cents per gallon. The prejudice against the use of the oil for domestic purposes is fast disappearing, and refiners now sell it largely for cooking purposes. In the New England States the cotton-seed meal is used as cattle food, the cattle being penned, and the manure utilised as a fertiliser; while in the South it is in most instances applied direct to the ground, or in combination with other fertilisers. The crop of cotton-seed of this State for the year 1882 is estimated at 450,000 tons.—*Gardeners' Chronicle.*

CINCHONA.

The following extract from a letter addressed to Messrs. Croysdale & Co., by their London Agents, Messrs. François Le Mair and Rivers Hicks, on the harvesting of Cinchona bark, will prove of interest to many of our readers:—

When slicing was commenced in India three years ago, it was with some trepidation that we observed the departure from the old, well-tried and extremely remunerative process of taking the bark by stripping, and was only when we were assured of the following being facts, that we expressed our approval, the correctness of which we shortly after saw reason to doubt, and later to be certain that the new process was a most lamentable failure. We were assured that the quantity of bark to be taken would be at least double that obtained under stripping. That the trees were more healthy under the slicing than under stripping. That the bark renewed more quickly under slicing than under stripping. That the yield of alkaloid, and especially quinine increased more quickly under slicing than under stripping. These four premises proved, as many growers believe them to be, and the case would of course be made out, and no sane man would take bark by stripping when he could shave or slice. The first slices were undoubtedly richer in quinine and other alkaloids than the strips taken off the same trees, but that of course had nothing to do with the system, the bark having been grown under the stripping process, and the extra richness was accounted for by their only having taken the outer and undoubtedly richer portion of bark which has not been sliced. The next question, viz, the greater healthiness of the trees under slicing than stripping, was the point which delayed our expressing our antagonistic feeling, for there was no doubt that the trees were healthier under slicing than under stripping, and the first deduction naturally to be drawn was that, if the tree were healthier, the bark must be better; if it were not so, some other influence must be at work. But further observation, that in spite of this phenomenon, bark from trees sliced was each time worse than the last, and that the rate of deterioration was an ever-increasing one, made us feel sure that the argument must be a false one, and in effect, when remembering that the sap of the tree goes up inside the tree, and is there transformed in Nature's laboratory, the leaves, and comes down outside, down the bark, and is deposited for the most part in the bark, in the shape of alkaloids, when one considers this, all is immediately plain, and actual every day experience of those whose life is to handle and value bark, triumphs over all the theories. In slicing, you cut through the storehouse of the alkaloid, and leave the contents of the bark on the tree, subject to leakage and to chemical changes, by being exposed to influences they were never intended to be subject to. So far for theory, which as business men we do not believe in. Our theory is made up from our experience. We do not make a theory first, so that even could this theory which we have compiled from observation of effects, be overturned by any argument, which seems to us very difficult, there would still remain the facts observed to be disposed of, and these are the things that convince us of the suicidal effects of slicing. We have never seen in any case coming through our hands, and where therefore we had means of verifying the whole matter, we have never seen second slices from identical trees, exceed in richness the first slices from those trees. We have observed in very many, too many cases, a bark arriving the first year in fine, bright, thick, rich slices, commanding the top value, arrive the next year in dull, sickly, deadly thin slices of very uncertain value, and of use to only a limited number of buyers. We have known cases of a crop of bark taken by slicing, decline in two years, by about 40 per cent in weight and about 30 per cent of the value, that is instead of every 100 lb. of 3s. bark, only 60 lb. of 2s. bark, making every allowance for the drop in the market. What the difference after three years slicing is, we do not know, but we are afraid it would be something deplorable, and it seems to us that about four years of slicing might reduce a 5 per cent bark to a valueless one. Our experience of comparison between the effects of the two processes being chiefly confined to figures, relating to bark from mature trees, you have to face a further complication, that is, that your figures, relating to young trees, which in the usual course would be fast improving in alkaloid yield, are likely to be confused by taking any increase in alkaloid occurring whilst slicing, as an effect of that system instead of, as we contend, in spite of the system, so that we should argue; that if in slicing you got an increase, that increase would be less than it should be by the amount of damage in leakage and chemical change of constitution of alkaloid, resulting from removing the protecting outer-layer of the bark. Under the process of stripping in alternate layers, on the other hand, you remove the whole apparatus containing the alkaloids, and the only places where damage can occur is at the edges of the alternate layers left on the tree, and great care is of course necessary in binding the tree up. The other disadvantage of stripping is the damage done to the exposed cambium, and this from two causes. 1st, Coolies' carelessness in piercing the cambium with their knives in removing the bark, instead of gently raising it when ready to rise. And the second arises out of the first, or is closely connected with it, taking strips off trees on which the bark has not renewed to a sufficient thickness to allow of its being taken without injury to the cambium. The second cause could easily be remedied by some skilled person going round and marking with a patch of paint, or some other easily distinguishable sign, which trees were to be taken. With proper care, trees will go on yielding fine bark for many years, but under slicing, a fine estate may be ruined, at least when mature, in four years. The damage done by slicing is much greater and sooner perceptible with crown than with red barks. We advise drying all barks at as low a temperature as possible, as any higher temperature than 90 is sure to act prejudicially upon the bark. Drying bark at a high temperature affects absolutely the character and constitution of the alkaloids, rendering the separation of the quinine a matter of great difficulty, in fact fatal to the bark.—*Madras Mail.*

MR. JENSEN AND THE POTATO DISEASE.

It is much to be hoped that the protective systems will be extensively tried this year, for all appearances point to a severe visitation of the Potato disease. Having received several communications upon this subject from Mr. Jensen during the past few months, and having his permission to make them public, I take the present opportunity of doing so. It is needless for me to describe over again his system of culture, beyond stating that it mainly consists of giving the Potatos a second or protective moulding when the first disease blotch is seen upon the foliage, in such a manner that the uppermost tubers have at least 5 inches of earth over them, at the same time bending the top so that they hang over the furrows in a half-erect manner; the object being to protect the tubers by a layer of earth from the spores of the parasitic fungus which causes the disease. When moulded up in the ordinary way the covering of earth over the uppermost tubers is not, as a rule, more than $1\frac{1}{2}$ or 2 inches.

Any cause which breaks the continuity of the earth covering of the tubers renders them more liable to disease. Thus the presence of an earthworm at a Potato root renders it more liable to have its tubers diseased than it would otherwise be. An examination of 600 Potato roots at Hverringe was made by Mr. H. Dreyer, for Mr. Jensen. It was then found that the average number of diseased tubers in the roots without earthworms was 22 per cent.; with one worm at each root, 35 per cent.; with two worms at each root, 46 per cent.; with three worms at each root, 58 per cent.; with four worms at each root, 71 per cent.

To demonstrate the power earth has in arresting and retaining the spores a cylindrical tube was taken, fitted at the bottom with a perforated plate. In this tube was placed a layer of earth 1 inch thick, which was compressed to $\frac{3}{4}$ inch, to represent the consolidation which naturally takes place in the moulding of Potatos; water was poured into the top of the tube containing spores, estimated by counting the number in a drop, and employing the requisite quantity to the number of 30,000. It was found that about 28,000 of the spores were retained by the earth, for only 2,000 ran through. The experiment was repeated, using, however, 5 inches of earth compressed to 4 inches. It was then found that out of the 30,000 poured in at the top only one or two ran through.

The views of Mr. Jensen upon the influence that temperature exerts over the Potato disease in connection with its geographical distribution are very interesting. It may be stated at once that he agrees with De Bary in considering that the disease is kept alive by the mycelium hybernating and not by the agency of resting-spores. Amongst his reasons for this view, are:—1. Because as a general rule Potatos sown after Potatos the preceding year are not more severely attacked by the disease than when they follow other crops. This he has found to be the case in a great number of instances (some hundred), although it is contrary to what is commonly thought in this country. 2. The date at which the Potato disease first appears in any year depends, not entirely upon the amount of rainfall, which of course exerts a powerful influence, but greatly upon the quantity of infected Potatos planted in spring. Last year, for instance, in England, France, and Denmark the disease appeared very early, and in Denmark at least was very severe.

Tubers attacked very early in the season will, as a general rule, be rotten at the time of lifting, and consequently the disease will have died in these tubers. The "after-sickness" will be less, because the foliage, and with it the fungus upon it, will have disappeared at the time of lifting in such years than when the disease has commenced later. Hence fewer Potatos having the disease in a hybernating state in them will be planted, and consequently the disease will have fewer starting points in the following year. We may, therefore, expect the disease will not be very early this year in its appearance in England, Denmark, and Western Europe, unless the weather be very rainy, which will, of course, favour the rapid spread of the disease. Two very early outbreaks of the disease never occur in successive years. There is, upon the contrary, a tendency for the first appearance to alternate between a late and early date; as, however, the weather has a great influence, this is not always so observable as it otherwise would be. In Denmark during the last twenty-three years the general outbreak has been eight years early, nine years late, six years medium. Of the eight early years it has been seven times after a late year and once after a medium; of the nine late years it has been four times after a medium and five times after an early; of the six medium years it has been twice after an early, and three times after a late, and once after a medium.

Thus we see two very early outbreaks have never followed one another, but a year that should be early may be late or medium from want of rain. The above has reference, of course, to the time when the disease is so general as to have been observed by farmers and Potato growers generally.

As a rule, it is, as before stated, only in those Potatos which are infected late in the year that the fungus hybernates, those which are attacked early in the year perish entirely. This year Mr. Jensen found only about 10 per cent. of diseased tubers which were sown in his garden produced affected shoots bearing conidia. The presence of conidia was detected upon the shoots a few days after they had appeared above ground, and for the last six weeks he has had the disease well developed in his garden, while it has not appeared in the gardens of his neighbours. As showing the rate at which it has spread from the diseased plant, he finds that till now it has not advanced more than a yard in ten days.

Now, if the outbreak of the disease was dependent upon resting-spores, the fact of two early outbreaks not following each other would not have been observed; on the contrary, an early outbreak one year would be most likely to be followed by a slight attack in the next year.

A much more important question, however, or rather series of questions, concerning the influence of temperature has been engaging Mr. Jensen's attention, which includes the following:—1. Where has the disease come from? 2. Why did it not appear earlier in Europe and North America than about the year 1840? 3. What is the distribution of the disease throughout the globe? In what regions can it never appear? What hitherto uninvaded regions will by-and-bye be visited by it if the importation of Potatos from infested countries be not prohibited? 4. Are there any means of rendering the outbreak late and sporadic in infected countries, and perhaps even of stamping it out altogether in the course of a few years?

During the last year Mr. Jensen has been studying the relationship existing between the temperature and the disease, and he is at present engaged in preparing a memoir on the subject, in French, in which these questions will be dealt with fully. Concerning the origin of the disease, Mr. Jensen believes it to have commenced in the Cordilleras in the northern part of South America, where it has existed from remote antiquity—as long indeed as the Potatos themselves. The fungus was imprisoned within those hills by the hot air which for hundreds of miles surrounded them on all sides. When the Potatos were introduced into North America and Europe the parasite was separated from its host, for, under ordinary circumstances, neither the mycelium nor the spores can be sent through the torrid zone without losing their vitality. The separation between parasite and host lasted till about 1840, *i.e.*, about 300 years. The employment of steamers (for before 1840 the number of steamers was but very small), the great guano traffic which sent many ships to the kingdom of the Potato foe—the employment of ice perhaps—for by the means of ice the Potato fungus can be sent anywhere,—all these circumstances were favourable to the transmission of the disease to the temperate countries of the northern hemisphere; in fact it is simply warmth that for 300 years separated the fungus from its host. The same separation can with complete certainty be effected now in the course of a few hours by means of an elevated temperature applied to the seed Potatos without injuring their growing power in the least. To make the process practical, Mr. Jensen employs a comparatively high temperature; but with a lower temperature the same result can be obtained, only it requires to be applied for a longer time. Certain precautions are necessary to prevent injury to the Potatos, but these can be easily met by a suitably constructed apparatus which Mr. Jensen has devised. These discoveries have been communicated to the *Société Nationale d' Agriculture de France*. The distribution of the disease is more dependent on the mean maximum temperature in summer than on the mean day temperature, hence the disease does not go so far south in continents as on islands. Speaking generally, the disease does not exist in continental lowlands in the northern hemisphere to the south of the fortieth parallel of latitude; the disease does not exist in tropical countries where the mean temperature amounts to 25° C. (77° Fahr.) for any considerable time during the year. It is not found in mountainous districts within the tropics, except under very rare circumstances, because its introduction to such places is very difficult. It probably exists in all countries with a temperate or cold climate in the northern hemisphere where Potatos are grown. It may be found in temperate climates in the southern hemisphere. It is not found in Australia, although in many parts of that quarter of the world it would thrive if introduced.

Respecting the influence of an elevated temperature upon the development of Peronospora infestans, I have only one word to add, and that is to draw attention to the way in which it thrives upon outdoor Tomatos in this country compared to those grown under glass.

In conclusion, I may say that the above is collated from various papers and circulars of Mr. Jensen and from private letters written to me. I only wish he had found some one better able to express his views and place the result of his labours in a more lucid manner before the British reader. Charles B. Plowright.—*Gardeners' Chronicle.*

CARNAUBA, OR STONEWAX.—This peculiar wax is intensely hard, and its melting point very high—too high for utility, as regards candles at least (185° F.). It is, however, I believe used largely on the Continent as an adulterant, or, perhaps legitimately, a hardening mixture, and enters largely into the composition of varnishes, heel-balls, &c. The colour varies from light yellow to deep gray green, and it can be bleached to an intense white. Carnauba wax is found adhering as a thin film, like varnish, to the leaves, stalks, and the berries especially, of a Brazilian palm, the *Copernicia cerifera*. From these the wax is boiled off, and skimmed into moulds. When congealed, its likeness to stone is so great that, were it not for the low sp. gr. (999), one might easily class it with minerals. The composition of stone-wax is very uncertain. Lewy, a great authority on waxes, finds it to contain 80 per cent. of carbon; and Allen vouches for the presence of a notable quantity of free myricyl or melissic alcohol $C_{30}H^{61}_{H}\}O$. The quantity produced is very large, but I am not in possession of trustworthy statistics.

The next, and last, of the true waxes is *Myrtle wax* (Myrica tallow). This soft green substance is formed on the berries of the *Myrica cerifera*, an American tree shrub. The berries grow in small clusters along the stem, and, when ripe, are covered with a tolerably thick rind of the wax, which is removed by boiling. This substance is also used chiefly in adulteration, though, from the very low melting point (123° F.), the use must be limited. The composition is chiefly palmitic and myristic acids, with a little glycerine, but has never been accurately determined. *Japan wax*, also called "tree wax," ought properly to rank as a fat, being a palmitate of glycerine, which latter it yields upon saponification. It is derived from the roots of several trees of genus *Rhus*, chiefly from the *Rhus succedanea* of the East Indies. The use of this wax as an adulterant is checked by its disagreeable odour—otherwise, it is a very useful substance; it enters largely into the composition of vegetable wax candles; much used as a substitute for those of genuine bees-wax. Its sp. gr. is about ·999, the m.p. 120° F. There are several other waxes, of great use in their native countries, as *palm wax*, from the stem of the *Ceroxylon andicola*, Brazil, and *ocuba wax*, from the *Myrica ocuba* of the same country; also Andaquies wax, Cuba wax, and others of uncertain animal origin. The two first-named furnish a large portion of the candle power of northern South America.—*Journal of the Society of Arts.*

CHINESE TEA TRADE.—The returns of the export of tea from China and Japan during the past season continue to show a great decline in the shipments to this country. In the twelve months ending the 31st May, the total consignments to us were in round numbers:—

	lb.
1882-3	170,000,000
1881-2	164,000,000
1880-1	175,000,000

To the Continent the shipments were—9,360,000 lb. in 1882-3, as compared with 10,100,000 lb. in 1881-2, and 7,200,000 lb. in 1880-1. Accompanying this decline in the supplies of tea which Europe has obtained from China, there has been a large increase in the supplies from India, and the Indian, product would thus appear to be gradually ousting that of China from our markets.—*Journal of the Society of Arts.*

MR. HERMANN MÜLLER, the distinguished German naturalist, who has made the cross-fertilisation of flowers, and the insects which perform this work, his special study, has very clearly explained why such flowers as the well-known lungwort (Pulmonaria officinalis) and others of the same natural order have two colours, red and blue; the former colour is generally assumed first, and the latter as the flowers get older. He proved by examination that all the blue flowers of the lungwort were empty of honey, and the stigmas of their pistils were supplied with pollen. Mr. Müller concludes that the blue colours of the older flowers of the lungwort, whilst increasing the conspicuousness of the clusters of flowers at the same time indicate to intelligent bees to which plants they should restrict their visits, to their own, as well as to the plant's profit. Verily the more intimately we are acquainted with the biological relationships of flowers, the more do we discover that "every freckle, streak, and stain" has a distinct meaning, and bears some active relationship to the well-being of the plant. In some instances the colours and markings may even remain for some time after their real cause for existence has ceased.—*Australasian.*

JAMAICA:—*Cinchona Plantation, Gordon Town.*—Shortly after I sent you the specimens of "Native bread" so kindly noted at p. 472, vol. xix., I placed some of them in a pot of ordinary potting mould, and I have discovered that they are covered with mycelium, issuing from the tuber in a similar form to the roots of a Gloxinia, and on the side where they are somewhat indented, there is issuing a growth in appearance similar to sketch. This may be only a stronger mycelium growth, and as yet it is hardly enough developed to judge or hazard an opinion as to what it may become. I have sketched the size of the tuber as accurately as possible. On examining a tuber which had been broken, I find it to be covered on the broken part with a growth very similar to the substance of a Polyporus, which, though quite white when uncovered, became in a few minutes of a yellow tint. The tubers are placed for observation in a temperature under glass from 65° to 75° Fahr. I shall watch with much interest the further growth of the mycelium, and should you desire it, will inform you of the result of the observation, and I would willingly undertake to perform any experiments you might suggest to further my research.—F. HART, Superintendent, Government Cinchona Plantation. —*Gardeners' Chronicle.*

SILK-WORM CULTURE IN CEYLON.—The *Central Blatt für Textil Industrie* states that the superstitious views of the Buddhists had, until recently, prevented the extension of silk-worm culture in Ceylon. According to the latest accounts, however, this opposition has been overcome, and silk is occupying much attention in several districts. The numerous insects and reptiles of the island have been found to render progress difficult; but it is expected that, by the adoption of such precautionary measures as are usual in tropical countries, the new enterprise will finally be successful.—*Journal of the Society of Arts.*

FROG AND GRUBS.—A friend of mine, who loves flowers, gardening, and Nature generally, and has done good service to natural history, fed a medium-sized frog, a few days ago, with six good fat larvæ of the daddy-long-legs (of which we have a pest in these parts), and this after an earthworm, which he was literally tucking in when found. He "pouched" the sixth grub as smartly as he did the first, "and still he sighed for more." For gardeners the moral of this little story is obvious. A robin in my own garden feeds himself and family largely on these "varmint." Do animals feeding on "such small deer" derive pleasure from internal wriggles?—T. HAMETT HARRISSON, in the *Field.* —*Gardeners' Chronicle.*

A NUTMEG GATHERER.—Amongst some interesting specimens recently received at the Kew Museum from Timerlant, collected by Mr. H. O. Forbes, is an instrument such as is used in Banda for gathering nutmegs. The instrument is made of spilt bamboo, and forms a kind of basket of an oval-form, with an opening on one side. At the upper part of this opening are two projecting prongs of hard wood, set pretty close together; at the opposite end is a light bamboo handle. The whole apparatus is very light, and in gathering the nutmegs while yet, of course, in their fruit, the instrument is pushed amongst the branches of the tree and the fruit caught between the two prongs of hard wood, previously described. By a jerk of the instrument the fruit is detached, and falls at once into the basket below. The contrivance is extremely simple, and does away with the necessity of erecting stages for the purpose of gathering the fruits, which is done in some countries.—*Planters' Gazette.*

BRITISH HONDURAS.—The most important as well as the richest river valley in the colony is that of the Old River, sometimes called the Belize River. This extends in a wide sinuous course from the town of Belize at the sea coast to the western frontier; in the upper portions the valley widens into broad expanses of rich fertile plains, in some cases thirty or forty miles in breadth, covered by Cohune Palm. I carefully examined this district, and worked my way to the frontier station—the Cayo—near which a Coffee plantation has recently been established. With the exception of some six Sugar estates, and the same number of Banana plantations, this Coffee plantation is the only attempt hitherto made to establish a systematic course of culture in the colony, the bulk of the people being employed, and the chief trade of the colony depending upon mahogany and logwood cutting which, when good prices are ruling, are apparently very remunerative industries. In the forest of the western districts I found the rubber tree of Central America (Castilloa elastica) very abundant. This tree (a member of the Bread-fruit family) is especially suitable for cultivation on account of its preferring a loamy, sandy soil, and being a deep feeder it might be utilised as a shade tree in cultivated areas with great advantage. I spent two days with a rubber gatherer in order to observe the methods for bleeding the tree and preparing the rubber; and I have brought with me botanical specimens of the tree, some seed, as well as a sample of the rubber. I hope soon to make a special report on this tree and its produce. I am, also, making arrangements to procure a large quantity of the seed, when ripe, for distribution amongst Cacao planters in this island. Trees at ten years old yield from 4lb. to 7lb. of rubber, which is valued at from 2*s.* 3*d.* to 3*s.* per pound. If carefully managed, the trees can be bled every three or four years. Another interesting plant found wild in these forests was the indigenous Cacao of Central America; this differed from all kinds I had met previously. An examination of the pods, which are of a golden-yellow colour, led to the conclusion that this "Tempasco" or "Socunusco" Cacao is the yellow form of the celebrated "Caracas" Cacao. Should such prove to be the case, there is little doubt that this yellow variety will prove as much superior to the red (Caracas) form, as the yellow Forastero does to the red (Trinidad) Cacao. Many other interesting plants of timber and dye woods, as well as of plants of medicinal and economic value, were met, many of which I have no doubt are capable of being utilised both in British Honduras and in other British possessions. D. MORRIS.—Director of Public Gardens and Plantations, Jamaica.—*Gardeners' Chronicle.*

TEA IN DIMBULA.—A planter of great experience, particularly in tea, makes the following very valuable suggestions to those about to embark in this enterprise, which are worth studying. He says:—"In my opinion the cultivation of tea in the low-country and the cultivation of it in Dimbula are two very different things, and the bushes cannot be treated the same. That tea will pay, possibly all over Ceylon, there seems to be little doubt, but I would advise those up-country who intend planting up coffee to base their calculation on 350 lb. an acre. They will probably get more, but it is as well to be safe: and then again I would be inclined to say: don't plant up your good coffee. It does not follow that good coffee land will be good tea land: and when a man has a good piece of coffee land he had better keep it and cultivate it, for there is much bad coffee land that will grow tea admirably. With three products on an estate carefully attended to there should be no waste of labor. A tea estate alone will be found more expensive working than is generally supposed but with other products there need not be—for want of a better word—economy (? waste) of labor." Undoubtedly, though tea will pay to grow even at great altitudes, such tea must receive different treatment to that in the low-country, in the same way that coffee at 5,000 ft. requires totally different treatment to coffee at 1,500 ft. No doubt, as time goes on, our planters will learn by experience how to treat tea at both extremes of altitude. —Local "Times."

THE GOLDEN APPLE.—Mr. Ronald McLeod, Mount Tröodos, Cyprus, writes to a daily contemporary as follows:—"It will, I think, be a subject of interest to know that the identification of the fruit which in the Old Testament and in ancient Greek writings is called the 'Golden Apple' has become possible. 'The three Golden Apples given by Venus to Meilanion, whereby he won the race with Atalanta, were plucked, it is said, either from the Garden of the Hesperides or from an orchard in Cyprus.' Any proof helping to establish the identification of this fruit will come naturally with greater weight from Cyprus, the home of Aphrodite. In Cyprus at the present day in early summer almost every garden has trees laden with 'ta chrysomela,' 'Golden Apples,' and the bazaars of the towns are filled with the fragrant fruit. The modern Greek name for the Apricot is 'to Berykokkon,' but the Cypriote still calls it by the ancient name 'to chrysomelo,' since he knows no other, thus carrying the mind back to the distant past when Cyprus was the Garden of the Eastern Mediterranean, and fit to be the favourite residence of the Goddess of Beauty. The 'Golden Apple' of the Book of Proverbs is also doubtless, the Apricot. The reference in the Old Testament apply, in all respects, to this fruit tree alone. It has been abundantly cultivated in Palestine from early times; its foliage forms a 'delightful shade,' and is bright and pale like 'pictures of silver,' while, it bears 'Apples of Gold' of 'fragrant smell' and 'sweet to the taste.' Dr. Clarke says that the Apricot tree appears to be indigenous to Cyprus. If this be so, the 'Apples of Gold' of Proverbs xxv. 2 are certainly Apricots. If, on the other hand, as is also asserted, the Apricot is a native of Armenia, then both the tree and probably its name were thence introduced at some early period into Cyprus. When the constant intercourse of Cyprus with the Eastern mainland in all ages is borne in mind, together with the fact of the particular commercial dealings which existed between the Israelites and the Phœnicians at a time when Cyprus was largely colonised by the latter, and when, for a while, it owned allegiance to Hiram King of Tyre, there is the strongest probability for the assumption that the fruit which the Greek afterwards called the 'Golden Apple' is identical with that which in King Solomon's time was known by the same name; and both names were derived from a common source."—*Journal of Horticulture.*

MR. STORCK OF FIJI AND CARBOLIC ACID REMEDY FOR COFFEE LEAF DISEASE.

It will be seen from Mr. Storck's letter (on page 213) that he is very indignant with those of our correspondents who have expressed scepticism as to the value of his specific for leaf-disease, especially Mr. Jardine, from whom he expects the reparation of a gentleman. This reparation is to take the form of fresh experiments after a fashion minutely described, in which strips of tin and of sacking or blanketing are to be used. To set the question at rest, we should be very glad if so careful an observer as Mr. Jardine would institute the experiment suggested. We confess to hopelessness, however, in regard to Mr. Storck's liquid remedy, as much as with reference to Mr. Schrottky's powder cure. Each was confident that he had discovered "a perfect cure," thus bearing out Sir Joseph Hooker's statement as to the numerous competitors for the phylloxera prize Mr. Schrottky came amongst us and in theory made out a wonderfully strong case. He insisted that in practice he had fulfilled his theory, in the face of adverse opinions by planters most interested in success if he had achieved it. Mr. Storck promised to come to Ceylon, but now makes no sign of fulfilling his promise. His original statements were to the effect that he had discovered and successfully applied a complete remedy, and we always felt and wrote:—"In that case why not rid Fiji of the pest in the first place, and having done that come to Ceylon and do likewise and claim the reward, which would be liberally and cheerfully paid, were the ravages of leaf-disease stayed?" Now, however, while Mr. Storck is as confident as ever that in carbolic acid he has found a radical cure for *Hemileia vastatrix*, he acknowledges that he is still in the stage of experiment as to the best form of acid to use and the best means of applying it. It is natural that Mr. Storck, who is no chemist, equally with Mr. Schrottky, who is, should cling to belief in his nostrum. But until he has made large and decisive experiments in the scene of his residence, where leaf-disease is nearly as virulent as in Ceylon, he must excuse us if we distrust the liquid carbolic acid cure as much as the powder remedy. In this case of Mr. Storck's the proverb "Physician heal thyself" properly and fully applies. When his experiments are really successful, we shall be glad to learn from him and from the coffee planters of Fiji.

PLANTING IN CEYLON: THE "MONERAGALLA" DISTRICT.

(CONCLUDED.)

The climate of Moneragalla is not the dry and arid district people are generally led to believe. As compared to most of the Kandy country, it is perhaps dry, or, what would express it better, it is unnecessarily wet for the cultivation of most economic plants. Men living upon the Namanakula range, who watch the Moneragala range from their bungalows, assured me they believed it had a heavier rainfall than the Badulla hill itself. As the crow flies, the eastern coast cannot be more than 30 miles distant, passing steamers upon clear days beings distinctly visible from the top of the hill by the naked eye; which proximity to the sea may in a great measure account for the rainfall. Again, strange to say, the rain clouds during the dry months do not come cross from the Haputale or Badulla range, which follow the Madulsema feature, but pass across from Rakwana over the lower ranges below Haputale. On my return I passed through and stayed a week in the Haputale district and on several occasions saw showers in the line of country I describe, when none fell in Haputale. Annexed is a return for 4½ years of the rainfall taken upon Maragalla estate by Mr. Betts, which is very interesting. It will be observed that the distribution is quite as regular as any other part of Uva:—

Total	...	74·75	94·42	91·41	94·47	

Trinidad in the West Indies, I am assured by a friend, has only 65 inches in the year. Upper Rajawella in Dumbera shows a yearly average over a eleven years of 55·78 inches; Kurunegala in nine years 84·09; Maragala estate, Moneragalla district, in four years an average of 88·76—more than either Kurunegala and Rajawella. Upon "Delgolla" estate, over four years, we average nearly 100 inches. Although there had been a month with little or no rain at the period of my visit to Moneragalla, I could not be otherwise than struck with the vigour of the cocoa trees and how well they were carrying the crop upon the large trees on Raxawa estate. As with coffee, so Uva will, in all probability, where the soil is deep and suitable, grow cocoa equally profitably and well, and as, we will hope, no such pest as leaf-disease will ever attack it, it will thrive for many years to come.

There are still blocks of forest land in the hands of private parties; some with very fine and rich soil—finer by far than is met with in the generality of forest now obtainable in Ceylon. They, however, are not purchasable at prices at which land of inferior quality can be obtained elsewhere.

It is not altogether free of drawbacks, the chief of which is having no really good bridle road, whereby it can be comfortably reached; without the possibility and probability of being intercepted in wet weather by an impassable stream. Thus, in continued rain, the district is cut off from the rest of the world, and will be so, as long as the Passera route is recognized outlet. Indeed, every thing should be done by all interested to have a thoroughly well-traced tavalam road constructed from the north of the Hill to Yalecoombera. Fever at first was severe and continuous: of late there has been less of it, though still the coolies are not by any means free from its attacks. Time no doubt will overcome these evils, and, if once cocoa at low elevations and cardamons at high, come fully into bearing, I think Moneragalla will be one of the most, if not *the* most, prosperous districts in Ceylon.

The scenery is as beautiful as I have ever beheld, and I know no finer view than can be seen from Kowdawa upon a clear day. The blueness of the distant hills is a very pretty and peculiar feature—at least it struck me so at the time of my visit being new to me in Ceylon. Sportsmen, I am told, can still find plenty of game to the east and south of the hill—bears, leopards, deer and elephants are still plentiful, peacocks have been seen in the district; and I heard it is quite a come for leopards.

The necessaries of life are by no means dear. Fowls were offered to me at R2 the dozen and the oranges are particularly fine. A butcher kills at Mupany twice a week. Batticaloa-grown rice is usually purchasable at R3·50 the bushel. Milk can be procured in most villages at two annas a bottle. Thus the outlines of a good and wholesome meal are always at hand.

The most direct route to Colombo is by Wellaway, which is 30 miles from the foot of the hill. There are by this route several rivers to cross. Myself and friend took this way across to Haputale, staying a night at Butale. We found the small resthouse there in such a dilapidated condition and so abounding in ticks and vermin that I hardly knew what we should have done had not the Korale taken us to his house. The soil around Butale was rich and the paddy fields appeared extensive. When on a visit to the Straits some years ago I naturally took some interest in tobacco cultivation, and on passing through Butale, it occurred to me that the land around was in many places well suited for this industry. The native Sinhalese were, as in most places I have passed through on this trip, sickly-looking, while the Moors always have at Butale, as elsewhere, all the appearance of health and vigour. As we travelled from Moneragalla to Wellaway, we frequently met herds of tavalam cattle carrying stores and caddie-stuffs to Mupany, from Koslande and Haldummulla; evidently preferring this more direct route to the recognized road via Passera. Indiancorn was plentiful and was offered us once at R1·12½ per bushel, beautifully milled and clean looking.

As we passed through the sandy beds of rivers, we occasionally saw the tracks of a spotted deer or sambur, but only once did we disturb some large wild animal upon the side of the road, as we were passing through some forest which went away with a crash, and, on our passing a stream just beyond, we saw the fresh tracks of a sambur, which must have been the animal started. It did not occur to us that the country we passed through abounded with game, but we thought it well suited for hunting with hounds with guns in the likely passing places. About mid-way between Butale and Moneragalla, I should think fine sport might be obtained. The country thereabouts is exceedingly pretty; full of open glades and small forest-clad hills. Water, however, is scarce during the South-West monsoon, but in February or March the weather and climate should be thoroughly suitable for such sport. There are roads, I am told, from both Ella and Passera to Butale; so it would be easily accessible in a day's journey.

From Butale to Wellaway was about 12 miles, along an almost straight road. At the last-named place we had a look at the late Mr. Cruwell's Liberian nursery, and were somewhat surprised to see how many of the trees were still retaining their vigour in the scrub growing up around them.

In conclusion, I may only repeat what I have said before—that to my mind those interested in Moneragalla have only to be careful and grow such economic plants as pay them best, and unanimously determine upon and obtain their outlet, and they are bound in time to prosper with a climate such as they have, with rarely a wet morning, a good tavalam road to Yalcumbera, tavalam transport cheap, rice from Batticoloa, and the sea within 35 miles by road. I hardly see why they should be in a hurry for further cart-road extension for years to come. Cocoa can be shipped without machinery to hull and prepare it; so in all probability, if this industry extends, Batticaloa will be the outlet. W. F. L.

AN OLD PLANTER ON HIS TRAVELS.

I have been over a good part of the coffee, tea, and cocoa districts. The former I need not say much about, as I am not a man capable of doing justice to the article that has got its death-sentence pronounced, but all unbelievers should read Mr. Bosanquet's paper, and move a little about in the different districts with their eyes open, and they will still see coffee giving good crops and more that will do so when we get a good season. If anyone wants to see what coffee can do take a drive out to Dumbara. Say take a trap and go out the new road and return by the Gonawattie ferry. "Tea is the thing that is to do wonders for Ceylon": well and good: it will do where coffee won't, and I say go in for it, for there is no doubt but it will pay well in some districts; take Ambagamuwa and Maskeliya, they appear to be the home of the plant, and it will I hope recoup the proprietors in these districts for the loss they have been having for the last few years. I only say this: don't be again putting all your eggs in one basket, don't neglect good coffee as I see many doing and putting in tea.

Cocoa is far and away the product that takes my fancy: my friend and I went out to Dumbara to see it in its glory. No man that has not seen Rajawelle knows what Ceylon is: both of us were amazed to see the cocoa growing on patches that we had last seen as bare as the Government road. Pallakelly no doubt carries off the prize, but I believe the cocoa is older there than on the other places. What struck me was the perfect order all the estates were in. When I knew them first, and for years after, they were in a mass of weeds; now they are as *clean* as any young clearing, so clean that even the king of clean weeding, P. M., would have a difficult task to find a weed in seed to present to the superintendent, as he did once to one I know with the remark "Give that to the kangany Mootoo Allagan." At one time it was thought you could not clean a weedy estate: if such is the idea now I say go to Dumbara and see what has been done with those places. I met one of the managers there, and he told me he was weeding twice a month for 87c. and another for R1. I could hardly take it in until I made further enquiries. After looking round I came to the conclusion that those old hands down there can teach the younger ones in the new districts how to keep their estates in good order for little money; I can see nothing but hard pegging that could do it. I was told that the cocoa will not do with much shade, and I saw fine old trees being cut down, trees that have been landmarks since ever the estates were opened. I only hope some of the superintendents are not taking down too many of the trees and letting in the wind but I was told cocoa could stand a good gust of wind if other things are favourable and other things are certainly favourable in Dumbara for its growth. There is or was a fine "cocoa walk" to the right of Port of Spain in Trinidad, and there was not a shade tree in it, but it was on the lee side of the island. B. W.

TEA SALES.

A very excellent innovation has recently been made by some of the leading brokers, who have been offering tea at public sale in larger parcels, instead of making a separate offer for each lot of nine half-chests in a parcel. The latter was no doubt an appropriate way of selling tea when it was worth as many shillings a pound as it is now worth pence, but with the present great consumption it involves a wearisome loss of time to no good purpose. The objection is made that to offer tea in very large lots would diminish competition, and this is true, but the offers might readily be made in lots of, say, 25 or 50 packages. At the present time, when trade is so dull, the purchases of the majority of dealers are materially reduced, and perhaps too large parcels have in some cases been offered; but there is surely a mean between offering nine packages at one time, and putting up 200 packages in one lot. Now that the great improvement of offering larger lots has once been made—though, with the zeal of reformers, the change made may have been too violent at first—it appears very unlikely that the old practice of offering six to nine packages of Congou separately will be revived, for at the present day there is absolutely no reason for the loss of time occasioned by such retal offers. It is understood that this reform is due to the acceptance of a suggestion, made by one of the dealers, by the enterprising firm of importers who have of late years done so much to open up the tea trade. It is much to be wished that they would go a little further, and in addition to offering Congous at sale in large lots that they would invoice them in the same way, abandoning at a blow the whole antiquated, costly, and useless warrant and weight-note system, which causes all the delays in invoicing and delivery, for which the tea trade is so notorious. Supposing 200 half-chests at 1s to be sold, instead of making over twenty separate invoices on the weight-notes, each of which involve six or seven separate calculations or 120 to 140 in all, the broker would invoice, say, 12,000 pounds at 1s., or £600, and then add the lot money, and deduct the deposit on the parcel in a lump sum. The invoice would be accompanied by the dock landing account, from which the dealer would procure the separate weights, and check the parcel. When delivery was required, the dealer would apply for the number of chests he wanted, and hand a cheque of so much a chest, less deposit, in exchange for which, as in all other branches of the Grocery trade, he would get a delivery order up to the value of his cheque. On the supposition that the present deposit system is to remain unchanged, with its alleged advantage to the larger dealers, and its disadvantage to the importers in limiting the trade, some change would have to be made in the details. At present the form of the weight-note gives the dealer a probably not quite adequate security, but people accept it, as losses have hitherto rarely, if at all, occurred through the receiver of deposits failing to deliver the teas; and so long as this is the case, it is not worth the while of the larger buyers to question the odd arrangement by which they give credit to the sellers. Without weight-notes, the form of security given would, so the lawyers say, probably have to be some sort of receipt for the disposition from the seller, in which the latter also instructed the dock company that the buyer had a lien or mortgage on the parcel.—*Produce Markets' Review.*

COFFEE GROWING IN COLOMBO.—If you want to see a fairly good coffee tree doing its level best under very exceptional circumstances walk down the road to Polwatta, pass the entrance to the office door, and at the very corner of a road near by and nearly opposite to the door referred to you will see the tree with a good crop in it, berries in clusters well-formed. It is a cheering sight.—*Cor.*

QUEENSLAND: ITS PROGRESS AND RESOURCES, BY MR. ARTHUR J. STANESBY.—Perhaps the best idea of the capabilities of Queensland soil and climate can be formed from an inspection of the fine Botonical Gardens in Brisbane, where, under the able direction of Mr. Walter Hill, the curator, are cultivated, in a small space, a host of plants, representative of nearly every part of the world. Cotton, flax, coffee, spices of various kinds, and even tea may there be seen in a flourishing condition in a collection to enumerate which would take me more than the whole evening. Considerable progress has already been made in the cultivation of cotton and tobacco in Queensland, and both of these industries are likely to become important. In the year 1882 the yield of ginned cotton in the colony was 183,488lb., the produce of 973 acres under cultivation. This return shows an increase of yield as compared with the previous year of 57,752lb., 354 acres of land having been applied to this use more than in 1881.—*British Mercantile Gazette.*

WYNAAD.—I have just been inspecting the work of a very serious foe to cinchona. The stump of a young succirubra tree has been bored clean through the centre to the distance of about a foot. The tunnel thus made is about as large, round as an ordinary wooden penholder, and the "beast that did it" is a horrible yellowish white grub, evidently a very near relation to our old enemy the coffee borer. This, if it increases much, will be a very serious addition to our troubles. The wild pigs here are still doing a great deal of damage to the young cinchonas gnawing the bark, and even breaking down many of the trees. The fall in the price of bark is also alarming us; in fact with that, and short crops, and the dullness of the coffee market, our spirits are by no means what they used to be, and we naturally feel much depressed—decidedly blue, in fact. Years ago, perhaps six or seven, before the eras of gold or cinchona, we were all wild on the subject of "shade." Of course there were factions; those who believed, and those who disbelieved in the new craze. I noticed, especially the other day, a crowning triumph to be recorded, for shade-promoters. I happened to pass through a field on an old estate, which I had not seen for several years. The last time I did so it was a slight to make a planter weep—abandonment and desolation, borer and leaf rust, being written on every bush. We were rather inclined to scoff, perhaps at the proprietor who enthusiastically declared there was salvation for the place yet in the shape of shade. Countless jacks and figs were planted, and time, patience and good cultivation did the rest. Now the shade having been judiciously thinned, but still remaining pretty thick, picturesqueness is combined with utility, and a prettier field could not be found in the district. The coffee quite covers the ground and has a nice crop on it, the foliage looking dark and glossy, and wholly free from leaf-disease. The two and three years old cinchona planted amongst it, is as fine as any I have seen for the age. Altogether, it is a flourishing example in favour of shade, and generous cultivation.—*Madras Times.*

CULTIVATION OF THE SUGAR-CANE IN AUCKLAND, NEW ZEALAND.—From experiments that have been made by Mr. Justice Gillies, the following results were obtained:—From 12 to 18 tons of topped and stripped cane per acre can be produced on average soils with ordinary culture. Fifty per cent of the weight of stripped cane can be expressed, and the juice averages over 11 lb. per gallon weight. To produce a crystallisable syrup the juice must be evaporated to one-fifth of its bulk, but the main difficulties are the evaporation and crystallisation.—*Gardeners' Chronicle.*

MR. A. SCOTT BLACKLAW.—The *Jornal do Commercio* of Rio de Janeiro in its issue of 27th June announces the return to that city of Mr. Blacklaw, who, as representative of the Rio de Janeiro Central Sugar Factories and directing engineer of the works in course of construction at Mangaratiba and Araruama, had been visiting those places for inspection. It seems that in the former place the acreage under cultivation of sugarcane is very small—scarcely enough to supply half the quantity of sugar which the factory has contracted to produce yearly; but there are large tracts which can be brought under this cultivation. At Araruama, on the other hand, the plantations can easily supply all the cane that will be needed by the factory there. Mr. Blacklaw has advised the extension of the railway to Mangaratiba and the running of a steam launch to the various plantations. The *Jornal* recommends the Government to lease the waste lands in Mangaratiba to small holders, native or foreign.

BIRDS' WINGS EXPORTED FROM CEYLON.—An ex-Ceylon resident now stationed in the Straits Settlements sends us the following interesting note:—"In your report of a meeting of the Royal Asiatic Society, Colombo, some doubt is expressed as to what purpose the kingfishers' and blue jays' wings exported from Ceylon to China are put to. I think I can tell you. I was dining a few nights ago with the head of the Chinese here (a very remarkable man), and after dinner, before going over to his theatre, where we were to witness a performance of the 'Wayung,' a Chinese play, I saw a picture under glass in a carved ebony frame like a dressing glass standing on a carved ebony table. The picture represented a conflict outside a Chinese castle; there were knights on horseback heated and furious, raining blows upon each other, fair ladies loafing about doorways and windows to pick up the tip as to who was the best jouster, and the whole thing except the horses and the faces was done in jays' or kingfishers' wings. Every shade was used, and the effect was not only curious but very pretty."

THE COFFEE INDUSTRY IN TRAVANCORE has not proved very successful and in view to reduce the taxes payable on coffee lands, the Travancore Planters' Association has resolved upon appealing to the Travancore Government to grant them certain concessions. The planters wish the Government to levy a duty on coffee exported instead of the land tax now levied. We read in the *Travancore Times* that the coffee planting industry on the hills of that province has not turned out so well as was at one time expected—many planters have been ruined, others are on the verge of ruin, and unless the Travancore Government helps them so that the land tax may not fall too heavily on the planters, the coffee enterprise must steadily decline and in a short time, the planters will have to desert the hills of Travancore. In respect to coffee cultivation, we learn from the last published administration report of Travancore that no sales of coffee land took place in the year—there was no demand. The demand on account of land assessment was R25,630, the collections amounted to R8,329 and the balance R17,187. "The uncollected balance is owing to the very depressed condition of this industry." The quotation we have made ought to be sufficient to induce the Travancore Government to make some concessions and induce the planters to carry out an industry which, though now in a "depressed condition," may revive and help toward an industry which, if successful, would be alike advantages to the Government as well as those intimately connected with it.—*Madras Standard.*

Correspondence.

To the Editor of the Ceylon Observer,

MUSTARD AS AN INSECTICIDE.

Dear Sir,—Regarding the suggestion of your correspondent "Diogenes" to sow mustard as a preventative to grub, if I did not mention it in a former letter, it can do no harm to add in support that the same proposal came to me, from a friend who has had the advantage of several years' practical study of high farming, under a very able and successful Professor of Agriculture at home; and to whom indeed my thanks are due for statement of a theory already before submitted in reference to atmospheric conditions, in connection with leaf-disease, and short crops:—though—and without any reason still to the contrary—whether it was correctly chronicled is another question.

As for the plan of sowing mustard, it seems to me open to just this one drawback: that, though it might prove, where applied, of use, there is less certainty whether it would be of much *public benefit*—unless universally adopted—and is this possible?—as the grubs would hardly be killed; and though, even after their transformation into beetles, they might leave the estate in question, it would only be to remove to, and increase the supply on, the neighbouring properties. Of the beneficial results enumerated, as likely to arise from it, dug in the form of a green crop as a manure, I don't see there can be two opinions. X.

[If mustard does not kill the grubs, it will at least conserve nitrates and enrich the soil.—Ed.]

MR. STORCK ON THE CEYLON EXPERIMENTS WITH CARBOLIC ACID AS A REMEDY FOR *HEMILEIA VASTATRIX.*

Belmont, Rewa River, Fiji, July, 6th 1883.

Dear Sir,—I felt not a little surprised and indignant on reading the naive accounts of what Mr. Jardine calls "some facts" for me, when he at the very opening of his paper shows how far he has departed from the elementary rules laid down by me, and serenely states how he established his vessels at 40 feet apart "to make them cover 2 acres." Not only did I in my very first paper inform your readers that I placed my vessels (I started with some 80) at 24 feet each way in consideration of the small area, and give plain reasons for so doing, but I repeatedly afterwards reverted to the same circumstance, and a few months ago gave a scale of distribution for experiments on different areas according to size. What is the use of all my waiting when experimenters will not follow directions as simple and explicit as important towards ultimate success? Mr. Jardine does not mention the pattern of his vessels, nor does he with one word refer to the amount of effect even *his* treatment must have had upon the preservation of foliage, which is the chief aim of my method, and this is what the gentleman would dignify by the term of "facts." Then he proceeds to call my system a hopeless failure, and, owing to his reputation of a careful and intelligent planter, his letter is held up by the press as gospel and a dire warning to his fellow-planters.

I have long apprehended that this would be, if known to me, the character of a good many so-called "experiments" and adverse "facts." From what I can gather, the trials of the Ceylon Company, Limited, are the only instance of intelligent and persevering application of my treatment, and consequent "encouraging results," imperfect as it hitherto was.

Now, Mr. Jardine, after damaging my credit and our common cause in the manner and to the extent he did, owes me the reparation of a gentleman, and I shall presently point out to him how it is to be made. For a considerable time past, during my experiments with different qualities of acid, I believed to notice (I am not a chemist), particularly with the cruder samples I handled, a peculiarly pungent odor, other than that of carbolic acid. It was always more noticeable when the acid was being agitated, or exposed to the atmosphere in thin sheets, poured upon wood, or when a piece of rag was saturated with it. But when a body of acid an inch deep or more was exposed, this peculiar pungency would wear off, very likely because unable to penetrate the more sluggish layer of fluid above it. This used generally to be the case after about 3 weeks of exposure with a simultaneously marked decline in the effects of the vapor upon the fungus. This pungent principle I have now ascertained to be cresylic acid, a substance always present in appreciable quantities in the cruder descriptions of carbolic acid, and a very important factor in its composition as regards its character of an antiseptic. I wrote to Messrs. Calvert about this, but they do not seem to have quite understood me at the time. In the mean time I had devised various methods for keeping up an automatic agitation in the body of the acid set out for evaporation on the principle of capillary attraction, my aim being to draw to the surface and expose to free and uniform volatilization all the constituents of the carbolic acid, instead of having perhaps some of the most active and important of them bound up and lying comparatively idle in the vessels. For this end I used and recommended firstly sand, afterwards a round floating wick, and latterly an upright concentrical collar of bagging. All these devices left something to wish for until I perfected the latter contrivance by giving it the vertical support of a strip of tin or other sheetmetal, and it is this improvement which I hereby challenge Mr. Jardine to carry out strictly according to the following directions.

Put vessels of proper dimensions (4-5 inch diam.) 24 feet each way apart (smaller vessels proportionately closer) so as to cover a space and shape of as nearly as possible a square acre (the vessels in Mr. Jardine's possession will just do it). Cut strips of any worthless sheetmetal of about 2 inches in width or wider if the space below the roof of the vessels will allow it, and bend them into the form of a circle just so much smaller, that they, when set upright into the bottom of the vessel, will leave a clear space of about ½ inch between the inner wall of the vessel and the collar. Then take a strip of fairly stout and sound bagging or blanketing double the width of the metal strip, fold it over your collar, and set it into the bottom of your vessel fringe downwards. This done, give 2 oz. of crude acid for a month's supply, and report yourself again at the end of that time. In preparing your materials measure it so that, at least the bagging, it will slightly overlap, and, after doubling over, give the stuff just one stitch with a needle to hold the whole together. When set into the supply of acid in the bottom of vessel, they will completely saturate themselves within 10 minutes, and evaporation will go on under the most favorable conditions. This may read very circumstantial, but is not so in practice; it forms a very simple though permanent improvement, and one man ought to make 200 a day of these collars or hollow cylinders.

I think that instead of offering the reckless criticisms and gratuitous utterances of incredulity upon my system, your planters had, particularly those among them who knew or had the opportunities of learning more about the chemical nature of carbolic acid than I for some time had, instead of crying me down, better have assisted me in thinking out improvements and offered suggestions of such. However I am now quite content to have arrived at what I did without anyone's assistance. This undertaking of mine is a battle against one of the subtlest phenomena of nature, a remedy for which is not just to be cut and dried; but no amount of adverse criticism shall discourage me or turn me from my purpose for one instant after what I have seen and proved to my satisfaction. I have cured coffee trees and small areas of such from *H. vast.* and know that it can with still greater advantage be done on large ones; I have set myself the task and complete it I shall and will, notwithstanding the degree of virulence the disease has attained in Ceylon, of which I have a very lively conception after reading as much about it as I have.

As for those who profess to have seen my experiments and have gone away spreading and publishing all sorts of reports, they simply did n't see what they saw, and generally knew more of *Hemileia vastatrix* than I do. They belong to the class of those among your correspondents, who weekly cram your paper with their views of inherent disease, mildew, excrements of moths, and others who would scare the fungus away with lime and ashes (very good things in themselves) and saw it settle again "like a swarm of bees on a neighbour's fruit-trees." I have myself to blame for showing them anything at all.—I remain, dear sir, yours very faithfully,

JACOB P. STORCK.

QUESTIONS ANENT TEA.

Haldumulla, 23rd August 1883.

Dear Sir,—I shall feel obliged if you or any of your readers can inform me how many seeds a maund of tea seed contains, and the average number of plants one may expect per maund. How long after pruning should picking be recommenced, at an elevation of 5,000 feet?—Yours truly, ENQUIRER.

[The number of seeds in a maund varies according to the size of the seed, but 25,000 seedlings as the result of sowing a maund of seed may be deemed good. Cultivators of tea at low elevations may answer the second query, but the rule we mentioned the other day of not plucknig except from twigs about 8 inches in length is a good one.—Ed.]

COFFEE: INTERMEDIATE CROPS AND WEEDS.

Dear Sir,—When Baron Liebig told us to grow an intermediate crop, to what question was that a reply? Was the question "What shall we do best for ourselves?" or was it "What shall we do best for the coffee?" I say the latter was the question, and the reply was, grow an intermediate crop. Without considering for a moment we planted intermediate crops, that would benefit ourselves and which have proved substitutes and very poor substitutes. We did not want to go to Baron Liebig to be told to grow substitutes, we quite ignored the fact, that we had asked what would benefit the coffee and also that Baron Liebig had told rus befoe, that "the whiteweed contained tho very essential food of the coffee tree." Now if we look back to the time when estates were not kept thoroughly clean, we have proof that weeds were beneficial to coffee. Take estates, take districts. Rothschild's when it was not kept clean used to give forty thousand bushels of parchment every year as regularly as clockwork, what came over it after it was kept clean? Take Delta it used to give enormous crops, and one year I believe gave eighty thousand bushels of parchment: what has come over it since being kept clean. Take Hangooranketty: it used to give a profit of £40,000 a year, although a large portion of that coffee was over a hundred years old, and yet after being kept clean it is worked at a loss. Take the old estates in Uva when they were weedy: they had to shovel any remainder of the old crop into the nearest stream to make room for the new crop: what has come over them since they have been kept clean? Was not Haputella a warning to us. When it was opened it was conducted on the clean weeding system, what became of the first proprietors? (excepting a few very rich ones who were able to stand out?) The same that we are all drifting to, if the present system is still enforced and when they were ruined the estates got weedy and the next proprietors made fortunes. Was not Rakwana considered a fine district, was not Doloshage a good district, was not Matale considered the crack district of Ceylon, and what has come over Uva that it is considered wonderful for one estate in it to give eight cwt. an acre? Did not the merchants of former days make princely fortunes, and had they not such confideuce in coffee that they considered that they could not invest their money on anything safer than lending it on coffee? Take the merchants now-a-days: go round and try and get a loan or take a drive round Colombo, and see the number of mills that have been closed one after the other as crops got shorter, and shorter, walk into one of those that are open, and instead of seeing the piles of coffee one may see a few casks of coffee and a little cinchona being pressed into bales. Then see what one of the directors of the Oriental Bank said at one of their last meetings, he said "that they must remember that Ceylon in former days did a great deal for the Bank." What has Ceylon done for it for some years past. Then see what one of the directors of the Ceylon Company said at one of their last meetings: he said "in former years they got large dividends." Take their reports for some years past and see what the Chairman says. He commences by saying, that the weather had been unfavourable for the blossom, but hoped that next year would be better, and went on year after year till those hopes got too stale to hold out to the shareholders, and then they turned their hopes to cinchona. When estates were weedy, we did not hear of leaf-disease or grub. I hope now I have convinced you and your readers that what ails our coffee is only a natural consequence, and can only be remedied by natural means. If there are any that will still hunt after shadows for nostrums, I must remind them of the dog that went after his shadow. There is a medium in all things, even in weeds. I do not say that there should be no weeding, and I do not say that we should allow the weeds to grow up so as to choke the coffee, and some places may be so improvished that weeds alone will do no good. Coffee has been called King Coffee and kings have their carpets and yet there are those that will deprive King Coffee of his: let him have his carpet and he will still be King.—Yours truly,

G. F. HALLILEY.

INDIGO IN CEYLON.

Dear Sir,—In Dr. Nolan's "History of the British Empire in India and the East," he says that during the time of the Dutch rule indigo was cultivated in, and exported in considerable quantities from, Ceylon, but since the British acquired the island that that cultivation has fallen off. As I do not believe there are any indigo plants in the island, can you, or any of the many readers of your valuable paper, inform me as to whether indigo has received extensive cultivation, and large quantities been exported since Ceylon became a British colony, if so where, and why it is not still cultivated? What part of the island is the soil likely to be suitable for the growth of indigo, as Dr. Nolan further says, the plant is indigenous, and the soil of Ceylon adapted to yield a superior quality under proper management. I certainly do not see myself, why indigo should not succeed in Ceylon and give a handsome profit, as everyone more or less is going in for something new to replace poor "old coffee." Any information in regard to above, will be gratefully received by, yours truly,

INQUIRER.

[In the introductory review of the Ceylon planting industry in our Handbook for 1876-8, we made the following remarks:—

The cultivation of Indigo in the Seven Korales, begun by the Dutch in 1646, was unsuccessful, and Governor Barnes in 18.6 lost money over this article. Mr. Henley, a Bengal planter, tried indigo also in the Southern Province but failed in his attempt to grow it properly.

In Bennett's *Ceylon and its Capabilities*, chap. IX., the subject is fully treated of, the author complaining bitterly of the neglect of indigo by the British, the last export having taken place in 1793. He says the district of Tangalla is best suited for indigo. Mr. Lemarchand cultivated indigo at Jaffna, but his crop was eaten off by insects.—Ed.]

GENUINE CALISAYA MORADA SEED FROM BOLIVIA.

Dear Sir,—I have just been reading over the report of a meeting of the Linnean Society in the *Tropical Agriculturist* for July last (page 25), on the subject of cinchona; and as a point I think generally of some importance, I trust you will kindly afford me space to correct a slight and very natural mistatement made at the time by Mr. Howard, in crediting others with a position, I have hitherto supposed, I alone really could lay claim to. Whether the fact of having a relative of some twenty years' residence in the country, possessing intimate friends in a position to supply it, justifies me in adhering to the belief, that I am the only one who has so far been able, or can still at all rely on procuring, genuine seed of the sort, it is not my object now to discuss: rather for those whom it may interest to form their own opinions. Let it suffice to point out, that it is not a question of how to get supplies of seed "so-called" of the best varieties—no trouble about this in quantity—the difficulty is, and it is apparently as great a one as ever, to procure it genuine. Here, Mr. Millie's letter in the *Tropical Agriculturist*, for, I think, October or November 1882, may well be referred to! and I cannot alter my belief in the impossibility of procuring other than spurious seed through the medium of any professional seed collector or commissioned agent, and as solely a business transaction; though not here at all, meaning to imply that those by whom I notice it stated to have thus been procured at all doubt the merit of the supplies, that they have thus received: however, it is a point open to discussion, and it will be interesting to receive further evidence of how far I am right or wrong in my opinion. It is true there are now in Bolivia large plantations of trees of the best varieties, of a sufficient age to yield seed; but it unfortunately is equally true that the Bolivians are still jealous of the monopoly; and that the adjoining forests teem with allied but worthless kinds. This brings me to another point it would be interesting to have some more light thrown on! I am under the impression that in another and fuller report of the same meeting "Zamba Morada" and "Naranjada" are characterised as varieties of calisaya; and I notice that Mr. Owen (*T. A.* July p. 35) thus represents them:—"There are I believe several sorts of calisaya distinguished in Bolivia, by the red or yellow in the leaves and midrib, or by the green of the leaf, such as Morada, Zamba Morada, Roja, Naranjada, and Calisaya Verde." Markham in his work "Peruvian Bark" writes thus:—"Morada Naranjada, (Cinchona Ovate. var. *a vulgaris* Wedd.) Zamba Morada, (the B. rufinervis variety of C. Ovata), the bark of the B. rufinervis variety is habitually used to adulterate the calisaya which it very closely resembles, and is called Zamba Morada by the Cascarilleros." Of course these remarks refer to Ovata, a quite district and virtually worthless kind. Though the incident is a curious one, there are both "Zamba Marada" and "Naranjada" *Calisaya*! and "Zamba Morada" and "Navanjada" *Ovatas*—this is evidently conclusively shewn by the fact, chronicled in the same number of the *Tropical Agriculturist*, that the Indian Government have purchased several ounces of "Calisaya Zamba Morada, clean seed." To doubt it, unless the *Madras Mail* is responsible for having mistakenly inserted the word "Calisaya," is to question the professional understanding of the learned heads of the Indian cinchona departments, which forbid us. Should though by any chance a misprint for "Ovata" have been made it would be very interesting to know what object the Indian Government can have had in procuring it; unless for stock plants for grafting? and, if so, for the purity of the better kinds already established there, it is surely to be hoped that these Ovatas will be *reduced* before blossoming?

With regard to Calisaya Verde, Markham gives the following:—"Gironda and Martinez told me, that there were three kinds of Calisaya trees: namely *Calisaya fina*, *Morada* and *Verde*. They added, that the latter was a very large tree *without* any red colour in the veins of the leaves." Now, coupled with, I think, the fact, that all other Calisayas recognized as *green-leafed* varieties invariably support their discription by a marked absence of color in the leaf, it is difficult to reconcile the above account of *Calisaya Verde* with plants of the sort recently introduced; which according to Mr. Owen, and a writer from Dimbula;—and in fact I can endorse what is said from the appearance of plants I have myself seen, raised from seed purchased *as Calisaya Verde*,—have come up of quite a variety of different types both as to shape and size of leaf and color, *red, green and yellow intermingled with purple*. It certainly puzzled me, how specimens of *Ledgeriana* came to be found amongst Calisaya Moradas; but that there must be some slight mistake has apparently been already ably shewn by Dr. Trimen. What though I still less can understand, is why it should be desired to associate the latter (*Calisaya Morada*) or *Calisaya Verde*, with, and as it were draw credit to either from, *Ledgeriana*! Considering that, not only is Calisaya Morada regarded in Bolivia as by far the richest bark, and altogether most valuable variety, but that, as pointed out by Mr. Owen, Markham himself saw a specimen that at about a year old, was seven feet high, and six and-a-half inches round the trunk,—a growth no *Ledgeriana* has, or ever will be known to equal,—I personally should prefer claiming for it a quite distinct individuality. *As the finest cinchona known, Calisaya Verde*, may be better adapted to the very low elevations, and of even finer growth, but the bark though good is according to all accounts, much inferior; and such a growth as Markham from personal observation describes is surely good enough to satisfy any one. He speaks of *Calisaya Morada* as being just of a shade darker green in the leaf than *calisaya fina*, with crimson veins and in one locality, the leaves are said to become quite a bright purple all over the underside. Apart from the fact that I am told, it comes from 'one of the best plantations,' the plants from my seed both in growth and otherwise would seem so far to answer well to the discription given. And that they are really highly thought of by good authorities, I must suppose, not only from the expression of his opinion, but that the largest holder (whose right to be regarded as a good judge of cinchona I think no one here would attempt to question) has already secured in advance on my own terms—terms I am quite satisfied with—possibly all that will next come to hand. Equally favorable accounts has reached me, too, from India, the plants having been sold individually at a price which on a moderately large scale would at once amount to a small fortune; one I fancy a good few men at the present time would be glad to retire on. At least, speaking for myself; though entertaining an entirely hopeful view of the island's future—for I quite belive what Mr. Tytler was right in saying "It was not yet 9 a.m. here!" I don't see how this can be doubted, with the immense new field for enterprise now offering, under the most favorable circumstances conceivable regarding new products—if even you limit these to cinchona, cocoa and tea? This is to say nothing against coffee; but it would be out of place meanwhile to predict a further development of the resources of the country from it, however fully it may in the future add its quota, in view of the entire cessation of extensions as regards I fear both varieties; and in spite of the encouraging results apparently still to be obtained by judicious cultivation. As regards Liberian coffee, speaking from a case under my notice, there cannot be a doubt about it, both as to quantity and quality; and this at but a light additional outlay. C. R.

P. S.—Since writing the above I have been shown a letter received from a seed merchant at home, in which he offer two kinds of Calisaya; one said to yield 8 per cent Sulph. Quinine, and the other more: names not given, but they are stated to be *from the same estate in Bolivia that Ledgeriana came from!* So that after all the species as first introduced by Ledger is the scion of cultivated trees, obtained by him from a known estate. This throws a new light on the recent controversy. Dr. Trimen, after this, will no doubt fain heave a saddening sigh over the faded *beauties* of the banks of the "Mamore"—though Mr. Moens' indignant denial needs no conjecture! But what in the balance are their opinions—though we here choose to value them—with those of our great scientific experts at home? I speak of men in the position of Messrs. Howard and Holmes, unless it be on the oft proved circumstance in connection with other branches of natural science, that "closet professors" (though a vast amount of valuable information must be of course accredited to them) have, times out of the number, been shown to be absolutely wrong in their conclusions by "field naturalists," be it as it may or may not be less scientific, but who, and as keen observers, have had the opportunity of studying their subject, in full life and development, in its native, or *accepted* home. One feels constrained to speak with bated breath; but may it not be just possible, that this *as a fact* may find support, as with other ologies—also regarding cinchona? When speaking of "closet professors" I simply mean home authorities who, though—as no one can gainsay their enthusiasm—doubtless eagerly enough longing for it, have not the opportunity of studying from life save in a "hot-house" or "menagerie"! I don't mean to say if you sent them a leperesed coffee leaf whole trees and patches are occasionally to be met covered with, they would class it as "variegated laurel"; but I do think it probable from all I have read lately, and before on cinchona, they would be as likely as not to seize on it as new and interesting species. For instance, I see noticed in several papers, as another kind of Calisaya Morada, "C. Morada *Veluta*." I feel sure that in Bolivia not more than one kind of "*Calisaya* Morada" is recognised by planters there, or a distinction made on slight variations in habit and leaf that may occur—any more than in the case of Ledgeriana amongst practical men here, in India, or Java—*Calisaya* Morada! *Calisaya* Morada!—Ledgeriana! Ledgeriana! C. R.

[This lengthy, somewhat obscure, and at the end wild, letter is really an advertisement, to the effect that although seed merchants pretend to be able to obtain cinchona seed of the best varieties from Bolivia, seed of the true Calisaya Morada can be obtained only through C. R., the seed and seedlings being worth their weight in gold. We cannot promise to insert any more letters of a like nature. It is obvious that proof of the superiority of our correspondent's seed can only be afforded by resulting plants.—ED.]

BRAZIL AND JAVA COFFEES.

(From the *India Mercury*, 28th July.)

An article on Coffee Culture, in the *Algemeen Handelsblad* of 20th ultimo, directs attention to a memorial of the Chamber of Commerce at Batavia to the (Netherlands) India government, concerning the prospects of Java coffee, in connection with the influence which the competition of Brazil and the extension given the plantations there, effect on the Java coffee prices. The Chamber is of opinion, that this might have been prevented (?), if government had been better informed by the Consuls of the condition of the coffee-culture in general, and that of South-Africa in particular. The Chamber, therefore, proposes an investigation *in loco*, to be made by a commission of three experts (members) with charge of reporting on:

a. the extent of the area planted;

b. the productiveness and length of life of the coffee plant;

c. the manner of planting;

d. the available labouring forces with regard to: 1st Slavery; 2nd Free labour; 3rd Means of transport and ditto expenses;

e. costs of production;

f, the pecuniary means of the planters with reference to the low coffee prices these last two years.

The Indian Government concedes, in answer, the great development the coffee-plantations have attained in South America, and acknowledges the utility of probing the evil of the competition which the Java-coffee has to dread, both as to quality and quantity, of the Rio and Santos coffee; but it wishes provisionally to confine itself to the gaining of consular informations, deeming an inquiry or investigation as proposed by the Chamber of Commerce at Batavia as yet unnecessary.

While awaiting the report of the Consul General of Netherland at Rio de Janeiro, which will, no doubt, be full of interesting matter, we make bold to offer in the following lines to those interested in this great question, a few observations derived from the most reliable quarters.

a. The extent of planted coffee area in Brazil does not exceed 50 or 60 thousand square kilometres, and is distributed over the provinces of Rio, Mines, San Paulo, Espirito Santo, Bahia and Ceará: the area in Brazil, however, of ground fit for the culture of coffee exceeds two millions of square kilometres.

b. The length of life of the coffee plant is various; in Rio and Espirito Santo it lives 15 to 25 years, in Minas 20 to 30 years, in Paulo 35 to 40 years and even more.

As to its productiveness, it can only be stated that the number of coffee trees in Brazil is estimated at a total of more than a thousand millions, and the annual produce at an average of 400 millions of kilogrammes

c. The manner of planting is rather advanced; in Brazil the systems of all coffee producing countries are known, and the best methods are put in practice.

d. The available labour is diminishing in slaves and increasing in free labourers, and it is noteworthy that the produce rises, notwithstanding the cypher of the slave population is constantly declining.

By the increase and improvement of the means of conveyance—railways, steam navigation, provincial and local roads, general expenses are much reduced.

It is known that in Brazil more than 4,000 kilometres of railroad are in progress, mostly running through the coffee districts. The tariffs for the carriage of coffee have of late been reduced by 10 to 25 per cent.

e. Also the expenses of production have been considerably economized, by employing steampower for peeling, sifting and many other improvements.

f. The pecuniary circumstances of the planters in the principal provinces have not suffered from the decline of the coffee prices during the last two years, as, of course, economy has conformed to circumstances. There is every reason to suppose that the present prices of the article in Brazil are in general near about profitable, while the Government, as well as the producing classes, are continually endeavouring by judicious measures to lower the cost prices as much as is consistent with the improvement of the quality. As to the recently made plantations, which, especially in San Paulo and Minas, are assuming vast proportions, it is believed that the present produce will obtain, or perhaps even increase.

Such is, in a few words, the probable import of the Consular Report in view.

We wish, however, to add, that in Central America, too, the coffee produce as to quantity (18 per cent of the total produce) does not decline in the least, though the culture in those parts, both as to cost price and improvement of quality, is behind Brazil. Nor must Mexico be lost sight of; perhaps this country has a prospective future in the coffee culture, near at hand.

Further the produce of Ceylon, India, Australia, and Africa (about 9 per cent of the total) deserves mention, about which the Chamber of Commerce at Batavia is better informed than we are.

I must furthermore be allowed to observe that Brazil must not be accounted a rival, but the greatest producer. Indeed, the Brazil crops amount to about 60 per cent of the consumption of the world; Java furnishes about 15 or 16 per cent. We wish most seriously to combat the idea of "competition" because such a conception would lead to a wrong conclusion; the disparity between produce and sale, or rather between supply and demand, is the great question that must be kept in view.

Two years ago, a clear-sighted man in Brazil, the late Minister of Agriculture and Commerce, Buarque de Macedo, called all the influential men of agriculture and commerce together, to hear their opinion about the measures to be taken, to prevent the economical crisis that might result from the decline of the coffee prices.

Among these were also some members of the Centro da Lavoura e Commercio; these took upon themselves the task of studying the subject and reporting upon it to Government. A few days afterwards, the Centro presented the result of their researches to the Minister. The Centro understood that causes of a transient nature had led to overproduction, or rather to a great accumulation of provision in proportion to the demand, a sort of crisis occurring occasionally in other branches of industry. In short, instead of seeking for the causes in foreign countries alone, the Centro proposed to the Minister, to take immediate measures of indirect protection in favour of the planters and the produce, and to make in foreign parts the most practical propaganda for coffee in order to augment the consumption of the article in those markets where it was already on sale, and further to open up new outlets for it in Europe and America. The Minister yielded to those proposals, and the Centro set about their task with the greatest energy and most praiseworthy devotion, as is proved from their account of the first coffee show at Rio de Janeiro, and from a pamphlet lately published at Amsterdam, and obtainable in the Brazilian section of the International Exhibition, near the interesting collection of samples of coffee, exhibited there by the care of the Centro.

This numerous, and as regards variety, rich collection of samples of Brazil coffee (879 exhibitors, 911 plantations, 1,003 samples) gives a graphic image of the superiority of Brazil in the great coffee trade as regards the quantity as well as the cost price in proportion to quality.

It is therefore incorrect to apply the term of competitor simply to Brazil, where the facts point to that country as the centre of the coffee trade, and controlling the coffee markets of the world.

As now this state of things will for the present not undergo any change, it appears to us, both reasonable and practical, that other countries should act in concert with the great American producer, rather than institute inquiries that may be influenced by various causes. For, in fact, the hope of seeing, in a problematic future, the productive powers of other other countries decline, leads to false conclusions; it is not in the power of the Chamber of Commerce at Batavia, to bring any change in existing conditions, which are controlled only by the universal laws of commerce.

These informations are given unasked, but with the greatest readiness and sincerity, in name of the great Union "Centro da Lavoura e Commercio" that takes so lively an interest in all that regards the coffee trade in general. For certain these few lines are not worth a hundred thousand guilders, which sum the Chamber of Commerce calls a trifling sacrifice, against the expected results of the inquiry they desire, but yet there is very little wanting in these informations to lead us to a practical result. The C. of C. has only to complete them by taking up the general catalogue of the Brazilian Section, which will be shortly published at the International Exhibition through the exertions of the Centro, and we are convinced they will come to derive profit from the co-operation of Brazil, and to consider this country not as a competitor to be dreaded, but as a powerful and generous confederate in the great coffee question.

If Netherlands will go hand in hand with Brazil in the persevering task of gaining propaganda for the article of coffee, especially where new markets are to be secured, and that in the first place in the core of Russia, then there is no doubt but the prospects of Java coffee will be much better secured by consequent eventual increase of the consumption. than by trusting to a possible, but yet highly improbable, diminution of the productive powers of South America.

(Signed) ED. LEMOS,

delegated Commissioner of the Brazilian Section of the International Exhibition at Amsterdam.

28th June 1883.

THE FRUIT CROP OF 1883.

The returns from all parts of the United Kingdom sent us by trustworthy reporters, to whom we are greatly indebted, enable our readers, as it has enabled us, to get a bird's-eye view of the general condition of fruit production for the present year. One of the most remarkable features of these returns is found in their singular unanimity with respect to various fruits, for north and south, east and west alike, have to deplore on the one hand the almost total failure of some, and the same fruits, whilst they equally have to rejoice over the abundance of others. If we regard the intrinsic value of the various kinds, however, to a great fruit-consuming people, we shall find that the large crops of certain fruits far more than counterbalance those which have failed—as for instance, if Apricots are few, Peaches seem to be fairly abundant; and while Plums and Pears are scarce, the enormous crops of Apples—*par excellence*, the fruit of the nation—and of bush fruits, and wholesome Strawberries, far more than outweigh the former's shortcomings. Indeed, were all other fruits as thin as some are, yet would the splendid Apple crop, the very best without doubt, because so universally good, that we have had for ten years or more, suffice to mark 1883 as a red-letter year in the diaries of fruit growers.

It is not possible to take leave of what is not an altogether unclouded *résumé* of the fruit crops without commenting upon the great social and economical value a good fruit crop is to the kingdom. By it myriads live; by it the wealth of the country is increased, and vast sums of money are liberated for employment in other profitable channels. By it also the comforts and pleasures of the people are vastly increased, and may we not hope the health also. From afar come sad accounts of choleraic visitations, but these are the products of dirt and of foulness, not of the consumption of ripe, wholesome fruits. We trust no foolish alarms will interpose to prevent our growers from reaping to the full the benefits to which they are entitled from the plentiful Apple crop. Better a thousand times to purchase good fruit then poisonous liquid compounds and cheap questionable solids, the constituents of which none can tell. If we will take of the good things of God, surely none better merit such an epithet than a luxuriant crop of delicious wholesome fruits.—*Gardeners' Chronicle.*

THE MANUFACTURE OF SAGO.

Sago-making, both with the Papuan and the Malay population, is the great occupation of their life. Sago is extracted from the interior of the stem of several species of palm, which grow in swamps or in "swampy hollows on the slopes of hills," even when exposed to the influence of brackish or salt water. The midribs of the large leaves are used in the place of the otherwise all useful bamboo pole; houses are built of them, and they form excellent poles for roof-match (or *atap*); split, they are used for flooring; boxes are made of them and the leaves combined, and they supply material to place between the chinks in the walls of log-houses. The starch stored in the interior, under the name of "sago," almost entirely supplies the food of thousands of people. A tree is selected just before it has commenced to flower; it is cut down and split open, and with a heavy mallet the soft pith-like interior in which the starch is stored is broken down into the the shell formed by the split stem. This is gathered up into baskets, until the whole is extracted and only a mere skin, half an inch in thickness, remains of the original solid trunk. The starch-laden pith is now transferred, in baskets woven of the midribs of the leaves, to the washing-place, where, by means of an apparatus also made of the sago-palm, the starch is washed out of the fibrous mass with which it is mixed into a trough where it settles down as a sediment. After the trough is nearly full the mass of starch which is of a reddish-brown colour, is made up into cylindrical masses, each weighing about 30lb., and neatly covered with sago-leaves. These cylinders are known in commerce as "raw sago;" we only see the refined article in shops in Europe, and though then nice-looking it has lost much of its characteristic flavour. Boiled sago is eaten by the natives with salt, limejuice, and chillies, or made up into cakes, which are very excellent, and extensively used in the Malay Archipelago. "It is," remarks Mr. Wallace "truly an extraordinary sight to witness a whole tree-trunk, perhaps 20 feet long and four or five in circumference, converted into food with a little labour and preparation. A good-sized tree will produce 30 *tomans* (or bundles of 30lb. each), and each *toman* will make 60 cakes of three to the pound. Two of these cakes are as much as a man can eat at one meal, and five are considered a full day's allowance: so that, reckoning a tree to produce 1,800 cakes, weighing 600lb., it will supply a man with food for a whole year. The labour required to produce this is very moderate. Two men will finish a tree in five days, and two women will bake the whole into cakes in five days more; but the raw sago will keep very well, and can be baked as wanted, so that we may estimate that in 10 days a man may produce food for the whole year. This is on the supposition that he possesses sago-trees of his own, for they are now all private property. If he does not, he has to pay about 7s. 6d. for one; and as labour here is valued at 5d. a day, the total cost of a years' food for a man is about 12s. The effect of this cheapness of food is decidedly prejudicial, for the inhabitants of the sago countries are never so well off as those where rice is cultivated. Many of the people have neither vegetables nor fruit, but live almost entirely on sago and a little fish."—*The Peoples of the World.*

THE COMPOSITION AND ADULTERATION OF TEA, COFFEE, SUGAR, &c.

Coffee has, like tea, been the subject of numerous investigations, but the following analysis by Payen is most frequently quoted:

Cellular Tissue	34·00
Hygroscopic Moisture	12·00
Fat	13·00
Starch, Sugar, Dextrin, and Vegetable Acids	15·50
Legumin	10·00
Chlorogenate of Potash and Caffeine	3·5 to 5·0
Nitrogenous portion	3·00
Free Caffeine	0·80
Thick insoluble Ethereal Oil	0·001
Aromatic Oil	0·002
Mineral Constitnents	6·697

We have obtained the following results from two samples of coffee, both in the raw and roasted condition:

	Mocha.		East Indian.	
	Raw.	Roasted.	Raw.	Roasted.
Caffeine	1·08	·82	1·11	1·05
Saccharine Matter	9·55	·43	8·30	·41
Caffeic Acids	8·46	4·74	9·58	4·52
Alcohol Extract containing Nitrogenous and Colouring Matter	6·90	14·14	4·31	12·67
Fat and Oil	12·60	13·59	11·81	13·41
Legumin or Albumin	9·87	11·23	11·23	13·13
Dextrin	·87	1·24	·84	1·38
Cellulose and Insoluble Colouring Matter	37·95	48·62	38·60	47·42
Ash	3·74	4·56	3·98	1·13
Moisture	8·98	0·63	9·64	1·13
	100·00	100·00	100·00	100·00

Thus the large quantity of caramel produced in chicory and some other roots in the process of roasting, furnishes the means of applying a simple and convenient preliminary test for detecting their presence in coffee.

When a few grains of coffee containing chicory are placed on the surface of water in a test-tube or wineglass, each particle of chicory becomes surrounded by a yellowish-brown-coloured cloud which rapidly diffuses itself in streaks through the water, till the whole acquires a brownish colour.

Other sweet roots when present will produce under like conditions the same effect as chicory, but not so rapidly or perceptibly as the latter. Pure coffee under similar conditions gives no sensible colour to the water until after the lapse of about a quarter of an hour. The relative colouring power of coffee, chicory, and a variety of other vegetable substances used in the adulteration of coffee was determined by Messrs. Graham, Stenhouse, and Campbell. This was done by infusing equal quantities of each substance in water, as in the preparation of coffee for domestic use, filtering the infusions and observing the colour in glass tubes of about 1 inch in diameter. The solutions, which were prepared, at 212° F. (100° C.), were made very dilute, and, for comparison, a standard solution was prepared by dissolving 1 part of caramel, carefully made from cane-sugar in 2,000 parts of water. To produce a depth of colour equal to that of the standard solution, a larger proportion of the adulterating substance is required, than the 1 in 2,000 of the standard.

The following table exhibits the actual weights required of each substance when roasted and prepared in imitation of coffee, to be dissolved in 2,000 parts of water, to produce an equal depth of colour:—

Caramel	1·00
Mangold Wurzel	1·66
Bouka (a coffee substitute)	1·56
Black Malt	1·82
Carrots	2·00
Chicory (darkest Yorkshire)	2·22
Maize	2·86
Rye	2·86
Red Beet	3·33
Bread Raspings	3·34
Acorns	5·00
Highly roasted Coffee	5·77
Medium-roasted Coffee	6·95
White Lupin Seed	10·00
Peas	13·53
Beans	13·33

It will thus be seen that 2·00 parts of carrot, or 2·22 of chicory, have the same colouring power as 6·95 parts of medium-roasted, or 5·77 of highly-roasted coffee, or of 3·64 parts of bread raspings, or 13·33 parts of roasted beans.

Another respect in which infusions of coffee, chicory, and some other substances differ from one another is that of their specific gravities. When, in a sample of coffee, the adulterant has been identified by a microscopical examination, the difference in the densities of the infusions becomes immediately available for estimating the proportion present. In preparing the infusion, 100 grains of the ground substance are placed in 1,000 grains by measure of distilled water. The temperature of the mixture is then raised to the boiling-point, where it is maintained for half a minute. The resulting infusion is next filtered, and the specific gravity of the filtrate taken at a temperature of 60° F. (15·5° C.) This will be found to vary according to the substance employed, in the manner shown in the subjoined table:—

SPECIFIC GRAVITIES OF SOLUTIONS AT 60° F.

One part of Substance to 10 parts of water.

Lupin Seed	1002·1
Acorns	1002·9
Peas	1007·3
Mocha Coffee	1008·0
Beans	1008·4
Plantation Ceylon Coffee	1008·7
Java Coffee	1008·7
Jamaica Coffee	1008·7
Costa Rica Coffee	1008·9
Carrots	1017·1
Black Malt	1021·2
Turnips	1021·4
Rye Malt	1021·6
English Chicory	1021·7
Red Beet	1022·1
Mangold Wurzel	1023·5
Maize	1025·3

It will be seen from this table that the low specific gravity of the coffee infusion distinguishes it from the roots and cereals. If an infusion of a sample of coffee containing 20 per cent of rye malt were prepared in the manner described, its specific gravity would rise above 1009·5—the number corresponding to the infusion of coffee of the highest density—and would approach 1021·6—the number corresponding to rye malt—almost exactly in the proportion in which the latter was present.

There is a considerable difference between the quantity of sugar present in roasted coffee and in many of the vegetable substances used for its adulteration, particularly chicory and the other sweet roots, and it is sometimes practicable to make this the means of affording confirmatory proof of adulteration.

The amount of sugar in coffee, and in a great variety of vegetable substances, has been determied, both before and after roasting, by the process of fermentatiou and distillation.

The results obtained by Messrs Graham, Stenhouse, and Campbell are given in the following tables:—

Varieties of Coffee.	Sugar per cent.	
	Raw	Roasted
Plantation Ceylon	7·52	1·14
Java	6·73	0·48
Costa Rica	6·72	0·49
Jamaica	7·78	0·0
Mocha	7·40	0·50
,,	6·40	0·0
English	25·23	17·98
English (Yorkshire)	32·06	9·86
Mangold Wurzel	23·68	9·96
Carrots (ordinary)	31·98	11·53
Turnips ,,	30·48	9·6
Beet Root (red)	24·06	17·21
Parsnips	21·70	6·98

The fermentation test has the advantage of being easily applied, and the results might, in combination with the microscope, prove useful in some cases. In applying the test, the process described when treating of sugar is followed.

There are some cases in which the character of the ash affords evidence of adulteration. The ash of coffee is distinguished by the absence of soda, and also by the extremely small proportion of silica it contains, the amount of which varies from 0·17 to 0·45 per cent. On the other hand, the amount of silica or sand in the ash of chicory varies from 10·69 to 35·85 per cent.; barley, from 17·3 to 32·7; oats, from 37·82 to 50·28; and rye, from 0·69 to 11·6. Thus it is sometimes practicable to obtain valuable information without making a formal analysis of the ash, by simply digesting it in hydrocholoric acid, and observing the character and quantity of what remains insoluble. The presence of one per cent or upwards of silica in the ash of a sample is sufficient to raise a suspicion of adulteration. It is not often that an analysis of the ash of a suspected sample is resorted to in practice; it is a tedious operation, and would only be performed with the view of confirming the results obtained by some of the other methods of examination to which reference has been made.

The relative solubility in ether of coffee and a variety of vegetable substances used to adulterate it, may, in some cases, be found useful as a confirmatory test for indicating the character and the proportion in which the adulterating substance is present. Coffee yields much more soluble matter to ether than do sweet roots, cereals, and leguminous seeds generally. Thus roasted coffee, when agitated four times successively in ten times its weight of either, gives from 14·79 to 15·10 per cent of oil and resin, including a small proportion of caffeine. Roasted chicory when similarly treated, gives 7·72 per cent of extract. Roasted maize gives 4·30 per cent., and roasted beans 1·57 per cent. The deficiency of fat in the sweet roots and other vegetable substances is frequently made up in the roasting by the addition of American or Australian tallow to prevent burning, and in applying the ether test it is therefore necessary to guard againgst being misled by the presence of a small proportion of foreign fat.

It is very rare, as already stated, that any mineral matter such as oxide of iron is now employed to give colour or weight to coffee. The oxide is usually in such a fine state of division that it cannot be seen by the naked eye, or be detected and identified by the microscope. When the presence of such a compound is suspected it is necessary to burn a given weight of the coffee and observe whether the ash is of a deep red or yellowish-brown colour, and if so it is probable that oxide of iron has been added, and it will be necessary to determine the amount of iron in the ash and compare the result with the quantity found in genuine coffee, or the proportion that may be present in mixtures of chicory and coffee.

Burnt Sugar.—When a sample of coffee which is free from roots and other foreign vegetable substances, imparts to water a deep and rapid colouration, there is reason to suspect that burnt sugar has been added. The black shining particles of the caramel can usually be distinguished by the naked eye from the dull light brown fragments of coffee, and be removed for examination. The solution of the separate particles in water, and the high colour they impart to it, are indicative of burnt sugar.—*India Mercury.*

MAHOGANY IN HONDURAS.—A recent report from Honduras says that the cutting and shipping of mahogany is entirely carried on by British capital. Last year a little over 2,500 tons were shipped in British and Norwegian vessels, all direct to London. There was an unprecedentedly long spell of dry weather, which was favourable for the trucking operations of the wood, and it was expected that the exports this year would greatly exceed those of last. Green fruit and Cocoa-nuts suffered very much from the dry weather. Cocoa-nuts have been in great demand in the New York and Philadelphia markets, and prices ruled higher throughout the year than has ever been known before, 37 dols. per thousand being freely given. They were also scarce, caused principally by a grub having attacked the trees, and in many instances causing their death. It is to be regretted that no remedy has as yet been found to eradicate the evil.—*Gardeners' Chronicle.*

SANDAL WOOD IN CHINA.—According to the Imperial Maritime Customs Reports of China, the importation of Sandal-wood into Ningpo during 1881 amounted to 1,066 piculs, which was more than double that of the preceding year. "This article," it is stated, "was in much demand, owing to unusually extensive repairs in the temples during last year, which period was considered an especially propitious one for building operations. Much Sandal-wood was also required and consumed in joss-sticks, for the worship of the freshly gilded idols. Nevertheless, owing to its higher value, the demand for Sandal-wood is not so large as it was formerly.—*Gardeners' Chronicle.*

DARJEELING, 13th August 1883.—The "rain it raineth every day" In this part of India, even in the hills, and probably nowhere else in greater force than in Darjeeling, when Jupiter Pluvius wills it—and he does will it for at least three months of the year with a vengeance. Anything from 3 to 5 inches in twenty-four hours will not take the wind out of the sails of an average Darjeelingite during the last half of June and the whole of July; but the last three weeks of June astonished the acclimatised nerves of even one of the oldest inhabitants, by bringing several tons of earth on to one of the out-offices attached to his house, and killing a pony—nearly besides making a raw pancake of the *kutcha* edifice. This accident occurred to the adjoining building occupied by Mr. Justice Cunningham last year; when the honorable gentleman was obliged to take refuge in the "Eden Sanitarium," and was one of its first inmates. However, according to the meteorological report, the rainfall up to last Saturday is 8 inches below the corresponding date of last year. We have had a good deal of cholera in the district during the last two months, and at one time the disease came unpleasantly near Darjeeling; but I am happy to say that, except one or two very doubtful cases amongst coolies not a single case occurred in the station. However, the disease was not going to leave us without carrying off at least one European victim in the person of Mr. C. Christison, a promising young fellow not long out from home, and employed as an assistant on one of the Lebong Company's gardens. He was carried off in about ten hours: poor fellow! It is a strange coincidence that his father died of the same disease a few years since. The heavy rain has now thoroughly flushed the filthy *johras* from whence the coolies as a rule derive their drinking water, and the result is, that no cases of cholera have been reported of late. It is a fact proved to demonstration that where the lines are kept clean and the coolies looked after a bit, the gardens always escape infection. That precautions of this kind will pay is proved by the fact that on one estate in this district at the beginning of the epidemic no less than 75 deaths occurred in one week; the result, and the natural result, being that the remainder of the coolies bolted, and the garden was practically shut up for over a month; consequently it was impossible either to pick off the leaf or to keep the place clear of jungle. The result being a very heavy money loss to the proprietors. It has always been a proverb amongst planters, that "a cholera year is generally a good one for tea." The proverb has held good in this district this season. Owing to drought at the beginning of the year the "first flush" did not come out so fast and in such quantity as to preclude its being taken off the bushes before it became hard, and the result has been, that the quality of tea manufactured in the district during March, April and May has been much superior in every way compared with that of the corresponding months of the last three previous years. I may say with confidence, that the same superior quality has been maintained throughout. It is now certain that the outturn of tea from the hill gardens this year will be a long way behind that of last. You hear of many gardens being up to date maunds and maunds behind last year and behind several previous years, and as there are only some six or seven weeks now before manufacture will be almost nominal, it is quite impossible that the total estimate for the district framed at the beginning of the year can be even approximately reached.—*Indigo Planter's Gazette.*

MARKET RATES FOR OLD AND NEW PRODUCTS.

NATIVE EDUCATION: PROGRESS OF AGRICULTURE IN CEYLON.

It is no exaggeration to say that by industry directed by intelligence and enterprise the rice crops of Ceylon could be doubled in quantity and improved largely in quality. And while admiring the intellectual achievements of some of the more than 800 pupils in Mr. De Soysa's noble colleges and schools, we were glad to hear the Lieut.-Governor and the Director of Public Instruction appreciate the still greater value of the practical education which will be afforded to native youth of the right stamp in the Industrial School and re-modelled Experimental Farm which the large-hearted and munificent De Soysa is about to endow. In connection with this latter institution prizes should be given to young men who distinguished themselves by science applied to the soil in good, honest, manual labour, as well as in theory. And, in connection with the Department of Public Instruction or otherwise, prizes should be given by Government, associations, and individuals, as we some time ago suggested, not only for the best and most productive grain fields but for the best cultivated plots of root culture and their produce; for grafted fruit trees (such as oranges and mangoes) and improved fruits and vegetables of all kinds, from the pineapple to the pumpkin. It is not enough that produce, the origin of which may be doubtful, should be sent to Shows, but persons well qualified to judge should go to the fields and topes and gardens, to examine and report on the style of culture adopted and the results in produce obtained. Specimens of grain should be thrashed in their presence, and yams, sweet potatoes, &c., uprooted, counted and weighed. The fruits could, of course, be examined as they grew, and so with overground vegetables, such as pumpkins, cucumbers, &c. The state of fences, the absence of weeds, and the appearance of general tidiness and care should tell; as also the use of improved implements for tillage and harvesting; the application of suitable manures, &c. To advocate and carry out such measures as these are worthy of the real friends of the natives. No doubt it is one of the principal functions of the press to expose real wrongs and insist on their being redressed. But the case of Ireland shows how the progress of a country and a people can be effectually stopped, and only bad passions and cruel crime fostered, by so-called friends of the country who trade on grievances and invent new ones as the old are righted. If we know ourselves at all, we feel that we are true friends of the natives, and we prove it by not only advocating improvements calculated to benefit them even more than Europeans, such as railways and roads and bridges, as well as education and irrigation works, but by urging the natives themselves to lay aside their effeminate prejudices in favour of sedentary and clerical occupations and to take earnestly to manly industry and spirited enterprize, such as have raised Britain and other countries of the west to the proud eminence they enjoy in civilization, wealth and progress. And the main reason why we make the educational institutions founded and endowed by the native philanthropist Mr. Charles De Soysa the text of such an article as this is, that we believe the gentleman named to be just the model "friend of the natives." Not contented with providing intellectual education for his countrymen he is about to add the means of practical training in those useful arts of life, without which and their application there can be no accummulation of wealth, no increased comfort, no healthy progress, and, we may safely add, no genuine religion. The faith which has done so much for the world is founded on spiritual belief, it is true; but Christianity is eminently practical, and one of its greatest teachers who worked with his own hands as a tent-maker said:—"If any man will not work neither let him eat." We know well that brain work is often the hardest and most weary work of any, but brain work alone can never keep the wheels of the world going or satisfy the necessities of human nature. Those necessities depend for their supply, mainly, on the most being made of the soil, the rainfall and water and the climate: on industry guided by science, in an improved agriculture such as Mr. Charles De Soysa is about to aid by the application, well and benevolently directed, of a portion of his wealth: wealth the origin of which the Lieut.-Governor so truly remarked yesterday was good, hard work on the part of Mr. De Soysa's progenitors. If the Sinhalese are to be ranked amongst the progressive peoples of the earth, they must work not less but more, only with more intelligence, and, therefore, with much greater and more profitable results than did their ancestors.

THROUGH THE TEA DISTRICTS OF NORTH INDIA:—No. III.

(By a Ceylon Planter.)

NOWGONG, ASSAM.

In a previous letter I described the general character of the land in Assam, and discussed some questions in connection with field cultivation and building; in this letter I propose commencing with the consideration of the labour and transport difficulties of Assam, especially in regard to the effect which these have on cost of production of tea. The labour for working tea estates in Assam is procured from two sources, the local villages and the cooly districts of Bengal. The former labourers are known as Cacharris, a term which is applied to all local labour. They are generally engaged for short terms only, and receive R5 and R6 a month, subject to deductions for non-attendance. This source of labour is a very uncertain one, and the class of men are very untrustworthy. On the occurrence of sickness in the lines, they frequently decamp in a body, to the serious loss and inconvenience of their employers, and any row between one of them and the manager will probably lead to the loss of the whole force. They are, in fact, a most independent race, and it requires great tact to manage them properly.

The Bengali labour is generally imported under three years' agreements, on the expiry of which term it is the custom to offer a bonus as an inducement to them to re-engage for a term of years. This labour supply is the only dependable one in most localities, but the difficulties in the way of procuring it are considerable. It is the usual custom to send native recruiters to the villages, but the restrictions placed by Government on the departure of emigrants, though well-meant, make the difficulties and expense of recruiting very great. In some cases European assistants are sent down to supply the gardens with labour, and the work they have to do is of a most unpleasant nature. The bribery of native officials from the lowest to the highest is a necessary preliminary apparently to securing labour. All proposed immigrants are examined by Government officials regarding their willingness to go, and their fitness for the journey; this, admirable though it no doubt is in theory, and necessary though ti may be, adds greatly to the expense the difficulties of recruiting. It is also very generally stated that the local European Government officials do not look on the departure of their ryots, who contribute to the local revenue, and on whom the prosperity of the distinct dep nds, with a favourable eye; and it appears that very little help and guidance can be obtained from them. With the police and other native officials, whose power in the case of native recruiters is absolute, bribery is the only possible road to success.

I met one planter in Assam who had been engaged in recruiting labour personally, and who had, been treated in the most shameful way in consequence. It appears that he visited the labour districts, and through his native subordinates, succeeded in collecting and forwarding the required labour; in doing this it is to be presumed that he hurt the susceptibilities of some native official: for, a short time after he arrived at the estate a warrant for his arrest, signed by a European magistrate at the place at which he had been staying, and granted at the instance of a native headman, arrived at the estate, and he was taken back all the way to Bengal. The charge was one of having wrongfully induced a certain labourer a woman whoseav name was mentioned, to leave the disstrict against her will. A lawyer from Calcutta was engaged to defend Mr. B——, and witnesses taken from the Assam garden to Bengal. The case was then proved to be an utterly false and frivolous one, without the smallest foundation, and it was shown that the magistrate had granted a warrant of arrest for a European planter at many hundreds of miles distance, on the mere statement of a petty native headman, unsupported by any trustworthy evidence. The expenses of the case amounted to R3,000, which the estate had to pay, and no redress was obtained beyond a severe reprimand to the official in question from Government. This case greatly excited public attention at the time, and is evidence of the unfriendly spirit which is said to be shown by the local official mind to the recruiting of labour.

The cost of importing Bengali labour, greatly increased as it is by the local expenses, is a very serious item in the estimate for tea planting and cultivation The amount per head varies in different localities, but ranges between R50 and R100, in most cases closely approaching the latter figure, and the whole of it unrecoverable. Even at this cost, however, it is impossible, in most ca es, for gardens to keep themselves fully supplied with labour, short-handedness being a frequent cause of loss of crop and neglect of proper cultivation. On the expiry of the term for which the labourer has engaged, generally three years, it is the custom to give a "bonus" of R20 or so to retain his services for a further period. This system has at times led to much ill-feeling and loss, the crimping of time-expired labourers having once been common. A proper understanding on the subject has now been come to in most parts, and crimping, or "inslaving" as it is termed in India, is comparatively rare.

The outbreak of an epidemic, or an abnormally unhealthy season, leading to a large percentage of deaths amongst the coolies, means a very serious direct pecuniary loss to the garden beyond what arises from neglected cultivation. All these points, the unreliable character of local labour, the difficulty and expense of importing Bengalis, and the serious loss that an epidemic causes to a garden, make the labour supply, though apparently cheaper, in reality dearer and less satisfactory than that of Ceylon.

We are constantly complaining in Ceylon about the forms which we are required to keep in connection with the medical care of coolies; having seen what the Indian Government require of Assam planters in this respect, I cannot but think that we are comparatively easily treated.

I have before me at the present moment a copy of the various forms which have to be kept on the estates, and duplicates of which have to be forwarded to Government. They are nineteen in number!! A *separate* register of imported, local, and free labourers. A register of deaths of contract labourers, adult free labourers, children under 16, adults living in the lines not on contract, children of all females living in the lines whether on contract or not, and so on, all separate and distinct. Then registers of sick, of vaccination, and of desertion; a daily attendance roll. The monthly return of births and deaths has ( ) columns, and there are also half-yearly returns. In fact, returns of labourers are in their infancy in Ceylon. To appreciate the high pitch of development to which redtape can be brought Assam must be visited.

Every garden has to keep a native doctor of some kind to at'end to the coolies, and groups of gardens in small districts support a European medical man among them: in fact, the cost of medical attendance on coolies is decidedly heavier in Assam than in Ceylon.

One of the chief grievances which planters have against the present labour laws, and the method in which they are enforced, is the great amount of Government interference in all matters between master and labourer. It is the duty of the Commissioner to visit all the gardens in his district, muster the coolies, and make enquiries as to whether they have been paid to date, what their pay is, what tasks they have to perform, what amount of sickness there has been amongst them: in fact, to hear and enquire into any complaints they may have to make.

Of course, when the Commissioner is a sensible man he does his work in such a way as to discourage frivolous complaints on the part of coolies, but the immense power with which he is invested might cause incalculable harm in the hands of an incompetent crochetty man. Amongst other things, the Commissioner has the power to cancel all cooly agreements, and stop cultivation in a garden under certain circumstances, one of which is a death-rate over seven per cent (epidemics apart), another the coolies' pay being in arrears. When I mentioned that in Ceylon it was usual to have several months' pay in hand, and that the coolies preferred getting two or three months' pay at one time, whilst in some cases financial causes have left them unpaid for a year and over, the statement was received almost with incredulity, and I was told that in Assam such a thing was impossible. The system of paying coolies, and of keeping their accounts, is quite different to ours, and very much simpler in the case of local labour. The Sirdar's name is alone entered in the accounts, and against it the total number of coolies who have worked during the month at R3, R4, or R5, as the case may be, and the total sum so arrived at is paid into his hand for distribution. Strange to say, the coolies prefer this system to any other, and attempts to deal with them direct have failed. Imported labourers are differently treated, and more according to the Ceylon system.

Extra plucking is always paid for in cash on the spot, at a very fair rate, generally one pice (¼ anna) per lb. of leaf, the task being ordinary 16 lb. for men and 14 lb. for women; some of tho latter of course making considerable sums during the season in this way. The task is in fact very much the same that is usually got in Ceylon, though, of course, it is always varied in accordance with the size and abundance of the flush. The field cultivation is generally carried on by the local labourers, it being a style of work to which they are accustomed, and requiring less skill and practice than plucking and manufacture which works are mostly performed by tho more per manent imported labourers. The hoeing of land is done entirely by task work, and good coolies will frequently earn double and in some cases almost treble pay in a day. Whilst on this subject I cannot refrain from remarking on the great improvement our decimal system is on the anna and pie system in value in India. With our somewhat elaborate check-roll, the latter system would be most inconvenient. It can scarcely be denied that the close supervision exercised by Government over the imported labourers and their treatment has had a beneficial effect. It is said that at one time the mortality used to be very great, in spite of the large pecuniary interest which planters had in the lives and health of their coolies: this was due chiefly no doubt to the unhealthy state of the country there, but there can be no doubt that the precautions and care exercised by Government have done good.

Another great difficulty in Assam is *transport.* At present goods are carried by cart or boat to the Brahmaputra and thence transported to Calcutta in flats attached to the steamers. The rates charged by the steamer companies are very high, and make the transport of tea from the gardens to the shipping port from two to four times as much as the average rate in Ceylon. The heaviest charges, however, aer on goods taken up to the district, against stream; and consequently the cost of lead, nails, boxes, and machinery, &c., is enormously increased. As an example I was told of some roofing iron for a factory which cost £50 at home, and the freight on which from Calcutta to Tejpore amounted to about R750.

In transport therefore as well as in labour Ceylon has great advantages over Assam at present. At Debrooghur a railway is being made, is partially completed in fact, up through the tea districts, to where a very fine seam of coal is being worked, and there is a talk of this railway being continued in the direction of Calcutta; but the difficulties, rivers principally, seem very great.

The expense and delay of a journey up the river have been already mentioned: a daily service of very fast little steamers is now being started; they carry mails and passengers only, and do the journey from Dhubri to Debrooghur in a comparatively short time.

T. C. OWEN.

No. IV.

LAND REGULATIONS FOR TEA PLANTERS—FROM DHUBRI TO SILLIGORI—THE DARJILING STEAM TRAMWAY.

DHUBRI, ASSAM.

Up to about six years ago, land could be purchased from Government outright, but such sales are not now made, and tea land can only be procured on lease. The terms on which it is procurable are far less favourable than those granted in Ceylon. In the first place the timber on the land is valued and has to be paid for, and it is whispered that the Government assessor, when a native, as is generally the case, is not above accepting an inducement to put down the lowest possible figure. For fees at the outset, R1 an acre has to be paid, the sale is then gazetted, and the land put up at an upset price of R1 per acre. The purchaser then gets it on a 30 years' lease and has nothing to pay for 2 years; during the next 3 he pays 2 annas an acre; during the next 5 he pays 4 annas an acre; during the next 10 he pays 8 annas an acre; and during the final 10 years he pays R1 per acre The expired lease is then renewable at "cultivation" rates, which vary in amount, but are between 10 annas and a rupee an acre per annum.

This system is very easy for young gardens of course, as the amount is no great consideration for several years, but as large reserves of forest are generally maintained, the tax in after years becomes no trifling one, and amounts to a very considerable sum from first to last. The consideration of such subjects as machinery, manufacture, fieldwork, etc., I will enter on later.

The journey from Dhubri to Silligori is a strange and very unpleasant one. A steamer starts from the former place in the morning and takes you to Jatrapur about midday; here you get out and mount a trolly, pushed by coolies, which conveys you about ¾ mile to Dharlla; here you get into another steamer which takes you to Kurigram; thence there are 18 miles of 2 feet railway to the Teesta, which is crossed in another steamer, landing you at Kaunia, from whence runs a branch of the metre gauge railway connecting Sara and Silligori.

These changes, occurring as they did amidst heavy rain, were very unpleasant, but the most trying thing was about half-a-mile of flooded land between the landing-stage at Kaunia and the resthouse. The only possibility was to take off shoes and stockings and wade, the luggage being booked through and inaccessible, and this was rendered dangerous from the extreme slipperiness of the soil under water.

A further change at Parbatipur, where there is a stoppage in a waiting-room between 11 p. m. and 2 a. m, and another at Silligori to the tramway, complete the list, which renders it a tiresome journey at any time, but a most unpleasant one in wet weather.

The Darjiling railway having a special interest for us at the present time, in view of the proposals for the construction of such lines in Ceylon, I will describe its course briefly, and give such particulars as I could gather regarding its working

The engines and carriages are very small as may be imagined, the latter holding three people in a seat, only through the very considerable projection of the floor beyond the wheels at either side. From Silligori the line runs along one side of the old cart road for some miles when it begins to rise at a gradient of 1 in 28, which is maintained almost the whole way up to Darjiling.

At two or three points on the line, complete loops are made in order to gain height, and the way these are constructed is most ingenious. In other places, for the same purpose, the train runs up a regular zigzag, at each turn running into a siding, and then, when the points have been changed, backing on to the upward rails. These turns being always in pairs, the position of the engine in front of the train is maintained.

The curves in the line used to have a minimum radius of 60 feet, and the gradients were as steep as 1 in 22. It was found, however, that this was very trying to the rolling-stock and permanent way, and the course of the line has been changed in many places, so that now the minimum curve radius is 90 feet, and the ruling gradient 1 in 28. These changes in the course of the line are frequent along the lower portions, and in some places the new line is seen running for miles along the one now in use, and which is shortly to be abandoned. All these changes have, it is needless to state, cut up the old cart road terribly, and the latter is scarcely passable for carts: in fact, when the course of the line is permanently settled, the cart road, in spite of its destruction, will have contributed little to help the railway. Up to Teendaria the country through which the line passes is very liable to landslips, the soil is micaceous, and has no tenacity, and every few hundred yards landslips of greater or less extent, which are constantly moving in wet weather are come across. In a spot a loop, which had been made at the end of a spur from the main hill, had entirely collapsed during the late rains, and the engine and carriages had to be taken separately up a temporary line to the top, the passengers walking up a short cut. It is only by the incessant and praiseworthy exertions of the railway staff, that this portion of the line is kept open during the rain, and the greatest credit is due to them for their hardwork. Leaving Silligori at 7·45 a.m., Teendaria is reached at 10·45, and Kurseong at 1 30 p.m. The latter place is the centre for a number of tea estates which adjoin the line, but lower down in the Terai the forest in either side of the road is all Government reserve, kept for the sake of the valuable sal timber it contains.

Leaving Kurseong about 2, Darjiling is reached at 4 p.m. Between these points the soil is clayey, and hence slips are less frequent. The maximum speed at which the trains are supposed to travel is 8 miles an hour, but as a matter of fact the general rate is 10 miles, both up and down hill, and on one occasion, when the train had been delayed by slips, we reached 14 miles an hour on the flat. The actual distance from Silligori to Darjiling is about 50 miles, which takes 8 hours. The stoppages are frequent and unnecesarily long, and there can be no question that the journey could be greatly shortened. The general management of the line seems to be exceedingly bad. In spite of the short time the railway has been in existence, thousands of rotten sleepers are to be seen along the road, arising it is said from the contractor who supplied them, having used the right wood, sal, but having cut them from small trees which had no heart wood. The rails first laid down were too light, and have in parts been replaced by heavier ones to stand the strain round the sharp curves. Another complaint is the strange way in which the enginedrivers are treated. The line is a very difficult and risky one, requiring most careful driving and thorough knowledge of the road, and yet the enginedrivers are being constantly changed and replaced by new men. A short time ago some of the best and steadiest drivers had an increase of pay from R150 to R175 a month, this increase has been suddenly, and, as it appears, capriciously taken away, and the men have lately resigned. Through mismanagement, and the unfortunate character of the country, the expense of the line must have very largely exceeded what was estimated, and yet the company is advertised as paying a dividend of 7½ per cent. In spite of all faults, the railway must be considered a great success, and it is certainly a wonderful convenience, and relief to the Darjiling district. I was unable to ascertain the cost of construction, as the returns have not yet been made up, but it is said that they will shortly be published. On our good roads, and with the experience gained by the Darjiling Company, similar lines should be easy of construction in Ceylon, and would prove a great boon to those interested. The question of constructing such a line, where no roadway exists, is one for professional opinion, but to an outsider it would appear that such a line, with sufficient traffic to support it, in a country so little given to slips as ours is, could not fail to be a financial success.

When figures regarding the cost of the line are published they will not be a fair criterion as regards the cost of a similar line in Ceylon: large allowances must be made for the cost of clearing slips, and for the correction of errors in the selection of engines, rails, sleepers, &c.: allowance must also be made for the double construction of the line in many places.

Two kinds of engines are used on the line, large and small, but the latter are now all being replaced by the former, which are more suitable. The large engines can take up loads of 500 maunds now, and when the new line is opened throughout they will take 600 maunds. The scenery on the line up to Darjiling is magnificent and full of interest. The first part of the way lies through forest consisting almost entirely of sal, the most valuable hard wood tree in this district. The line soon emerges from the forest and commences to climb a spur of the hills, with large valleys on either side, at the bottom of which lie the Terai tea gardens, with their unenviable notoriety as hotbeds of fever and cholera. At a distance it is difficult to distinguish the cultivated land in the slopes from the large area of "chena" and native cultivation with which it is surrounded, but on the plains, which stretch away from the hills to open country, the straight outlines of the tea gardens are plainly marked out in the midst of the heavy forest in which they lie. On the left, two large rivers are clearly distinguishable, the further one being the boundary between British territory and Nepaul, and beyond which any British subject crossing does so at his own risk. On the right is another large river, the Teesta, swollen like the others by the recent rains, and beyond which lie the Dooars, the rising tea district of India.

At Kurseong, where a stoppage is made for a late breakfast, there is a comfortable hotel, into the verandah of which the train runs by a siding. Here the cold air of the hills begins to be felt, and it becomes advisable to change one's white clothes for something warmer. Between Kurseong and Darjiling the highest point reached is at Jore bungalow, about three miles from the latter place, where the train stops for a short time.

Darjiling itself, and the scenery around it, has been often described by able pens, and I will not attempt to enlarge on the theme. The town is situated in the saddle of a mountain with deep valleys on either side, and commands a magnificent view of the snowclad Himalayas, with Kinchinjunga standing prominent as the highest peak; Everest the highest mountain in the range, cannot be seen from here. Tiles for buildings must be a great difficulty in Darjiling, as every house has to be cut out of the hillside, or built up, and the appearance of the houses dotted about in the hillside is most picturesque. In the cold weather, the station is frequently deep in snow, and the forest trees in the neigbourhood, by the numerous dead branches they bear, give evidences of the very heavy fall of snow which occured last winter, when most of the roads in the vicinity were covered to a depth of a foot and eighteen inches.

T. C. OWEN.

THE EXTENSION OF INDIAN IMMIGRATION TO THE NATIVE STATES AT THE STRAITS.

From the *Straits Times* we quote as follows:—

The Official Note published in yesterday's *Gazette*, embodying the principles on which emigration from India to the Straits Settlements will in future be conducted, is a long and elaborate one. It is signed by the Hon. E. C. Buck and Major Fischer, on behalf of the Indian Government, and by the Hon. Major McNair, the Hon. W. E. Maxwell, and Mr. Sneyd-Kynnersley, on behalf of the Straits Government. It may be taken, we presume, to represent the views of both Governments upon this long-vexed question, both Governments being now in accord upon the point that Indian Immigration to the Straits is a desirable thing, and should be encouraged and made as free and unrestricted as the nature of things will allow. It may also, we imagine, be taken for granted that the views and wishes and experience of the planters of the Straits, who met the Commission in Penang, have been taken into account, and weighed as fully as they deserved. As it seems to be intended to pass an Ordinance enacting as law the principles embodied in the Note, full opportunity will be given of discussing them in the Legislative Council. From a cursory perusal of them, they seem to be as fair and reasonable as any regulations can be, if it is granted, as we suppose it must, that regulations are necessary at all, and free and unrestricted immigration would not be preferable. The Note closes with the important announcement, the result of Mr. Buck's visit, that "all objection to the engagement of Indian coolies for labour on estates in native states on the Malay Peninsula in which there is a Resident subordinate to the Governor of the Straits Settlements will be withdrawn by the Government of India. Indian labour may be introduced in these States in future as freely as into the Colony, on the understanding that all regulations introduced into the Ordinance to be in force in the Colony affecting the statute-labourer shall be carried out under the direction of the Resident and his Officers, and that the Straits Government will guarantee that this is done."

It is proposed that the general superintendence of Indian immigration will be under the charge of an officer with the title of "Indian Immigration Agency," instead of "Protector of Immigrants," and this Officer's powers will extend to the Native States. A draft Ordinance has been drawn up by Mr. Buck and Major Fischer, in communication with Mr. W. E. Maxwell, embodying the principles of the Note, which will submitted to the Legislative Council. In this Ordinance it is proposed to prohibit as far as possible the emigration of Indian coolies to the Colonies of other European Powers with whom the Government of India has no convention or to the neighbouring Asiatic States not under British protection. This will not apply to traders, shopkeepers, &c., but it is proposed to make it penal in the Colony for any Native of British India to leave the Colony for any place other than British India, unless he is provided with a certificate stating that he is not a labourer or of the labouring class. These certificates will be issued by the Indian Emigration Department at Madras, or by the Indian Immigration Agent's Department here. It is also to be made penal for the master of a vessel or other persons to convey uncertificated immigrants from the Colony. It is left to the Legislative Council to fix whether contracts for labour shall be for two or three years, but a work-day is fixed to consist of nine hours' actual work. [The effect of the concession made to the Straits Settlements and Malay native State, will be an appreciable competition with Ceylon for Tamil labour.—ED.]

HANDBOOK TO THE FERNS OF BRITISH INDIA, CEYLON AND THE MALAY PENINSULA.

BY COL. R. H. BEDDOME.

With 300 Illustrations. Calcutta: Thacker, Spink & Co., 1883. [Printed in London.] Impl. 16mo. pp. xiv., 500. [Price in London 18s.]

It is scarcely necessary to say that Ceylon is a country eminently rich in ferns: it is so, not only in mass of individuals, but in number of different kinds. The latter fact is best realized by a comparison with the flowering plants of the colony; if we reckon our species of ferns at 230—a fair average of conflicting views—this is a larger number than is possessed by any natural order of Phanerogams represented in Ceylon, and indeed is not far off 1-12th as many as the whole of our flowering plants. This implies a wet well-wooded country with considerable elevations, conditions which are met with principally in the S. W. quarter of the island: in the N. half and on the E. and W. coasts, ferns are but few and far between.

In the excellent manual before us the area treated of embraces besides Ceylon the whole of British India including Burmah and the Malay Peninsula—in fact it is precisely that of the "Flora of British India" now in progress—and the total number of species described is 570, so that Ceylon possesses over 2-5ths of all the ferns found in this extensive region.

It is also an obvious fact, that, from some not very evident cause, ferns have become of late years in Ceylon as elsewhere, much more than any other group of plants, objects of interest to amateurs and collectors. Many persons who never think of closely observing the trees, shrubs and herbs they see around them are yet keen and devoted fern-hunters; and the botanist is often amused by being asked by these if he has collected any new *ferns*, as though no other plants could possibly be the object of his researches. This remarkable popularity has led to much careful examination at many hands, and here in Ceylon it is not probable that much more remains to be done in the way of discovering new kinds. Yet how careful search is rewarded, even in a well-worked field, is evidenced by the discovery, some years back of two new Filmy-ferns (*Trichomanes parvulum* in Kelebokka and *T.* "*Wallii*"—not yet described—at Labugama) and more recently of a Maidenhair (*Adiantum æthiopicum*) in Dimbula and a tiny adder's tongue (*Ophioglossum lucitanicum*) on Dambulla rock. Of these we notice that only the *Adiantum* is given by Col. Beddome for Ceylon, and he has also omitted to credit us with *Ophioglossum nudicaule*, *Gymnogramma leptophylla*, and (a more singular oversight) the common *Cheilanthes tenuifolia*.

Collectors in Ceylon have long wanted a trustworthy guide to enable them to ascertain the names of their Ferns, by bringing into a convenient form the material contained in a voluminous and costly literature. Dr. Thwaites' catalogue contained in the last part of his "Enumeratio" (1864), and admirably worked out at first hand, has of course been the basis of our knowledges and the subsequent work of Baker, Beddome and Clarke in Indian Pteridology has been recorded and made available here by the catalogues of Mr. G. Wall and Mr. W. Ferguson. But in none if these are any descriptions given, and they have not therefore met the want alluded to.

This is, however now fully supplied in the present Handbook, and no one could be better qualified for the task than Col. Beddome. His 24 years' official connexion with the Forests of S. India gave him every opportunity for extended and repeated observation and collection; of these he fully availed himself, and long since earned the gratitude of botanists by the extensive series of 660 quarto plates, with descriptions, of the ferns of India, the publication of which extended over many years and will always form a standard work of reference. In his present small book he gives us a duly classified condensation of his larger works revised and brought to date; his retirement and residence near London having enabled him to fully avail himself of the great herbaria, and test by reference to type-specimens all his previous determinations. We have now brief but sufficient descriptions of every species, references, localities, distribution over the globe and often critical observations. The illustrations add very greatly to the practical usefulnes of the book, fully 3-5th of the species being figured. They are reductions by some photographic process of the large plates already alluded to, and are used in the most handy manner by being intercalated with the text. As each figure is lettered with the name of the plant, the running series of numbers seems unnecessary, especially as there are no references to them in the text, though the exigencies of the printer have sometimes divorced the figure some distance from its descriptive letterpress. A scale should also have been given, as the figures have not been all equally reduced. The get-up of the volume is all that could be desired, beautifully printed and singularly free from misprints; almost the only error noticed is the curious one which dates the preface 50 years ago. There is also a full index, and (a minor mercy yet one for which thanks are due to the publisher) the book is issued with the leaves ready cut.

A few words may be said with reference to the *nomenclature* of Ferns, and the causes of its great complexity. In Mr. Wall's check-list of Ceylon Ferns, printed in 1879 for labelling collections, the names given are those of Hooker and Baker's "Synopsis Filicum" and these are no doubt generally followed. It contains 215 species (and about 30 varieties and forms) arranged under 43 genera; Colonel Beddome's Handbook gives us only 225 species (and about 20 varieties) but these are placed under no less than 70 genera. It is this difference in the estimate of genera that is the principal cause of the variation of names. Those who have been accustomed to consult the large works of Beddome will be prepared to find him employing as genera the names used to define sub-genera only in the "Synopsis Filicum." Botanically this course has much to justify it, but one outcome of it is that the names of fully half of our Ferns become different from those to which we were accustomed. This is a serious matter for the amateur who thinks a Fern should have one name and stick to it; as a matter of fact most have as many names as a London thief, an Irish rebel, or any other person who does not wish to be too easily recognized.

So difficult indeed has it been found to group the Ferns into any really natural and well-defined genera, and so many and various have been the attempts, that the synonymy has become at last so intricate and involved that the ordinary laws of botanical nomenclature have had to be relaxed, and a different principle—that namely acknowledging a right of priority in specific names alone whatever may have been the genus under which they may have been first published—permitted. But this concession has by no means lessened our name-changes: rather has it increased them, for pteridologists think themselves now bound to use the original specific name when discovered, and thus many well-established later names have to give way. Thus our well known *Gleichenia dichotoma* has to become *G. linearis* because long years ago Burman called it "*Polypodium lineare*." This is a rather technical digression, but may partially serve to explain how it is that ferns have so many names.

How thoroughly the Indian Ferns must now be known is clear from the fact that the present book contains only two new species. Col. Beddome's views on species-limitation are moderate; he has reduced to varieties, however, more of our "species" than he has raised "varieties" to species, so that on the whole our Ceylon Fern-list is a little reduced. Twenty-three species are given as peculiar to, or as it is termed endemic in, Ceylon. Colonel Beddome follows Mr. Clarke in giving *Cyrtomium falcatum* for this island, but the authority for this statement is not given.

There need be no hesitation in cordially recommending this Handbook to all interested in the beautiful plants of which it treats, and predicting for it the wide circulation it deserves. H. T.

NOTES ON STRAITS SETTLEMENTS.—No. 10.

By H. Cottam.

THE LARUT GARDEN—BUNGALOW—SUPERINTENDENT'S HOUSE—COFFEA ARABICA—COFFEA LIBERICA—CINCHONA LEDGERIANA—BAD SOIL—WESTERN ASPECT—RAINFALL—VIEW OF THE MINES AND TOWN OF THAIPENG—THE NURSERIES—MY POOR CINCHONA SEED—TRACING AT A GRADIENT OF ONE FOOT IN SEVEN—MAXWELL'S HILL—BIRCH'S HILL—THE SANATORIUM CLEARING AND GUNONG HEJOU—GRAND VIEW OF PERAK, PENANG AND OTHER ISLANDS

The Larut garden was opened about the same time as the Gapis mountain experimental garden, but somehow or other has not been planted entirely. Underneath the sanatorium bungalow there is a small field of about five acres of *Coffea arabica*, and this was in a matted state like so many umbrellas. After looking round amongst the Klings we found two who had been to Kandy and knew how to prune, so at it we went and soon whipped the coffee into shape, opened out the centres Haputale fashion: the result was a fine blossom, set in March, and leaf-disease almost disappeared though still hovering around as a kind of "sword of Damocles" hanging by a thread ready to totally annihilate. There were about 6,000 or 7,000 coffee plants in beds and under trees, and these we fostered and planted out into the clearing. This was of course after I had taken over charge of the garden, for Mr. Wray (junr.) is actually the curator of the Perak Museum, though at present the Perak Museum is a myth! However, specimens are being got ready, by the curator, and the present site of the Museum is underneath the court-house. The superintendent's house on this wonderful Larut garden is like one of your pulping-houses, bertum leaf, attap roof and planked, with sliding window shutters to economize glass two rooms, not exactly snug, because the wind gets in through the cracks in the floor and wall and bullies nature's soft nurse on stormy nights. I found a couple of bags of coffee very badly cured in the bungalow: the Klings gathered it for my predecessor by contract for so many cents a kattie, and the way they pulped it was by using their paddy pounder instead of the fingers and thumbs: the consequence was as you would naturally suppose a rotten sample of parchment with 50 per cent black. Since Mr. W. left, this system has been quite abolished, and the cherry gathered and brought to me to be cured properly for the Calcutta Exhibition. The 2,500 *Coffea liberica* we gave Mr. L. Wray from our lower garden are alive but not doing so well as they might have done; the soil is bad, the aspect western, and the elevation too high and cold for them; they may, however, do better when warmer weather comes. I am writing of what appeared in February last, and this is July, a warm month, and the Liberians are making an effort like Mrs. Dombey, and will no doubt "get much stronger."

Let it be remembered I am only making a casual report on the Larut Garden, having nothing to do with it at the time, but only living on it in my bathing machine between the sanatorium bungalow and the superintendent's house. Why Mr. L. Wray was retained as superintendent when drawing curator's pay is still a mystery to me? Of course we got wet every day in the jungle, the rainfall on this side of the country being over 300 inches per annum! The view of the mines and town of Thaipeng, with sometimes a view of Penang, could be obtained in fine weather, and when not obscured by mist. The nurseries here were miserable arrangements, the sheds badly made and leaking and the beds not prepared soil, but just shovelled together anyhow, with clods as big as a coconut: so much for cheap and nasty work, though doubts may be entertained as to the cheapness of the work. My poor cinchona seed was nowhere, just sown broadcast on a lot of clods without side shade to the beds and the roof leaking, miserable apology for nursery making. I never saw such plantation work in all my life as was to be met with on this Larut Government experimental garden. As for the Ledger plants put out into the clearing, one would hardly guess they was cinchonas of any kind little thinking, that they were the far famed Ledgeriana Cinchona, planted out 3 *feet high* with a pair of small leaves at the top like miniature coconut trees. Some of these monster *Ledger seedlings*, (two years in nursery I do not believe) were propped up between two thick stakes, and reminded the writer very much of an old gentleman between two policemen, who lost his way on Christmas night after dining not wisely but too well. To keep these extraordinary ledgeriana seedlings in position a piece of coir rope has been tied round the poor things' necks and attached to the stakes before mentioned. Was ever anything so absurd? Then the road making, nearly all of it is traced at a gradient of one foot in seven, a very ugly gradient and very expensive to maintain in order, at the extravagant rates of wages and contracts paid to Malays and Chinese. The road to be traced is a most difficult one to trace, but this we shall come to in next letter (No. 11.); suffice it to say that there are three mountains or big hills to wind round at the base before reaching the foot of Gunong Hejou, Maxwell's Hill named after Assistant Resident Maxwell and who by-the-bye is always very highly spoken of by the "colonists" of Perak—officials rather, for colonists there are very few indeed, nearly every one in the place being directly or indirectly connected with the Perak Government except Capt. Schutze of Waterloo, and the new arrival the manager of the French Company, Mr. McIntyre and Australian staff and one or two more Birch's Hill is named after the lamented Mr. Birch, late Resident, who was murdered by the Malays. This hill reaches an elevation of 4,200 feet above sea level, and a few trees have been felled to enable visitors to get a comprehensive view of the surrounding country, and the sea coast. Two or three trees are still standing, and covered with initials of cockneys who have spent a "'appy day" by ascending to Birch's Peak. The sanotarium clearing at the foot of Hejou, or rather on a sharp spur connecting Birch's Hill with Gunong Hejou, offers a still better view, including Kwala Kangsa and the Perak river on the one side, the Government experimental gardens at Gapis; and Thaipeng to the right of Schutze's 5,000 acres of forest; perhaps this is the finest view to be got in Perak. Great things are to be done at the sanotarium clearing. A big house or bungalow to be built, a lawn tennis court, ferneries, orchid-house, flagstaff and goodness knows what, and the superintendent, whoever he is then, will be expected to work up there every day, get himself ill by not getting his grub, and all for $60 a month. True he will get a grand view of Perak and Penang and other islands, but might just as well turn lighthouse keeper in the middle of the broad ocean, unless he be a married man, and then of course his anchor is down for life.

There are numbers of visitors to Maxwell Hill sanotarium bungalow, who first have to ask permission from the authorities of the Perak Government to go up the hill for a few days or weeks, and in some cases officers of the Goverument are sent up. On the whole this is rather agreeable than otherwise to the superintendent, as he gets somebody to talk to of an evening and exchange a few growls, which of course does the liver a world of good, and rubs off the accumulated mould, and the moss people talk of, gathered by those good people who are not rolling stones. When very young, we remember possessing a very superior plaything called a kaleidoscope; well, when you gave it a twist, something new, beautiful and startling appeared to view, and such is the case with the Maxwell's Hill bungalow, every new arrival seems somewhat different in manner, appearance, and ideas, and as for hobbies, bless you, they are too numerous to mention; the hobbies of the genus globe-trotter consist in non-perishable articles such as sticks, rattan canes, and *Penang lawyers*. Now a Penang lawyer seems a queer name for a walkingstick and requires some explanation. To begin with, Penang means arekanut, and lawyer a corruption of the native Malay name given to this particular variety of wild arekanut; but suppose we regard the stick in its literal English meaning, no one can deny that as a Penang lawyer, to say nothing of the direct saving of six shillings and eightpence, the argument would be a very forceable one indeed! With all the rapid progress made with the tin mining enterprize in Perak, where, on the mines are naturally daily disputes, it is strange to say, but nevertheless true that there is not a single lawyer in Perak. What a monotonous place Sinhalese must think Perak where they cannot indulge their little weakness for litigation and stake their last cent on the glorious uncertainty of the law. It should always be borne in mind, that under a despotic Government where lawyers have been hitherto tabooed; in the event of annexation to Great Britain, the first select few would have a fine field open to practice here in Perak, the people being wealthy and the courts very busy as a rule, for the Chinese follow out the advice given by the old Governor to his son, "Make money—honestly if you can, but mind you make it."

NOTES ON CINCHONA BARK.

By David Howard.

A curious evidence of the singular scientific acumen shown by the late Mr. McIvor in working out his process for renewing cinchona bark is given by some of the samples of "renewed" *C. succirubra* bark which reach us from Ceylon.

As is well known, in Mr. McIvor's process, alternate strips of the bark were removed down to the cambium, and the tree wrapped round with moss. The bark then renews over the whole surface, the new bark consisting almost entirely of cellular tissue, the total alkaloid being increased, and the cinchonidine giving place to quinine.

The "renewed" bark to which I call attention, on the other hand, shows a totally different structure; there is a mere skin of cellular tissue, the remainder being remarkably fibrous.

The explanation is not far to seek, the shaving process recommended by M. Moens as a substitute for Mr. McIvor's process gives good results just in proportion as it imitates the latter process. If the cut is sufficiently deep to cause the effusion of new bark, if I may so call it, the result both in quantity and quality of the renewed bark closely resembles that yielded by the stripping process.

But if, as is often now the case, the shaving is merely superficial and carried all round the tree the result is entirely different; in this case there is little or no formation of cellular tissue to replace that removed, a fresh epidermis forms, but apparently the circulation is carried on in the remaining fibrous tissue, which in fact seems to be developed further. The alteration in the competition of the alkaloid which is so characteristic of the true renewal does not take place in this case; if there is any change it is rather in the direction of an increase of the cinchonidine instead of quinine.

The subject is not merely interesting from the light it throws upon McIvor's process, but is one of great commercial importance. Unless the shaving process is so carried on as to produce, at least in part, the beneficial results of the older process of renewal it will lead to grievous disappointment, for the trees seem to suffer more from the wrong treatment than from the right.

It is to be feared that in many cases the temptation to get a quick return from the plantation by over-frequent and unskilful shaving is risking not only the quality of the crop but the health of the trees. Some planters are even advocating a return to the barbarous system of coppicing; but it is difficult to believe that this will generally be the case, with the strong evidence before their eyes of the benefits to be obtained by the more scientific system of treatment.

I do not venture into the vexed questions of hybrids and species in red bark; but when I find that "red bark" can be obtained yielding up to 4 and 5 per cent. of quinine from natural bark, I am very sure that there is a great field for skill in the selection or cultivation of cinchonas. There is much to be learnt in these matters. In the last drug sales, some samples of bark marked "hybrid" gave 4 per cent. of quinine, while others, also "hybrid," gave only 1 per cent. of quinine.

It is evidently no easy matter to distinguish by the eye the different varieties of trees which produce red bark of widely different quality. Some time ago I analysed a number of samples of bark from individual trees, sent me by J. A. Campbell, Esq., from Ceylon. They were renewed bark from trees giving red bark of very fine quality; the plants were all from the same nurseries, and were supposed to be of identical quality.

I found, however, that they varied very widely in the richness of the bark, as will be seen from the following table:—

	Quinine.	Cinchonidine.	Cinchonine.	Quinidine.
No. 1	... 6·2	0·3	0·3	0·1
" 2	... 2·6	0·6	trace	0·4
" 3	... 2·0	1·6	1·2	0·2
" 4	... 4·0	0·2	0·2	0·1
" 5	... 4·0	0·2	0·7	0·7
" 6	... 2·3	0·5	1·2	0·8
" 7	... 2·3	0·9	1·7	0·0
" 8	... 2·8	0·3	1·3	0·1
" 9	... 4·1	0·1	0·2	0·1
" 10	... 3·9	0·1	0·2	0·2

Mr. Campbell tells me that "notwithstanding the extraordinary difference in the analysis there is little difference to be seen between the most of the trees. Some are pubescent, however, and some are glabrous; some have rounder leaves than others and in some the flower is white, except in the centre of the corolla tube which is pink. Others again, have pink flowers. No. 1, 2, 4, 9 and 10 are what we used to call hybrids; of these 4, 9 and 10 are much like officinalis in leaf and bark. No. 2 is sub-pubescent in leaf and only a moderate grower, the leaf being rounder than 4, 9 and 10, and lighter in colour. No. 1 is exactly what we would imagine, from Mr. Cross and Colonel Beddome's description, to be a true Pàta de Gallinazo. Leaf glabrous shiny on upper surface, soft, flat, and pointed at end; a fine grower considering the soil it is in." It is evident, therefore, that no general description will suffice to guide a planter in selecting the best sorts, but that the subject requires a minute study of individual trees of which the bark has been analysed.

Calisaya bark shows equal variations between different trees. I have found individual trees growing together in Ceylon to vary from 3·1 per cent. to 9·2 per cent quinine, and individual trees similarly growing together in the Wynaad to vary from 7·6 per cent. to 0·7 per cent of quinine.

These variations can hardly be attributed to soil; the red barks were all growing in similar soil and under similar circumstances, and the Ceylon calisayas were also apparently growing under similar conditions.

No doubt soil does influence the richness of the bark to a very great extent; samples of bark from trees grown on poor soil, as far as my experience goes, always test below similar barks on rich soils. The richest bark, both succirubra and calisaya, that I have tested from Ceylon has been from land richly manured for coffee.

I think I have given instances enough to show how great are the possibilities of advantage in selection of the richest varieties of bark, while the study of soils, and the best mode of manuring and of preserving the bark, offer a wide field for profit to the intelligent planter. It is evident that if an 8 per cent. bark can be obtained from a tree giving an equal crop to those yielding 1 per cent. bark the increased value of the crop must be out of all proportion to the extra care in selection. Whether planters will have to adopt grafting or propagation by layers or cuttings, or whether it will prove practicable to obtain certain results from selection of seed or plants, is a matter of experience. Everything points to a great overproduction of inferior bark, but there is little fear of the better qualities bringing remunerative prices if wisely cultivated.—*Pharmaceutical Journal.*

COFFEE PLANTING IN JAVA.

Even now while old King Coffee is, in Ceylon, metaphorically, if not literally, in the shade, our readers may be interested in the curious account of coffee culture in Java which we quote from the *Queenslander.* As the writer, Mr. A. J. Boyd, received his information second hand, it is not surprising to find him falling into mistakes. For instance, it will be news to Ceylon planters that pruning includes the process of "making a few nicks in the stem, and wherever those nicks are made a new branch will appear." Instead of choosing ground for a coffee estate "at least 500 feet above sea-level," we in Ceylon with our experience would say "at least 1,500 feet," but we certainly should not insist on every stump being cleared away and the land left like a garden in appearance before attempting to put in a plant. As we choose rainy weather for planting, too, it is only in very exceptional cases indeed that coffee plants are watered in Ceylon. With an average of 1,200 plants to the acre, the operation would be fearfully expensive. As in Java they plant 8 7 feet, the number of trees to an acre is only about 780. Taking the average yield per acre, then at 6 piculs (3 to 9 specified) of 136 lb. each, we get 816 lb. or rather more than 7 cwt per acre, and over 1 lb. per tree. Before leaf-disease, grub and unfavourable seasons attacked our coffee so disastrously, the average yield per acre in Ceylon was little, if at all, below that of Java. With the fewer trees in Java, the rate per tree was of course higher in the Dutch colony. Does it accord with experience in Ceylon that "red berry" as gathered from the trees in the "pluks,"—"voor," "main," or "full," and "after," loses in the process to clean coffee 61·75 per cent of bulk and 81·8 per cent of weight—that is that 100 lb. of "cherry coffee" yields not quite 19 lb. of marketable beans? We know that the average result of a ton of parchment coffee as it comes down by our railway is 12 cwt., so that the reduction at this stage is 40 per cent. We can easily believe, considering the amount of moisture in cherry coffee, that, at least, 40 per cent is lost in pulping. The Java cultivation is a reduction equal to 55 per cent of bulk and 41 per cent of weight in the pulping process. It is a curious result, if correct, that the weight of the parchment skin should be 1·8 per cent more than that of the pulp: the loss by pulping being 40 per cent, and again by clearing away the parchment 41·8. Wages of 6d to 10d per diem, *plus* the produce of a rice field, are not bad. The number of labourers per acre agrees pretty closely with what was common in Ceylon, but the Ceylon planters do not believe in "talgrass" growing amongst young plants, any more than in shade trees for the mature, unless indeed the influence of shade trees on *Hemileia vastatrix* is found to be as good in other places as a recent visitor to the Kelebokka valley found was the case on an estate there. Our readers are, of course, aware that the *dadap* of Java is an *erythrina*, and it is an *erythrina* which is the "mother tree" of cacao in South America and the West Indies. As the *erythrinas* cast their leaves once a year, they let in plenty of light and air periodically, besides the supply of manure from their leaves. The *Albizzia Moluccana* is a grand shade tree (the leaves turning down at night), but the objection to it is its exceeding bitterness. We are surprised to find the life of a Java coffee tree valued at only 20 years, but careless treatment and rough handling may shorten the life of the plants, although we scarcely see why they should be held responsible for the introduction of leaf-disease as well as the aggravation of its effects. The rich, volcanic soil is much in favour of the coffee in Java, but we suspect we have not yet heard the last or the worst of coffee disease in that region. The calculations as to cost of production, preparation, &c., will be interesting to Ceylon planters; but when *everything* is taken into consideration we confess we doubt a profit of 50 per cent. Actual results are generally much lower than those shown on paper. At this time of day the pulper figured is primitive enough, being worked by hand labour; but they have now some of Messrs. John Walker & Co.'s best pulpers in Java.

COFFEE PLANTING IN JAVA.

By A. J. Boyd.

[written for the "queenslander."]

The following information respecting the cultivation of the coffee plant, and the after treatment of the berry, was obtained by the writer at Batavia from a planter of many years' experience at Sourabaya. That gentleman very kindly gave me the fullest particulars when I told him that I wished to publish an article on the subject for the benefit of Queensland. It may be relied upon that the information is correct, as I verified it on another occasion by questioning other experienced settlers in Java.

Having selected a suitable locality, at least 500ft. above the sea level, the first thing to be done is to prepare the ground by clearing and burning. Every agriculturist in Queensland knows what clearing scrub land means, so there is no need to describe the process, which is precisely similar in Java, with this exception, that whilst the Queensland farmer merely burns off the scrub timber, and plants corn for the first three years amongst the stumps, the Dutch planter clears his land of trees and stumps, and undergrowth, and leaves his land like a garden in appearance before he attempts to put in a plant.

The ground being prepared, he procures

THE SEED,

which fluctuates in price, but may be set down at an average of 50 guilders per picul (136 lb.). (A guilder is equal to about two shillings.) The seed is sown in beds, at distances of 2 in. apart, and the beds are then shaded with grass.

As soon as the plants are about 8 in. high the planting out must commence. The planting seasons are in April and October.

The ground is marked out in rows 8 ft. one way and 7 ft. the other. The land on a hill side is terraced, and catch drains are runs cros the hill from east to west to a catch the wash during heavy rains. The seedlings are planted in hollow drills at the distances above mentioned (8 ft. by 7 ft.) in soft holes. The tap root must be carefully guarded from injury, and each plant must be watered when planted. When the seedling stands properly in its hole (the tap root not bent) loose mould is to be drawn in around the roots, but all the pressure must be done *on top*—the soil surrounding the tap below must not be pressed. The seedlings being thus carefully planted,

SHADE TREES

must be provided for, as the coffee plant requires shelter from the too fierce rays of the sun. It is, however, better to let the plants grow a little before putting in the shade trees, as the required shade can be provided at first by allowing the tall grass to grow between the plants, but not very close to them. The shade trees most generally used are the *Dadap* (native name), *Albizzia*, and *Sengon*. The first is the best, and gives the right amount of shelter. When the plants have grown up a little the shade trees may be planted, one being in the place of every fourth tree. Thus, if there is a row of four coffee trees, the next tree on either side will be a dadap. Thus an area covering 672 square feet will be protected by four shade trees. When the coffee plants begin to take root, and are 2 feet high, the stems of the shade trees should be 5 feet high.

When the trees grow up, if the roots of a shade tree are found to interfere with those of the coffee plant, the former should be taken up and a fresh one planted On the

TREATMENT OF THE PLANT,

after these preliminaries have been carefully attended to, depends the success of a coffee plantation. In the first place, no hoe must be allowed near the stem of the tree, and in this respect the coffee tree resembles the orange tree, which suffers materially if its surface rootlets are cut by a hoe. All weeding near the tree must be done by hand. At the age of from two and a-half to three years the trees begin to blossom. This blossom is much like that of the jessamine. In a short time the blossom falls and the coffee bean appears. Now is the time to work zealously at the destruction of weeds, but as soon as some of the beans begin to turn red all work at weeding must cease and no more must be done to the ground until the crop comes off. If the tree during its growth should shoot too freely, the practice of "topping" adopted by the planters of Ceylon, must be resorted to.

HOW TO TOP.

At the top of every coffee tree there is a bud. This must be nipped off with the finger nails. The strength of the tree will then be diverted to the branches and the tree will not grow higher about 7 feet which is considered the proper height in Java. Pruning should be done very carefully, and with great judgment. Too many branches must not come away, as the crop lies along these branches. If pruning has to be done a few nicks are made in the stem and wherever these nicks are made a new branch will well appear.

The work of bud-nipping and pruning (*i.e.*, of causing additional branches to grow) having been duly performed, and the branches subsequently being laden with the green berry, the "voor pluk" comes on. This is the first gathering of ripe seed, and the yield may be said to be merely nominal.

The "voor pluk" begins in February, the "main pluk" in May or June. This is the "full pluk," when the heavy portion of the crop is gathered. The "after pluk" is a general sweep of fallen seed.

Plucking must be got through in two months. Now give the trees a rest, and let no work be done amongst them. By-and-by hoeing must be carried on as before. But the rest must last about a month.

YIELD AND DURATION OF LIFE.

The coffee tree is at its best and bears most freely at the age of five years. At this period of its existence, in good seasons, it will yield an average of from three-quarters of a pound (English) to one and a-quarter pound of clean coffee. Should signs of failure be visible, the trees must be renovated with a good top-dressing of well-rooted manure, and the top-dressing must be lightly covered with soil. Properly handled, a coffee tree will last for from fifteen to twenty years; but if carelessly treated and roughly handled the coffee leaf disease is certain to put in an appearance, and as a consequence the plantation will go to ruin.

TREATMENT OF THE FRUIT.

I now come to the working of the berry, and will suppose the planter to have taken off a fair average crop. There are two ways of working the fruit.

The common preparation is as follows:—The ripe beans, when they come from the tree, are emptied out on a drying ground until ready for hulling. This drying ground slopes gently away from a centre, and allows all moisture to drain away. In about a month, or if the weather be exceptionally fine in fifteen days, the beans are dry enough for "hulling." This operation will be easily understood to mean taking off the dry "hull" or husk of the bean, and is easily performed in a machine for the purpose, called a trough mill. All the black seeds are sorted out, and then the second quality is taken out separately. The value of these two qualities is as 40 guilders to 18 guilders per picul (136 lb.). The second quality will average 20 per cent of the whole.

By the second process, called the West Indian preparation, the coffee is put into a pulping machine, with water at once from the tree. The pulper takes off the outer red skin, and the bean, separated into its two halves, falls into a reservoir beneath. The water is now let in, and the beans well washed. The empty beans and light skins float, and are skimmed off.

The coffee is allowed to remain in the reservoir from thirty to thirty-six hours, to allow of fermentation setting in. This process is necessary for the purpose of removing the inner silver skin, and if well carried out the object is perfectly achieved; but with careless fermentation the silver skin adheres to the berry, and cannot afterwards be removed. From the pulper the berries are removed to the

DRYING GROUND.

There it is spread to a depth of from 4 in. to 5 in., and remains until it has become quite crisp. Arrangements must be made by which the coffee can be shovelled and covered if a shower of rain should come on. The drying grounds are, as before stated, slightly dome-shaped, and the floor cemented. In size they average 100 ft. long by 70 ft. broad. Three of these are required for every fifty acres under coffee cultivation.

Artificial drying by means of hot air pipes is now going on, and the cost of this method only reaches 35 to 38 cents per picul of dry coffee, as against 1 guilder 50 cents to 1 guilder 80 cents per picul by the old process.

COST OF CULTIVATION.

In order to make this portion of the present article intelligible to the reader unacquainted with Dutch terms, I must make a few explanations.

Land, in Java, is reckoned by the "bahoe" (pronounced *bough*.)

A "bahoe" is equal to 7,050 mètres, or about 1¾ acre.

A "takka" is a small measure of 516·5 cubic inches capacity; and 65·32 takkas of Red Berry produce 136·21lb. English of clean coffee.

"Red Berry" is the ripe fruit as it comes from the tree.

"Glondong" is the dried Red Berry; "Native Glondong" is the Red Berry with 4·7 per cent of water remaining in it.

"Parchment," or "Gaba" (the Malay name), is pulped coffee, with the inner skin not removed.

"Gewone Bereidung" (ordinary preparation) is the term for coffee unpulped.

"W. I. Bereidung" is the wet preparation (*i. e.*, pulped.)

A "catty" is the 1-100th part of a picul.

WEIGHTS AND MEASURES.

English lb.		Amsterdam lb.		Kilogrammes.		Piculs.
2240	equal	2056·42	equal	1016·4	equal	16·4514
112	,,	102·80	,,	50·84	,,	·8228
28	,,	25·70	,,	12·71	,,	·2057
1	,,	·918	,,	·4536	,,	·007348

NOTE.—1 A. lb.=1·09th English, but shows 1½ E. lb. per ton extra. 136·2 E. lb.=1 picul, but shows ½ E. lb. per ton extra.

The reader will, after studying the above figures, be in a position to comprehend without difficulty the cost of carrying on a coffee plantation, and of manufacturing (if I may use such a term) the marketable commodity.

Each "bahoe" requires one man and his family for its cultivation. They have one thousand trees to attend to; but of course during the plucking season as great a number of hands as possible is put on in order to get this important work over in two months. On an estate comprising 500 bahoes (875 acres) about 800 pluckers will be employed. A single girl will pluck about 150lb. of Red Berry per day.

The cost of plucking varies, but may be set down at 2 rupees (1s. 8d.) per picul of 136 lb. of clean coffee. Six piculs of Red Berry equal 1 picul of clean coffee.

The wages for cultivation are very trifling. There is a teeming population of workers in Java, and, as a consequence, wages are almost nominal. The style of payment in vogue in Java is to give a man a bit of rice ground, on which he grows his own food, together with about 30 to 50 cents (6d. to 10d.) per day. The plantation hands live contentedly on this, what would appear to us in Queensland, miserable pittance. But when I state that for less than one penny-halfpenny I succeeded in satisfying an average English boy with cakes at Batavia it will be seen that the simple wants of a non-carnivorous race such as those inhabiting Java can easily be supplied.

THE YIELD OF COFFEE,

like that of every other product which is dependent upon atmospheric phenomena for its success, varies in different seasons. The very best yield ever known in Java was 13 piculs of clean coffee per bahoe, or 1768 lb. English, equal to about 867 3-7 lb. per acre. An average yield is from 3 to 9 piculs of clean coffee per bahoe.

The cultivation of the land in Java is carried on under pec. uliar

GOVERNMENT ARRANGEMENTS.

No European can buy land in Java; but he obtains a lease of his land for seventy-five years. For the first seven years the planter pays no rent, but after this term he pays from two to five guilders per bahoe per annum. The planting districts are allotted by the Government, and land is given to natives who will undertake to plant it. These native planters are under the supervision of district headmen, who are themselves supervised by comptrollers. The comptroller is subject to an Assistant-Resident, who in his turn is overseered by a Resident, and so on. The natives are obliged to grow, clean, and deliver coffee to the Government stores, at the rate of 14 guilders per picul for first quality, and 7 guilders for second quality. In due time sales are held by Government agents, and the crop goes to the highest bidders. First quality coffee brings (now) about 38 guilders, and 2nd quality 15 guilders 25 cents per picul. At one time 9 guilders, 11 guilders, and 14 guilders were the ruling rates. One native prince ("pengiran"—prince), Mankoe Nogoroe, called by the natives Kandjeng Goesti (God Almighty), gets 25 rupees per picul. His land yields 70,000 piculs annually. This wealthy prince keeps up his own army of cavalry and artillery. He lives in Solo (native name for Soerakarta), in Mid Java.

THE NUMBER OF HANDS REQUIRED

at an estate mill is as follows:—Pulper, two men; huller, two men; stoker, one man. Pickers or sorters are also required. Each sorter can sort 6-10ths picul per diem.

I am in a position to be able to give the actual results of operations at a mill in Sourabaya (Java).—

975 takkas pulp=823 takkas parchment; loss, 15·4 per cent.

252 takkas pulp=206 takkas parchment; loss, 13·5 per cent

170 takkas pulp=147 takkas parchment; loss, 11·2 per cent.

754 takkas Red Berry=364 takkas Glondong; loss, 51·7 per cent.

Thus from pulp to parchment there is a loss of 15 per cent to the highest figure, discarding the fractions.

1 takka parchment = 6·5 Amsterdam lb.
1 ,, ,, produces 5 lb. clean coffee
1 ,, ,, ,, ·25 lb. second quality, or a total of 5·25 lb.
1 takka Glondong = 6·35 Amsterdam lb.
1 ,, Red Berry = 10·85 ,,
1 ,, Clean Coffee = 10·6 ,,
1 ,, Pulped Coffee = 14·43 ,,
5 ,, Red Berry produced of Pulp Coffee 31·75 Amsterdam lb.
5 takkas Red Berry produced in cubic inches 1157·81 = 2·25 takkas.

Therefore 5 takkas Red Berry lose 55 per cent in bulk nearly, and 41·4 per cent in weight.

1 picul Red Berry = 11·5 takkas.
1 ,, ,, = 5·175 Pulp Coffee,

which, reduced 15 per cent in drying, = 4·398 takkas of dry parchment, or a reduction of 61·8 per cent from Red Berry. Therefore 4·398 takkas parchment yields 21·99 of clean coffee; or 1 picul in weight of Red Berry = 2,199 Amsterdam lb. of clean coffee; or 11·5 takkas = 2,199 Amsterdam lb. Thus 5·68 times these quantities = 1 picul of clean coffee, or 65·32 takkas of Red Berry, or 5·68 of Red Berry = 1 picul clean.

Five takkas of Red Berry weigh 54·25 Amsterdam lb., and when pulped equals 2·25 takkas=31 75 lb., which dried to parchment loses 15 per cent in bulk, and therefore yields 1·9125 takkas of parchment, which in turn yield 9·5625 Amsterdam lb. of clean coffee for the 5 takkas of Red Berry: or 1 takka Red Berry, weighing 10·85 Amsterdam lb., produces 1·9125 of clean coffee: thus again showing that Red Berry reduced to pulp loses 55 per cent of bulk and 41 per cent of weight, and from the Red Berry to clean coffee loses in bulk 61·75 per cent, and in weight 81·8 per cent.

One takka pulp weighs 14·43 Amsterdam lb. (Pulp refers to coffee just from the pulper.) This reduces in drying ·85 of a takka, and produces 5·25 lb. clean coffee. The capacity of the hand pulper per day of ten hours is 1110 5 takkas of Red Berry=500 takkas pulp coffee=425 takkas parchment=17 piculs clean coffee.

THE DRYING-HOUSE.

On the Toempang Estate, Sourabaya, this building, which is 40 ft. long by 30 ft. wide, contains:—

1 table 13 ft. 6 in. × 24 ft. × 3 in. deep.
1 ,, 8 ft. 6 in. × 20 ft. × 3 in. ,,
2 ,, 26 ft. × 36 ft. × 3 in. ,,

equal to containing 1980 takkas, which, with parchment, represents 79 piculs of clean coffee, or 102·96 takkas parchment and 100·5 takkas Glondong=54·34 clean coffee.

One hundred takkas Red Berry produces 48·3 takkas Glondong. Therefore the cost of working Red Berry by the West Indian process up to parchment is as follows:—

	Guilders.	cts.
Contents of drying-house 79 piculs parchment costs to bring in as Red Berry (5160 takkas, at 15 cents) ...	774	04
Five days pulping and washing ...	12	00
Thirty-six hours drying costs in wood ...	2	70
Four stokers	1	60
Six men working coffee in house ...	2	40
	792	74

Total cost for 79 piculs, 10 guilder 03 cents per picul.

TO WORK GLONDONG.

Drying-house capacity, 1980 takkas.

	Guilders.	cts.
Glondong costs to buy, 20 cents per takka...	396	00
Four days, or 96 hours, drying costs for wood	7	20
Stokers	4	80
Working coffee	6	40
Total for 54·34 piculs ...	414	40

MILLING OPERATIONS.

One hundred piculs coffee per day costs in mill-house :—

	Guilders.	cts.
Five cubic metres wood, at 60 cents...	3	00
Eight coolies, at 40 cents ...	3	20
One mandoor (chief) ...	2	50
One mandoor ...	1	00
Coolie to pack house ...	5	00
Sizing, at 50 cents per picul ...	50	00
Total...	64	70
Thus from red berry to parchment the cost per picul is ...	10	03
Parchment to Government stores ...	0	64
Total...	10	67
From native Glondong to good dry Glondong costs... ...	7	62
To Government pack house ...	0	64
Total ...	8	26

One proof (trial) taken with 1,380 takkas of native Glondong produced in piculs 38·02 of clean coffee, or 36·29 takkas per picul. A second proof of red berry to parchment gave for 5,630 takkas 61·79 per cent of parchment. One takka of Glondong (native) weighs 6·35 Amsterdam lb., and yields clean coffee 3·44 A. lb., or loses in weight 45 per cent; 1,380 takkas Glondong=38·03 clean coffee; 1 takka clean coffee 10·6 A. lb.; 138 takkas Glondong=448·46 takkas of clean coffee, or a loss of 67·5 per cent. This, added to 4·7 of the loss from native to good dry,=72·2 per cent the total loss from native Glondong to clean coffee.

RETURN.

	Guilders.	cts.
100 piculs clean coffee, or 3810 takkas costs for drying	35	38
For working in house	64	70
100 bags	40	00
	140	08

or delivered in town 150 guilders, or 1 to 2 rupees per picul.

The average price in the market of plantation coffee is 50 rupees per picul.

The actual cost per picul of working and delivering in town, at reasonable distance, is ...	1	80
Say cost of growing	20	00
	21	80
Selling price of first quality	50	00
Profit	28	20
Deduct 6 per cent for second quality	1	69
Net profit	26	51

It will thus be seen that the business of coffee growing is a very profitable one to those engaged in it. Like every other agricultural product, it requires knowledge and care. I have no doubt that there are many suitable localities in Queensland where the industry would succeed, and with our liberal land laws and freedom of sale the profits should be much larger than in Java, but cheap, very cheap, labour must be procured, or coffee-growing, sugar-growing, rice, and other tropical products must be all relegated to the limbo of departed probabilities.

SCOTTISH ASSAM TEA COMPANY (LIMITED).

Capital £91,040 in 9,101 shares of £10 each. Directors: Messrs. W. Finlay, G. Williamson, W. Forbes, and T. R. Marshall. Area under cultivation, 668 acres.

The report of the directors presented at the nineteenth annual general meeting of the shareholders of this concern is as follows:—

It is with very great regret that the directors have to record the death of the company's manager, Mr. A. Cruickshank, who has been manager since 1875.

TEA CROP, 1882, AND REALISATION THEREOF.

Calculated on the usual basis of 4 lb. green leaf to 1 lb. of manufactured teas, the total produce during season 1882 amounted to 183,840 lb. of tea as against 192,576 lb. in 1881, being a decrease of 8,736 lb. Deducting loss by red and coarse leaf, weighing, firing, packing samples, etc., the actual quantity manufactured was 179,674 lb. whereof 160 lb. retained for use of factories, and 179,514 lb. packed per invoices.

The following table exhibits details of the monthly produce from each of the gardens during 1882, and a comparison of the results with the out-turn for 1881, and with the manager's estimate for 1882:—

	Out-turn for 1881.	Estimate for 1882.	March.	April.	May.	June.
Heelekah	122,116	132,000	1,564	3,390	13,009	13,610
Mazengah ...	60,072	64,000	446	638	5,084	10,214
Karsoolie	10,388	12,000	62	264	1,875	2,090
	192,576	208,000	2,072	4,292	19,968	25,914

	July.	August.	Sept.	Oct.	Nov.	Dec.
Heelekah	26,072	21,780	11,723	10,925	3,930	106 001
Mazengah ...	12,712	13,502	9,160	7,798	3,798	63,352
Karsoolie	2,950	2,819	2,482	1,280	665	14.487
	41,732	38,101	23,365	20,003	8,393	183,840

After deducting the usual buyers' allowance of 1 lb. per chest, the total quantity of tea accounted for by brokers amounted 176,421 lb. This has all been realised, producing a gross sum of £11,525 6s 1d, being an average of 1s 3¾d per lb., as against an average price for 1881 of nearly 1s 6d per lb., the difference being attributable to a general decline in the market price of tea, and not to any inferiority in the quality of the Company's produce.

An analysis of crop 1882, and comparison thereof with crops 1880 and 1881, is given in the appendix to the report.

ACCOUNTS.—The accounts of the Company for year ending December 31st, 1882, have been duly audited, and are appended to the report. They consist, as usual, of balance sheet and profit and loss account, with relative appendix.

From the profit and loss account it will be observed that the total revenue for the year 1882 has amounted to	£12,113	0	7
And that the total expenditure has been ...	11,635	9	6
Showing a surplus on the transactions applicable to the year of ...	£477	11	1
To which there falls to be added balance brought forward from 1881, as shown in balance-sheet... ...	1,130	9	1
Making sum at credit of profit and loss account, as at December 31st 1882... ...	£1.608	0	2

Out of which sum your directors propose to pay a dividend of 2 per cent. free of income-tax, which will require £1,591 16s, and leave £16 4 2 to be carried forward to next account. While regretting that they are not on this occasion in a position to recommend a larger dividend, your directors would point out that the decrease in the price of crop, as compared with 1881 (in which respect the Company is by no means singular) represents a sum of upwards of £1,750, or fully 2 per cent on the Company's capital, and that at least another 1 per cent is accounted for by extra expenditure under the heads of buildings and machinery, which it is hoped will not occur again for some years.

LABOUR.—The number of coolie labourers on the gardens at 31st December, 1881, was as follows :—Men, 279; women, 207; children, 55; total, 541. Including new coolies recruited or imported, and deducting time-expirees who have left the gardens, and deaths and runaways during 1882, the number of coolies on the gardens at 31st December, 1882, stood as follows :—Men, 302; women, 226; children, 55; total 583. The average monthly number of coolie labourers on the gardens, during 1882, was 626, in addition to which a moderate supply of local labour is generally obtainable; but as the number of coolies had at December 31, 1882, again fallen below the point at which it is desirable that the labour force should be maintained, 80 additional coolies have since been sent up to the gardens, and it is possible that more may be required. From latest information, it would appear that the acting manager was to endeavour to supply himself locally with any additional labourers, and so save the expense of any further importation at present; but in this he may not be entirely successful.

PROSPECTS FOR 1883.

The manager estimates the probable out-turn of tea during 1883 as follows:—

	Acres for five years and over.	Tea lb.
Heelekah	388	136,000
Mazengah	200	66,000
Karsoolie	80	16,000
	668	218,000

Up to May 7 the out-turn of tea, as compared with corresponding period last year, had been as follows:—

	1882.	1883.
Heelekah	lb 5,634	lb 1,721
Mazengah	1,318	604
Karsoolie	326	265
	lb. 7,308	lb. 2,590

The falling-off in out-turn is general throughout the tea districts—the season being a very late one—and is entirely owing to want of rain. Under date May 8, however, the acting manager writes as follows:—"I enclose tea statemente for first week of May, from which you will notice that ws are still behind, owing entirely to want of rain; but during the last four days we have had the much-looked-for downpour, and when I start plucking again I hope to pick up quickly." From subsequent accounts it is satisfactory to know that the out-turn of the week ending May 14 was nearly three times in excess of the preceding week, from which it would appear that the rain was having the desired effect.

FRESH FIELDS AND PASTURES NEW: CALIFORNIA.

(*By a Ceylon Planter.*)

To see and judge California aright required a great deal more time than we had at our disposal; still the information we picked up during our short stay may be of some value to the readers of the *Observer*, and it is with this hope we send it on. It was early in the morning of the 19th April that we got into the harbour of San Francisco. When it was daylight we got up to have a look at the place, and found muddy water, a chill wind, a choppy sea, and an ugly town. The sky too was overcast, and an old boy—customhouse official—sitting on the companion, in answer to our enquiry if this were the far-famed Californian climate, "smoiled a smoil" and guessed it was. "Then we'll turn in," we said, and did. After breakfast and before we got alongside of the wharf—the tide would not let us earlier—the rain came down in thick sheets, customhouse officer giving no comfort. "Had been such a dry spring, that he guessed it might rain two or three days on end;" for which speech he was then and there mentally voted to be a drivelling idiot. All the same, we looked out disconsolate enough on the muddy waters, the threatening sky the dripping sheds, the sloppy streets, and came to the conclusion that the bad weather which had been with us all across the Pacific was still to be our heritage. It was a bad introduction to California; but there was some comfort in the thought that things could not be worse,

We need not stay to speak of the city of San Francisco: it was the orchards, the vineyards and orange groves of Southern California we had come to see, and to reach there we travelled by the Southern Pacific Railroad instead of the Union Pacific, which is the more direct route to New York.

The first place to be visited was Fresno—a ten hours' run or so from 'Frisco,' in the neighbourhood of which are located some of those colonie, which claim to be so suited for people of limited means. In one of those a man may take up his twenty, forty, sixty, or more acres, work it with his own hands, and while building up for himself a home in this new country not want altogether the advantages of near neighbours and the pleasures of society. The isolation which usually obtains in the new settlement is to a great extent absent here.

You hear of all classes who have gone in for colony settlement: mechanics working at their trades in the city or elsewhere, and getting their block brought into bearing with their savings; clerks at the desk with a friend in the colony looking after their interests while toiling on in the meantime, getting reports sent, paying occasional visits, and eventually throwing up their commercial calling and turning fruit growers; families scattered abroad able to re-unite and continue close neighbours under the orchard system of Southern California.

Cultivation in California has literally made "the desert rejoice and blossom as the rose," and this has been done by water. Without water miles upon miles of what are now fruitful fields would have remained as barren as the sea-shore. In more than one place we saw the line of demarcation between the cultivated and uncultivated portions strikingly manifest as we crossed the boundary of the well-kept orchards into what was a veritable howling waste. So necessary is water in many parts of California, that one of the chief things the seller has to see to is to buy water rather than land. Certainly much faith must have been needed by those who thought of irrigating that sandy soil, so hopeless does it appear to the uninitiated. To give an idea how much this is so, we travelled south with a New Zealand farmer and his wife and child. He was from the rich Canterbury plains, and intended to stay a night here, and a day there, as they went on their way across to New York. But, so disgusted was he with the barren outlook, and the seemingly sandy waste through which the train was running, that he changed his mind at the last moment, and despite the fact that he was without dinner or sleeping car he refused to get out at Fresno, willing rather to face the discomforts of a night journey unprepared as he was, and went on direct to Los Angelos.

Certainly there was not much visible to encourage a visit from our agriculturist: and besides the weather was abominable. A cold wind was howling over the plain, raising clouds of sand, and chilling you to the bone. We certainly did think it a black lookout, and for the time being considered that the accounts we had read of the fine climate of the land dropping with fatness, of its carpet of flowers, and of its surpassing beauty, were Yankee swindles. Of Fresno itself we claimed to have more or less acquaintance. In the pages of *Harper's Magazine* we had seen an illustration of its townhall, a building of some pretensions in print, an ugly pile in reality, from which the plaster was scaling off; but as we walked across the few hundred yards from the railway station to the hotel, ankle-deep all the time in the shifting sand, it did occur to us that a good road would have been, in our eyes at least, a more substantial monument of progress. However, we were there, and we made up our minds to postpone our verdict till we had seen what another day would bring forth.

We got into conversation after dinner with an American from the Eastern States, who was settled in Fresno, and he told us that when he came first he disliked California so much that he returned to his old home, to find he had made a mistake, and came away back again. He had then a high opinion of the state; told us of men arriving with only five hundred dollars, knocking along "anyhow" for some years, and bye-and-bye getting to have a place of their own. He himself knew several clerks in 'Frisco, and families also, who had gone in for small sections in a colony, and were likely to do well. After a bit I asked him for a peep at the dark side of the shield, and it was, as far as I could make out, the unpleasant sandstorms, and the railway monopoly. But he spoke in a hesitating tone, as if there were a good deal more behind, adding at last. "That is the worst of it: you never knew or hear anything of the dark side of California until you are committed." We had a letter of introduction to an old Ceylon sinna durai, Oleander, his place of residence, and next morning drove off after breakfast to call on him. Things were not looking a bit brighter: it seemed as if we were at Port Said, so dry and barren was the place, and the cold wind was driving the sand before it in clouds. A mile or two of this brought us to the first of the orchards, when everything changed for the better. True there was still the chill wind blowing, only it did not bring with it dust and small pebbles, but rustled the foliage of the trees, and swayed the rich alfalfa grass; and, instead of a waste, there were bright flowers, neat cottages peeping from among blossoming shrubberies, and irrigating channels full of charm, also carrying forward to the adjacent district its power to beautify and bless. I fancy it was the contrast to the barren country we had come through which made the rural beauties of the older colonies about Fresno so marked. In time we reached Oleander, to be disappointed, however: the gentleman for whom we had the letter was gone, some months before, to Lake County, a part of the country away to the north. But the luck was not altogether against us, for we were directed to a gentleman, the agent for the Washington Colony, who turned out to be well acquainted with the Ceylon man I had hoped to see. This gentleman had been a pioneer most of his life. Educated for the law, and on the bench at one time, he was called Judge in consequence, but his health failed, so he took to an open-air life, and, like most Americans, had shown the national restlessness. In his day he had founded several colonies, some of which had been very successful: but there he was at his old pioneer labours, instead of resting content in some of the places he had reclaimed from nature. He had great hopes of the ultimate success of Washington Colony, and we got a good deal of information regarding it. As agent of the colony, he honestly told us that he did his best to try and induce people to take up land and become sellers, so that a needful allowance should be made in his opinions and views. From the top of a barn, to which he had a flight of steps running over the roof. We saw the boundaries of this new colony, and had the occupied portions pointed out. The land was divided into twenty acre lots, and the price asked was forty dollars an acre for cash, or fifty dollars credit. In the latter case one hundred and fifty dollars had to be paid down for every twenty acres selected, and the balance had to be paid up, in three years, with interest at ten per cent, which was payable every six months.

The colony is a fruit-growing one; and ere long it was hoped that a cannery would be erected for the preserving of the fruit, which would save the expense of sending it elsewhere. Forty acres can be cultivated by one man: but if the proprietor desires the work can also be done by contract. It was considered, that the levelling and heavy work at the beginning should be given out in this way if possible. Labour was dear: two dollars a day, for white labour, and one dollar fifteen cents for Chinese; a Chinese cook for the house, who could wash as well, would get thirty dollars a month. The cost of bringing an orchard into bearing—partly fruit trees, and partly vines—was estimated at one hundred and twenty-five dollars an acre, exclusive of a house, which could be erected at an outlay of fifty or sixty dollars a room. If a man did his own work, of course, it would make all the difference. The above is for all labour paid.

We could not learn what were the average returns from these small holdings, but judging from the comfortable appearance of the older colonies, and the well-to-do style of the people about, a living could evidently be made. The Judge was of opinion that a man with nothing but his hands would do well in California, if he were not ashamed of work and were willing to tackle it; but if he had five hundred dollars or more after he arrived so much the better. He let out a drawback urged against his colony, that there were fever and ague about. He, however, had been three years there and had not had either. The Judge's wife "ran" the post office—an exceedingly pleasant and intelligent lady, and whose appearance was not that of fever-stricken. Still I had the feverishness of the place confirmed a day or two after at Los Angelos. The driver of our carriages then hearing we had come from Fresno, said quite incidentally. "They use lots of quinine in that place"; that he had been there the year before and got such a dose of fever, that it took a long time to shake it off. He added after some cross-questioning on our part: "Some have it, and some haven't: but it is a fine bit of country and coming on fast."

We were not able to verify all the figures given above; we learned, however, that the price asked by the Judge for the land was high—for that kind of land—and that if a man intending to settle would take time to look about for himself, he could do very much better.

We saw the work which was being done on the section on which the Judge was located, and the progress the fruit trees had made in the three years or so, and certainly they promised well. We did not think, however, that any other of the cultivated blocks were to be compared to it, and one which we visited, owned and worked by a man who had thought of Ceylon, but the decay of coffee had sent him to California, had all the appearance as if the owner were half-hearted about it. When we called at his hut, the end of a barn, we saw at a glance that living "anyhow" meant a sad want of comfort.

Schools were to be found in the colonies—state schools, where a plain education was to be had, but if anything above the very common were desired, then the children had to be sent elsewhere. The judge had a daughter sent East to school, Philadelphia in fact, some thousands of miles from Fresno!

Bright as these little colonies appear, there is a cloud over them at present. Fruit-growing is overdone. This we found to be a pretty general opinion, although it was naturally hoped, that, as the growth of the American nation was so rapid, the consumption would soon over take the supply, and the industry be again profitable. We were, however, too short a time in the place to do ought else than reflect the ousopinio of others, and our readers will understand this.

The rising industry in California is vine-growing. This was universally admitted, and through, the kindness of a friend who was acquainted with an experienced vine grower, I submitted a few questions on the matter, and have got exhaustive answers in reply. They speak for themselves, and although in this enterprise money may clearly be made, it is evidently not the kind of thing a teetotaler can take up. Still as the information has been sent me all the way from California, I post it on, leaving it with you to make what use of it you may. While at Fresno and Los-Angelos, we visited several large vineyards and "wineries," the latter immense places. The capital sunk in them is very great, and the wine stored in the vats totalled a large amount. A quarter of a million of gallons was the quantity in one of those "wineries" alone.

About Los Angelos there were miles of orange groves, but the generality of the fruit we tasted was not very good. We were not able to collect any particulars regarding this enterprise, except that it had been a very profitable one: that the price of oranges had fallen, while five hundred dollars an acre would not buy a good orange grove in bearing.

California is a difficult place to get to from Ceylon; still, once there, it is a cheap place to live in. If in the monster hotels of San Francisco, perfect palaces, you have to pay for your ease, cheaper ones can be had if you have a mind to, while in other places of the State they are moderate enough. Two dollars a day was the charge at the best hotel in Fresno, while a substantial reduction would be made to a board or by the week or month. In California, as in New Zealand, the great thing for the intending settler is to look well about before buying, and then only to buy *good land.*

We will close this letter by a story we heard of a man who had made a bad selection. As a result of this, he suffered both in body and in mind, and came to take very gloomy views of things. A friend visiting him, when things were at their worst, tried to cheer him with the remark, "that really, after all, what he wanted was some good society and more water." The gloomy man looked gloomier at that, and replied: "That is all that h— wants." J. L. D.

Replies to Queries on Vine Culture.

1st Q.—The price of land suitable for growing vines, per acre?

Such lands are to be found all the way up from $20 to $150 per acre, according to location. Fifty dollars per acre for 300 to 500 acres would be a fair price in some good locality in Sonorna or Napa valleys not far distant from railroad or water transportation.

2nd Q.—The cost of water-right?

The greater portion of our northern grape growers do not use irrigation at all. It has to be resorted to only in those few parts of the State, like Fresno, and a few other interior valleys, where the annual rainfall is small. I would not advise to buy grape lands where it is needed, because it costs at least five dollars per acre per annum. By buying lands at $50 per acre, when it is not necessary, you gain within eight to ten years the purchase price of your lands. Thus water-right for vine culture should be dispensed with by buying the right kind of lands. And then, as a rule, vineyards need little or no irrigation. Vines grow in dry countries, not in wet ones. Warm, light and dry soil on mountain sides is preferable. Damp valley land is far from being so good. In Napa and Sonorna valleys, so reputed for their fertility and healthfulness, rain is always sufficient, and there is not an instance known there of a crop having been lost on that account.

3rd Q.—The cost of clearing the land and planting it? For first year for 100 acres:—

Ploughing and harrowing at $2 50 per acre	$250
Laying out the land and planting at $10 ...	1,000
100,000 cuttings, *phylloxera-proof*, at $10 per 1,000	1,000
After cultivation at $2·50 per acre ...	250
Hoeing at $1 per acre	100
Wear and tear on the farm, repairs, taxes 3 per cent on $50 per acre	300
	$2,900

SECOND YEAR.

Replanting with *rooted vines*, cuttings having not thriven the first year. This may not amount to more than 5 per cent or 10 per cent, but it is wiser to take a maximum of 20 per cent. Replanting 20 acres at $2·50...	$50
20,000 rooted vines or $40 per 1,000 ...	800
Pruning on about 80 acres at $1 per acre ...	80
Ploughing and harrowing three times at $7...	750
Hoeing near the vine	100
Wear and tear, repair taxes	300
	$2,080

THIRD YEAR.

Graping at $10 per acre	1,000
Pruning and removing wood at $3 ...	300
Three cultivations at $7·50	750
Hoeing near the vine at $1·00	100
Wear and tear, repairs, taxes	300
	$2, 50

FOURTH YEAR.

Pruning at $4 per acre ..	$400
Three cultivations at $7·50 ..	750
Hoeing at $1	100
Wear and tear, repairs, taxe ..	300
	$1,550

Recapitulation.

100 acres 1st year	$2,900
,, 2nd ,, ...	2,080
,, 3rd ,, ...	2,450
,, 4th ,, ...	1,350
	$8,980

With the fourth year a moderate crop can be expected of say 2 tons of grapes to the acre (value $30 per ton taken as purchaser's expense), which will more than reimburse the outlays of that year, and cover the expenses to the fifth year, when a crop of fully 4 to 6 tons per acre can be safely depended upon, especially considering the fact that *rooted vines* being used the 2nd year to replace the cuttings that did not thrive, it saves a year on the same, which would be lost otherwise. Beginning with the 5th year, the yearly cultivation would not exceed $20 per acre, and taking as a basis the minimum average crop of 4 tons to the acre at $30 per ton, we would have a nett income of $100 per acre.

The above are not fancy figures, as one finds most generally in land companies' pamphlets or in newspapers. They are calculated on the cost of running a farm, with a foreman, labourers by day and by the year, with necessary animals, good implements, wear and tear, and the buildings, the cost of which for a farm of about 200 acres would be as follows:—Barns and residence $2,500
Seeds, food, agricultural implements, horses, mules, cows and harness 2,500

$5,000

It should also require a general superintendent to keep accounts and direct the work. A salary, such as said superintendent should receive, would weigh heavily on a small farm of 100 or 200 acres, and for that reason I would advise to work on at least 400 acres in vineyards, and an additional 100 acres for farming purposes, wheat, pasture, &c, making in all a farm of about 500 acres.

4th Q.—How long before it comes into full bearing?

This is embodied in the above reply to query No. 3.

5th Q.—After the land has been planted how much per acre does it cost to keep it in good order?

From $15 to $20 per acre per annum.

6th Q.—How much per acre might be expected from a fair average vineyard at say 3, 4, and 5 years old, from grapes alone?

Third year nothing: land worth then $250 to $300 per acre. Fourth year 2 tons of grapes of a value of $30 per ton: land worth then $350 to $400 per acre. Fifth year 4 tons: land worth then fully $500 per acre. Sixth year and afterwards 5, 6, 7, 8, 9, 10 tons and more to the acre according to the year. A good average, a bad and a good year taken altogether, can be safely calculated on at 5 to 6 tons to the acre per year: and the land would rise in value to $600 at $700 per acre, and even more if it is well located near railroad or water transportation. For that reason especially, I would recommend to buy at the start high price lands, $50 to 60 or even $75 per acre should not be too much in order to secure such ultimate results. Such lands as I refer to, when in full maturity are worth in France fully $1,000 per acre (francs 12·500 per hectare) and there is no reason in the world, why they should not be quite as much worth here, when California wines are better appreciated, which is being done very rapidly in this country, where the consumptions will keep always ahead of the productions.

7th Q.—Would vine growing pay, selling the grapes and not making wine with them?

Vine growing pays, and will continue to pay on a bas of 7-10ths to 8-10ths for the vine grower, and 2-10ths to 3-10ths for the wine maker. Winemakers are generally wine merchants who organize distilleries and wineries, such as there are many already in Napa and Sonoma valleys. Their main object is to make certain types of wines to sell under determined brands. If they buy wine from farmers who make it themselves, they find so many different qualities, on account of the manner in which each understands fermentation, that it becomes a difficult task to blend all these products, and make out of it a uniform brand of their own. But when they buy the grapes and make the wine themselves, in the first place they find it more profitable, and then they can regulate fermentation in the way they please; and it is only by such method that they can attain that uniformity of quality which is so indispensable to their trade. This accounts for their desire to buy grapes, even if they have to pay 8-10thr of the *whole profit* that can be expected from both vine growing and wine making. This saves to the vine grower the large expenses of winery, distillery, huge cellars, cooperage, additional care and risks, especially the one to have the wine turning sour before delivery. By doing both, wine growing and wine making one is expected to nett from $120 to $130 per acre but it is much safer to be satisfied with $100 to $110 nett per acre, getting rid thereby of all those large outlays and risks.

8th Q. Does the raisin industry succeed, and are the prospects as good as wine?

Table grapes bring about $40 per ton: but out of one acre you may not expect more than 3 to 4 tons to the acre of raisins good to be boxed. The remaining 2 or 3 tons will have to be sold to the wine maker, who will pay less, as the picked raisins that would make good wine are gone. Then will come the cost of the boxes, the hand work, the packing, the delivery, and, finally, it will be more difficult to sell raisins to merchants on time, mostly, than to sell the grapes to a wine maker who willpay cash.

To resume all that is said above, I would suggest the exploitation of about 500 acres of land. 100 for farming purposes and 400 to be planted in vineyards, and I would pay about $50 per acre for the land. The whole cost to maturity would be about as follows:—

500 acres of land at $50 per acre	$25,000
Barns and residence	4,000
Implements, horses, mules, cows, harness, seeds, feed 1st year	4,000
Cultivation 1st year on 400 acres vineyards	11,600
Do 2nd do do ...	8,320
Do 3rd do do ..	9,800
Do 4th do do ...	6,200
Superintendent 4 years at $3,000 per annum	12,000
	$80,920

Receipts, beginning with the 4th year.—

4th year 400 acres vineyards and 100 acres farming	$25,000
5th do do do ,,	35,000
6th do and succeeding ones each	40,000
	$100,000

Iss ueltt r from the above that, with the crop of the 6th year, all the outlays of the first four years would be all paid up, leaving besides a handsome surplus on hand of $15,000 to $20,000, and the succeeding years would *nett* an average of $40,000 each. It should be remembered that a vineyard when in full bearing is good to last more than a century; also that by planting only *phylloxera-proof cuttings* there is no fear to be had of the *only scourge* which has ever been known to kill vines absolutely. All other known diseases of the vine are at the surface, on the leaves mostly, and they can be easily coped with when they are present without much of expense, and without serious loss to the crop.

Should you intend to do anything in this matter for the coming season, I would suggest you to lose no time about it, if you want to enjoy the prices of this year. Unless the land is ready to begin work by October or November next, it would postpone operations for one year, and all the probabilities are that the lands will be much higher than now, after the next crop will be in. The selection of the land, the negotiations, inspection of title, contracts &c., would absorb fully two months' time, and for all those reasons I think no time should be lost.

At all events, should you conclude to engage in such an enterprise, you will make an investment as sound, sure and profitable as can be desired, for the reason that the land by itself, even if not put under cultivation, will rise in value from 10 per cent to 15 per cent per annum on its present valuation, and will continue to do so for many years to come until vinelands reach the highest prices at which they are selling in Europe.

San Francisco, May 31st, 1883.

BRAZIL COFFEE CROPS, AND THE TRUTH ABOUT BRAZIL.

From Messrs. Kern, Hayn & Co.'s Reports we gather that from both Rio and Santos the exports for the season which ended on 30th June exceeded all previous figures. We give the comparison for three years:

	1880-81. tons.	1881-82. tons.	1882-83. tons.
Rio ...	254,399	228,286	265,291
Santos ...	71,117	90,041	108,532
Total...	325,516	318,327	373,823

The aggregate for last season is equal to 7,476,460 cwt. But crops very considerably smaller are anticipated for both districts in the present season.

The interesting statement by a Brazilian, which we copied on page 216 from the *India Mercury*, gave valuable facts respecting the great impetus given to coffee cultivation in the South American empire by the command of slave labour, and the extension of railway facilities to an extent which is loading the country with debt. But the writer is wrong about the effects of over-extension.

HAYTI COFFEE.

"Up to ten or twelve years ago," says the Boston *Commercial Bulletin*, "Boston furnished a very good market for Hayti coffee. The growers, however, exercised no care in handing it and sent it to the market ungraded and uncleaned, and the demand in consequence gradually fell off. Owing to the enormously increasing production of Rio, its place was easily filled by this cheap coffee, and those consumers who preferred a mild coffee could obtain Maracaibos, Savanillas and Bogotas, though at higher prices. While the trade with the United States in this coffee fell off, that with Europe increased, and it is one of the principal coffees used in France and Germany, the people there not being so exacting as regards grading and cleaning as are Americans. These shipments are made direct from Hayti to Europe, and also by way of New York, where sometimes a cargo finds a purchaser, the coffee being very well adapted for mixing with Maracaibos and Javas. This was, in fact, one of its principal uses, when imported extensively into this country. The coffee itself has a mild, pleasant flavor, which, with its cheapness, would commend it to many coffee drinkers if it were properly cleaned and graded. A firm in this city prominent in the West India trade, and which shipped large quantities of the coffee to Europe, resolved to try the experiment of cleaning and grading it for the American market, and for this purpose furnished their establishment at East Boston with the proper machinery about a year ago. The coffee is graded into Nos. 1, 2, and 3, and peaberry, refuse and black. The experiment proved a success though there is considerable waste in cleaning."—*Rio News.*

THE TREATMENT OF RUBBER: IMPORTANT FOR PLANTERS.

Mr. T. Christy of London writing on 9th August with reference to R's letter on page 615 of the *Tropical Agriculturist*, says:—

"I am delighted to see some people are waking up, and I am glad to let them know how far I have got in regard to the treatment of *milky gum.* As soon as the milk is collected, weigh out a pound or any given weight, then get some cheap spirit. If the strength can be discovered so much the better. When all is ready pour in some spirit on the milk and if watched, and of the proper strength all the *rubber* or guttapercha will run up in veins to a lump. Of course the less spirit used the better: then note the quantity of spirit required and write it down. Take the ball of rubber and put it into clean water and wash it as you would butter and put it to dry in cakes in the sun. This washing gets rid of the resin and gum that cause the 'elastic' gum to be brittle. Some sort of gutta I have found go quite hard when treated. I have tried alum and on some 'milks' this has an effect, but I do not get so large a yield of elastic gum as with spirit."

TEA must grow as well in the rich low flats of Matale (Ceylon) as in any district in the island: some leaves and a specimen of a "sucker" of a few weeks' growth brought before us are simply magnificent. They are from Mr. Fraser's Wariapolla plantation, near Matale town, which is also famous for its cocoa walks. Tea cultivation higher up on the Lubugama side has also been found to be a financial success, the returns of crop so far being very satisfactory.

CINNAMON is one of the articles honored with princely charges. We have an account sale before us shewing the gross value realized by a shipment at £147 19s. 3d., against which are charges aggregating £30 8s. 1d., or over 20 per cent. Deducting freight, the charges amount to over 12½ per cent. Another account sale shewing £77 15s. 10d. as the sale price of the produce, disclosed only £56 14s. 10d. as net proceeds—no less than £21 1s. or over 25 per cent being absorbed by freight and London charges. A third account shows £455 4s. 4d. as the gross proceeds, reduced by £86 of charges, which do not include, of course, the local transport, packing and shipping charges. If these London charges, which seem modest enough in Commission and brokerage, can be reduced, they can be done only by united action and persistent agitation. Feeling how little can be achieved by so small a unit as Ceylon, some producers deem it best to sell their produce locally; but there is small satisfaction even in this, for purchasers here are quite equal to the computation of London prices less London charges, and offer no more than the just equivalent of the net proceeds. Cinnamon growers, feeling that they are still further weighted by quarterly London sales, are agitating through the Agricultural Association for more frequent auctions. As it is, one or two Continental Firms are the only local purchasers, chiefly on commission for their principals in Europe. English merchants do not compete with them, avoiding the risk of their consignments reaching London just too late for one sale, and having to wait three months for the next. It is to be hoped that monthly auctions may secure better prices, if not in London, at least locally, by leading to increased competition among merchants who, with the gift of charging, may have the gift of securing a reduction in those London charges which seem so capable of reduction. An attempt should be made to find out whether the charges, now felt to be heavy, are really legitimate, or whether their reduction can be reasonably expected. Especially in the case of tea—an industry capable of almost unlimited expansion because the demand for the article should know no limit—should a vigorous attempt may be made to protect it from charges which may give it the death-blow at a time when the future of the colony seems so closely wound up with it.—Ceylon "Examiner."

CEYLON PLANTERS AT "TEA" IN NORTHERN India.—We regret to learn that Mr. Packer, one of the batch of young men who recently left Ceylon to take up appointments on Assam tea gardens, died of fever shortly after reaching his destination.

TEA IN INDIA.—The value placed on "Tea in India" may be judged from the following advertisement in the London *Times* of August 10th:—Wanted, a partner in a matured tea estate, who would go out to undertake management. Capital £4 000 or £5,000. Apply S. E., care of Ingram and Co., 67, Lincoln's-inn-fields.

COCO AND COCOA.—In reply to a query in your May issue. The word Coco is, I believe, the Portuguese "Coco," signifying an ugly mask, or a monkey's face. It was applied to the fruit of the coconut palm because of the imagined resemblance to a face, which is formed by the three cavities at the base of the nut corresponding to the three original carpels. Cacao is said to be derived from the Central American word Cacauatl, the native name of the plant. It has been corrupted into cocoa, by a curious substitution and transposition of letters. It is needless to say the two words Coco and Cacao have no relation to each other. The coconut palm grows freely on the whole of the coast of the island of Ceylon. The Sinhalese vernacular word for coconut is Pol, which comes from the more reputable Sinhalese word Pala, a fruit (or the fruit of all the fruits, to the low country Sinhalese this is the most important) which is itself derived from the Sanskrit word Phala. The Sanskrit word for the coconut palm is Narikéra, which comes from the roots Narika, a watery place, and Ir, to grow (literally the tree which grows by the water) and the old Sinhalese word derived from this Sanskrit root is Neli. Although the coconut is not a native of India, its introduction is of undoubted antiquity, as it is mentioned in many old Indian medicine works; for example, Charaka Samhita, Susruta, Vagbhata Tantra, and Raghuvansa, many of which date back long before the time of Buddha (nearly 2,500 years ago). The Maldivian word for the coconut is Karhi, which is almost the Sanskrit word Kera. The cacao plant * now flourishes in Ceylon, failure of the coffee crop having induced planters to turn their attention to it along with other new products and some very creditable sales of the produce have been made in the London market.—*W. Knight James, F.R.G.S., Colombo, Ceylon.*—*Science Gossip.*

WYNAAD, 23rd Aug.—I came across an article in the columns of your contemporary the 'Mail' anent the *pros* and *cons* of cinchona barking. It struck me as rather a one-sided argument to totally condemn the system of shaving or slicing, as compared with the old plan of stripping. One-sided I say, because, though the writer brings forward proofs to show that, under the shaving process, the quality of the bark is bound to deteriorate, he casually forgets to mention the fact that such is also the case under the stripping process. It has been a great mistake to suppose that a tree can bear to be shaved entirely any more than it could be expected to endure wholesale stripping. The shaving process must, therefore, be conducted on similar principles as that used for stripping, *i. e.*, alternating portions of the bark must only be operated on at a time. As far as I can discover from personal observation and enquiry, the result of the stripping system has proved equally unsatisfactory, as far as the yearly deterioration is concerned, and we are told that the quality of the Government bark, which is stripped, not shaved, proves the fact. The first renewal of bark as a rule may be considered of such increased value as compared to that of the original bark, that, by allowing for subsequent annual decrease, we may roughly average it as reducing in quality at such a rate that in four years or so the produce will be of the same value as the first and original stripping. After that, the decrease might become more perceptible, and coppicing the necessary result. Probably it will be decided as being a case of six of one and half a dozen of the others when the subject has been more fully experimented upon. Our weather continues light and pleasant, all that the greatest professional growler amongst us could desire. Of course there are no more coolies up, and how we are to get our crops picked, is a matter of some consideration to many of us.—*Madras Times.*

* Which Mr. James ought to have said is entirely distinct from the coconut palm.—ED.

THE AMMONIAC-WATER OF GAS-WORKS UTILIZED FOR AGRICULTURE.

The *Journal des usines à Gaz* records a few facts in one of its latest issues, concerning the good results that have been obtained in Belgium, by aspersing meadow-land with the ammoniac-water from the Gas-works.

This liquid is so much appreciated by the farmers in the environs of Malines, that all the water of the gas-works of that city has, of late years, been eagerly brought up by the farmers at 60 or 65 cents per hectolitre.

If we are well informed, the farmers in North Brabant are equally eager to buy up this liquid for the same purpose.

The liquid is mixed with from two to four times the quantity of water, and then spread over the land. The technical periodical in question, mentions a letter from a correspondent, from which it appears that in rainy seasons the ammoniac-water is used without the addition of water; in that case a hundred hectolitres of the liquid is sufficient to manure a hectare of land thoroughly. In dry seasons 50 per cent of water is added, and then two hundred hectolitres per hectare, are required to obtain the same result.

We must add that the liquid must be aspersed as equally as possible over the land. Watering-carts such as are used to water the roads are the most efficient.—*India Mercury.*

COFFEE AND TEA.

The annual report of the New York Chamber of Commerce, recently received, contains some statements respecting the course of the coffee and tea trades which are worthy of the serious attention of producers. Regarding coffee, the report says:—

"The chief feature has been over-production. Supplies have continually poured in, far beyond the demand, largely increased, though it has been, by the falling-off in price. Under these conditions the trade has been, of course, unsatisfactory to all concerned in it. Moreover, there has been a radical change in its methods, old channels having been abandoned for new to such an extent, that a new era is said to have commenced in the trade. By the increased facilities in communication and transportation, the foreign factor has been brought into close relation with the jobber, without the intervention of the commission merchant on the sea-board. The increased distribution of roasted coffee has produced a great change in the general course of business. But in these changes it is noticeable that New York has been a gainer. The bulk of the increase in consumption has been taken from this port. At present she holds the control of the markets of the United States, which consumes one-fifth of the entire supply of the world, and she bids fair to become the controlling coffee market.

The general features of the trade in tea have not been unlike that in coffee. The entire course of the business has been changed. The bankers extend facilities to the jobbers, who now make direct purchases at the ports of supply In this multiplicity of transactions it is extremely difficult for the large importer to form any sure judgment as to the quantities or qualities which may come forward, and the course of the market is full of surprises. In 1880 the large importers, who had never favored the disposal of teas at auction, gave their support to a new auction room. In 1881 the brokers formed an auctioneer association and new plans are on foot for still further modification. These attempts at change show the unsatisfactory nature of the trade in its present form.—*Planters' Gazette.*

THE PLANTING INDUSTRY ON THE NILGIRIS.

It is really marvellous to observe the extent to which the hills of Ootacamund have been clothed with plantations during the past fifteen years, and the diversity and numbers of the trees planted. Tea, cinchona, acacias and gums of all sorts, pines, tanning bark trees, melanoxyolous, &c., flourish together in a manner calculated to surprise the planter from other climes, and to demonstrate an adaptibility of soil and climate for the cultivation of the most diverse products of the vegetable kingdom, such as could not be equalled in any other part of the globe. It is impossible to get a clear and full view of Ootacamund since these plantations have grown up, unless one ascends to the summit of Dodabetta, the highest point on the Nilgiris, and then a vast panorama of luxuriant verdure can be observed, that would fascinate the gaze of any true æsthete. Only here and there can a house be seen peeping out from amid a mass of foliage. In the Botanical Gardens which show forth prominently at the foot of the mountain, rare flowers and shurbs from many lands mingle their leaves and blossoms together, and bloom side by side The term, "Garden of India," might appropriately be applied to this lovely spot. It might be thought from all this that Ootacamund should be the paradise of Planters; but such is far from being the case. The planting community of the hills is at the present time passing through a crisis of a grave and important nature. A series of bad seasons, and the numerous destructive pests, which first attacked coffee, and are now steadily transferring their attention to cinchona, have caused great depression in planting matters, and rendered the out-look for planters gloomy. Over coffee "Ichabod" has to be written, and cinchona has developed enemies in such unexpected profusion and variety as to occasion serious alarm among those who, heedless of the proverb anent putting all one's eggs in the same basket, have invested the whole of their capital in the enterprise. Under these circumstances, it is unfortunate that the planting community should be hampered by Government restrictions regarding the destruction of wild animals which ravage their estates, and the vagaries of so-called Settlement Officers. These last appear to have been named in a spirit of irony, as they generally contrive to unsettle everything, and greatly annoy planters. This the planting community should resent by calling an indignation meeting, and protesting against the arbitrary proceedings to which they are subjected. Perhaps, then, Government might take measures to redress their grievances. The planters should bear in mind the trite old saying that "the gods help those who help themselves," and should act unitedly and resolutely for the repeal of impracticable regulations, and the redress of their wrongs.—*Madras Times.*

SUGAR AND BEAN-CAKE AT SWATOW.

Reporting on the trade of Swatow, China, for the year 1882, Mr. Consul Phillips says there are at Swatow two factories which merit notice—the sugar refinery and the bean-cake factory, both of which are doing a profitable business, and a stranger arriving at the port and seeing clouds of smoke issuing from the lofty chimneys has the impression left upon his mind that Swatow is a busy and a thriving place.

Large quantities of sugar are refined here. At first the out-turn was 25 tons a day of raw sugar, but now it makes 50 tons a day. The tables which accompany the report show that some 138,088 piculs of white sugar were sent to Hong Kong in 1882. Of this 113,000 piculs underwent a process of refining at the refinery. Up to the present this establishment has only had machinery adapted to cleansing the sugar from molasses and impurities by the Weinrich patent process, the cleansed sugar being all shipped to the refinery in Hong Kong, owned by the same company, where it undergoes the complete process of refining through animal charcoal, after which it is fit for direct consumption. Buildings are now being erected at the refinery at Swatow for the reception of these animal charcoal filters, and the necessary machinery in connection therewith, which will make the refinery a complete refining establishment capable of turning out the refined sugar in a finished state.

The cultivation of the Sugar-cane has been largely developed since the establishment of the refinery at Swatow, and much of the land formerly used for growing sweet Potatos, Rice, &c., has been put under sugar cultivation. Owing to the cheap rates of freight and steady steamer communication with the Rice producing ports, Rice can be laid down at such a price as to compete successfully with the home-grown article, and the tendency will be, now that the natives can depend on purchasers for their sugar, they will cultivate the article more and more. This will cause an increase in the trade of the port, for while there will be more sugar to export, there will be more Rice to import, and also bean-cake, to be used as manure for Sugar-cane. This increased cultivation of sugar, besides offering scope for refining industry, commands the attention of merchants, as it is now frequently possible to export sugar with profit to the large markets of England and America, and this branch of business is yearly receiving more attention. Supplies of sugar from the smallest sea-ports in the neighbourhood are greatly increasing, doubtless attracted to Swatow by the certainty of a market, which results in what would be sent away in junks being to a certain extent transferred and exported in foreign steamers. A considerable quantity of sugar is still sent to Hong Kong in junks, the lowness of the duty when shipped by them (about half the foreign duty is charged) more than making up for the comparatively cheaper freight by foreign steamers. The quality of the sugar grown in the neighbourhood is very fair, comparing favourably with that of Manilla in price. Only a very small proportion of the crop is unclayed sugar, the manufacture and packing of clayed sugar being better understood and more largely engaged in than in any other port in China. There are some six Europeans and 100 Chinese engaged in the refinery.

The bean-cake manufactory is entirely a Chinese venture, and is situated among the foreign hongs at Swatow. It was first started some three years since. At its commencement it turned out only 200 cakes a day, in the second year of its existence 300 cakes a day, and last year 400 cakes a day. One thousand catties of Beans make nineteen bean-cakes, each weighing 47½ catties; besides which bean-oil to the amount of 112 catties is also extracted. The cakes are in the form of the Chefoo bean-cakes, and their cost is about the same as those imported from that port and Newchwang.—*Gardeners' Chronicle.*

THE DWARF PALM TREE.

ITS INDUSTRIAL IMPORTANCE.

The increasing employment of paper, stuffs, yarn, for several sorts of carpets, has given rise to a perservering search after materials to replace straw, rags, etc.

The Ramah especially advanced by M. Favier, an old engineering officer, is now so brought into notice, that its use is constantly increasing, notwithstanding the difficulties experienced in the beginning, and which are not yet entirely overcome.

The Alfa is also already exported and worked; the English derive it from Algeria, and after working it into various stuffs sell it to France. But in that same Algeria, which furnishes the Ramah and the Alfa, there is another plant not less abundant and equally rich in its fibrous quality, this is the Dwarf-Palm, a plant that grows wild and is a kind of dog-grass to the country and a plague to the farmer.

For ever so long, the Arabians have been acquainted with the fibrous nature of this shrub, but they have never utlized more than the leafy tops; in short, the dwarf-palm has ever been regarded as a parasite and more as a nuisance than as a tree that could yield any advantage.

M. Reynaud, a Frenchman, has discovered a means to turn all the parts of the plant to a profitable use, besides using the roots for fuel. From the stem to the topmost leaves every part is converted into fibre of the very best quality.

The plants are put into a basket, which is set in a large copper, filled with a particular kind of lye, and exposed for a time to a certain degree of warmth. The stuff thus obtained has now become soaked and soft enough to detach the fibre easily. By some contrivance or other, the stuff is removed from the bath into a reservoir to be drained; the moisture strained is collected to do service a second time. It is then passed through rollers and hatchelled. While collecting the fibre it must be well flushed with cold water. According as a particular degree of fineness is to be given to the fibre, it is passed from one machine to another, still combing and rincing, to come at last into a reservoir of clean water, where it is separated, wrung dry and either made up for sale, or else spun by machinery.

In this operation, not only the leaves, but also the stalk on which they grow, are utlized, and even the stem, which in the dwarf-palm rises immediately above the root. It is therefore sufficient to cut off the dwarf-palm immediately below the stem, or else to pull it up, roots and all, and and cut these off afterwards, for so one has the whole plant, which can be worked with the branches, leaves and all, even when they have lain by for years.

A kind of vegetable horse-hair (crin végétal) more or less stripped of the coarser fibre, is also procurable, and is much finer and stronger than any of the hitherto known fibre, and it seems it will be able to supercede all others. It washes like wool, and can be used for mattrasses.

Before discolouring it, which can be easily done in water charged with chlorate, this hair, wound into skeins, will easily take any colour desired; by a combined process to prevent its losing what tannin it contains, it is preserved against rotting, and is besides a preservative on account of the slight aromatic scent it retains; moreover water will not penetrate it, but rolls off the surface, while the tissue is uncommonly tough and strong. For the cordage of ships it is better suited than what is now used, and it is stronger and impervious, for the tannin it contains.

When the fibre comes from the waterbath, it is carried to the spinning-machine, where the threads are spun to the desired thickness, to make rope, cables, carpets, pantaloons, shirts or sewing-thread; in short for all the uses to which flax and hemp are otherwise applied.

From a view to political economy this important article gives the following results:

To make white woven goods, it can be bleached before or after the manufacture this also the case with the pulp for papermaking, which is of an excellent quality.

The expenses for erecting a factory where 3,000 kilos of hatchelled flax can be produced daily, are:

Grounds, including sheds	fr.	20,000
Steam-engine and machinery	„	50,000
A combing machine	„	5,000
Horses, harness, carts, ...	„	10,000
Eventual expenses	„	10,000
Total...	fr.	95,000

Expenses, wages, etc. are per work-day as follows:

The conveyance of 6,000 kilogr. of raw dwarf-palm to the factory at 2 fr. per 100 kilo.	fr.	120,00
Chemicals	„	120,00
Wages	„	50,00
Fuel	„	22,00
Freight for 3,000 kilogr. of hatchelled flax to France à 40 fr. per ton	„	120.00
Office expenses, house-rent at Paris ...	„	70,00
Stay in Algeria, salaries, interest on capital, valued at 250,000 fr...	„	45,00
Unforeseen expenses	„	30,50
Total	fr.	578,00

These are the expenses for furnishing 3,000 kilogr. of hatchelled flax, sold at the moderate stated price of 80 fr. per 100 kilos, gives ... ... frs. 2,400,00

Deduct expenses	578,00
Remains net profit per day ... ... „	1,822.00

So more than twice the working capital.—*India Mercury.*

ANOTHER WORD ABOUT COFFEE IN THE PARCHMENT.

From a circular of the firm Chabot and Andres at Rotterdam we extract the following:—

According to the accompanying statistics the importation of coffee in the parchment from July 1882 to mid-April 1883 has been:

For Rotterdam - -	101,752 bags
For Amsterdam - -	86,253 bags.
	188,005 bags

against about 150,000 bags in 1881-82.

So it appears from this, too, that the conviction is gaining ground more and more, that sending in the parchment is in the interest of the proprietors. The results obtained in this season leave no more doubt about it, and we are persuaded this manner of supply will increase from year to year as we prophesied in our confidential pamphlet of June 1882. Not to fall into repetition we will merely refer what we said then about the advantages of peeling in Netherland.

With respect to the recent crop, our impression is, that the quality on the whole is not so good as the former years. On account of the rains, the curing and especially the drying had to be hurried in many cases, by which the coffee has suffered.

The artificial drying seems not as yet in all respect to have been very successful, perhaps partly in consequence of precipitation, and it is our conviction that unless the greatest care be observed, there is imminent danger of spoiling the quality once for all.

The time the fermentation is made to last we deem of great importance.

Several friends have sent us parcels for working, with the statement that this coffee had fermented 12, 18, 24, nay even 48 hours. Our experience, however, has taught us, that a fermentation of 36 hours is best for preserving a fine colour. The colour of the parchment must be no index. Yet some people are apt to conclude from the more or less clear and yellow colour of the parchment, to the hue of the coffee itself; but this seems to us no standard whatever.

We repeat therefore, that in the first place everything depends on the kind and way of curing in India; this has the greatest influence on the quality. The peeler and operator in Netherland has to take care that the coffee remains what it has become by the juidcious treatment of the planter. And this he can do. The drawbacks which presented themselves in the beginning have been overcome, though it is not to be denied, that there exists a good deal of difference between the process of one peeling-etablishment and another, which must effect the ultimate quality.

The peeling itself is quite a mechanical operation, but without the necessary technical knowledge, this appearently very simple process may spoil the coffee which however does not imply that, with the same machinery end the application of the same technical knowledge, all parcels would require the same treatment.

Therefore we regard every parcel of coffee on its own merits. It must be treated according to its nature, not only in the peeling, but also in sorting and shifting.

So we have not deemed it desirable to follow the system of most peelers, and to work the coffee after peeling in the five stereotyped qualities, as: *Coarse, Middling-coarse, Fine, Roundbean and Piksel*, but rather, when our friends have left it to our judgment, we have acted according to circumstances.

Next to much appreciation, however, this has occasionally to our regret given rise to misapprehension on the part of some, who judged more or less superficially. There were some who attended only to the high fancy-price received for 10 to 15 per cent extra-coarse of their coffee, forgetting that the remaining 65 to 90 per cent, just on that account, yielded proportionally much less.

We work according to the quality of the coffee entrusted to us. When no particular order is given us, we only look to the highest possible average price. By this we have found much satisfaction, and in the March auction of the *Nederlandsch Handel-Maatschappij* 2,129 bags of Bantam R. 86/95 treated by us, fetched one with another about 3½ cents more than 1,106 bags of Bantam A- 79/85 treated at Amsterdam, while the original article was one and the same.

The manner of calculating the expenses varies, but in general it must come to the same thing, notwithstanding this there are some who offer all possible apparent, but inconceivable advantages and which indeed are only imaginary.

We will mention by the by, that the proprietor of an Amsterdam peelery once visited the Rotterdam importers and showed them samples treated by them; these samples were, it was said, of one and the same parcel, but showed a difference of colour, which difference, they said, was obtained by a peculiar arrangement of the peeling-machine, which however was and must remain a secret of the proprietors. Our friends drew our notice to it, and consequently we have endeavoured to solve the riddle.

Now we affirm, that the utmost that can be attained by peeling, is that the actual colour of the coffee in the shell be preserved; which can be easily ascertained. If, however, a change of colour takes place, by which for instance, the coffee assumes a darker hue than the original colour in the shell, it must be a consequence of the influence of foreign substances, with which the coffee must have been in contact. This simple assertion needs no further demonstration, and has been scientifically proved on samples of parcels from the abovementioned peelery.

Now we do not believe this preparing will keep its ground in the long run, as the greasy smell to which coffee is subject, must act injuriously on the delicate flavour of the W. J. A. It is possible to be misled a single time by that preparation, for in a small sample the scent is not so easily perceptible, so that in busy times, when a commissioner examines as many as a hundred samples in one day he may not observe it, and often does not become aware of it to his detriment till the coffee is received and despatched, and all complaints are of no use, the seller haling dealt *bona fide* and sold on sample. But if the good name of the plantaion itself will not have suffered much—for such dealings do not remain a secret, is another question.

Therefore we thought it our duty to make the above communication, the more as the entrusting of the working of coffee in the parchment demand unlimited confidence.—*Ibid.*

ON THE CHEMICAL COMPOSITION OF VINERY SOILS.*

Dr. Thudicum, in his *Origin, Nature, and Use of Wine*, draws attention to the fact that "the most luxuriant growth of the Vine and its richest bearing power are met with in the paludal districts of the Gironde," and shows that this is due to the Vine requiring "for its upper and main roots a territory which must not be clogged with water, but be pervious to it, and admit air at frequent intervals. But at the same time it requires a constant supply of water within easy reach of the roots. It, therefore, lives best on ground which, although not itself soaked with water, can constantly attract it from the subsoil by means of the capillary attraction due to porosity." A soil, therefore, similar to No. 1 is not suitable for the growth of the Vine; first, because it will not allow of water finding its way upwards from the subsoil; secondly, because it will not allow of the excess of water passing through it to the drains; and, thirdly, because it does not allow of the atmospheric air passing through or into it.

The geological formation on which a vinery stands is most important, as upon that depends very greatly the preliminary operations and additions necessary to ensure success. The carboniferous sandstone, old and new red, oolitic and chalk formations form congenial soils which can readily be worked up. The boulder clay is most successful, but requires in many cases, where stiff, much preliminary handling. Too much care cannot be taken to have thorough and efficient drainage. This must not, however, be got by a large admixture of sand, but should rather be obtained by burning clay, when an open semi-porous mass is obtained, with the potash salts rendered more available to the plant root. Another great advantage is that the excess of animal life, as also the dangerous plant life, more especially fungoid growths, are destroyed by the heat, and thus one great pest of Vine life reduced to a minimum.

No 2 soil deserves notice from its peculiar position. The vinery is situated on the slope of a hill, which at that part consists of trap rock. The soil is laid directly on the rock, which comes so close to the surface that the site for the vinery required to be blasted out, and the stokehole could only be drained by similar means. Yet the house has been eminently successful, and the reason does not seem far to seek. The drainage water finds its way by natural gravitation downwards, leaving the soil always friable and open. At the same time the position of the houses on the side of a hill insures a supply of water from the upper portions, but which only reaches the Vine roots growing close to the rock. Another cause is the open nature of the soil. The mechanical analysis shows the presence of 49·631 per cent of coarse sand, 20·193 per cent of fine sand, and 16·263 per cent of clay. These ingredients should be more correctly given as "trap particles," for they are made up of finer and coarser portions of disintegrated rock. The potash salt is mostly derived from the natural soil. Whilst this house is at present extremely fruitful it will be very necessary to carefully feed the plants so as to retain it in its present condition. It differs from sandy agricultural soils in open borders by the moisture being obtained by capillary attraction from below, and carrying with it the soluble ingredients from the soil of the upper part of the hill. At the same time the upward movement of the water will tend to carry with it the soluble salts of the Vine soil, which with ordinary drainage would be lost.

* "On the Chemical Composition of Vinery Soils, with Notes on the Best Classes of Soil, and of the Composition of the Varieties of Manures suited to the Cultivation of the Grape Vine." By W. Ivison Macadam, F.C.S., F.I.C., &c., Lecturer on Chemistry, and Analytical Chemist, Edinburgh. Read before the Scottish Horticultural Association, Edinburgh, October, 1882.

The position of this house on the rock, with little if any natural soil, seems to be one of the best suited to Grape culture. On the Continent some of the most successful vineyards are those at high elevations—perched on a ledge of rock on a hillside, with so little natural soil that what the plant requires must be carried from the plains below, and many times afterwards retained in its place by basket-work, yet with all these seeming disadvantages yielding a crop many of our gardeners would envy. In such cases little or no manure is given, for the natural denudation caused by rain is such as to compel regular supplies of fresh soil obtained from the alluvial plains. These soils are mostly from volcanic districts, and contain much potash in combination. Not unfrequently the hills themselves are extinct volcanos. In planting a vinery on the side of a trap hill, and with alluvial soil from the district, we are simply taking advantage of Continental experience, and provided the house have a proper exposure to the sun, the results must be successful.

All the authorities I have consulted advocate the manuring of the borders during autumn as being the time calculated to yield the greatest results. The manures differ much. Drs. Thudicum and Dupré advocate the employment of farmyard manure, and draw attention to the farms attached to some of the Continental vineyards, and which are specially kept up for the purpose of supplying the manure necessary. M. Ville, in his excellent *Treatise on Artificial Manures*, recommends two manures which he has found successful in his experiments on the Vine, and which are composed according to the following recipes:—

	No. 1.	No. 2.
Calcic superphosphate	528	352
Nitrate of potash	440	176
Nitrate of soda	...	396
Calcic sulphate	352	220
	1·320	1·144

Difficulty will be experienced in compounding these mixtures, as nitrate of potash is both costly and difficult to obtain, whilst its place cannot be taken by any single salt.

Thomson's Vine Manure.

Potassic oxide (K,2O)	1·144
Calcic oxide (CaO)	18·926
Phosphoric anhydride (P2O5)	29·141
Carbonic anhydride (CO2)	2·165
Sulphuric anhydride (SO3)	6·902
Sodic oxide (Na2O)	1·901
Silica	7·640
Moisture	9·480
**Organic matter, &c....	22·698
	100·000
**Yielding ammonia	1·41

Very good results have been obtained by Mr. Malcolm Dunn, of Dalkeith, from the use of a manure manufactured from a formula of my own. Besides Mr. Dunn several other members of this Association have also tried the compound, and it has given satisfaction to all. Since last session I have changed the manure slightly, adding one more element and arranging the proportions of the other bodies to correspond. This compound has been in Mr. Dunn's hands during the past season, and has proved itself superior to the old mixture. It has also been employed under my own supervision on Vines and general greenhouse plants, such as Pelargoniums, Fuchsias, Carnations, Camellias, &c., and has yielded splendid results. My own greenhouse plants have been in full flower all the season, and are now showing good heads. The Camellias are especially well budded.

In applying these concentrated manures it is advisable to give a dressing during autumn, and after the buds begin to swell a regular small dose once a week, this latter being simply sprinkled over the surface of the soil. M. Ville says that the absence of any one of the indispensable elements of a plant food lays the plant open to be attacked by disease, and instances his experiments on the non-presence of potash salts on the Vines, &c. The leaves of the plants did not attain full development, whilst the stems were not one-fourth the size they should have been. By July the leaves became red, spotted with black, and then dried up so as to be easily pulverised in the fingers. What is true of potash salts is equally true of the other mineral ingredients. The stem cannot thrive without calcium salts, or the fruit without phosphates, and the sap must contain nitrogen, as a life-giving property.—*Gardeners' Chronicle.*

WHAT IS THE SOURCE OF LEDGER BARK.

AT a meeting of the Linnean Society, on May 3, a paper on this subject was read by Mr. J. E. Howard, F.R.S., the substance of which we had intended to lay before our readers as soon as the paper should be published in the Journal of that Society. A report of Mr. Howard's paper has, however, in the meantime reached the Colonies and has provoked a somewhat animated discussion, as a result of which Mr. T. N. Christie, one of the leading cinchona planters of Ceylon, has forwarded to us samples and notes which he hopes may clear up the points in dispute.

The point at issue appears to be whether the plant named "*Cinchona Ledgeriana*" by Dr. Trimen is a true species or only a variety of *Cinchona Calisaya*. Mr. Howard published in his 'Quinology of the East Indian Plantations' a description by Dr. Weddell of a variety of *Cinchona Calisaya*, which he named *Ledgeriana*. Of this plant three plates were figured all of which were drawn from plants grown from seed bought of Mr. Ledger in 1883, and cultivated in Java.

In November 1881, Dr. Trimen, who had then seen, in a growing state, the "Ledgeriana" trees as known to planters in Ceylon, and as recognized by Mr. Moens of Java, described the Ledgeriana tree as a distinct species, in the *London Journal of Botany* for that month, giving the features which he considered distinctive, and a full description of every part of the plant as well as a figure of the leaves, flowers and fruits. To this description of the Ledgeriana plant, as a good species, Mr. J. E. Howard appears to have taken exception in the paper read before the Linnean Society, and so far as we understand the remarks made, or reported to have been made, by him, he believes "the tree figured "as *C. Ledgeriana*, Moens, to be no Calisaya at all, but a "species, standing intermediate between *C. Calisaya* and "*C. micrantha*, or a mere variety of *C. micrantha*," probably var. *Calisayoides*, and he thinks "it will be evident to any botanist" that the plates as well as the description differ very widely. But it is a further question whether the plant thus referred to is that described in Weddell's Notes (Translation, p. 10). Mr. Howard adds, "On Mr. Moens' own authority, I claim that mine alone are authentic," and he seems further to have stigmatized Dr. Trimen's typical plant as derived apparently from seed of uncertain origin, given by Mr. McIvor.
